Correlation Coefficients and Semantic Textual Similarity

Abstract

A large body of research into semantic textual similarity has focused on constructing state-of-the-art embeddings using sophisticated modelling, careful choice of learning signals and many clever tricks. By contrast, little attention has been devoted to similarity measures between these embeddings, with cosine similarity being used unquestionably in the majority of cases. In this work, we illustrate that for all common word vectors, cosine similarity is essentially equivalent to the Pearson correlation coefficient, which provides some justification for its use. We thoroughly characterise cases where Pearson correlation (and thus cosine similarity) is unfit as similarity measure. Importantly, we show that Pearson correlation is appropriate for some word vectors but not others. When it is not appropriate, we illustrate how common non-parametric rank correlation coefficients can be used instead to significantly improve performance. We support our analysis with a series of evaluations on word-level and sentence-level semantic textual similarity benchmarks. On the latter, we show that even the simplest averaged word vectors compared by rank correlation easily rival the strongest deep representations compared by cosine similarity.

1 Introduction

Textual embeddings are immensely popular because they help us reason about the abstract and fuzzy notion of semantic similarity in purely geometric terms. Distributed representations of words in particular (Bengio et al., 2003; Mikolov et al., 2013a; Pennington et al., 2014; Bojanowski et al., 2017; Joulin et al., 2017) have had a massive impact on machine learning (ML), natural language processing (NLP), and information retrieval (IR).

Recently, much effort has also been directed towards learning representations for larger pieces of text, with methods ranging from clever compositions of word embeddings (Mitchell and Lapata, 2008; De Boom et al., 2016; Arora et al., 2017; Wieting et al., 2016; Wieting and Gimpel, 2018; Zhelezniak et al., 2019) to sophisticated neural architectures (Le and Mikolov, 2014; Kiros et al., 2015; Hill et al., 2016; Conneau et al., 2017; Gan et al., 2017; Tang et al., 2017; Zhelezniak et al., 2018; Subramanian et al., 2018; Pagliardini et al., 2018; Cer et al., 2018).

Comparatively, there is little research into similarity measures for textual embeddings. Despite some investigations into alternatives (Camacho-Collados et al., 2015; De Boom et al., 2015; Santus et al., 2018; Zhelezniak et al., 2019), cosine similarity has persistently remained the default and unquestioned choice across the field. This is partly because cosine similarity is very convenient and easy to understand. Sometimes, however, we have to resist what is convenient and instead use what is appropriate. The core idea behind our work is to treat each word or sentence embedding as a sample of (e.g. 300) observations from some scalar random variable. Hence, no matter how mysterious word vectors appear to be, just like any samples, they become subject to the full power of traditional statistical analysis. We first show that in practice, the widely used cosine similarity is nothing but the Pearson correlation coefficient computed from the paired sample. However, Pearson's r is extremely sensitive to even slight departures from normality, where a single outlier can conceal the underlying association. For example, we find that Pearson's r (and thus cosine similarity) is acceptable for word2vec and fastText but not for GloVe embeddings. Perhaps surprisingly, when we average word vectors to represent sentences, cosine similarity remains acceptable for word2vec, but not for fastText any longer. We show that this seemingly counterintuitive behaviour can be predicted

Proceedings of NAACL-HLT 2019, pages 951–962
Minneapolis, Minnesota, June 2 - June 7, 2019.

by elementary univariate statistics, something that is already well known to researchers and practitioners alike. Furthermore, when there are clear indications against cosine similarity, we propose to repurpose rank-based correlation coefficients, such as Spearman's ρ and Kendall's τ, as *similarity measures* between textual embeddings. We support this proposition by a series of experiments on word- and sentence-level semantic textual similarity (STS) tasks. Our results confirm that rank-based correlation coefficients are much more effective when the majority of vectors break the assumptions of normality. Moreover, we show how even the simplest sentence embeddings (such as averaged word vectors) compared by rank correlation easily rival recent deep representations compared by cosine similarity.

2 Related Work

At the heart of our work is a simple statistical analysis of pre-trained word embeddings and exploration of various correlation coefficients as proxies for semantic textual similarity. Hence, any research that combines word embeddings with tools from probability and statistics is relevant. Of course, word embeddings themselves are typically obtained as the learned parameters of statistical machine learning models. These models can be trained on large corpora of text to predict a word from its context or vice versa (Mikolov et al., 2013a). Alternatively, there are also supervised approaches (Wieting et al., 2015, 2016; Wieting and Gimpel, 2017, 2018).

A different line of research tries to move away from learning word embeddings as point estimates and instead model words as parametric densities (Vilnis and McCallum, 2014; Barkan, 2017; Athiwaratkun and Wilson, 2017). These approaches are quite appealing because they incorporate semantic uncertainty directly into the representations. Of course, such representations need to be learned explicitly. In some cases one could estimate the densities even for off-the-shelf embeddings, but this still requires access to the training data and the usefulness of such post-factum densities is limited (Vilnis and McCallum, 2014). In other words, these approaches are not very helpful to practitioners who are accustomed to using high-quality pre-trained word embeddings directly.

Arguably, statistical analysis of pre-trained word embeddings is not as principled as applying a probabilistic treatment end-to-end. Any such analysis, however, is very valuable as it provides insights and justifications for methods that are already in widespread use. For example, removing the common mean vector and a few top principal components makes embeddings even stronger and is now a common practice (Mu and Viswanath, 2018; Arora et al., 2016, 2017; Ethayarajh, 2018). These works view word embeddings as observations from some D-dimensional distribution; such treatment is naturally suitable for studying the overall geometry of the embedding space. We, on the other hand, are interested in studying the similarities between individual word vectors and require a completely different perspective. To this end, we see each word embedding itself as a sample of D observations from a scalar random variable. It is precisely this shift in perspective that allows us to reason about semantic similarity in terms of correlations between random variables and make the connection to the widely used cosine similarity.

Finally, we propose using rank-based correlation coefficients when cosine similarity is not appropriate. Recently, Santus et al. (2018) introduced a rank-based similarity measure for word embeddings, called APSynP, and demonstrated its efficacy on outlier detection tasks. However, the results on the word-level similarity benchmarks were mixed, which, interestingly enough, could have been predicted in advance by our analysis.

3 Correlation Coefficients and Semantic Similarity

Suppose we have a vocabulary of N words $\mathcal{V} = \{w_1, w_2, \ldots, w_N\}$ and the word embeddings matrix $\mathbf{W} \in \mathbb{R}^{N \times D}$, where each row $\mathbf{w}^{(i)}$ for $i = 1, \ldots, N$ is a D-dimensional word vector. Popular pre-trained embeddings in practice typically have dimension $D = 300$, while the vocabulary size N can range from thousands to millions of words.

We now consider the following: what kinds of statistical analyses can we apply to $\mathbf{W}$ in order to model semantic similarity between words? One option is to view all word embeddings $\mathbf{w}^{(1)}, \mathbf{w}^{(2)}, \ldots \mathbf{w}^{(N)}$ as a sample of N observations from some D-variate distribution $P(E_1, \ldots E_D)$. For example, we can fit a Gaussian and study how all 300 dimensions correlate with each other. Perhaps we can fit a mixture model and see how the embeddings cluster. We

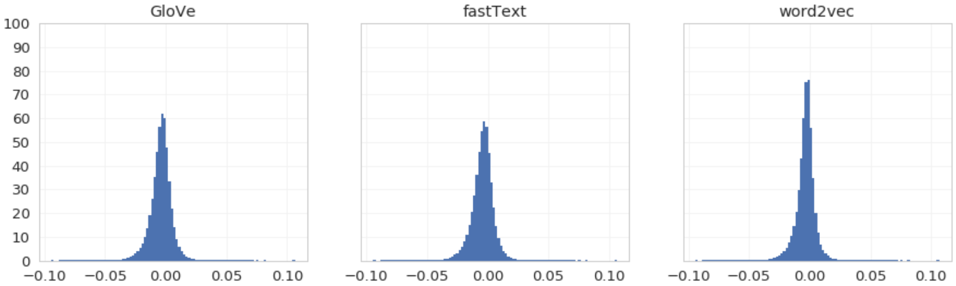

Figure 1: Normalised histograms of the mean distribution for three commonly used word embedding models: GloVe (Pennington et al., 2014), fastText (Bojanowski et al., 2017), and word2vec (Mikolov et al., 2013b,c).

could also normalise them and study their distribution on the unit sphere. It is clear by now that $P(E_1, \ldots, E_D)$ is suitable for describing the overall geometry of the embedding space but is not very useful for our goals.

If we are to reason about similarities between individual word vectors, we should instead be looking at the transpose of $\mathbf{W}$. Putting it differently, we see $\mathbf{W}^T$ as a sample of D observations from an N-variate distribution $P(W_1, W_2, \ldots, W_N)$, where W_i is a scalar random variable corresponding to the word w_i. This distribution is exactly what we need because the associations between W_i captured by P will become a proxy for semantic similarity. Often we are only interested in pairwise similarities between two given words w_i and w_j; thus the main object of our study is the bivariate marginal $P(W_i, W_j)$. To lighten up the notation slightly, we denote the two words as w_x and w_y, and the corresponding random variables as X and Y. We also refer to $P(X, Y)$ as the joint and $P(X)$, $P(Y)$ as the marginals. In practice, of course, the actual $P(X, Y)$ is unknown but we can make inferences about it based on our sample $(\mathbf{x}, \mathbf{y}) = \{(x_1, y_1), (x_2, y_2), \ldots (x_D, y_D)\}$.

First, we might want to study the degree of linear association between X and Y, so we compute the sample Pearson correlation coefficient

$$\hat{r} = \frac{\sum_{i=1}^{D}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{D}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{D}(y_i - \bar{y})^2}}, \quad (1)$$

where $\bar{x}$ and $\bar{y}$ are the sample means

$$\bar{x} = \sum_{i=1}^{D} x_i, \qquad \bar{y} = \sum_{i=1}^{D} y_i. \quad (2)$$

Let's view $\mathbf{x}$ and $\mathbf{y}$ as word embeddings momentarily and compute cosine similarity between them

$$\cos(\mathbf{x}, \mathbf{y}) = \frac{\sum_{i=1}^{D} x_i y_i}{\sqrt{\sum_{i=1}^{D} x_i^2}\sqrt{\sum_{i=1}^{D} y_i^2}}. \quad (3)$$

We see now that Equation (1) and Equation (3) look very similar; when the sample means $\bar{x}$, $\bar{y}$ are zero, cosine similarity and Pearson's $\hat{r}$ are equal. The real question here is whether or not they coincide in practice. Putting it differently, if we take any single word vector $\mathbf{w}$ and compute the mean (across the D dimensions), is this mean close to zero? It turns out that it is, and we can show this by plotting the distribution of the means across the whole vocabulary for various popular word embeddings (see Figure 1). We find that the means are indeed highly concentrated around zero; quantitatively, only 0.03% of them are above 0.05 in magnitude. It follows that in practice when we compute cosine similarity between word vectors, we are actually computing Pearson correlation between them.

However, is this always the right thing to do? When the joint $P(X, Y)$ is bivariate normal, Pearson correlation indeed provides a complete summary of association between X and Y, simply because the covariance is given by $\text{cov}(X, Y) = r_{XY}\sigma_X\sigma_Y$. However, Pearson correlation is extremely sensitive to even the slightest departures from normality – a single outlier can easily conceal the underlying association (Pernet et al., 2013). When the normality of $P(X, Y)$ is in doubt, it is preferable to use robust correlation coefficients such as Spearman's $\hat{\rho}$ or Kendall's $\hat{\tau}$.

Spearman's $\hat{\rho}$ is just a Pearson's $\hat{r}$ between ranked variables

$$\hat{\rho} = \frac{\sum_{i=1}^{D}(r[x_i] - \overline{r[x]})(r[y_i] - \overline{r[y]})}{\sqrt{\sum_{i=1}^{D}(r[x_i] - \overline{r[x]})^2}\sqrt{\sum_{i=1}^{D}(r[y_i] - \overline{r[y]})^2}}, \quad (4)$$

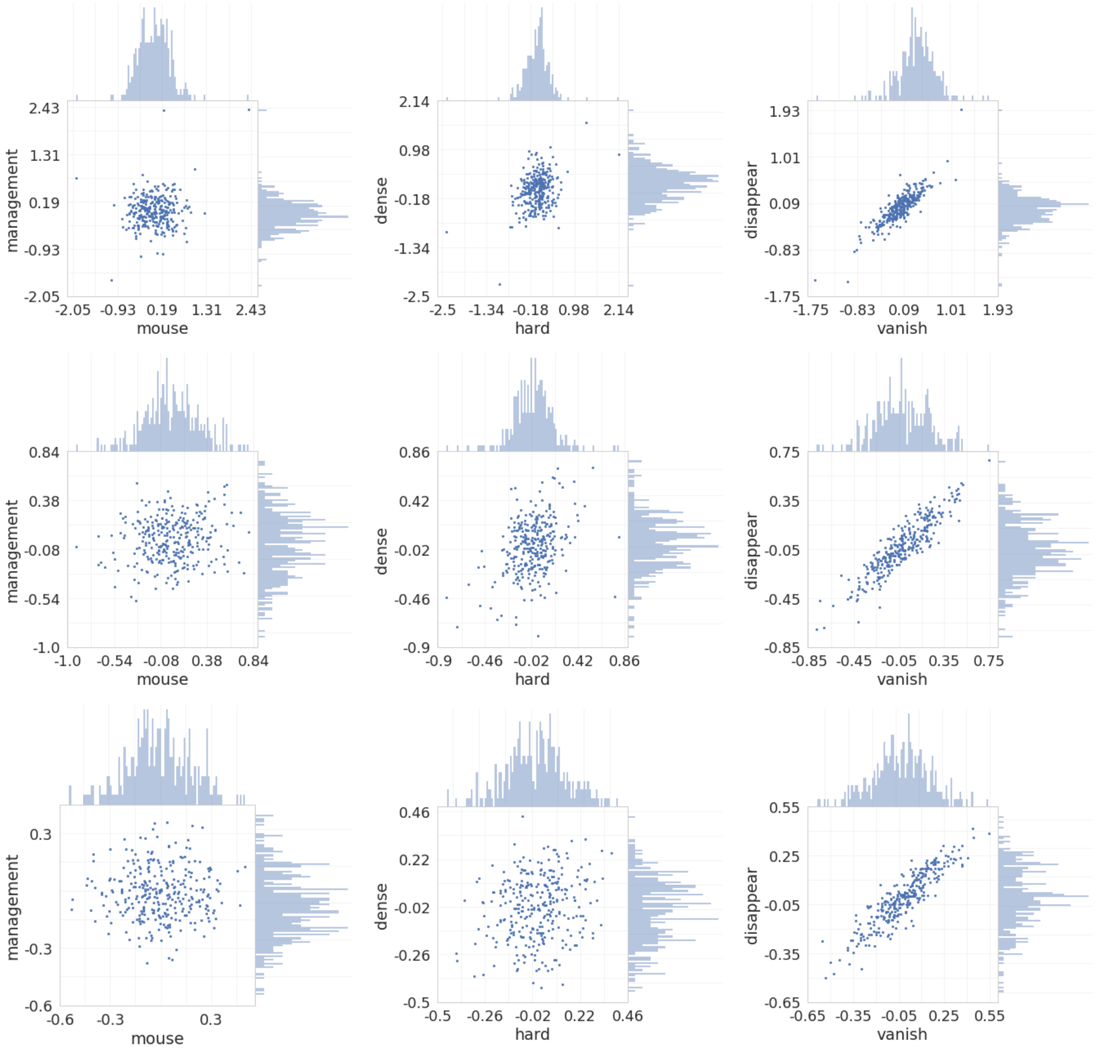

Figure 2: Scatter plots of paired word vectors, along with histograms (100 bins) of individual word vectors. Rows from top to bottom correspond to one of three common models: GloVe (Pennington et al., 2014), fastText (Bojanowski et al., 2017), and word2vec (Mikolov et al., 2013b,c). Columns from left to right correspond to increasing degrees of semantic similarity between the words, and accordingly increasingly pronounced linear correlation between the word vectors. Both the scatter plots and the histograms exhibit the presence of heavy outliers for GloVe vectors, which damage the efficacy of Pearson correlation in reliably capturing statistical associations. The outliers are relatively less pronounced for fastText vectors and much less pronounced for word2vec vectors.

where $r[x_i]$ denotes the integer rank of x_i in a vector $\mathbf{x}$ (similarly $r[y_i]$), while $\overline{r[x]}$ and $\overline{r[y]}$ denote the means of the ranks. Kendall's $\hat{\tau}$ is given by

$$\hat{\tau} = \frac{2}{D(D-1)} \sum_{i<j} \operatorname{sgn}(x_i - x_j)\operatorname{sgn}(y_i - y_j) \quad (5)$$

and can be interpreted as a normalised difference between the number of concordant pairs and the number of discordant pairs. These rank correlation coefficients are more robust to outliers than Pearson's $\hat{r}$ because they limit the effect of outliers to their ranks: no matter how far the outlier is, its rank cannot exceed D or fall below 1 in our case. There are also straightforward extensions to account for the ties in the ranks.

The main point here is the following. It is tempting to chose cosine similarity as the default and apply it everywhere regardless of the embedding type. Sometimes, however, we should resist using what is convenient and instead use what is appropriate. For example, if the samples corresponding to the marginals $P(X)$ and $P(Y)$ already look non-normal, then we conclude the joint $P(X, Y)$ cannot be a bivariate normal and the appropriateness of cosine similarity should be seriously questioned. In some of these cases, using a rank-based coefficient as a similarity measure be-

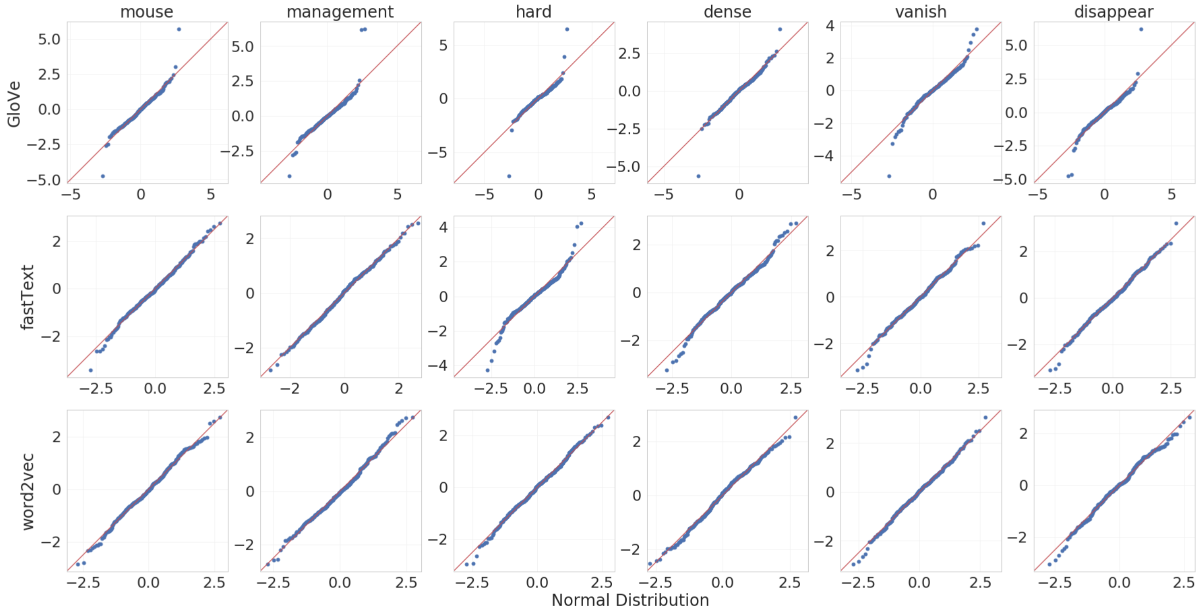

Figure 3: Q-Q plots comparing the theoretical quantiles of a standard normal distribution (horizontal axis) against the sample quantiles of standardised (Mean 0, SD 1) word vectors from three commonly used models: GloVe (Pennington et al., 2014), fastText (Bojanowski et al., 2017), and word2vec (Mikolov et al., 2013b,c). Perfect fit to the 45-degree reference line would indicate perfect normality. Note the pronounced discrepancy between the normal distribution and GloVe vectors due to the presence of heavy outliers. The discrepancy is relatively less pronounced for fastText vectors and much less pronounced for word2vec vectors. Figure 2 provides an alternative visualisation of the same phenomena.

tween word embeddings would be a much better alternative. It will capture the association better, which could in turn lead to large improvements in performance on the downstream tasks. In general, of course, even normal marginals do not imply a normal joint and care should be exercised either way; however we found the normality of marginals to be a good indication for cosine similarity within the scope of the present work. In the next section we illustrate how the ideas discussed here can be applied in practice.

4 Statistical Analysis of Word Embeddings: A Practical Example

No matter how mysterious word vectors appear to be, just like any samples, they are subject to the full power of traditional statistical analysis. As a concrete example, let's say we decided to use GloVe vectors (Pennington et al., 2014). We treat each vector $\mathbf{w}_i$ as if it was a sample of 300 observations from some scalar random variable W_i. We take a few hundred of these vectors, run a normality test such as Shapiro-Wilk (Shapiro and Wilk, 1965) and find that the majority of them look non-normal ($p < 0.05$). As there is a considerable evidence against normality, we flag these vectors as 'suspicious' and look at them closer. We pick a few vectors and examine their histograms and Q-Q plots, seen in Figure 2 and Figure 3 respectively; the latter in particular is a statistical tool used to compare empirical and theoretical data distributions, and is explained further in the caption of Figure 3. In both cases we observe that while the bulk of the distribution looks bell-shaped, we always get a couple of very prominent outliers.

Next, we can also visualise our word vectors in a way more directly relevant to the task at hand. We take some pairs of words that are very similar (e.g. 'vanish' and 'disappear'), moderately similar ('hard' and 'dense'), and completely dissimilar ('mouse' and 'management') and make the scatter plots for the corresponding pairs of word vectors. These are also presented in Figure 2. We see that for similar pairs the relationship is almost linear; it becomes less linear as the similarity decreases, until we see a spherical blob (no relationship) for the most dissimilar pair. However, we again face the presence of bivariate outliers that are too far away from the main bulk of points.

Given this evidence, which course of action shall we take? Based on the presence of heavy outliers, we reject the normality of GloVe vectors and rule out the use of Pearson's r and cosine similarity. Instead we can use rank correlation coefficients, such as Spearman's ρ or Kendall's τ, as they offer more robustness to outliers. Note that in this particular case, it may also be acceptable to winsorize (clip) the vectors and only then proceed with the standard Pearson's r. We evaluate the proposed solution on word-level similarity tasks and observe good improvement in performance over cosine similarity, as seen in Table 1.

Of course this exploration is in no way specific to GloVe vectors. Note that from Figure 2 and Figure 3, we also see that word2vec vectors in particular tend to be much more normally distributed, meaning that we don't find strong evidence against using Pearson correlation; this is again backed up by Table 1.

This example helps illustrate that proper statistical analysis applied to existing textual embeddings is extremely powerful and comparatively less time-consuming than inventing new approaches. Of course, this analysis can be made as fine-grained as desired. Quite coarsely, we could have rejected the use of cosine similarity right after the Shapiro-Wilk test; on the other hand, we could have used even more different tests and visualisations. The decision here rests with the practitioner and depends on the task and the domain.

5 Experiments

To empirically validate the utility of the statistical framework presented in Section 3, we run a set of evaluations on word- and sentence-level STS tasks. In all experiments we rely on the following publicly available word embeddings: GloVe (Pennington et al., 2014) trained on Common Crawl (840B tokens), fastText (Bojanowski et al., 2017) trained on Common Crawl (600B tokens), and word2vec (Mikolov et al., 2013b,c) trained on Google News. All the source code for our experiments is available on GitHub[1]; in the case of the sentence-level tasks we rely also on the SentEval toolkit (Conneau and Kiela, 2018).

Table 1: Spearman's ρ on word similarity tasks for combinations of word vectors and the following similarity metrics: cosine similarity (COS), Pearson's r (PRS), Spearman's ρ (SPR), and Kendall τ (KEN). **N** indicates the proportion of sentence vectors in a task for which the null hypothesis of normality in a Shapiro-Wilk test was *not* rejected at $\alpha = 0.05$. The **V** column indicates the type of the best performing method: a rank-based correlation coefficient (R), a non-rank-based correlation or measure (N), or a tie (=). The winners in **V** were determined by comparing the top rank-based method for that vector/task combination with the top non-rank-based method. Winners were assigned only when the difference was statistically significant as determined by 95% BCa confidence intervals.

First we consider a group of word-level similarity datasets that are commonly used as benchmarks in previous research: *WS-353-SIM* (Finkelstein et al., 2001), *YP-130* (Yang and Powers, 2005), *SIMLEX-999* (Hill et al., 2015), *SimVerb-3500* (Gerz et al., 2016), *RW-STANFORD* (Luong et al., 2013), *Verb-143* (Baker et al., 2014), *MTurk-287* (Radinsky et al., 2011), *MC-30* (Miller and Charles, 1991). These datasets contain pairs of words and a human-annotated similarity score for each pair. The success metric for the experiments is the Spearman correlation between the human-

---

[1] `https://github.com/Babylonpartners/corrsim`

annotated similarity scores and the scores generated by the algorithm. To avoid any confusion whatsoever, note that here Spearman correlation serves as an evaluation criterion; this is completely unrelated to using Spearman correlation as a similarity measure between word embeddings as proposed in Section 3. Bias-corrected and accelerated bootstrap (Efron, 1987) 95% confidence intervals were used to determine statistical significance. We report the results for different combinations of word vectors and similarity measures in Table 1. The main takeaways from these experiments are the following:

- There is no significant difference between the results obtained with cosine similarity and Pearson correlation. This is because empirically, the means across dimensions of these word vectors are approximately zero, in which case cosine similarity and Pearson correlation are approximately the same.
- Rank correlation coefficients tend to perform on par or better than cosine and Pearson on tasks and word vectors where there is a high proportion of non-normally distributed word vectors (over 90%). This makes sense because it is precisely in the non-normal cases where Pearson correlation fails.
- When word vectors seem mostly normal, our analysis does not tell us definitively whether cosine similarity or rank correlation should perform better, and indeed we see that cosine and Pearson perform on par or better than Spearman and Kendall.

In the second set of experiments, we use the datasets from the sentence-level Semantic Textual Similarity shared task series 2012-2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017). The success metric for these experiments is the Pearson correlation between the human-annotated sentence similarity scores and the scores generated by the algorithm. Again, this use of Pearson correlation as an evaluation criterion is completely unrelated to its use as a similarity measure between sentence embeddings. Note that the dataset for the STS13 SMT subtask is no longer publicly available, so the mean Pearson correlations reported in our experiments involving this task have been re-calculated accordingly.

For these experiments we use averaged word vectors as a sentence representation for various types of word vector, with similarity computed by the different correlation coefficients as well as cosine similarity and APSynP (Santus et al., 2018). We report these results in Table 2, and the full significance analysis for each subtask in Table 4. We also compare the top performing combination of averaged word vectors and correlation coefficient against several popular approaches from the literature that use cosine similarity: BoW with ELMo embeddings (Peters et al., 2018), Skip-Thought (Kiros et al., 2015), InferSent (Conneau et al., 2017), Universal Sentence Encoder with DAN and Transformer (Cer et al., 2018), and STN multitask embeddings (Subramanian et al., 2018). These results are presented in Table 3. Our observations for the sentence-level experiments are as follows:

	task	**N**	**COS**	**PRS**	**SPR**	**KEN**	**APS**
GloVe	STS12	.01	52.1	52.0	53.4	52.6	**53.8**

	STS13	.94	58.2	**58.3**	57.9	58.2	57.2
	STS14	.96	**65.6**	**65.6**	65.5	**65.6**	64.1
	STS15	.96	67.5	67.5	67.3	**68.3**	66.5
	STS16	.96	64.7	64.7	64.6	**65.6**	63.9

Table 2: Mean Pearson correlation on STS tasks for methods using combinations of word vectors and similarity metrics. All methods use averaged word vectors to represent sentences. The similarity measures are: cosine similarity (COS), Pearson's r (PRS), Spearman's ρ (SPR), Kendall τ (KEN) and APSynP (APS). **N** indicates the proportion of sentence vectors in a task for which the null hypothesis of normality in a Shapiro-Wilk test was *not* rejected at $\alpha = 0.05$

- The conclusions from the word-level tasks continue to hold and are even more pronounced: in particular, cosine and Pearson are essentially equivalent, and the increase in performance of rank-based correlation coefficients over cosine similarity on non-normal sentence vectors is quite dramatic.

Approach	STS 12	13	14	15	16

Table 3: Mean Pearson correlation on STS tasks for a variety of methods in the literature compared to averaged fastText vectors with different similarity metrics: cosine similarity (COS), Spearman's ρ (SPR), and Kendall τ (KEN). Values in bold indicate best results per task. Previous results are taken from Perone et al. (2018) (only two significant figures provided) and Subramanian et al. (2018). † indicates the only STS13 result (to our knowledge) that includes the SMT subtask.

- Averaged word vectors compared with rank correlation easily rival modern deep representations compared with cosine similarity.

Finally, the fraction of non-normal word vectors used in sentence-level tasks is consistent with the results reported for the word-level tasks in Table 1. However, we observe the following curious phenomenon for fastText. While there is no evidence against normality for the majority of fastText vectors, perhaps surprisingly, when we average them to represent sentences, such sentence embeddings are almost entirely non-normal (Table 2). Empirically we observe that many high-frequency words or stopwords have prominently non-normal fastText vectors. Although stopwords constitute only a small fraction of the entire vocabulary, they are very likely to occur in any given sentence, thus rendering most sentence embeddings non-normal as well. While it's tempting to invoke the Central Limit Theorem (at least for longer sentences), under our formalism, averaging word vectors corresponds to averaging scalar random variables used to represent words, which are neither independent nor identically distributed. In other words, there are no easy guarantees of normality for such sentence vectors.

6 Discussion

In this work, we investigate statistical correlation coefficients as measures for semantic textual similarity and make the following contributions:

- We show that in practice, for commonly used word vectors, cosine similarity is equivalent to the Pearson correlation coefficient, motivating an alternative statistical view of word vectors as opposed to the geometric view, which is more prevalent in the literature.
- We illustrate via a concrete example the power and benefits of using elementary statistics to analyse word vectors.
- We characterise when Pearson correlation is applied inappropriately and show that these conditions hold for some word vectors but not others, providing a basis for deciding whether or not cosine similarity is a reasonable choice for measuring semantic similarity.
- We demonstrate that when Pearson correlation is not appropriate, non-parametric rank correlation coefficients, which are known to be more robust to various departures from normality, can be used as similarity measures to significantly improve performance on word- and sentence-level STS tasks.
- Finally, we show in particular that sentence representations consisting of averaged word vectors, when compared by rank correlation, can easily rival much more complicated representations compared by cosine similarity.

We hope that these contributions will inspire others to carefully investigate and understand alternative measures of similarity. This is particularly important in the realm of sentence representations, where there are many more complex ways of constructing sentence representations from word embeddings besides the simple averaging procedure tested here. It is worth exploring whether a more subtle application of rank correlation could help push these more complex sentence representations to even better performance on STS tasks.

A final and fascinating direction of future work is to explain the non-normality of certain types of word vectors (and in particular the presence of outliers) by analysing their training procedures. Preliminary investigations suggest that unsupervised

Table 4: Pearson correlations between human sentence similarity score and a generated score. Generated scores were produced via measuring Spearman correlation (SPR), as explained in Section 3, and cosine similarity (COS) between averaged word vectors. Values in bold represent the best result for a subtask given a set of word vectors, based on a 95% BCa confidence interval (Efron, 1987) on the differences between the two correlations. In cases of no significant difference, both values are in bold.

objectives based on the distributional hypothesis are probably not to blame, as word vectors trained without relying on the distributional hypothesis, such as those of Wieting et al. (2015), still exhibit non-normality to some degree. The actual causes remain to be determined. We believe that understanding the reasons for these empirically-observed characteristics of textual embeddings would be a significant step forwards in our overall understanding of these crucial building blocks for data-driven natural language processing.

Abstract

The task of Natural Language Inference (NLI) is widely modeled as supervised sentence pair classification. While there has been a lot of work recently on generating explanations of the predictions of classifiers on a single piece of text, there have been no attempts to generate explanations of classifiers operating on pairs of sentences. In this paper, we show that it is possible to generate token-level explanations for NLI without the need for training data explicitly annotated for this purpose. We use a simple LSTM architecture and evaluate both LIME and Anchor explanations for this task. We compare these to a Multiple Instance Learning (MIL) method that uses thresholded attention make token-level predictions. The approach we present in this paper is a novel extension of zero-shot single-sentence tagging to sentence pairs for NLI. We conduct our experiments on the well-studied SNLI dataset that was recently augmented with manually annotation of the tokens that explain the entailment relation. We find that our white-box MIL-based method, while orders of magnitude faster, does not reach the same accuracy as the black-box methods.

1 Introduction

Large-scale datasets for Natural Language Inference (NLI) (Bowman et al., 2015; Williams et al., 2018) have enabled the development of many deep-learning models (Rocktäschel et al., 2016; Peters et al., 2018; Radford et al., 2018). The task is modeled as 3-way classification of the entailment relation between a pair of sentences. Model performance is assessed through accuracy on a held-out test set. While state-of-the-art models achieve high accuracy, their complexity makes it difficult to interpret their behavior.

Explaining the predictions made by classifiers has been of increasing concern (Doshi-Velez and Kim, 2017). It has been studied in natural language processing through both black-box analysis, and through modifications to the models under investigation; we refer to the latter approaches as *white-box*. Common black-box techniques generate explanations of predictions through training meta-models by perturbing input tokens (Ribeiro et al., 2016; Nguyen, 2018; Ribeiro et al., 2018) or through interpretation of model sensitivity to input tokens (Li et al., 2016; Feng et al., 2018). White-box methods induce new features (Aubakirova and Bansal, 2016), augment models to generate explanations accompanying their predictions (Lei et al., 2016; Camburu et al., 2018), or expose model internals such as magnitude of hidden states (Linzen et al., 2016), gradients (as a proxy for model sensitivity to input tokens (Li et al., 2016)) or attention (Bahdanau et al., 2014; Xu et al., 2015).

Premise:	Children smiling and waving at a camera
Hypothesis:	The kids are frowning
Label:	Contradiction

Figure 1: Example of token-level highlights from the e-SNLI dataset (Camburu et al., 2018). Annotators were provided a premise and hypothesis and asked to highlight words considered essential to explain the label.

Model explanations typically comprise a list of features (such as tokens) that contributed to the prediction and can serve two distinct purposes: acting either as a diagnostic during model development or to allow for a rationale to be generated for a system user. While methods for explaining predictions may output what was salient to the model, there is no guarantee these will correspond to the features that users deem important.

In this paper we introduce a white-box method that thresholds the attention matrix of a neural entailment model to induce token-level explanations.

Proceedings of NAACL-HLT 2019, pages 963–969
Minneapolis, Minnesota, June 2 - June 7, 2019.

To encourage the model's prediction of salient tokens to correspond better to the tokens users would find important, our approach uses Multiple Instance Learning (MIL) (Maron and Lozano-Pérez, 1998) to regularize the attention distributions.

We compare this against two black-box methods: LIME (Ribeiro et al., 2016) and Anchor Explanations (Ribeiro et al., 2018); both white- and black-box methods are applied to a simple neural architecture relying on independent sentence encoding with cross-sentence attention, and thus could also be applied to more complex architectures of the same family. Finally, we also compare against a fully supervised baseline trained to jointly predict entailment relation and token-level explanations. Our experiments are conducted on e-SNLI (Camburu et al., 2018), a recently introduced extension to SNLI (Bowman et al., 2015), containing human-selected highlights of which words are required to explain the entailment relation between two sentences (see Fig. 1).

Our experimental results indicate that regularizing the model's attention distributions encourages the explanations generated to be better aligned with human judgments (even without our model having explicit access to the labels which tokens annotators found important). Compared to the baseline thresholded attention mechanism, our method provides an absolute increase in token-level precision and recall by 6.68% and 28.05% respectively for the hypothesis sentence for e-SNLI explanations.

We also found that attention based explanations are not as reliable as black-box model explanation techniques, as indicated by higher F_1 scores for both LIME and Anchor Explanations. This is consistent with findings of contemporaneous work by Jain and Wallace (2019). However, we do show that, if generating explanations from a model is a requirement, incorporating an explicit objective in training can be beneficial. This can be particularly useful in practicw due to the computational cost of black-box model explanations, which in empirical evaluation we found to be orders of magnitude slower (0.01 seconds vs 64 seconds per instance).

2 NLI Model

The model we use for both white- and black-box experiments is based on an architecture widely adopted for sentence-pair classification (Lan and Xu, 2018). It comprises the following:

Word Embeddings We use pretrained GloVe embeddings (Pennington et al., 2014) that were fixed during training.

Sentence Encoding Both the premise and hypothesis are independently encoded with the same LSTM (Hochreiter and Schmidhuber, 1997), yielding $\mathbf{h}^p$ and $\mathbf{h}^h$ respectively.

Attention A matrix of soft alignments between tokens in the premise sentence and the hypothesis sentence is computed using attention (Bahdanau et al., 2014) over the encodings. Like Parikh et al. (2016), we project the encoded sentence representations using a feed-forward network, f_{attend}, ($u_i = f_{attend}(h_i^p)$, $v_j = f_{attend}(h_j^h)$) before computing the inner product: $\tilde{A}_{ij} = u_i^T v_j$. Given a premise of length m, the attention distribution for the hypothesis sentence is $\mathbf{a}^h = \text{normalize}(\tilde{A}_{m,*})$ where linear normalization is applied ($\text{normalize}(w) = \frac{w}{\|w\|_1}$). Likewise for the corresponding hypothesis of length n, the premise attention distribution is $\mathbf{a}^p = \text{normalize}(\tilde{A}_{*,n})$.

Output Classifier We predict the class label through a feed-forward neural network, f_{cls}, where both attended encodings of the premise and hypothesis final hidden states are concatenated as input: $f_{cls}([a_m^p h_m^p; a_n^h h_n^h])$. The logits are normalized using the softmax function, yielding a distribution over class labels $\hat{y}$.

Training The model is trained in a supervised environment using cross-entropy loss between the predicted class labels for an instance $\hat{y}$ and the labeled value in the dataset, formally defined in Section 3.

3 Generating Token-Level Explanations

Let $\mathbf{x}^p = (x_1^p, \ldots, x_m^p)$ and $\mathbf{x}^h = (x_1^h, \ldots, x_n^h)$ be sequences of tokens of length m and n respectively for the input premise and hypothesis sentences. Let y represent an entailment relation between $\mathbf{x}^p$ and $\mathbf{x}^h$ where $y \in \{\text{entails}, \text{contradicts}, \text{neutral}\}$. Labeled training data is provided of the form $\{(\mathbf{x}_k^p, \mathbf{x}_k^h, y_k)\}_{k=1}^K$. For each instance, the model must generate an explanation $\mathbf{e}$ defined as a subset of zero or more tokens from both the premise and hypothesis sentences: $\mathbf{e}^p \in \mathcal{P}(\mathbf{x}^p)$, $\mathbf{e}^h \in \mathcal{P}(\mathbf{x}^h)$.

We generate token-level explanations by thresholding token attention weights. Concretely, we select all tokens, x, with a weight greater than a threshold. While similar to Rei and Søgaard (2018), we incorporate a re-scaling using the tanh function: $\mathbf{e}^p = \{x_i^p | \tilde{a}_i^p \in \tilde{A}_{*,n} \wedge \tanh(\tilde{a}_i^p) \geq \tau\}$ and likewise for the hypothesis.

3.1 Multiple Instance Learning

Thresholding the attention distributions from our model will give an indication of which tokens the model is weighting strongly for the entailment task. However, as mentioned in the introduction, there is no guarantee that this method of explaining model behavior will correspond with tokens that humans judge as a reasonable explanation of entailment. To better align the attention-based explanations with the human judgments, we model the generation of explanations as Multiple Instance Learning (MIL) (Maron and Lozano-Pérez, 1998). In training the model sees labeled "bags" (sentences) of unlabeled features (tokens) and learns to predict labels both for the bags and the features. In MIL, this is often achieved by introducing regularizers when training. To encourage our NLI model to predict using sparser attention distributions (which we expect to correspond more closely with human token-level explanations), we introduce the following regularizers into the loss function:

R_1: This entropy-based term allows us to penalize a model that uniformly distributes probability mass between tokens.

$$\begin{aligned} R_1 &= \sum_{k=1}^{K} \left(\mathbb{H}(\mathbf{a}_k^p) + \mathbb{H}(\mathbf{a}_k^h)\right) \\ &= -\sum_{k=1}^{K} \left(\sum_{i=1}^{m} a_{k,i}^p \log a_{k,i}^p + \sum_{j=1}^{n} a_{k,j}^h \log a_{k,j}^h\right) \end{aligned} \tag{1}$$

R_2: This term, adapted from a loss function for zero-shot tagging on single sentences (Rei and Søgaard, 2018), penalizes the model for breaking the assumption that at least one token must be selected from both premise and hypothesis sentences to form an explanation. The only exception is that, following the e-SNLI dataset annotation by Camburu et al. (2018), if the neutral entailment is predicted, no tokens are selected from the premise.

$$\begin{aligned} R_2 = \sum_{k=1}^{K} \Big(&(\max_i a_{k,i}^p - \mathbb{I}[k_c \neq \text{neutral}])^2 \\ &+ (\max_j a_{k,j}^h - 1)^2 \Big) \end{aligned} \tag{2}$$

R_3: This term, also adapted from Rei and Søgaard (2018), encodes the assumption that not all tokens must be selected in the explanation. This is achieved by penalizing the smallest non-zero attention weight, which has the effect of encouraging at least one weight to be close to zero.

$$R_3 = \sum_{k=1}^{K} \left((\min_i a_{k,i}^p)^2 + (\min_j a_{k,j}^h)^2\right) \tag{3}$$

The loss function used for training of our proposed model incorporating the regularizers which are controlled with hyperparameters is:

$$L = \sum_{k=1}^{K} \sum_{c \in C} y_{k,c} \log \hat{y}_{k,c} + \alpha R_1 + \beta R_2 + \gamma R_3 \tag{4}$$

4 Alternative Models

4.1 Black-box explanations of NLP models

We use two established black-box model explanation techniques for generating token-level explanations: LIME (Ribeiro et al., 2016) and Anchors (Ribeiro et al., 2018). Both techniques probe a classifier by making perturbations to a single input and modeling which of these perturbations influence the classification. To adapt these for use in NLI, we make a simple modification that runs the analysis twice: once for the premise sentence and once for the hypothesis sentence on the NLI model described in Section 2.

LIME Generates local explanations for a classifier through the introduction of a simple meta-model that is trained to replicate a local decision boundary of an instance under test. The training data is generated through observing the impact on classification when removing tokens from the input string.

Anchor Explanations Considers the distribution of perturbed instances in the neighborhood of the instance under test through word substitution to identify a rule (a set of tokens in our case) for which the classification remains unchanged.

4.2 Supervised Model

For a supervised model we build upon the model discussed in Section 2, adding components to support LSTM-CRF-based tagging (Lample et al., 2016). We use the following architecture:

Model	Runtime (s) per instance	Token Explanation (%)					
		Premise			Hypothesis		
		P	R	F1	P	R	F1
Fully Supervised LSTM-CRF	0.02	86.91	40.98	55.70	81.16	54.79	65.41
Thresholded Attention (Linear)	**0.01**	19.96	19.67	19.56	46.70	34.92	39.89
+ MIL Regularizers (R1)	-	16.59	15.67	16.12	50.02	42.44	46.01
+ MIL Regularizers (R2 + R3)	-	18.19	20.18	19.13	51.29	50.73	51.00
+ MIL Regularizers (R1 + R2 + R3)	-	19.23	26.21	22.18	53.38	62.97	57.78
LIME	64	**60.56**	**48.28**	**53.72**	**57.04**	**66.92**	**61.58**
Anchors	10	42.06	20.04	27.14	53.12	63.94	58.03

Table 1: Token-level scores for human-selected explanations of NLI using the e-SNLI dataset. The select-all baseline precision for the premise is 18.5% and 35.2% for the hypothesis.

Context Encoding We use the same pretrained GloVe embeddings (Pennington et al., 2014) that were fixed during training. The premise and hypothesis sentence were independently encoded with the same LSTM (Hochreiter and Schmidhuber, 1997) yielding $\mathbf{h}^p$ and $\mathbf{h}^h$ respectively and attended to as per the description in Section 2.

Outputs The model is jointly trained with two output objectives: a labeling objective and a tagging objective. During training, the losses for both tasks are equally weighted. The first output objective is the three-way SNLI classification over the pair of sentences. This is the same component as the model presented in Section 2.

The second objective is a binary tagging objective over the highlighted token-level explanations. We use a jointly-trained LSTM-CRF decoder architecture (Lample et al., 2016) which operates a CRF over encoded representations for each token. In our model, we independently decode the premise and hypothesis sentences. The inputs to our CRF are the attended premise and hypothesis: $\mathbf{a}^p \odot \mathbf{h}^p$ and $\mathbf{a}^h \odot \mathbf{h}^h$ respectively (where $\odot$ is the point-wise multiplication between the attention vector and the encoded tokens).

5 Experiments

We evaluate the generated explanations through evaluation of token-level F_1 scores comparing them against tokens selected by humans to explain the entailment relation using the e-SNLI dataset (Camburu et al., 2018). The development split of the e-SNLI dataset is used for hyperparameter selection and we report results on the test split. Where multiple annotations are available for a sentence pair, the union of the annotations is taken. We also report average runtime per sentence in seconds measured using 1 thread on an AWS c4.xlarge instance.

Implementation Details The model is implemented in AllenNLP (Gardner et al., 2018) and we optimized our model with Adagrad (Duchi et al., 2011), selecting the models which attained high hypothesis F_1 without greatly affecting the accuracy of entailment task (approx 81% for the thresholded attention model). The cell state and hidden dimension was 200 for the LSTM sentence encoder. The projection for attention, f_{attend}, was a single layer 200 dimension feed forward network with ReLU activation. The final feed forward classifier, f_{cls}, dimension was $(200, 200, 3)$ and ReLU activation over the first 2 layers. For the comparison against black-box explanation mechanisms, we use the code made public by the authors of the respective works setting any hyperparameters to the default values or those suggested in the papers.

Results Our experimental results (Table 1) indicate that the LIME black-box explanation technique over the model described in Section 2 provides token-level explanations that are more similar to human judgments than thresholding the attention distributions. We show that the addition of MIL regularizers for generating explanations using thresholded attention improved precision and recall hypothesis explanations. However, similar improvements were not realized for the premise sentence. While the black-box methods generated better explanations than thresholded attention, they were 3 orders of magnitude slower.

Only LIME was able to generate good token-level explanations for the premise. This is in contrast to the attention-based explanations of the premise (in the model that LIME was run on) which could not generate satisfactory explanations (see row 2 of Table 1). This supports findings in recent works (Jain and Wallace, 2019) that indicate that attention does not always correspond to other measures of feature importance. We also found that the black-box model explanation methods behave differently given the same model under test: the premise explanation generated by the Anchors method was more in line with what the model attended to, reflected by the lower recall.

The fully supervised model had high precision yet (relatively) low recall. We observed it has a bias towards predicting common words that often appear in highlights (e.g. 'man', 'woman', 'dog', 'people') for both premise and hypothesis sentences rather than highlighting keywords that would form an instance-specific explanation. This behaviour is also more pronounced in the premise sentence highlights rather than the hypothesis. We reason that this due to how the SNLI dataset was constructed: a premise sentence was used to generate 3 hypothesis sentences (entailed, contradicted and neutral). This is corroborated by a survey of 250 instances from the SNLI dataset, where we found that all or part of the subject noun phrase remained unchanged between the premise and hypothesis sentences 60% of the time. While the supervised model correctly captured commonly occurring text patterns, as demonstrated by the high F_1 scores, this behaviour alone was not sufficient to identify tokens that correlated with the entailment label. We found that most of the commonly predicted tokens by our supervised model did not appear in lists of features highly correlated with the entailment label (Poliak et al., 2018; Gururangan et al., 2018).

6 Conclusions

In this paper we explored how to generate token-level explanations from NLI models. We compared the LIME and Anchors black-box methods against a novel, white-box Multiple Instance Learning (MIL) method and a fully supervised baseline. The explanations generated by LIME were more similar to the human judgments of the tokens that justify an entailment relation than the attention thresholding approach. This corroborates contemporaneous work (Jain and Wallace, 2019) indicating a lack of correspondence between attention and other measures of feature importance.

The MIL method we introduced steered the attention distributions over tokens in our model to correspond closer to the human judgments allowing better explanations to be generated. Even though, when considering the token-level F_1 score, the attention-based explanations were not as good as the black-box techniques we evaluated, they were orders of magnitude faster.

The attention thresholding model we tested did not generate satisfactory explanations had low F_1 for the premise sentences. A possible explanation for the poor performance is what is found by Rei and Søgaard (2018) who show that MIL regularizers performed better when there is a higher degree of association between the sentence-level label and the token-level labels. Our model used *independent* encodings of the premise and hypothesis but in NLI there is a strong dependence between the two sentences; thus the entailment prediction should be explained through pairwise token comparisons (e.g. synonyms, upward entailment, etc.). In future work we plan to address this by adding explicit cross-sentence semantic knowledge (Joshi et al., 2018).

Abstract

Complex Word Identification (CWI) is the task of identifying which words or phrases in a sentence are difficult to understand by a target audience. The latest CWI Shared Task released data for two settings: monolingual (i.e. train and test in the same language) and cross-lingual (i.e. test in a language not seen during training). The best monolingual models relied on language-dependent features, which do not generalise in the cross-lingual setting, while the best cross-lingual model used neural networks with multi-task learning. In this paper, we present monolingual and cross-lingual CWI models that perform as well as (or better than) most models submitted to the latest CWI Shared Task. We show that carefully selected features and simple learning models can achieve state-of-the-art performance, and result in strong baselines for future development in this area. Finally, we discuss how inconsistencies in the annotation of the data can explain some of the results obtained.

1 Introduction

Complex Word Identification (CWI) consists of deciding which words (or phrases) in a text could be difficult to understand by a specific type of reader. In this work, we follow the CWI Shared Tasks (Paetzold and Specia, 2016; Yimam et al., 2018) and assume that a target word or multi-word expression (MWE[1]) in a sentence is given, and our goal is to determine if it is complex or not (an example is shown in Table 1). Under this setting, CWI is normally treated using supervised learning and feature engineering to build monolingual models (Paetzold and Specia, 2016; Yimam et al., 2018). Unfortunately, this approach is infeasible for languages with scarce resources of annotated data. In this paper, we are interested in both monolingual and cross-lingual CWI; in the latter, we build models to make predictions for languages not seen during training.

Sentence	Target word/MWE	Complex?
Both China and the Philippines flexed their muscles on Wednesday.	flexed	Yes
	flexed their muscles	Yes
	muscles	No

Table 1: An annotated sentence in the English dataset of the Second CWI Shared Task.

While monolingual CWI has been studied extensively (see a survey in Paetzold and Specia (2017)), the cross-lingual setup of the task was introduced only recently by Yimam et al. (2017b), who collected human annotations from native and non-native speakers of Spanish and German, and integrated them with similar data previously produced for three English domains (Yimam et al., 2017a): News, WikiNews and Wikipedia.

For the Second CWI Shared Task (Yimam et al., 2018), participants built monolingual models using the datasets previously described, and also tested their cross-lingual capabilities on newly collected French data. In the monolingual track, the best systems for English (Gooding and Kochmar, 2018) differed significantly in terms of feature set size and the model's complexity, to the best systems for German and Spanish (Kajiwara and Komachi, 2018). The latter used Random Forests with eight features, whilst the former used AdaBoost with 5000 estimators or ensemble voting combining AdaBoost and Random Forest classifiers, with about 20 features.

In the cross-lingual track, only two teams achieved better scores than the baseline: Kajiwara and Komachi (2018) who used length and frequency based features with Random Forests, and

---

Proceedings of NAACL-HLT 2019, pages 970–977
Minneapolis, Minnesota, June 2 - June 7, 2019.

Bingel and Bjerva (2018) who implemented an ensemble of Random Forests and feed-forward neural networks in a multi-task learning architecture.

Our approach to CWI differs from previous work in that we begin by building competitive monolingual models, but using the same set of features and learning algorithm across languages. This reduces the possibility of getting high scores due to modelling annotation artifacts present in the dataset of one language. Our monolingual models achieve better scores for Spanish and German than the best systems in the Second CWI Shared Task. After that, we focus on language-independent features, and keep those that achieve good performance in cross-lingual experiments across all possible combinations of languages. This results in a small set of five language-independent features, which achieve a score as high as the top models in the French test set. Finally, we analyse the annotation of the datasets and find some inconsistencies that could explain some of our results.

Code for all our models can be found at: `https://github.com/sheffieldnlp/cwi`

2 Problem Formulation

We tackle the binary classification task in the Second CWI Shared Task (Yimam et al., 2018), in which a model decides if a target word/MWE in a sentence is complex or not. Following common practice, we extract features from the target word/MWE and its context, and then use a supervised learning algorithm to train a classifier. For training and testing our models, we use the annotated datasets provided for the Second CWI Shared Task (see Table 2 for some statistics).

Dataset	Train	Dev	Test
English (EN) - News	14,002	1,764	2,095
English (EN) - WikiNews	7,746	870	1,287
English (EN) - Wikipedia	5,551	694	870
Spanish (ES)	13,750	1,622	2,232

French (FR)	N/A	N/A	2,251

Table 2: Number of annotated samples in each dataset for each language.

3 Monolingual Models

3.1 Features Description

Our feature set consists of 25 features that can be extracted for all languages considered (English, German, Spanish and French). They can be divided into three broad categories: features based on the target word/MWE, sub-word level features, and sentence-level features to capture information from the target's context. As we intended that our features be applicable across languages, we drew on features found to be useful in previous work on CWI (Yimam et al., 2017b, 2018). We made use of the python libraries spaCy[2] (Honnibal and Montani, 2017) and NLTK[3] (Loper and Bird, 2002). Details on the resources used for extracting each feature can be found in Appendix A.

At the **target word/MWE level**, we experimented with features such as Named Entity (NE) type, part-of-speech, hypernym counts, number of tokens in the target, language-normalised number of characters in each word, and simple unigram probabilities. These features are linguistically motivated. The perceived complexity of a MWE may be higher than that of a single word, as each component word can be complex, or simple component words can be synthesised into a complex whole. Similarly, infrequent words are less familiar, so we would expect low-probability target words to be found more complex. Along these lines, proper nouns could be more complex, as there is a vast number of NEs, and the chance that a person has encountered any one of them is low. We would expect this trend to reverse for the NE type of organisations, in combination with the Enlgish-News dataset, as organisations mentioned in news articles are frequently global, and so the chance that a person has encountered a proper noun *that is an organisation* is often higher than for proper nouns in general. In total, 14 features were used at the target word/MWE level.

Our **sub-word level** features include prefixes, suffixes, the number of syllables, and the number of complex punctuation marks (i.e. punctuation within the target word/MWE, such as hyphens, that could denote added complexity). We would expect certain affixes to be useful features, as language users use sub-word particles like these to identify unknown words: by breaking up a word like "granted" into "grant-" and "-ed", readers can fall back on their knowledge of these component pieces to clarify the whole. A total of 9 sub-word features were used in the monolingual models.

Finally, **sentence level** features with linguistic

---

[2] `https://spacy.io/`

[3] `https://www.nltk.org/`

motivations were also considered. Long sentences could be harder to understand, which makes it more difficult to figure out the meaning of unknown words contained within them. Also, long sentences are more likely to include more unknown words or ambiguous references. Therefore, we considered sentence length (i.e., number of tokens in the sentence) as a feature. In addition, we extracted N-grams (unigrams, bigrams and trigrams) from the whole sentence, since certain sentence constructions can help a reader understand the target word/MWE. For example, "A of the B" suggests a relation between A and B. We used 2 sentence-level features in total.

3.2 Experiments and Results

Following Yimam et al. (2018), we used Macro-F1 score to evaluate performance and for comparison with previous work on the datasets. We used Logistic Regression for all our experiments, as it allowed for easy exploration of feature combinations, and in initial experiments we found that it performed better than Random Forests. We evaluated both using the full feature set described before, as well as a two-feature baseline using the number of tokens of the target and its language-normalised number of characters. Results of our monolingual experiments are shown in Table 3.

Dataset	Dev		Test		
	BL	MA	BL	MA	SotA
EN - News	83.6	85.5	69.7	86.0	**87.4**
EN - WikiNews	80.4	82.8	65.8	81.6	**84.0**
EN - Wikipedia	74.2	76.6	70.1	76.1	**81.2**
ES	78.0	77.1	69.6	**77.6**	77.0
DE	79.5	74.6	72.4	74.8	**75.5**
Mean	79.1	79.3	69.5	79.2	N/A

Table 3: Macro-F1 for the baseline (BL), our monolingual approach (MA), and the state of the art (SotA) on the Dev and Test splits of each dataset.

In the test set, our baseline results (BL in Table 3) are strong, especially in German. Our full 25-features model improves on the baseline in all cases, with the biggest increase of over 16 percentage points seen for the EN-News dataset. Our system beats the best performing system from the Shared Task in Spanish (77.0) and German (74.5), both obtained by Kajiwara and Komachi (2018). However, the state of the art for German remains the Shared Task baseline (75.5) (Yimam et al., 2018). The best results for all three English datasets were obtained by Gooding and Kochmar (2018); ours is within two percentage points of their News dataset score. Furthermore, the mean score for our system (79.2) is close to the mean of the best performing models (81.0), which are different systems, while using simpler features and learning algorithm. The best-performing model in English, for example, used Adaboost with 5000 estimators (Gooding and Kochmar, 2018).

4 Cross-lingual Models

4.1 Features Description

Linguistically, the cross-lingual approach can be motivated by the relation between certain languages (such as French and Spanish both being Romance languages). In addition, there may be features identifying complex words that are shared even across language families.

To be able to test a model on a language that was unseen during training, the features the model works with must be cross-lingual (or language-independent) themselves. For example, the words themselves are unlikely to transfer across languages (apart from those that happen to be spelled identically), but the popularity of the words would transfer. This rules out some of the features we used for the monolingual approach (see Sec. 3.1), as they were language-dependent. One such feature is N-grams for the target word/MWE, which depend on the language, and so will only occur with extreme sparsity outside of their source language. For example, if applying a system trained on English to unseen French, the English phrases "à la mode" or "film noir" might reoccur in the French, since they originate from that language, but these are rare exceptions. What is more, a French loan-phrase may have different complexity characteristics to the same N-grams occurring in their native language. Therefore, we did not use these features in the cross-lingual system.

4.2 Experiments and Results

To find out which features were best suited for the cross-lingual approach, we performed an iterative ablation analysis (see Appendix B for details). Using this process, we arrived at our final cross-lingual feature set: number of syllables in the target, number of tokens in the target, number of complex punctuation marks (such as hyphens), sentence length, and unigram probabilities.

Furthermore, we analyse the effect of different language combinations on the performance of the cross-lingual model in order to investigate how the relationship between the languages trained and tested on would influence model performance. Recall that we only have training data for English, Spanish and German, but not French. We train models using all possible combinations (each language independently, each pairing, and all three) and evaluate on each of the four languages that have test data (i.e. the former three and French), excluding training combinations that include the test language. Results are shown in Table 4.

Table 4: Comparison of Test and Dev results for all permutations of training languages.

When testing on French, we achieved the highest performance by training on German only (75.8), followed closely by training on a combination of German and Spanish (75.7) and only Spanish (75.5). The worst performance was achieved by training only on English (69.2), and the performance also noticeably decreased for all training combinations that included English.

When testing on German, language choice had a weaker effect. The highest score came from combining English and Spanish (73.4), but using only one of those languages gave comparable results (72.6 for Spanish, 73.0 for English).

For Spanish, the best results were achieved when training only on German (72.6). Adding English to the training languages decreased the performance (70.8), which was even lower when training only on English (69.1).

Our cross-lingual	72.6	73.4	75.8

Table 5: Comparison between the monolingual and cross-lingual state of the art (SotA), and our cross-lingual system.

It is noteworthy that adding English to the training languages noticeably decreases performance for both Spanish and French, but not for German. One possible reason for Spanish and French not benefiting from English when German does is that both English and German are Germanic languages, whereas Spanish and French are Romance languages. Another possible explanation for the decrease of performance caused by training with English is that there are inconsistencies in the way MWEs in the datasets were labelled across languages, which we explore in Sec. 5.

We finally compare our cross-lingual models against the state of the art: the best monolingual system for Spanish and German, and the best cross-lingual system for French, where no monolingual systems exist. As Table 5 shows, our cross-lingual models come close to the best monolingual models for Spanish and especially for German. This is remarkable given how simple our model and features are, and that the approaches we compare against train complex models for each language. Furthermore, this points towards the possibility of extending CWI to more languages which lack training data.

Finally, Table 6 compares the coefficients for models trained on Romance and Germanic languages. Notably, use of complex punctuation (such as the hyphenation in "laser-activated" or "drug-related") and the number of tokens are inversely correlated w.r.t. the word or MWE being complex. More words in the target was correlated with complexity for English and German, and inversely correlated for Spanish.

5 Dataset Analysis

While examining our models' incorrect predictions, we observed inconsistencies in labelling in the datasets between target MWEs and their sub-words/sub-expressions (SWs).

Feature	Train	Coefficient
number of complex punctuation marks	EN	-0.693
	DE	-0.559
	ES	1.111
number of tokens	EN	-2.200
	DE	-0.534
	ES	1.420

Table 6: Coefficients for cross-lingual models trained on Germanic and Romance languages.

The First CWI Shared Task (Paetzold and Specia, 2016) used the annotations of a group (i.e. ten annotators on the training data) to predict the annotation of an individual (i.e. one annotator on the test data). The resulting inconsistencies in labelling may have contributed to the low F-scores of systems in the task (Zampieri et al., 2017). Although the Second CWI Shared Task improved on the first by having multiple annotators for all splits of the data, it contains some labelling inconsistencies arising from annotators now being able to label phrases, and words within them, separately.

More concretely, we found that across all datasets, 72% of MWEs contain at least one SW with the opposite label (see Table 7). While this makes sense in some cases, every SW in 25% of MWE instances has the opposite label. For example, “numerous falsifications and ballot stuffing” is not annotated as complex, despite its SWs “numerous”, “numerous falsifications”, “falsifications”, “ballot”, “ballot stuffing” and “stuffing” all being complex. Conversely, “crise des marchés du crédit” is complex, despite “crise”, “marchés” and “crédit” being labelled non-complex. It is difficult to see how classifiers that extract features for MWEs from their individual SWs could predict the labels of both correctly.

Furthermore, every target MWE in the Spanish, German and French datasets is labelled complex. This may bias a classifier trained on the Spanish or German datasets towards learning MWEs and long individual words (if length is a feature) are complex. In particular, this observation may help explain why adding English as a training language decreased the performance of our cross-lingual system when testing on French and Spanish (where all MWEs are complex). An analysis in Bingel and Bjerva (2018) further found that their cross-lingual French model was effective at predicting long complex words/MWEs but had difficulty predicting long non-complex words.

	C	NC	$\geq$ 1 Irreg.	All Irreg.
English	3,750	982	3,315	950
Spanish	2,309	0	1,747	760
German	502	0	374	178
French	242	0	192	82
Total	6,803	982	5,628	1,970

Table 7: MWE annotation analysis: numbers of MWEs labelled complex (C) and non-complex (NC), numbers with at least one SW ($\geq$ 1 Irreg) and all SWs (All Irreg.) having the opposite label.

It is also worth noting that considering a word or MWE as complex is subjective and may differ from person to person, even within the same target audience. Bingel et al. (2018) investigated predicting complex words based on the gaze patterns of children with reading difficulties. They found a high degree of specificity in misreadings between children, that is, which words they found complex when reading aloud. This variety of complexity judgements even within one target group points towards the high degree of subjectivity in the task, which may also partly explain the inconsistencies in the dataset.

6 Conclusion and Future Work

The monolingual and cross-lingual models presented achieve comparable results against more complex, language-specific state-of-the-art models, and thus can serve as strong baselines for future research in CWI. In addition, our analysis of the dataset could help in the design of better guidelines when crowdsourcing annotations for the task. Dataset creators may wish to only allow single words to be chosen as complex to avoid labelling inconsistencies. In case MWEs are being permitted, we suggest instructing annotators to chose the smallest part of a phrase they find complex (French annotators for the Second CWI Shared Task sometimes grouped individual complex words into a complex MWE (Yimam et al., 2018)).

Abstract

We consider the problem of learning distributed representations for entities and relations of multi-relational data so as to predict missing links therein. Convolutional neural networks have recently shown their superiority for this problem, bringing increased model expressiveness while remaining parameter efficient. Despite the success, previous convolution designs fail to model full interactions between input entities and relations, which potentially limits the performance of link prediction. In this work we introduce ConvR, an adaptive convolutional network designed to maximize entity-relation interactions in a convolutional fashion. ConvR adaptively constructs convolution filters from relation representations, and applies these filters across entity representations to generate convolutional features. As such, ConvR enables rich interactions between entity and relation representations at diverse regions, and all the convolutional features generated will be able to capture such interactions. We evaluate ConvR on multiple benchmark datasets. Experimental results show that: (1) ConvR performs substantially better than competitive baselines in almost all the metrics and on all the datasets; (2) Compared with state-of-the-art convolutional models, ConvR is not only more effective but also more efficient. It offers a 7% increase in MRR and a 6% increase in Hits@10, while saving 12% in parameter storage.

1 Introduction

Multi-relational data refers to directed graphs whose nodes correspond to entities and edges different types of relations between entities. An edge of the form (*subject*, *relation*, *object*) indicates that there exists a specific relation between the subject and object entities. Learning with multi-relational data plays a pivotal role in many application domains, ranging from social networks or recommender systems to large-scale knowledge bases (KBs) (Bordes et al., 2013; Jenatton et al., 2012). This work focuses on modeling multi-relational data from KBs, with the aim of predicting missing facts on KBs, a challenging task known as link prediction in statistical relational learning (SRL) (Getoor and Taskar, 2007).

Various SRL techniques (Nickel et al., 2016a) have been proposed for this task, among which vector space embedding models (Wang et al., 2017) are gaining increasing attention due to their superior performance and potential scalability. The key idea there is to learn and operate on latent features (embeddings) of entities and relations, so as to uncover non-trivial connectivity patterns in multi-relational data. Previous works of this kind tend to adopt shallow, simple models to extract latent features, e.g., the translation based models (Bordes et al., 2013; Wang et al., 2014) or the bilinear models and their variants (Jenatton et al., 2012; Yang et al., 2015; Trouillon et al., 2016). Using these simple models allows one to easily handle large-scale KBs, but usually at the cost of learning less expressive features. In fact, such simple models typically generate a single feature with each entry of the embeddings. The only way to increase the number of features (and thus their expressiveness) is to increase the embedding size (Dettmers et al., 2018). This potentially limits the performance of link prediction with a given number of parameters. To increase model expressiveness, there emerge some deeper, more complicated designs, in particular those on the basis of neural network architectures (Socher et al., 2013; Bordes et al., 2014; Dong et al., 2014; Schlichtkrull et al., 2017a). Such approaches, however, often have more parameters and are prone to overfit, at least on the (relatively small) benchmark datasets used by the scientific community (Nickel et al., 2016a).

Recently, Dettmers et al. (2018) devised ConvE,

Proceedings of NAACL-HLT 2019, pages 978–987
Minneapolis, Minnesota, June 2 - June 7, 2019.

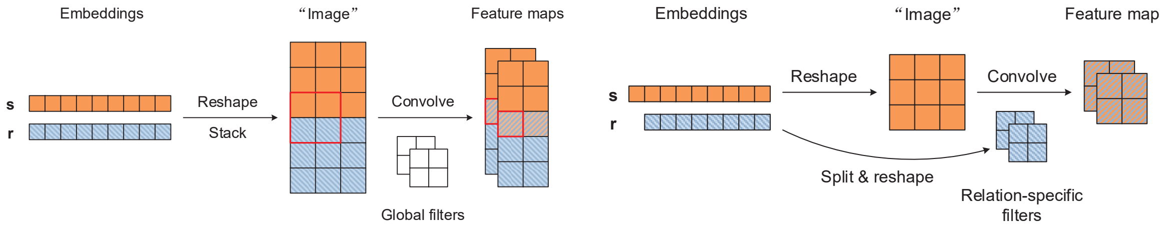
a multi-layer convolutional network which enables expressive feature learning while remaining highly parameter efficient. Given a subject-relation-object triple (s, r, o), ConvE first reshapes the vector representation of the subject s and that of the relation r into 2D matrices, and then concatenates the two matrices and feeds them into a 2D convolutional layer to extract higher-level, non-linear features, as illustrated in Figure 1(a). The resultant convolutional features are finally projected and matched with the vector representation of the object o via an inner product. Note that by sliding across the embeddings using small-sized filters, the convolution operator can easily generate much more features without increasing the embedding size. As such, ConvE offers increased expressiveness and achieves competitive performance in link prediction.

Nevertheless, despite its success, ConvE is still insufficient to fully capture the interactions between input entities and relations, which has long been recognized as crucial for modeling multi-relational data (Nickel et al., 2011; García-Durán et al., 2014; Trouillon et al., 2016). In ConvE, the (reshaped) representations of input entities and relations are simply stacked together and fed into a convolutional layer. Although 2D convolution is better than 1D convolution in modeling entity-relation interactions, typical 2D convolution with global filters on such a stacked matrix, however, can only model interactions around the concatenation line (Dettmers et al., 2018). Consider the example in Figure 1(a), where two matrices of size 3×3 are formed after reshaping, stacked, and fed as input to a convolutional layer. Convolving across the input with a global filter of size 2×2 will then be able to model interactions only in the regions where the two matrices adjoin (e.g., the region outlined in red). That means, only a small proportion of the output convolutional features (20% in this example, striped with orange and blue) will effectively capture entity-relation interactions, and the vast majority others will be entity- or relation-independent. This poses potential negative impacts on the link prediction task.

This paper, aiming at maximizing the interactions between input entities and relations, introduces ConvR, an adaptive convolutional network specifically designed for multi-relational data. As illustrated in Figure 1(b), the key idea of ConvR is to facilitate convolution across entity representations with its filters adaptively constructed from relation representations. Such adaptive convolution will model the interactions between the two types of input not only more naturally but also more effectively. Specifically, given a triple, the vector representation of the subject is reshaped and fed as input to a convolutional layer, while that of the relation is split and reshaped into a set of filters. ConvR then convolves across the input with these filters, enabling each filter (a part of the relation representation) to interact with diverse regions of the input (the entity representation). Through this adaptive convolution process, all the features generated will be able to capture entity-relation interactions (striped with orange and blue in Figure 1(b)). These convolutional features are finally projected and matched with the representation of the object.

Besides being more effective, adaptive convolution enables potentially more efficient modeling (in terms of the number of parameters). Compared with ConvE (Figure 1(a)), ConvR (Figure 1(b)) needs no global filters and generates smaller feature maps, making the follow-up projection layer roughly half as large as that of ConvE. The idea of adaptive convolution, in fact, is rather generic for the multi-relational scenario. By splitting and reshaping relation vectors, ConvR can be easily generalized to other paradigms such as 1D or 3D convolution, not restricted to the 2D setting. To facilitate a direct and fair comparison to ConvE where only 2D convolution is considered and tested, this paper takes the 2D setting as an example, and shows the superiority of ConvR over ConvE in this setting. We will investigate higher dimensional convolution in our future work.

Our contributions are as follows. (1) We propose a novel adaptive convolution model for learning with multi-relational data. Our approach, ConvR, takes full advantage of entity-relation interactions in a convolutional fashion, while still remaining highly parameter efficient. (2) We evaluate ConvR in the link prediction task on KBs and achieve very promising results on multiple benchmark datasets, including not only the popular WN18 and FB15K (Bordes et al., 2013), but also the more difficult WN18RR (Dettmers et al., 2018) and FB15K-237 (Toutanova and Chen, 2015). (3) We systematically compare the efficiency and effectiveness of ConvR and ConvE on FB15K-237, showing that ConvR can perform substantially better with a good variety of parameter settings. In particular, it offers a 7%



(a) ConvE: Convolution with global filters. (b) ConvR: Convolution with relation-specfic filters.

Figure 1: Reshaping and convolution in ConvE and ConvR. Entity-related neurons are marked in orange, relation-related ones striped with blue backslash, and those capturing entity-relation interactions striped with slash. White blocks stand for global filters applied to all input entities and relations.

increase in MRR and a 6% increase in Hits@10, with the total parameter number only 88% as large as that of ConvE.

2 Background

We consider multi-relational data represented as a graph, which can also be formalized as a set of subject-relation-object triples $\mathcal{G} = \{(s, r, o)\} \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}$. Here, $\mathcal{E}$ is the set of entities, and $\mathcal{R}$ the set of relations. Each triple (s, r, o) is composed of a subject entity $s \in \mathcal{E}$, a relation $r \in \mathcal{R}$, and an object entity $o \in \mathcal{E}$, indicating that there exists a relation of type r between the two entities s and o. Such triples are also called facts in knowledge bases (KBs).

We follow (Dettmers et al., 2018) and formalize link prediction on multi-relational data as a point-wise learning to rank problem, where the objective is to learn a scoring function $\psi : \mathcal{E} \times \mathcal{R} \times \mathcal{E} \rightarrow \mathbb{R}$. For any input triple (s, r, o), the higher the score $\psi(s, r, o)$, the more likely the triple is true. Various statistical relational learning (SRL) techniques have been proposed for this task. See (Nickel et al., 2016a) for a thorough review of such techniques, with their application on large-scale KBs.

This paper focuses on vector space embedding models, a branch of SRL with superior performance and potential scalability. Given an input triple (s, r, o), a model of this kind first maps the entities s, o and relation r to their distributed representations (i.e., embeddings), usually vectors $\mathbf{s}, \mathbf{r}, \mathbf{o} \in \mathbb{R}^d$ for efficient learning. A score is then defined for the triple by operating on these distributed representations, i.e., $\psi(s, r, o) = \phi(\mathbf{s}, \mathbf{r}, \mathbf{o})$. A great many approaches of this kind have been devised in the last few years, where a key difference is the designing of the scoring function $\phi(\mathbf{s}, \mathbf{r}, \mathbf{o})$. See (Wang et al., 2017) for a recent survey.

3 Adaptive Convolution on Multi-relational Data

This section presents ConvR, an adaptive convolutional network specifically designed for learning with multi-relational data. The key idea of ConvR is to facilitate convolution across entity representations with its filters adaptively constructed from relation representations, so as to maximize the interactions between the two types of input. Figure 1(b) provides a simple illustration of this idea. In the rest of this section, we detail the ConvR model, discuss parameter learning of it, and show its advantages over ConvE, a convolutional network achieving promising results in multi-relational link prediction (Dettmers et al., 2018). To facilitate a direct and fair comparison to ConvE, we focus on the 2D setting. But the idea can be easily generalized to other convolution paradigms.

The ConvR model Given a triple (s, r, o), ConvR maps the two entities s, o to vectors $\mathbf{s}, \mathbf{o} \in \mathbb{R}^{d_e}$, and the relation r to vector $\mathbf{r} \in \mathbb{R}^{d_r}$, where d_e and d_r are the embedding size of entities and relations, respectively. Then, the subject vector $\mathbf{s}$ is reshaped into a 2D matrix $\mathbf{S} \in \mathbb{R}^{d_e^h \times d_e^w}$ (where $d_e = d_e^h d_e^w$) and fed as input to a convolutional layer. As shown in (Dettmers et al., 2018), using 2D rather than 1D convolution would be able to extract more feature interactions and increase model expressiveness. The relation vector $\mathbf{r}$ is further split into blocks $\mathbf{r}^{(1)}, \cdots, \mathbf{r}^{(c)}$ with equal size, where each $\mathbf{r}^{(\ell)} \in \mathbb{R}^{d_r/c}$ is reshaped into a 2D convolution filter $\mathbf{R}^{(\ell)} \in \mathbb{R}^{h \times w}$. Here, c is the number of filters, h and w the height and width of each filter, and $d_r = chw$. Figure 1(b) gives a simple example of this reshaping process, where a subject vector of length 9 is reshaped into a 3×3 matrix, and a relation vector of length 8 is split and reshaped into

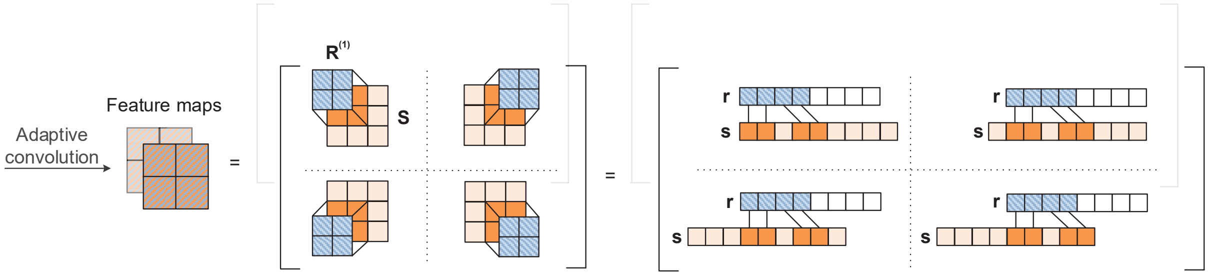


Figure 2: A simple illustration of adaptive convolution, where a 2×2 filter $\mathbf{R}^{(1)}$ (constructed from the first half of the relation vector $\mathbf{r}$) is convolved across a 3×3 input $\mathbf{S}$ (reshaped from the subject vector $\mathbf{s}$), generating a feature map of size 2×2. Each entry of the feature map could be calculated with certain dimensions of $\mathbf{r}$ and $\mathbf{s}$, marked with blue backslash and orange respectively.

two 2×2 filters.[1]

After reshaping, ConvR convolves across the input $\mathbf{S}$ using these adaptively constructed, relation-specific filters. For each filter $\mathbf{R}^{(\ell)}$, a convolutional feature map $\mathbf{C}^{(\ell)} \in \mathbb{R}^{(d_e^h - h + 1)\times(d_e^w - w + 1)}$ will be generated, with the mn-th entry calculated as:

$$c^{(\ell)}_{m,n} = f\left(\sum\nolimits_{i,j} s_{m+i-1,n+j-1} \times r^{(\ell)}_{i,j}\right), \qquad (1)$$

where $f(\cdot)$ is a non-linear function, e.g., ReLU (Krizhevsky et al., 2012). Figure 2 visualizes how such a feature map could be generated by convolving across the input with a relation-specific filter (the first equality sign "="), and how each entry of the feature map could be calculated with the original entity and relation vectors (the second equality sign "="). We can see that the adaptive convolution paradigm is quite effective in modeling entity-relation interactions. It enables rich interactions between input entity and relation representations at diverse regions, and all the convolutional features generated will be able to capture such interactions.

Finally, to compute the triple score $\psi(s, r, o)$, we flatten the convolutional feature maps $\mathbf{C}^{(1)}, \cdots, \mathbf{C}^{(c)}$ and stack them into a single vector $\mathbf{c}$. This vector is then projected into $\mathbb{R}^{d_e}$ by a fully-connected layer, and matched with the object vector $\mathbf{o}$ with an inner product, i.e.,

$$\psi(s, r, o) = f(\mathbf{W}\mathbf{c} + \mathbf{b})^{\top}\mathbf{o}, \qquad (2)$$

where $\mathbf{W} \in \mathbb{R}^{d_e \times c(d_e^h - h + 1)(d_e^w - w + 1)}$ and $\mathbf{b} \in \mathbb{R}^{d_e}$ are parameters of the fully-connected layer, and $f(\cdot)$ is again a non-linear function.

Parameter learning For learning the model parameters, we follow (Dettmers et al., 2018) and use 1-to-many scoring to speed-up training and evaluation. Unlike traditional 1-to-1 scoring which takes a triple (s, r, o) as input and directly scores it, 1-to-many scoring takes (s, r) as input and scores it against all candidate objects $o \in \mathcal{E}$ simultaneously, generating a score vector $\mathbf{p}^{s,r} \in \mathbb{R}^{|\mathcal{E}|}$. Each dimension of this score vector corresponds to an entity $o \in \mathcal{E}$, calculated as $p_o^{s,r} = \sigma(\psi(s, r, o))$, where $\psi(s, r, o)$ is the triple score defined in Eq. (2) and $\sigma(x) = \frac{1}{1+e^{-x}}$ the sigmoid function. For each input (s, r), we minimize the following cross-entropy loss:

$$\begin{aligned}\mathcal{L}(s,r) = -\frac{1}{|\mathcal{E}|}\sum_{o \in \mathcal{E}} y_o^{s,r}\log(p_o^{s,r}) + \\ (1 - y_o^{s,r})\log(1 - p_o^{s,r}),\end{aligned} \qquad (3)$$

where $y_o^{s,r}$ is a binary label. We have $y_o^{s,r} = 1$ if (s, r, o) is a valid triple and $y_o^{s,r} = 0$ otherwise. During optimization, we use dropout (Srivastava et al., 2014) to prevent overfitting. Specifically, we use dropout on the reshaped subject representations, the convolutional feature maps, and the projected vectors after the fully-connected layer. We also use batch normalization (Ioffe and Szegedy, 2015) on these representations to stabilize and speed up convergence. We use Adam (Kingma and Ba, 2014) optimizer and label smoothing (Szegedy et al., 2016) as suggested by ConvE.

Advantages over ConvE The most prominent advantage of ConvR over ConvE is its high ability to model entity-relation interactions in a convolutional fashion, which is crucial for learning with multi-relational data. ConvE, which convolves across stacked entity-relation representations with global filters, can only model interactions between

---

[1] During reshaping we consider the most natural ordering of the embedding entries. That means, a length-x vector is reshaped into a $y \times z$ matrix ($x = yz$) such that the first row of the matrix comes from the first z entries of the vector, the second row from the second z entries, and the y-th row from the last z entries.

the two types of input around the concatenation line, and only a small proportion of the convolutional features would be able to capture such interactions (see Figure 1(a)). ConvR, by contrast, enables entity-relation interactions at diverse regions, and all the convolutional features are able to capture such interactions (see Figure 1(b) and Figure 2).

Besides being more effective, ConvR might potentially be more efficient (in terms of the number of parameters). ConvE has a space complexity of $\mathcal{O}(d|\mathcal{E}| + d|\mathcal{R}| + chw + cd(2d^h - h + 1)(d^w - w + 1))$, where $d|\mathcal{E}|$ is to store entity vectors, $d|\mathcal{R}|$ relation vectors, chw the c global filters with size $h \times w$, $cd(2d^h - h + 1)(d^w - w + 1)$ the projection matrix in the fully-connected layer, and $d = d^h d^w$. As entity and relation representations need to be stacked in ConvE, they are usually of the same size, say d. In ConvR, convolution filters are adaptively constructed from relation vectors, so there is no need for global filters. Also, the input of the convolutional layer will be half-sized, generating smaller feature maps, and hence requires a smaller fully-connected layer. The space complexity of ConvR would be $\mathcal{O}(d_e|\mathcal{E}| + d_r|\mathcal{R}| + cd_e(d_e^h - h + 1)(d_e^w - w + 1))$. Although it could be possible to use different configuration of those common arguments in the two methods (e.g., different number of filters or entity vectors with different size), which may result in different memory cost, we empirically show that ConvR can perform substantially better than ConvE with a good variety of configurations, even those with fewer parameters (see the section “Parameter efficiency of ConvR” for details).

4 Experiments

In this section, we evaluate ConvR against competitive baselines in the link prediction task on multiple benchmark KBs. We also investigate parameter efficiency of ConvR against ConvE to further show its superiority.

4.1 Experimental Setup

Datasets We use four datasets for our experiments. The first two are the popular WN18 and FB15k, both released by (Bordes et al., 2013).[2] WN18 is a subset of WordNet for lexical relationships between words, and FB15k a subgraph of Freebase for generic facts. In most cases WN18 and FB15k encode a relation and its inverse relation at the same time. That means, once a fact is observed, there are usually two distinct triples created for it, e.g., $(s, \text{hyponym}, o)$ and $(o, \text{hypernym}, s)$, or $(s, \text{director-of}, o)$ and $(o, \text{directed-by}, s)$. As pointed out by (Toutanova and Chen, 2015) and (Dettmers et al., 2018), encoding inverse relations might suffer from test leakage, i.e., for each test triple (s, r, o), it is likely to find its inverse (o, r^{-1}, s) in the training set. To avoid this test leakage issue, we further use WN18RR (Dettmers et al., 2018),[3] a subset of WN18 with inverse relations removed, and FB15k-237 (Toutanova and Chen, 2015),[4] a filtered version of FB15k with both inverse and duplicate relations removed. Table 1 summarizes the statistics of the four datasets, where the training sets are used for parameter learning, the validation sets for hyperparameter tuning, and the test sets for evaluation.

Dataset	# Rel	# Ent	# Train	# Valid	# Test
FB15k	1,345	14,951	483,142	50,000	59,071
WN18	18	40,943	141,442	5,000	5,000
FB15k-237	237	14,541	272,115	17,535	20,466
WN18RR	11	40,943	86,835	3,034	3,134

Table 1: Statistics of the four datasets. Columns stand for the number of relations, number of entities, and number of triples in training/validation/test sets.

Evaluation protocol We adopt the ranking process proposed in (Bordes et al., 2013) for evaluation. For each triple (s, r, o) in the test set, we replace the subject s with every entity $e \in \mathcal{E}$, and calculate a score for the corrupted triple (e, r, o). Then we sort these scores in descending order to get the rank of the correct subject s. Since corrupted triples may also be valid, we remove those that already exist in either the training, validation, or test set during ranking, i.e., the *filtered* setting as called by (Bordes et al., 2013). This whole procedure is repeated while replacing the object o. We aggregate over all test triples, and report the mean reciprocal rank (MRR) and the proportion of correct entities ranked in the top n (Hits@n), with $n = 1, 3, 10$.

Implementation details We implement ConvR in PyTorch. In our experiments, we fix mini-batch

size to 128, initial learning rate to 0.001, and label smoothing coefficient to 0.1. Other hyperparameters are selected with grid search on the validation set. Specifically, we tune the entity embedding size $d_e \in \{100, 200\}$, filter number $c \in \{50, 100, 150, 200\}$, and filter size $h \times w \in \{3 \times 3, 4 \times 4, 5 \times 5\}$. All dropout ratios, i.e., ρ_1 on reshaped subject representations, ρ_2 on convolutional feature maps, and ρ_3 on projected vectors after the fully-connected layer, are tuned in $\{0.1, 0.2, 0.3, 0.4, 0.5\}$. On each dataset, we choose the optimal configuration with the highest MRR on the validation set within 1000 epochs, and report its performance on the test set. Table 2 lists the optimal configurations of ConvR on the four datasets.

Baseline methods We compare ConvR against a variety of competitive baselines, which can be roughly categorized into two groups:

- Methods that use (relatively) simple operations in vector space to model multi-relational data, including TransE (Bordes et al., 2013), DistMult (Yang et al., 2015) and its reimplementation (Kadlec et al., 2017), HolE (Nickel et al., 2016b), ComplEx (Trouillon et al., 2016), ANALOGY (Liu et al., 2017), TorusE (Ebisu and Ichise, 2017), Gaifman (Niepert, 2016), KBGAN (Cai and Wang, 2017), KBLRN (Garcia-Duran and Niepert, 2018), and Node+LinkFeat (Toutanova and Chen, 2015).

- Methods that further introduce multi-layer structures and non-linearity, in particular those based on neural networks, including R-GCN (Schlichtkrull et al., 2017a), Neural LP (Yang et al., 2017), ConvE (Dettmers et al., 2018), and ConvKB (Nguyen et al., 2018).

4.2 Link Prediction Results

Table 3 reports the results on WN18 and FB15k, and Table 4 the results on WN18RR and FB15k-237. On all the four datasets, the results for the baselines are taken directly from previous literature to avoid re-implementation bias. Since not all baselines have their results reported on all the four datasets, we cannot make the two sets of baselines compared in Table 3 and Table 4 exactly the same. From the results, we can see that: (1) On WN18 and FB15k, ConvR performs better than or at least as well as the baselines in almost all the metrics. (2) Compared to ConvE, it offers a 5% increase in MRR, a 7% increase in Hits@1, and a 2% increase in Hits@10 on FB15k. (3) On the more difficult WN18RR and FB15k-237, ConvR consistently outperforms most of the baselines, except for MRR score of ConvKB on FB15k-237. However, on WN18RR ConvR outperforms ConvKB on all known metrices, especially MRR. This discrepancy may be attributed to ConvKB's initialization with TransE on FB15k-237. (4) Compared to ConvE, it offers a 3% increase in MRR, a 14% increase in Hits@1, a 12% increase in Hits@10 on WN18RR, and an 11% increase in MRR, a 9% increase in Hits@1, an 8% increase in Hits@10 on FB15k-237.

4.3 Parameter Efficiency of ConvR

We further investigate parameter efficiency of ConvR against ConvE on FB15k-237. Specifically, we tune the number of filters $c \in \{20, 40, 60, 80, 100\}$ and the filter size $h \times w \in \{2 \times 2, 3 \times 3, 4 \times 4, 5 \times 5\}$, fix the other hyperparameters to their optimal configurations (see Table 2 for details), and show how the performance of ConvR (on the test set) will change as the number of parameters varies. For comparison, we directly show the performance and parameter efficiency of the optimal ConvE model, as reported in (Dettmers et al., 2018). The results are given in Table 5.[5]

From the results, we can see that: (1) The parameter number of ConvR steadily grows as the filter number c and filter size $h \times w$ increase, but the performance does not change much. That means, ConvR might achieve relatively good (though not best) performance with a potentially small number

---

[5] Note that some results reported here are even better than those reported in Table 4. This is because in Table 4 we determine optimal configurations according to MRR on the validation set, which may not necessarily lead to best performance on the test set.

of parameters. (2) ConvR consistently and substantially outperforms the best performing ConvE with all the configurations listed in Table 5. (3) In particular, even the most efficient configuration (i.e., $c = 20$ and $h \times w = 2 \times 2$) offers a 7% increase in MRR and a 6% increase in Hits@10, with its parameter number only 88% as large as that of ConvE.

5 Related Work

Link prediction is a crucial task for knowledge bases (KBs). A good variety of statistical relational learning techniques have been proposed for this task (Nickel et al., 2016a), among which vector space embedding models are most particular due to their superior performance and potential scalability. Early works of this kind tend to employ simple vector space operations for link prediction. For example, TransE (Bordes et al., 2013) takes relations as translations between subject and object entities. DistMult (Yang et al., 2015) uses multilinear dot product to characterize three-way interactions among subjects, relations, and objects. ComplEx (Trouillon et al., 2016) further generalizes DistMult to complex vector space. Using simple models allows one to easily handle large-scale KBs, but usually at the cost of less model expressiveness (Dettmers et al., 2018). HolE (Nickel et al., 2016b) tries to increase model expressiveness while keeping simplicity. It uses cross-correlation, i.e., the

inverse of circular convolution, to match subject and object entities, which has some similarity to our work. But HolE is not a typical neural network architecture. It does not learn multiple layers of non-linear features, and hence is less expressive than our approach.

A more direct way of increasing model expressiveness is to employ deeper, more complicated neural network architectures, e.g., multi-layer perceptron (Dong et al., 2014), semantic matching energy networks (Bordes et al., 2014), and neural tensor networks (Socher et al., 2013). This kind of approaches, however, often have more parameters and are prone to overfit (Nickel et al., 2016a). (Dettmers et al., 2018) recently devised ConvE, a multi-layer convolutional network which offers increased model expressiveness while remaining highly parameter efficient. After that, (Nguyen et al., 2018) propose ConvKB that explores the global relationships among same dimensional entries of the entity and relation embeddings. However, neither of them models the interactions between various positions of entities and relations. R-GCN (Schlichtkrull et al., 2017a) is another convolutional network designed for KBs, generalized from GCN (Kipf and Welling, 2016) for uni-relational data. But the convolution of R-GCN is conducted in a message passing manner, quite different from our work.

Convolutional neural networks have been successfully applied to a wide variety of domains, ranging from speech or visual recognition (Abdel-Hamid et al., 2014; Krizhevsky et al., 2012) to natural language processing (Collobert et al., 2011). Similar ideas of using adaptive or dynamic convolutional filters have been studied before (Lee et al., 2010; Jia et al., 2016; Kang et al., 2017). But most of such works focus on image or video processing. This work focuses on multi-relational data and devises an adaptive convolution paradigm particularly suitable for this scenario.

6 Conclusion

In this paper, we propose ConvR, an adaptive convolutional network specially designed for learning with multi-relational data. In contrast to previous work which convolves across stacked representations with global filters, ConvR adaptively constructs convolution filters from relation representations, and applies these filters across entity representations to generate convolutional features. This adaptive convolution paradigm enables rich interactions between entity and relation representations at diverse regions, and all convolutional features generated in this way will be able to capture such interactions. Experimental results on multiple benchmark knowledge bases show that ConvR achieves significant and consistent improvements against a variety of baselines. In particular, it is not only more effective but also more efficient than state-of-the-art convolutional models, offering a 7% increase in MRR and a 6% increase in Hits@10, while saving 12% in parameter storage.

As future work, we plan to devise convolutional paradigms that can maximize interactions not only between subject entities and relations, but also between object entities and relations. In ConvR, we use 1-to-many scoring to speed up training and evaluation. As a side effect, object representations can only interact with a hidden vector (output of the fully-connected layer) via an inner product, which potentially limits the performance of ConvR. It is worth investigating modeling these interactions while keeping the merit of fast training and evaluation.

Acknowledgments

We would like to thank all the anonymous reviewers for their insightful and valuable suggestions, which help to improve the quality of this paper. This work is supported by the National Natural Science Foundation of China (grant No. 61876223).

Abstract

Knowledge graphs have evolved rapidly in recent years and their usefulness has been demonstrated in many artificial intelligence tasks. However, knowledge graphs often have lots of missing facts. To solve this problem, many knowledge graph embedding models have been developed to populate knowledge graphs and these have shown outstanding performance. However, knowledge graph embedding models are so-called black boxes, and the user does not know how the information in a knowledge graph is processed and the models can be difficult to interpret. In this paper, we utilize graph patterns in a knowledge graph to overcome such problems. Our proposed model, the *graph pattern entity ranking model* (GRank), constructs an entity ranking system for each graph pattern and evaluates them using a ranking measure. By doing so, we can find graph patterns which are useful for predicting facts. Then, we perform link prediction tasks on standard datasets to evaluate our GRank method. We show that our approach outperforms other state-of-the-art approaches such as ComplEx and TorusE for standard metrics such as HITS@n and MRR. Moreover, our model is easily interpretable because the output facts are described by graph patterns.

1 Introduction

Knowledge graphs can be used to describe real-world relations as facts in a form that a computer can easily process and has been used for many artificial intelligence tasks (Hakimov et al., 2012; Daiber et al., 2013; Bordes et al., 2014). In a knowledge graph, a fact is represented by a labeled and directed edge, called a triple (h, r, t), where h and t are entity nodes and r is a relation label of an edge from h to t. Knowledge graphs such as YAGO (Suchanek et al., 2007), DBpedia (Auer et al., 2007), and Freebase (Bollacker et al., 2008) have developed rapidly in recent years and are used for many artificial intelligence tasks such as question answering, content tagging, fact-checking, and knowledge inference. Although some knowledge graphs already contain millions of entities and billions of facts, they might still be incomplete and some facts may be missing. Hence, we need to develop a system that can predict missing facts to complete knowledge graphs automatically.

Many kinds of models for *link prediction* have been developed to estimate unknown facts. Knowledge graph embedding models, which are the most widely used approach in this field, map entities and relations in a knowledge graph onto a vector space and obtain the latent underlying features. However, these models are generally difficult to interpret, as we do not know how information is processed in the models and the predicted facts are output without explanation.

In this paper, we construct statistical models based on *graph pattern matching*. These models are not only easy to interpret compared to knowledge graph embedding models but also outperform state-of-the-art models for link prediction.

Our main contributions in this paper are as follows:

- Defining *graph pattern association rules* (GPARs) for a knowledge graph.
- Introducing *a graph pattern probability model* (GPro) and discussing its flaws.
- Proposing a novel model, *the graph pattern entity ranking model* (GRank), which uses graph patterns to rank entities.
- Proposing distributed rankings to address the problem arising from having the same score for multiple entities.

Proceedings of NAACL-HLT 2019, pages 988–997
Minneapolis, Minnesota, June 2 - June 7, 2019.

- Evaluating the proposed models through link prediction tasks for standard datasets: It is shown that our model outperforms most state-of-the-art knowledge graph embedding models for the HITS@n and MRR metrics.

The remainder of this paper is organized as follows. In Section 2, we discuss related work on link prediction. In Section 3, we define the terms and notation used in this paper. In Section 4, we define standard confidences for GPARs and discuss their problems. In Section 5, we propose the GRank model to deal with these problems. In Section 6, we present an experimental study in which we compare our models with baseline results for benchmark datasets. In Section 7, we conclude this paper.

2 Related Work

We categorize related work for link prediction into two groups: work on knowledge graph embedding models (which are latent feature models) and work on observed feature models.

2.1 Knowledge Graph Embedding Models

Recently, knowledge graph embedding models have yielded great results in link prediction tasks. Knowledge graph embeddings models embed entities and relations on a continuous space and can be roughly classified into three types: translation-based models, bilinear models, and neural network-based models.

The first translation-based model was the TransE (Bordes et al., 2013) model, which gained attention because of its effectiveness and simplicity. TransE employs the principle $\boldsymbol{h} + \boldsymbol{r} = \boldsymbol{t}$, where $\boldsymbol{h}, \boldsymbol{r}$ and $\boldsymbol{t}$ are the embeddings of h, r and t, respectively. While this principle efficiently captures first-order rules, the TransE approach still has some problems. The conflict between principle and regularization is one of these problems and the TorusE (Ebisu and Ichise, 2018) model was recently proposed to solve this problem by embedding entities and relations on a torus manifold.

RESCAL (Nickel et al., 2011) was the first bilinear model, where each relation is represented by a square matrix and the score of the triple (h, r, t) is calculated by a bilinear map which corresponds to the matrix of the relation r and whose arguments are $\boldsymbol{h}$ and $\boldsymbol{t}$. Hence, RESCAL represents the most general form of a bilinear model. Extensions of RESCAL have been proposed by restricting bilinear functions, for example, DistMult (Yang et al., 2015) and ComplEx (Trouillon et al., 2016) restrict the matrices representing the relations to diagonal matrices.

Neural network-based models have layers and an activation function like a neural network. The Neural Tensor Network (NTN) (Socher et al., 2013) has a standard linear neural network structure and a bilinear tensor structure, and can be considered as a generalization of RESCAL, where the weight of the network is trained for each relation. Graph Convolutional Networks (GCNs) (Duvenaud et al., 2015; Defferrard et al., 2016; Kipf and Welling, 2017) exploit the convolution operator to capture local information for a graph, however these models are for undirected graphs. Relational GCNs (Schlichtkrull et al., 2017) and ConvE (Dettmers et al., 2018) are generalizations of GCNs for knowledge graphs.

Knowledge graph embedding is the standard approach for link prediction. However, it suffers from low interpretability, resulting in triples which are predicted without any clear reason.

2.2 Observed Feature Models

The main advantage of observed feature models over knowledge graph embedding models is their interpretability. Additionally, Toutanova et al. (2015) proposed a relatively simple logistic regression model, the Node+LinkFeat model, which utilizes only one-hop information in a knowledge graph and demonstrated that it performs far better for link prediction on standard datasets than most existing knowledge graph embedding models. However, it has also been shown that the Node+LinkFeat model cannot deal with a low-redundancy dataset because the model uses information which is too local. On the other hand, it has shown that a logistic regression model, the PRA model (Lao and Cohen, 2010; Lao et al., 2011), which utilizes multi-hop information do not have sufficient accuracy (Liu et al., 2016). This suggests logistic regression does not have enough power to deal with deep information. These studies have motivated research toward developing a more efficient model utilizing deeper information.

We begin by discussing GPARs, which were proposed recently by Fan et al. (2015), and have shown their usefulness for social network graphs

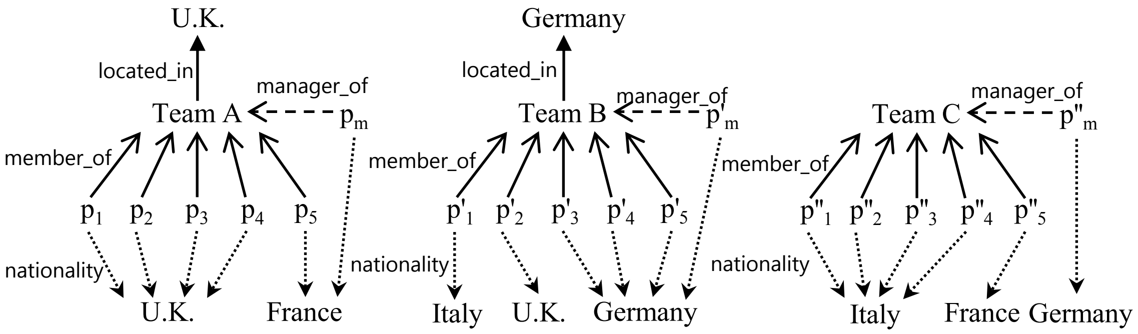

Figure 1: Graph G_{ex} of sports teams.

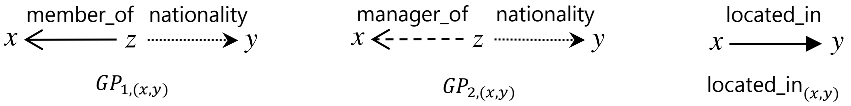

Figure 2: Graph patterns on G_{ex}.

because graph patterns can capture deeper information lying in a knowledge graph and a GPAR explicitly describe the process of prediction. However, the definition of GPARs by Fan et al. cannot be applied to a knowledge graph because Fan et al. assumes a different structure for a social network graph than a knowledge graph. In the following section, we define GPARs for a knowledge graph.

3 Preliminaries

In this section, we introduce the definitions and notation required to discuss GPAR-based models.

3.1 Graph Pattern Association Rules on Knowledge Graphs

We modify GPARs for application to a knowledge graph following the definitions of Fan et al. (2015).

Knowledge Graph: A *graph* is defined as $G = \{(h, r, t)\} \subset E \times R \times E$, where E denotes a set of entities and R denotes a set of relations. An element (h, r, t) of G is called a triple and represents the directed relation r between h and t.

An example graph G_{ex} is shown in Figure 1, where p_i represents a person, Teams "A", "B", and "C" represent sports teams, and countries are entities in E_{ex} with labeled arrows between two entities representing directed relations in R_{ex}.

Graph Pattern: A *graph pattern* on G is a graph $GP_{(x,y)} = \{(z_i, r, z_j)\} \subset V_{GP} \times R \times V_{GP}$, where V_{GP} denotes a set of variables, x and y are two designated variables, and R is the set of relations of G. We suppose V_GP has no redundancy, in other words, $\forall z \in V_{GP}, \exists(z_i, r, z_j) \in GP_{(x,y)}, z = z_i \lor z = z_j$.

Some examples of graph patterns on G_{ex} are shown in Figure 2, where $GP_{1,(x,y)} = \{(z, \text{member\_of}, x), (z, \text{nationality}, y)\}$, $GP_{2,(x,y)} = \{(z, \text{manager\_of}, x), (z, \text{nationality}, y)\}$, and $\text{located\_in}_{(x,y)} = \{(x, \text{located\_in}, y)\}$. Our focus in this paper is on finding useful graph patterns for link prediction.

Graph Pattern Matching Function: A *matching function* of $GP_{(x,y)}$ on $(h, t) \in E \times E$ is an injective function $m : V_{GP} \to E$ that satisfies the following conditions: $m(x) = h$, $m(y) = t$, and for all $(z_i, r, z_j) \in GP_{(x,y)}$, $(m(z_i), r, m(z_j)) \in G$. $M(GP_{(x,y)}, (h, t))$ denotes the set of all matching functions of $GP_{(x,y)}$ on (h, t). We say $GP_{(x,y)}$ matches (h, t) if there is at least one matching function of $GP_{(x,y)}$ on (h, t) (i.e. $M(GP_{(x,y)}, (h, t)) \neq \emptyset$).

For example, $m : V_{GP_{1,(x,y)}} \to E_{ex}$ $(m(x) = \text{Team A}, m(z) = \text{p}_1, m(y) = \text{U.K.})$ is a matching function of $GP_{1,(x,y)}$ on $(\text{Team A}, \text{U.K.})$.

GPAR: A *graph pattern association rule* (GPAR) AR is defined as $GP_{(x,y)} \Rightarrow r_{(x,y)}$, where $GP_{(x,y)}$ and $r_{(x,y)}$ are graph patterns and $r_{(x,y)} = \{(x, r, y)\}$.

For example, a GPAR $AR_1 = P_{1,(x,y)} \Rightarrow \text{located\_in}_{(x,y)}$ would indicate that if there is a matching function of $GP_{1,(x,y)}$ on (h,t), then it is likely that there is also a matching function of $\mathsf{located\_in}_{(x,y)}$ on (h,t), i.e. $(h, \mathsf{located\_in}, t)$ is a fact.

3.2 Reconstruction of Knowledge Graph to Queries

Our task is the *link prediction* of a knowledge graph, i.e. to predict the missing entity of a *query*, which is formally defined as follows:

Query: A *query* is a triple which is missing an entity: $(h, r, ?)$ or $(?, r, t)$.

We divide a knowledge graph G into queries and answers to use as training data for our model. Let $Q_{r,\text{head}}$ ($Q_{r,\text{tail}}$) denote the set of training queries missing a head (tail) entity for a relation r obtained from G; then $Q_{r,\text{head}}$ ($Q_{r,\text{tail}}$) is defined as follows:

$$\begin{aligned} Q_{r,\text{head}} &= \{(?, r, t) \mid (h, r, t) \in G\}, \\ Q_{r,\text{tail}} &= \{(h, r, ?) \mid (h, r, t) \in G\} \end{aligned}$$

In this case, the answers of training queries are defined as follows:

$$\begin{aligned} a_{(?,r,t)} &= \{h \mid (h, r, t) \in G\}, \\ a_{(h,r,?)} &= \{t \mid (h, r, t) \in G\} \end{aligned}$$

A knowledge graph usually contains only positive triples. Hence, we adopt the *partial completeness assumption* (PCA) (Galárraga et al., 2013, 2015) to generate negative answers.

Partial Completeness Assumption: if (h, r, t) is in G, then

$$\forall t' \in E, ((h, r, t') \notin G \Rightarrow (h, r, t') \text{ is negative}) \quad (1)$$

$$\forall h' \in E, ((h', r, t) \notin G \Rightarrow (h', r, t) \text{ is negative}) \quad (2)$$

The standard PCA definition consists only of Equation (1), but we add Equation (2) because we also need to allow negative answers for $Q_{r,\text{head}}$. Under PCA, negative answers for each question are defined as follows:

$$n_{(?,r,t)} = E \setminus a_{(?,r,t)}, \; n_{(h,r,?)} = E \setminus a_{(h,r,?)}$$

4 Standard Confidence and Problems

4.1 AMIE with GPARs

An association rule is essentially a binary classifier, i.e. the antecedent of an association rule matches or does not match, and an association rule is thus evaluated. Following this idea, we suggest the most straightforward way to define the *confidence*, which indicates the reliability of an association rule, is the conditional probability, which is the probability of the consequent given the antecedent for a GPAR. The conditional probability $Pr_{tail}(r_{(x,y)} \mid GP_{(x,y)})$ of a GPAR $GP_{(x,y)} \Rightarrow r_{(x,y)}$ to predict a tail is defined as follows:

$$conf_{tail}(GP_{(x,y)} \Rightarrow r_{(x,y)}) = Pr_{tail}(r_{(x,y)} \mid GP_{(x,y)}) = \frac{\sum_{(h,r,?) \in Q_{r,\text{tail}}} |\{t \in a_{(h,r,?)} \mid M(GP_{(x,y)}, (h,t)) \neq \emptyset\}|}{\sum_{(h,r,?) \in Q_{r,\text{tail}}} |\{t' \in E \mid M(GP_{(x,y)}, (h,t')) \neq \emptyset\}|}$$

For each query, the candidate entities found by the graph pattern are counted for the denominator while only correct entities are counted for the numerator. This confidence is used to evaluate GPARs only to answer queries with a missing tail because $Q_{r_{tail}}$ and its answers are used to define it.

Interestingly, GPARs with this confidence are equivalent to AMIE (Galárraga et al., 2013, 2015), which was proposed to find horn clauses for a knowledge graph, although AMIE was proposed before the appearance of GPARs. However, AMIE originally has only one confidence value for a GPAR because AMIE is not designed for link prediction. Hence, we introduce the following alternative definition for the confidence value to answer a query missing a head entity.

4.2 Standard Link Prediction Model and Problems

We define another confidence to deal with a query with a missing head entity as follows:

$$conf_{head}(GP_{(x,y)} \Rightarrow r_{(x,y)}) = Pr_{head}(r_{(x,y)} \mid GP_{(x,y)}) = \frac{\sum_{(?,r,t) \in Q_{r,\text{head}}} |\{h \in a_{(?,r,t)} \mid M(GP_{(x,y)}, (h,t)) \neq \emptyset\}|}{\sum_{(?,r,t) \in Q_{r,\text{head}}} |\{h' \in E \mid M(GP_{(x,y)}, (h',t)) \neq \emptyset\}|}$$

Additionally, we restrict matching functions to injective functions as defined in Section 3.1, which is different from AMIE, because the restriction avoids redundant matching functions which map multiple variables to the same entity and gives a good bias for real-world knowledge. For example, an GPAR $GP_{3,(x,y)} \Rightarrow \mathsf{sibling\_of}_{(x,y)}$, where $GP_{3,(x,y)} = \{(z, \mathsf{parent\_of}, x), (y, \mathsf{child\_of}, z)\}$, is helpful to predict siblings. However, let p represent a person, $GP_{3,(x,y)}$ matches (p,p) although p is not a sibling of p. The above restriction omits such concerns. For another example, a GPAR $\{(z_1, \mathsf{manager\_of}, x), (z_1, \mathsf{manager\_of}, z_2), (z_2, \mathsf{located\_in}, y)\} \Rightarrow \mathsf{located\_in}_{(x,y)}$ on the graph

G_{ex} in Figure 1 should not be considered helpful because $m(x) = m(z_2)$ holds for a matching function m of the antecedent pattern and as a result, the GPAR is almost tautological. We consider two confidence values for GPARs, $conf_{tail}$ and $conf_{head}$, referred to as the *graph pattern probability model* (GPro).

However, GPro cannot deal with queries where counting the number of matching functions is crucial. An example where the number of matching functions is important is shown in Figure 1. In G_{ex}, the country that Team C is located in is missing. One might guess that Team C is located in Italy because most of the Team C players have Italian nationality and the nationality of a player often matches the country that the team is located in. However, GPro underestimates the GPAR $AR_{1,(x,y)} = GP_{1,(x,y)} \Rightarrow \mathsf{located\_in}_{(x,y)}$, which is equivalent to one's guessing process: $conf_{tail}(AR_{1,(x,y)}) = 2/5$, while $conf_{tail}(AR_{2,(x,y)}) = 1/2$, where $AR_{2,(x,y)} = GP_{2,(x,y)} \Rightarrow \mathsf{located\_in}_{(x,y)}$. Hence, GPro judges $AR_{2,(x,y)}$ is more useful than $AR_{1,(x,y)}$, and as a result, GPro predicts Team C is located in Germany rather than Italy.

This problem is caused by considering a GPAR as a binary classifier, i.e. the matching number is not taken into account. For example, if we apply $AR_{1,(x,y)} = P_{1,(x,y)} \Rightarrow \mathsf{located\_in}_{(x,y)}$ to a query (Team A, $\mathsf{located\_in}$, ?) in the traditional way (as a binary classifier), the output will contain two entities with equal weighting, the U.K. and France, because $P_{1,(x,y)}$ matches (Team A, U.K.) and (Team A, France). Then, one of the output entities is correct and the other is incorrect. This is the reason why $AR_{1,(x,y)}$ is underestimated.

To deal with this problem, in this paper, we consider a GPAR as an entity ranking system by counting the number of matching functions of the antecedent graph pattern rather than considering as a binary classifier.

5 GPAR as Entity Ranking System and Evaluation Metrics

As well as considering a GPAR as a binary classifier, we consider it as an entity ranking system. Entities are ranked according to a score, based on their number of matching functions.

Moreover, we introduce the *distributed rankings* for entities, which are proposed to deal with situations where multiple entities have the same score. Then, we define the evaluation metrics for the distributed rankings to evaluate GPARs for link prediction.

These approaches overcome the problems shown in Section 4.2.

5.1 GPAR as Entity Ranking System

We consider a GPAR as a ranking system in this section to rank queries for which counting the number of matching functions of the antecedent is helpful, as shown in Section 4.2.

First, we define a scoring function whose arguments are a graph pattern $GP_{(x,y)}$ and a pair of entities (h, t). The scoring function returns the number of matching functions of a pattern on a pair, which is formally defined as follows:

$$score(GP_{(x,y)}, (h, t)) = |M(GP_{(x,y)}, (h, t))|$$

Given a pattern $GP_{(x,y)}$ and a query $(h, r, ?)$, we can obtain the $score(GP_{(x,y)}, (h, t'))$ for each candidate tail entity t'. Then we obtain the rankings of the tail entities in descending order of the scores. The head entity rankings for a query $(?, r, t)$ are also obtained in this way. This ranking method gives us new perspective when we apply GPARs to answer a query. For example, if we apply $AR_{1,(x,y)} = P_{1,(x,y)} \Rightarrow \mathsf{located\_in}_{(x,y)}$ to a query (Team A, $\mathsf{located\_in}$, ?) the U.K. will be ranked first and France second. In this situation, we can say that $AR_{1,(x,y)}$ works because the correct entity ranks higher than the wrong entity. We can basically evaluate a GPAR as an entity ranking system by evaluating output rankings by an evaluation metric for an ranking system such as the *mean average precision*. However, often multiple entities have the same score and traditional metrics cannot deal with the situation. To deal with this problem, we propose a new concept, called *distributed rankings*, and the corresponding metrics in the following sections.

5.2 Distributed Rankings

We propose distributed rankings where each entity can distribute over multiple ranks and each rank can have multiple entities, to deal with situations where multiple entities have the same score.

Traditional rankings of entities are represented by a matrix $Rank = (rank_{i,j}) \in \{0, 1\}^{n \times n}$, where n is the number of entities, and for each column and row there is one 1 element. In this matrix, columns represent entities and rows represent ranks. For example, $rank_{i,j} = 1$ means that the entity j has rank i. On the other hand, distributed rankings of entities are represented by a matrix $dRank = (drank_{i,j}) \in [0,1]^{n\times n}$, where the summation of a column or a row is equal to 1. Different from traditional rankings, the value of each element is continuous and multiple elements can be greater than 0 in a column or a row. For example, $rank_{i,j} = 0.5$ means that half of the entity j has rank i. Note that a traditional ranking matrix is a distributed ranking matrix.

Given a pattern $GP_{(x,y)}$ and a query $(h,r,?)$, We obtain distributed rankings of entities, $dRANK(GP_{(x,y)},(h,r,?))$, according to their scores as follows. Let a be the number of entities whose scores are greater than the entity represented by j and let b be the number of entities whose scores are the same as the entity represented by j. Then, $drank_{i,j}$, an element of $dRANK(GP_{(x,y)},(h,r,?))$, is determined to be $1/b$ for $a+1 \leqq i \leqq a+b$ and 0 otherwise. Distributed rankings of head entities for a query $(?,r,t)$ are obtained in the same way, and we refer to them as $dRANK(GP_{(x,y)},(?,r,t))$. Unlike traditional rankings, distributed rankings are uniquely determined from the scores of entities.

Traditional rankings can be evaluated by metrics such as the average precision or the cumulative gain. However, distributed rankings cannot be evaluated by these metrics. Hence, we require a different evaluation metric for distributed rankings.

5.3 Evaluation of GPARs as Entity Ranking System

We use a GPAR to obtain distributed entity rankings as shown in Section 5.1. In this section, we define a metric to evaluate distributed rankings of entities by generalizing the *average precision* to evaluate a GPAR.

For a pattern $GP_{(x,y)}$ and a training query $(h,r,?)$, the *distributed precision at k*, $dPre_k$, of $dRANK(GP_{(x,y)},(h,r,?))$ is defined as follows:

$$dPre_k(GP_{(x,y)},(h,r,?)) = \frac{\sum_{i=1}^{k}\sum_{t_j\in a_{(h,r,?)}} drank_{i,j}}{k}$$

where t_j is an entity represented by j and $drank_{i,j}$ is an element of $dRANK(GP_{(x,y)},(h,r,?))$. The elements related with correct entities ranked higher or equal to k are summed up as the traditional precision at k.

Dataset	# Entities	# Relations	# Training	# Validation	# Test
WN18	40,943	18	141,442	5,000	5,000
WN18RR	40,943	11	86,835	3,034	3,134
FB15k	14,951	1,345	483,142	50,000	59,071
FB15k-237	14,541	237	272,115	17,535	20,466

Table 1: Statistics of benchmark datasets. The numbers of entities, relations, training triples, validation triples, and test triples are shown.

Then, the *distributed average precision*, *dAP*, is defined for a pattern $GP_{(x,y)}$ and a training query $(h,r,?)$ as follows:

$$dAP(GP_{(x,y)},(h,r,?)) = \frac{\sum_{t_j\in a_{(h,r,?)}}\sum_{k=1}^{n} dPre_k(GP_{(x,y)},(h,r,?))) \times drank_{k,j}}{|a_{(h,r,?)}|}$$

where t_j is an entity represented by j, $drank_{i,j}$ is an element of $dRANK(GP_{(x,y)},(h,r,?))$, and n is the number of entities. The numerator of the average precision for traditional rankings is the summation of the precision at k for relevant entities. However, a relevant entity represented by j is distributed over multiple ranks in $dRANK$ so that the precision at k multiplied by $drank_{k,j}$ is summed over k where a relevant entity j is distributed. $dAP(GP_{(x,y)},(?,r,t))$ for a training query with a missing head can be defined in the same way. The *distributed mean average precision* for a GPAR $GP_{(x,y)} \Rightarrow r_{(x,y)}$ is defined as follows:

$$\begin{aligned} &dMAP_{head}(GP_{(x,y)} \Rightarrow r_{(x,y)}) \\ &\quad = \sum_{(?,r,t)\in Q_{r,\mathrm{head}}} \frac{dAP(GP_{(x,y)},(?,r,t))}{|Q_{r,\mathrm{head}}|} \\ &dMAP_{tail}(GP_{(x,y)} \Rightarrow r_{(x,y)}) \\ &\quad = \sum_{(h,r,?)\in Q_{r,\mathrm{tail}}} \frac{dAP(GP_{(x,y)},(h,r,?))}{|Q_{r,\mathrm{tail}}|} \end{aligned}$$

We also define dMAP with for the "*filtered*" (Bordes et al., 2013) rankings which are obtained from original rankings by eliminating entities whose corresponding triples (except the target triple) were included in the training dataset. "Filtered" dMAP (fdMAP) is the mean of the dAP of "filtered" rankings for each answer of queries.

We refer to GPARs considered as entity ranking systems with these dMAPs or fdMAPs as the *graph pattern entity ranking model* (GRank).

By using a graph pattern to rank entities, GRank is able to properly estimate GPARs where the number of matches is important as

Table 2: Mean Reciprocal Rank (MRR) and HITS@n scores obtained for the link prediction tasks on the WN18, FB15k, WN18RR, and FB15k-237 datasets. The highest result for each column is shown in bold. The results of TransE and TorusE were reported by Ebisu and Ichise (2018), the results of RESCAL were reported by Nickel et al. (2016), the results of DistMult and ComplEx were reported by Trouillon et al. (2016), the results of R-GCN and ConvE were reported by Dettmers et al. (2018), the results of PRA were reported by Liu et al. (2016), and the results of Node+LinkFeat were reported by Toutanova and Chen (2015).

shown in Section 4.2, unlike GPro. For example, $dMAP_{tail}(AR_{1,(x,y)}) = 1$, is the maximum value, while $dMAP_{tail}(AR_{2,(x,y)}) = 1/2$ in Figure 1. Hence, GRank can answer the query (Team C, located_in, ?) by applying $AR_{1,(x,y)}$.

6 Experiments

Our proposed models, GPro (Section 4.2) and GRank (Section 5), are evaluated through link prediction tasks and compared with other state-of-the-art link prediction models.

6.1 Datasets

Experiments were conducted on four benchmark datasets: WN18, FB15k (Bordes et al., 2013), WN18RR (Dettmers et al., 2018), and FB15k-237 (Toutanova and Chen, 2015) (details of these datasets are provided in Table 1). These datasets have been widely used in previous studies for evaluating model performance in link prediction tasks.

WN18 and FB15k were extracted from the real knowledge graphs WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008), respectively. WordNet is a well-known human-curated lexical database, and hence, WN18 is an easy benchmark of link prediction because it is well constructed and there are few missing or wrong facts. Therefore, link prediction models should perform well on WN18. Freebase is a huge knowledge graph of general facts and there are many missing facts. It is known that WN18 and FB15k have redundancy in the form of reverse relations. For this reason, when WN18RR and FB15k-237 are extracted from WN18 and FB15k, the inverse relations of other relations are removed.

6.2 Evaluation Protocol

We conducted the link prediction task following the same approach reported in (Bordes et al., 2013) to evaluate our models qualitatively and quantitatively. For each test triple (h_t, r_t, t_t) in a dataset, two queries, $(h_t, r_t, ?)$ and $(?, r_t, t_t)$, were constructed in the same way as in Section 3.2. Then, we obtained the rankings of entities for each query from each model as outlined in the following paragraphs. The rankings were ”filtered” by eliminating entities whose corresponding triples (except the target test triple) were included in the training, validation, or test dataset. The obtained rankings were scored by their mean reciprocal rank (MRR) and HITS@n, where MRR is the mean of the inverse of the ranks of corresponding entities and HITS@n is the proportion of test queries whose corresponding entities are ranked in the top n of the obtained rankings.

Next, we describe how to obtain rankings from models. We restricted antecedent graph patterns of GPARs to *connected* and *closed* (Galárraga et al., 2013, 2015) patterns whose size $|GP_{(x,y)}|$ was less than or equal to L to restrict the search space. A connected and closed patterns is a pattern connecting x and y without branches, as shown in Figure 2. L was chosen for each model among $\{1, 2, 3\}$ by MRR from the validation triples of each dataset. It took about four days to evaluate all candidate GPARs for GRank with dMAPs in FB15k using an *Intel Xeon Gold 6154* (3.00 GHz, 18 cores).

We now explain how we obtained the rankings for queries with missing heads. For each relation r, we chose the top 1,000 GPARs in descending order of the standard confidence, the dMAP, or the fdMAP to predict the heads. Let $GP_{i,(x,y)} \Rightarrow r_{(x,y)}$ be the obtained GPAR, where i denotes the rank. We defined the ordering for two entities for query $(?, r_t, t_t)$ as follows: for entities e_1 and e_2, we define $e_1 > e_2$ if there exists i' for which $score(GP_{i,(x,y)}, (e_1, t_t)) = score(GP_{i,(x,y)}, (e_2, t_t))$ for $i > i'$ and $score(GP_{i',(x,y)}, (e_1, t_t)) > score(GP_{i',(x,y)}, (e_2, t_t))$. We obtained the entity rankings with this ordering for each query. Rankings for queries with missing tails were obtained in the same way.

6.3 Results

The results of the link prediction tasks for our proposed models, GPro, GRank with dMAP, and GRank with fdMAP, are shown in Tables 2, where the results reported in previous studies are included for comparison.

In Table 2, the first seven models are knowledge graph embedding models and the following two models are observed feature models. Table 2 shows the effectiveness of the Node+LinkFeat model (Toutanova and Chen, 2015), although this model is very simple (high MRRs imply that the model also has high HITS@1s or HITS@3s). The Node+LinkFeat model performed well on WN18 and FB15k because these datasets often contain the reverse relations of other relations. In other words, it shows that knowledge graph embedding models failed to capture this redundancy. On the other hand, our proposed models, GPro and GRank, generally yield better results than the knowledge graph embedding models and results which are better than or comparable to Node+LinkFeat, which means that our models can also handle such redundancy. In particular, GRank with dMAP and fdMAP yielded the best results on FB15k. This indicates that taking the multiplicity of matchings and deeper information into account is important for knowledge graphs such as FreeBase that contain miscellaneous relations and are not well curated like WordNet. As a result, GRank performed well.

Table 2 also shows GPro and GRank yield better results for the WN18RR dataset than the other models. For FB15k-237, the performance of Node+LinkFeat is comparable with most of the other more sophisticated knowledge graph models and GPro does not yield good results because FB15k-237 has less redundancy. GRank also performs better than the most other models for the FB15k-237 dataset for the same reason as the FB15k dataset. However, our models do not utilize the information related to the co-occurrence of entities and relations in triples (node features (Toutanova and Chen, 2015)), while ConvE, Node+LinkFeat, and other models do. We also limited the size and the shapes of graph patterns because of the calculation time; we will address these and improve our models further in our future work.

Quality of Obtained Paths The examples of antecedent patterns ranked high by GRank with $dMAP_{tail}$ for FB15k are shown in Figure 3. The patterns shown for predicting the sibling relation are all correct as the antecedents of GPARs; however, the MAP of $GP'_{2,(x,y)}$ and $GP'_{3,(x,y)}$ are low. The reason for this is that $GP'_{2,(x,y)}$ works when an individual has more than two siblings. The MAP of $GP'_{3,(x,y)}$ is low because individual's parents are often missing in FB15k. However, they are still ranked higher than other patterns.

The produces_film relation is the inverse relation of the exective_produced_by relation in FB15k. Such patterns are very helpful when performing link prediction tasks, and GRank is able to find them. However, the MAP is not as high because of missing facts. GRank is able to use majority rules such as $GP'_{5,(x,y)} \Rightarrow$ film_produced_by(x, y) instead in such cases. This rule can be interpreted as stating that a particular film was likely to have been produced by a person who produced many films in the same production company.

Output triples of GRank (and GPAR-based models) are described by antecedent patterns unlike knowledge graph embedding models as shown here.

7 Conclusions

In this paper, we first defined GPARs for a knowledge graph and the standard confidence measures of GPARs for link prediction. Then, we pointed out the problems with the standard confidence measures and we introduced a new perspective using GPARs to rank entities to overcome these problems. We also proposed distributed rank-

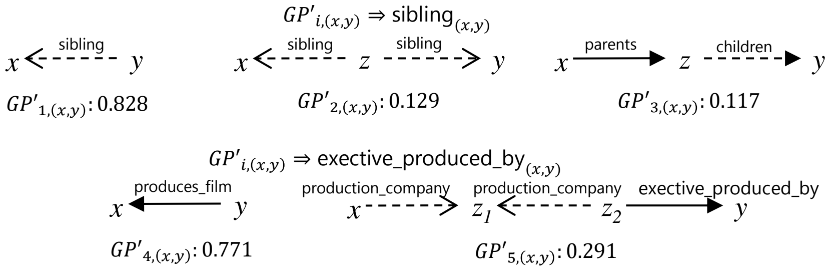

Figure 3: Examples of antecedent patterns for $dMAP_{tail}$ which were given high ranks by GRank for the FB15k dataset.

ings for situations where multiple entities have the same scores and defined metrics for them. This idea led us to propose the GRank model. GRank is easy to interpret because outputs are described by GPARs, unlike knowledge graph embedding models, and so efficient that it outperformed the state-of-the-art knowledge graph embedding models in link prediction tasks.

In future work, we will extend GRank to use more complex patterns. We considered only antecedent graph patterns whose sizes were less than or equal to 3.If we allow antecedent graph patterns to have larger sizes, then we may find more useful GPARs. We also restricted graph patterns to contain only variables and not constants. Hence, we did not use all of the available information contained in the knowledge graph. We believe that using such complex graph patterns will improve GRank further.

Abstract

Modern weakly supervised methods for event detection (ED) avoid time-consuming human annotation and achieve promising results by learning from auto-labeled data. However, these methods typically rely on sophisticated pre-defined rules as well as existing instances in knowledge bases for automatic annotation and thus suffer from low coverage, topic bias, and data noise. To address these issues, we build a large event-related candidate set with good coverage and then apply an adversarial training mechanism to iteratively identify those informative instances from the candidate set and filter out those noisy ones. The experiments on two real-world datasets show that our candidate selection and adversarial training can cooperate together to obtain more diverse and accurate training data for ED, and significantly outperform the state-of-the-art methods in various weakly supervised scenarios. The datasets and source code can be obtained from `https://github.com/thunlp/Adv-ED`.

1 Introduction

Event detection (ED) aims at detecting event triggers, which are often words or phrases evoking events in instances, and then identifying their specific event types. For example, we can extract the trigger "`married`" of the event "`Marry`" from the text "Mark Twain and Olivia Langdon `married` in 1870". Detecting and identifying events is an important subtask of event extraction and also beneficial for various downstream NLP applications, such as question answering (Yang et al., 2003), information retrieval (Basile et al., 2014), and reading comprehension (Cheng and Erk, 2018). Hence, many efforts have been devoted to detecting event triggers and types.

Most prior methods for ED are based on feature engineering, such as the token-level features (Ahn, 2006; Ji and Grishman, 2008) and the structured features (Li et al., 2013; Araki and Mitamura, 2015). As the rapid development of neural networks, various neural models have been proposed to directly embed textual semantic information into a low-dimensional space and then detect event triggers based on those feature vectors (Chen et al., 2015; Nguyen and Grishman, 2015; Nguyen et al., 2016; Ghaeini et al., 2016; Feng et al., 2016). These methods follow a supervised learning approach to train models on human-annotated data, and their requirement of human-annotated data is a bottleneck in practice. Considering weak supervision is widely adopted to take full advantages of large-scale raw data, especially some specific work for information extraction (Mintz et al., 2009; Riedel et al., 2010; Zeng et al., 2015; Cao et al., 2018), weak supervision has been explored to automatically label training data for ED (Chen et al., 2017; Zeng et al., 2018; Yang et al., 2018; Araki and Mitamura, 2018). Compared with those supervised ED methods, the weakly supervised methods can be generalized to real-world ED applications efficiently without intensive labor.

Although promising results have been achieved by these weakly supervised methods, there are still some severe problems for these weakly supervised ED models: (1) Weakly supervised methods naturally suffer from the inevitable noise in data. (2) Current weakly supervised ED models adopt sophisticated pre-defined rules and incomplete knowledge bases to automatically obtain data, which results in the auto-labeled data with low coverage and topic bias.

In order to construct a large-scale dataset with better coverage and reduce topic bias, we avoid adopting sophisticated pre-defined rules and heavy toolkits for semantic component analysis. Instead,

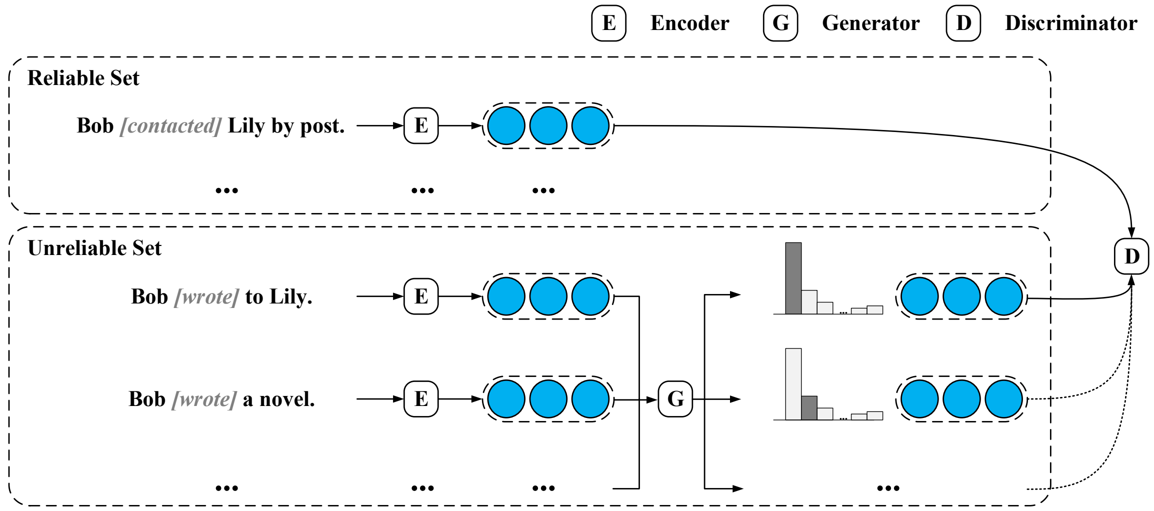

Figure 1: The overall architecture of adversarial training method for ED. The event type is `Contact`.

we propose a simple trigger-based latent instance discovery strategy, by applying an assumption that if a given word [1] serves as the trigger in a known event instance, all instances mentioning this word may also express an event. As compared with the sophisticated rules, this strategy is less restrictive in the correlation among words, triggers and event types. Hence, our strategy can obtain a candidate set covering more topics and instances without any manual design.

We further propose an adversarial training mechanism like Goodfellow et al. (2014); Radford et al. (2016), which can not only distill those informative instances from the candidate set but also improve the performance of ED model on a noisy scenario such as distant supervision. As shown in Figure 1, we split the dataset into a reliable set and an unreliable set respectively, and design a discriminator and a generator. The discriminator is applied to judge whether a given instance is informative and annotated correctly, and the generator is used to select the most confusing instances from raw data to fool the discriminator. The discriminator is trained with the reliable data as positive instances and the data selected by the generator as negative ones. Meanwhile, the generator is trained to select data to fool the discriminator. During the training process, the generator can provide large amounts of latent noisy data to enhance the discriminator, and the discriminator can influence the generator to select those more informative data. Since noisy data makes no effect on optimizing both the generator and the discriminator, when the generator and the discriminator reach a balance, the discriminator can boost resistance to noise and better categorize events, and the generator can effectively select informative instances to the discriminator.

We conduct experiments on both semi-supervised and distantly supervised scenarios. The experimental results demonstrate that our trigger-based latent instance discovery strategy and adversarial training method can cooperate to obtain more diverse and accurate training data as well as reduce the side effect of the noise problem, and thus significantly outperform the state-of-the-art ED models.

2 Related Work

ED has attracted wide attention recently. Traditional feature-based methods (Ahn, 2006; Ji and Grishman, 2008; Gupta and Ji, 2009; Riedel et al., 2010; Hong et al., 2011; McClosky et al., 2011; Huang and Riloff, 2012a,b; Araki and Mitamura, 2015; Li et al., 2013; Yang and Mitchell, 2016; Liu et al., 2016b) rely on manually designed features to detect the event triggers and event types. With the development of neural networks, various neural methods have also been proposed (Chen et al., 2015; Nguyen and Grishman, 2015; Nguyen et al., 2016; Duan et al., 2017; Nguyen et al., 2016; Ghaeini et al., 2016; Lin et al., 2018).

Furthermore, some efforts have been made to improve the performance of ED systems with external knowledge (Liu et al., 2016a, 2017), contextual information (Liu et al., 2018b), document-level information (Duan et al., 2017; Zhao et al.,

---

[1] We treat phrases as words in this paper.

2018) and multimodal integration (Zhang et al., 2017). Some advanced architectures have also been applied, such as attention mechanism (Liu et al., 2017, 2018a), graph convolutional networks (Nguyen and Grishman, 2018) and generative adversarial networks (Hong et al., 2018).

All the supervised methods above rely on human-annotated data, and the data is often restricted to a small scale due to the expensive human annotation. Hence, unsupervised methods (Huang et al., 2016; Yuan et al., 2018) and various weakly supervised methods on ED are proposed. Muis et al. (2018) adopt distant supervision to create training instances for low-resource language. Araki and Mitamura (2018) adopt WordNet (Miller et al., 1990) and rule-based methods to generate open-domain data without event-type labels. Chen et al. (2017) and Zeng et al. (2018) use distant supervision to generate large-scale data from existing structured event knowledge in knowledge bases. Liao and Grishman (2010a), Huang and Riloff (2012a) and Ferguson et al. (2018) conduct semi-supervised ED with bootstrapping. Nevertheless, due to the low coverage of existing knowledge bases as well as lack of advanced denoising mechanism, those weakly supervised methods still suffer from the problem of low coverage and noisy data.

Inspired by Szegedy et al. (2013) and Goodfellow et al. (2014), adversarial training has been explored for several NLP applications recently to resist noise, such as text classification (Miyato et al., 2016) and text generation (Xie et al., 2017; Chen et al., 2018). Adversarial training has also been adopted for information extraction (Wu et al., 2017; Hong et al., 2018; Qin et al., 2018; Wang et al., 2018; Han et al., 2018). These adversarial information extraction methods either generate adversarial instances by adding simple noise perturbation to embeddings (Wu et al., 2017; Hong et al., 2018), or mainly adopt models to denoise data and neglect to discover more training instances from raw data (Qin et al., 2018; Han et al., 2018). Compared with these methods, our adversarial method samples adversarial examples from the real-world data rather than generating pseudo noisy perturbations. Furthermore, our method not only denoises auto-labeled data but also labels unlabeled instances to extend datasets for higher coverage. Hence, our method can effectively alleviate low coverage, topic bias, and noise problem in ED.

3 Methodology

In this section, we introduce the overall framework of our proposed models for weakly supervised ED.

3.1 Framework

As shown in Figure 1, the overall framework consists of three modules, including instance encoder, adversarial training strategy, and their adaption for various weakly supervised ED scenarios.

The instance encoder is applied to encode the instances into its corresponding embeddings to provide semantic features for the other modules of our models. Given an instance $x = \{w_1, \ldots, t, \ldots, w_n\}$ consisting of n words and its candidate trigger t, we adopt several effective neural models to represent the semantic features of the instance x with the embedding $\mathbf{x}$. Details of the instance encoder are shown in Section 3.2.

After representing instances into their embeddings by the instance encoder, an adversarial training strategy is applied, which aims at highlighting those informative instances and filtering out those noisy instances from a large-scale unreliable dataset $\mathcal{U}$ under the guidance of another reliable dataset $\mathcal{R}$. The adversarial training strategy is the core module of our framework, and we will introduce its details in Section 3.3.

Each instance x in $\mathcal{U}$ and $\mathcal{R}$ will be labeled with a trigger word t and an event type $e \in \mathcal{E}$. If an instance does not have a trigger and cannot express any definite events, it will be labeled with a special event `NA`, which indicates that the event of this instance is not available. Before applying adversarial training, $\mathcal{U}$ and $\mathcal{R}$ are automatically labeled. The details of splitting and automatically labeling $\mathcal{U}$ and $\mathcal{R}$ for various weakly supervised ED scenarios, as well as utilizing adversarial training strategy to extend datasets, will be introduced in Section 3.4.

3.2 Instance Encoder

In this paper, we select CNN (Chen et al., 2015) and BERT (Devlin et al., 2018) as representative encoders to encode the given instances.

CNN After representing all words in the instance x into their input embeddings, including both word embeddings and position embeddings which encode the relative position to candidate triggers, CNN slides a convolution kernel over the input embeddings to get hidden embeddings as follows,

$$\{\mathbf{h}_1, \dots, \mathbf{h}_n\} = \text{CNN}\big(w_1, \dots, t, \dots, w_n\big). \quad (1)$$

BERT Similar to CNN, after summing word piece (Wu et al., 2016), segment and position embeddings of all words in the instance x as input embeddings, BERT adopt a multi-layer bidirectional transformer encoder (Vaswani et al., 2017) to get hidden embeddings as follows,

$$\{\mathbf{h}_1, \dots, \mathbf{h}_n\} = \text{BERT}\big(w_1, \dots, t, \dots, w_n\big). \quad (2)$$

Because the candidate trigger t splits the instance x into two parts, we follow Chen et al. (2015) to adopt a dynamic multi-pooling operation over the hidden embeddings to achieve the instance embedding $\mathbf{x}$,

$$\begin{aligned} [\overleftarrow{\mathbf{x}}]_j &= \max\{[\mathbf{h}_1]_j, \dots, [\mathbf{h}_i]_j\}, \\ [\overrightarrow{\mathbf{x}}]_j &= \max\{[\mathbf{h}_{i+1}]_j, \dots, [\mathbf{h}_n]_j\}, \\ \mathbf{x} &= [\overleftarrow{\mathbf{x}}; \overrightarrow{\mathbf{x}}], \end{aligned} \quad (3)$$

where $[\cdot]_j$ is the j-th value of a vector and i is the position of the trigger t. As CNN and BERT adopt a dynamic multi-pooling operation, we name them "**DMCNN**" and "**DMBERT**" in this paper.

3.3 Adversarial Training

As shown in Figure 1, the overall framework of our adversarial strategy consists of a discriminator and a generator. The discriminator is adopted to detect event triggers and identify event types for each instance in datasets. When given a noisy instance, the discriminator is also expected to resist noise and explicitly point out that there are no triggers and events. The generator is used to select instances from the unreliable dataset $\mathcal{U}$ to confuse the discriminator as much as possible.

Each instance $x \in \mathcal{R}$ is assumed to explicitly express its labeled trigger t and event type e. In contrast, each instance $x \in \mathcal{U}$ is assumed to be untrustworthy during the adversarial training, i.e., there is a certain probability that it is labeled incorrectly. Hence, we design the discriminator to judge whether a given instance can expose its labeled event type, which aims at maximizing the conditional probability $P(e|x,t), x \in \mathcal{R}$ and $1 - P(e|x,t), x \in \mathcal{U}$. The generator is trained to select the most confusing instances from $\mathcal{U}$ to fool the discriminator, i.e., selecting the instances by $P(e|x,t), x \in \mathcal{U}$. The training process is an adversarial min-max game as follows,

$$\begin{aligned} \phi_D &= \max\big(E_{x\sim P_{\mathcal{R}}}\big[\log\big(P(e|x,t)\big)\big] \\ &\quad + E_{x\sim P_{\mathcal{U}}}\big[\log\big(1 - P(e|x,t)\big)\big]\big), \\ \phi_G &= \max E_{x\sim P_{\mathcal{U}}}\big[\log\big(P(e|x,t)\big)\big], \end{aligned} \quad (4)$$

where $P_{\mathcal{R}}$ is the reliable data distribution, and the generator samples adversarial examples from the unreliable data according to the probability distribution $P_{\mathcal{U}}$. Although ϕ_D and ϕ_G are conflicting, noisy data in $\mathcal{U}$ has the side effect for both ϕ_D and ϕ_G. Hence, when the generator and the discriminator reaching a balance after sufficient training, the generator tends to select those informative instances with a higher probability compared with those noisy ones, and the discriminator boosts resistance to noise and can better categorize events.

Discriminator

Given an instance x and its labeled trigger t and event type e, the discriminator is responsible for judging whether the given instance exposes its labeled trigger and event type. After representing the instance x with its embedding $\mathbf{x}$, we implement the discriminator as follows,

$$\begin{aligned} D(e|x,t) &= \mathbf{e} \cdot \mathbf{x}, \\ P(e|x,t) &= \frac{\exp\big(D(e|x,t)\big)}{\sum_{\hat{e}\in\mathcal{E}} \exp\big(D(\hat{e}|x,t)\big)}, \end{aligned} \quad (5)$$

where $\mathbf{e}$ is the embedding of the event type $e \in \mathcal{E}$.

An optimized discriminator will assign high scores to those instances in $\mathcal{R}$, and meanwhile distrust those instances and their labels in $\mathcal{U}$. Hence, in practice, we formalize the loss function to optimize the discriminator as follows,

$$\begin{aligned} \mathcal{L}_D = &-\sum_{x\in\mathcal{R}} \frac{1}{|\mathcal{R}|} \log\big(P(e|x,t)\big) \\ &-\sum_{x\in\mathcal{U}} P_{\mathcal{U}}(x) \log\big(1 - P(e|x,t)\big). \end{aligned} \quad (6)$$

When optimizing the discriminator, we regard the component of the encoder and $D(e|x,t)$ as parameters for updating. This loss function $\mathcal{L}_D$ is corresponding to ϕ_D in Eq. (4).

Generator

The generator aims at selecting the most confusing instances from $\mathcal{U}$ to cheat the discriminator. We design the generator to optimize the probability distribution $P_{\mathcal{U}}$ to select instances. The generator computes confusing scores for all instances in

$\mathcal{U}$ to evaluate their perplexity and further computes the confusing probability $P_{\mathcal{U}}$ as follows,

$$\begin{aligned} f(x) &= \mathbf{W} \cdot \mathbf{x} + \mathbf{b}, \\ P_{\mathcal{U}}(x) &= \frac{\exp\big(f(x)\big)}{\sum_{\hat{x} \in \mathcal{U}} \exp\big(f(\hat{x})\big)}. \end{aligned} \tag{7}$$

where $\mathbf{x}$ is the embedding of the instance x computed by the encoder. $\mathbf{W}$ and $\mathbf{b}$ are parameters for a separating hyperplane.

We regard that the higher scores computed by the discriminator the instances have, the more confusing the instances are, because they are more likely to fool the discriminator to make a wrong decision. We expect that an optimized generator pays more attention to those most confusing instances. Hence, given an instance $x \in \mathcal{U}$ and its unreliable-labeled trigger t and event type e, we formalize the loss function to optimize the generator as follows,

$$\mathcal{L}_G = -\sum_{x \in \mathcal{U}} P_{\mathcal{U}}(x) \log\big(P(e|x,t)\big), \tag{8}$$

where $P(e|x,t)$ is computed by the discriminator. When optimizing the generator, we regard the component to compute $P_{\mathcal{U}}(x)$ as parameters for updating. This loss function $\mathcal{L}_G$ is corresponding to ϕ_G in Eq. (4).

There may be some instances in $\mathcal{U}$ labeled `NA` and these instances are always wrongly predicted into some other events. Thus we specifically use the average scores over all feasible events to replace their $P(e|x,t)$ in Eq. (8) as follows,

$$P(\text{NA}|x,t) = \frac{1}{|\mathcal{E}| - 1} \sum_{e \in \mathcal{E}, e \neq \text{NA}} P(e|x,t), \tag{9}$$

where $\mathcal{E}$ indicates the set of event types.

Training and Implementation Details

Because there may be large amounts of instances in $\mathcal{R}$ and $\mathcal{U}$, directly computing $\mathcal{L}_D$ and $\mathcal{L}_G$ is time-consuming, and frequently traversing the whole dataset of $\mathcal{R}$ and $\mathcal{U}$ also accordingly becomes difficult. For improving training efficiency, we sample subsets of $\mathcal{R}$ and $\mathcal{U}$ to approximate the essential probability distribution, and formalize a new loss function for optimization,

$$\begin{aligned} \tilde{\mathcal{L}}_D &= -\sum_{x \in \tilde{\mathcal{R}}} \frac{1}{|\tilde{\mathcal{R}}|} \log\big(P(e|x,t)\big) \\ &\quad - \sum_{x \in \tilde{\mathcal{U}}} P_{\tilde{\mathcal{U}}}(x) \log\big(1 - P(e|x,t)\big), \\ \tilde{\mathcal{L}}_G &= -\sum_{x \in \tilde{\mathcal{U}}} P_{\tilde{\mathcal{U}}}(x) \log\big(P(e|x,t)\big), \end{aligned} \tag{10}$$

where $\tilde{\mathcal{R}}$ and $\tilde{\mathcal{U}}$ are the subsets sampled from $\mathcal{R}$ and $\mathcal{U}$, and $P_{\tilde{\mathcal{U}}}$ is the approximation to Eq. (7),

$$P_{\tilde{\mathcal{U}}}(x) = \frac{\exp\big(f(x)^{\alpha}\big)}{\sum_{\hat{x} \in \tilde{\mathcal{U}}} \exp\big(f(\hat{x})^{\alpha}\big)}. \tag{11}$$

α is a hyperparameter that controls the sharpness of the probability distribution to avoid the weights concentrating on some specific instances. Finally, the overall optimization function is,

$$\mathcal{L} = \tilde{\mathcal{L}}_D + \lambda \tilde{\mathcal{L}}_G, \tag{12}$$

where λ is a harmonic factor. In practice, $\tilde{\mathcal{L}}_D$ and $\tilde{\mathcal{L}}_G$ in adversarial training are optimized alternately, and λ is also integrated into the learning rate of $\tilde{\mathcal{L}}_G$ to avoid adjusting λ additionally.

3.4 Adaption for Weakly Supervised Scenarios

In this section, we introduce the adaption of adversarial training strategy for various weakly supervised ED scenarios (semi-supervised scenarios and distantly supervised scenarios), as well as the method to automatically label and split the reliable set and unreliable set used for adversarial training.

Trigger-based Latent Instance Discovery

To utilize unlabeled data, we propose a simple trigger-based latent instance discovery strategy, which can automatically label trigger words and event types for raw data. The trigger-based strategy is based on a heuristic assumption that if a given word serves as the trigger in a known instance, all other instances mentioning this word in raw data are latent instances and may also express an event. For example, the word "`married`" serves as the trigger in the instance "Mark Twain and Olivia Langdon `married` in 1870" to expose the event "`Marry`", and then all instances in unlabeled data containing the word "`married`" will be picked up and added into a latent instance candidate set. As compared with the sophisticated rules used in existing weakly supervised ED models, our trigger-based latent instance discovery is simple, without the need of considering the correlation among words, triggers, and event types. Because our strategy is less restrictive, it is effective and efficient to obtain a large-scale candidate set without any special manual design. Meanwhile, the candidate set can cover much more instances and topics than the existing strategies.

Semi-supervised Scenarios

When adapting our adversarial training strategy for semi-supervised scenarios, we first use the small-scale labeled data to pretrain the encoder and discriminator to let them gain the ability to detect event triggers and identify event types to a certain extent. Then, we construct a large-scale latent candidate set based on our instance discovery strategy with the trigger words in the labeled data as heuristic seeds. We use the pretrained encoder and discriminator to automatically label triggers and event types for all instances in the candidate set to build noisy large-scale data. With the small-scale labeled data as the reliable set $\mathcal{R}$ and the large-scale auto-labeled data as the unreliable set $\mathcal{U}$, we can optimize the encoder, discriminator, and generator together to carry out adversarial training. During the adversarial training, when the discriminator and generator reach a balance after certain training epochs, all instances from the unreliable set $\mathcal{U}$ recommended by the generator and regarded as being labeled correctly by the discriminator will be adjusted from $\mathcal{U}$ to $\mathcal{R}$. Conducting adversarial training iteratively can identify informative instances and filter out noisy instances in $\mathcal{U}$, and accomplish utilizing large-scale unlabeled data to enrich small-scale labeled data.

Distantly Supervised Scenarios

The adaption for distantly supervised scenarios is similar to the adaption for semi-supervised scenarios. We first use the whole auto-labeled data to pretrain the encoder and discriminator. Then, the encoder and discriminator are used to compute confident scores for all instances in the auto-labeled set. By setting a particular threshold, we can split the whole auto-labeled set into two parts. The instances with scores higher than the threshold will be added into the reliable set $\mathcal{R}$, and the other instances with lower scores will be added into the unreliable set $\mathcal{U}$. After the whole auto-labeled set being split into $\mathcal{R}$ and $\mathcal{U}$, we can conduct adversarial training to reduce the side effect of those noise in $\mathcal{U}$ and enhance the discriminator for better identifying events. Intuitively, the reliable set $\mathcal{R}$ isolated from the auto-labeled set can be used as seeds to utilize more raw data in a similar way applied in semi-supervised scenarios.

4 Experiments

We evaluate our models on both semi-supervised and distantly supervised scenarios. Before introducing the detailed experimental settings and results, we list the hyperparameters first.

4.1 Hyperparameter Settings

For DMCNN, following the settings of previous work, we use the pre-trained word embeddings learned by Skip-Gram (Mikolov et al., 2013) as the initial word embeddings. We implement DMCNN by ourselves and follow the same hyperparameters used in Chen et al. (2015) for fair comparisons. For DMBERT, we follow the same hyperparameters used for $\text{BERT}_{\text{BASE}}$ in Devlin et al. (2018) and apply the pre-trained model[2] to initialize the parameters. We list the essential hyperparameters of the discriminator and the generator for adversarial training in Table 1.

Dropout Probability p	5×10^{-1}
Learning Rate α_{gc} for the generators (DMCNN)	5×10^{-3}
Learning Rate α_{dc} for the discriminators (DMCNN)	2×10^{-2}
Learning Rate α_{gb} for the generators (DMBERT)	2×10^{-5}
Learning Rate α_{db} for the discriminators (DMBERT)	1×10^{-4}

Table 1: Hyperparameter settings.

4.2 Distantly Supervised Scenarios

Dataset and Evaluation

For distantly supervised scenarios, we utilize the distantly supervised dataset developed by Chen et al. (2017) with FreeBase (Bollacker et al., 2008). The dataset contains $142,611$ labeled instances and 21 event types. Following previous work (Mintz et al., 2009; Chen et al., 2017), we evaluate our adversarial training mechanism by held-out evaluation. We report the precision-recall curves of recall under 0.7 since we mainly focus on the performance of those top-ranked results. To give a complete view of the overall performance, we also report the area under the curve (AUC).

---

[2] `https://github.com/google-research/bert`

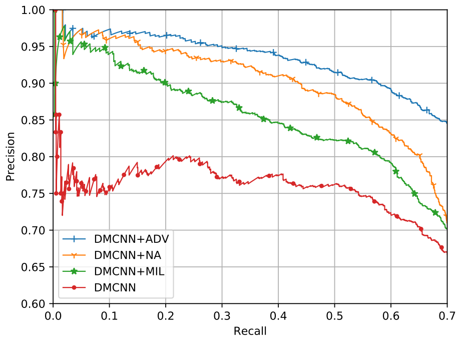

Figure 2: The aggregated precision-recall curves of DMCNN models.

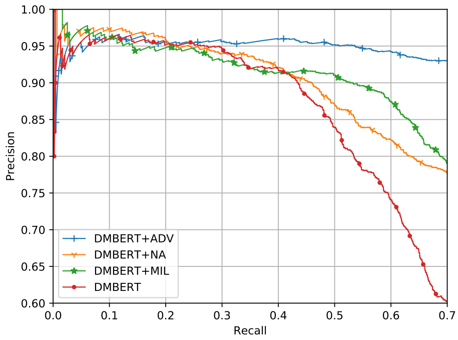

Figure 3: The aggregated precision-recall curves of DMBERT models.

To evaluate the effectiveness of our proposed models, we compare our adversarial training models (**DMCNN+ADV**, **DMBERT+ADV**) with various neural baselines, including: (1) **DMCNN** and **DMBERT** proposed in Chen et al. (2015) and this paper respectively, which are the basic models without any adaption to the noisy distant supervision. (2) **+MIL** models, which improve the basic models with multi-instance learning proposed in Chen et al. (2017) to alleviate the noise problem. (3) **+NA** models, which simply treat the instances in the unreliable set as negative instances with the label `NA`. This method could be regarded as a simplified version of our adversarial training to conduct ablation study. In this experiment, we separate the reliable and unreliable set by the confidence of the basic models following Section 3.4.

Overall Evaluation Results

The precision-recall curves of DMCNN models and DMBERT models are shown in Figure 2 and Figure 3, and the results of AUC are shown in Table 2. From the results, we can observe that: (1) BERT-based models significantly outperform the CNN-based models, which is due to the ability to capture contextual information as well as large-scale pre-training of BERT. And benefiting from the effective pre-trained parameters, the BERT-based models all have high precision when the recall is under 0.3. (2) The **+NA** models achieve similar performance with **+MIL** and even outperform them in low-recall range, but **+NA** models have the worst macro AUC. It indicates that the separation of reliable and unreliable set is effective but also have severe side effects, and our adversarial training method works well to overcome the side effect. (3) Our adversarial training method significantly outperforms all the baselines in every metric. This demonstrates the strong ability of our method to alleviate the noise problem on distantly supervised scenarios.

Method	AUC Micro	AUC Macro
DMCNN	67.6	38.7
DMCNN+MIL	75.7	43.3
DMCNN+NA	70.6	25.8
DMCNN+ADV	**85.5**	**50.7**
DMBERT	70.6	42.2
DMBERT+MIL	79.4	47.3
DMBERT+NA	74.0	38.6
DMBERT+ADV	**91.5**	**67.6**

Table 2: The AUC results (%) of various models.

4.3 Semi-supervised Scenarios

Dataset and Evaluation

For semi-supervised scenarios, we conduct experiments on a widely-used benchmark dataset ACE-2005 (Walker et al., 2006) containing 599 documents annotated with 8 types and 33 subtypes of events. Following the previous work (Liao and Grishman, 2010b; Li et al., 2013; Chen et al., 2015), we use the same test set containing 40 newswire documents, development set with 30 randomly selected documents and training set with the remaining 529 documents.

As described in Section 3.4, using existing triggers in ACE-2005 training set as heuristic seeds and our trigger-based latent instance discovery strategy, we construct a large-scale candidate set from the New York Times corpus (Sandhaus, 2008) and use our adversarial training strategy to filter out the noisy instances to build a new ACE-style dataset. We extend the ACE-2005 training set with the new dataset, and then test the models trained on the extended training set on the original test set. Our models trained on the original training set are named **DMCNN** and **DMBERT**, and our bootstrapped models trained on the extended dataset are named **DMCNN+Boot** and **DMBERT+Boot**.

We compare our bootstrapped models with various state-of-the-art methods on the ACE-2005 dataset, including: (1) The feature-based models. We select **Li's joint** (Li et al., 2013) as the representative, which achieves the best performance among feature-based models. (2) The vanilla neural network models, including the **DMCNN** (Chen et al., 2015) and **JRNN** (Nguyen et al., 2016). (3) The neural network models with external information, including **ANN-FN** (Liu et al., 2016a) leveraging the information of FrameNet (Baker et al., 1998), **DLRNN** (Duan et al., 2017) using document-level information, **GMLATT** (Liu et al., 2018a) utilizing multilingual attentions, and the bootstrapped model **DMCNN+Chen's DS** (Chen et al., 2017) trained with additional data distantly supervised by FreeBase (Bollacker et al., 2008). (4) The neural network models with advanced architecture, including: **Bi-LSTM+GAN** (Hong et al., 2018) utilizing GAN to conduct self-regulation, **GCN-ED** (Nguyen and Grishman, 2018) utilizing graph convolutional network to model dependency trees.

Overall Evaluation Results

The results are shown in Table 3. From the results, we have the following observations: (1) As compared with the basic **DMCNN** and **DMBERT**, the bootstrapped models achieve significant improvement (+1.7% and +0.5%). Furthermore, our **DMCNN+Boot** model achieves similar performance with the **ANN-FN** and **DLRNN** which design complex architectures to utilize the additional information. These results indicate that our methods can construct high-quality dataset without sophisticated rules and large-scale knowledge bases, and can effectively collect diverse instances which will benefit training models. (2) **DMBERT** and **DMBERT+Boot** achieve the best performance among all the models. This is benefiting from the effective architecture and the large-scale pre-training information of BERT, as well as the dynamic multi-pooling mechanism for ED. Our methods augment the training data to further enhance BERT, which achieve better performance and demonstrate the effectiveness of our models.

Method	Trigger Identification +Classification		
	P	R	F1
Li's Joint (Li et al., 2013)	73.7	62.3	67.5
DMCNN (Chen et al., 2015)	75.6	63.6	69.1
JRNN (Nguyen et al., 2016)	66.0	**73.0**	69.3
ANN-FN (Liu et al., 2016a)	77.6	65.2	70.7
DLRNN (Duan et al., 2017)	77.2	64.9	70.5
GMLATT (Liu et al., 2018a)	78.9	66.9	72.4
DMCNN+Chen's DS (Chen et al., 2017)	75.7	66.0	70.5
Bi-LSTM+GAN (Hong et al., 2018)	71.3	74.7	73.0
GCN-ED (Nguyen and Grishman, 2018)	**77.9**	68.8	73.1

Table 3: The overall performance (%) of different models on ACE-2005.

Method	Average Precision	Fleiss's Kappa
Chen et al. (2017)	88.9	–
Zeng et al. (2018)	91.0	–
Our First Iteration	91.7	61.3
Our Second Iteration	87.5	52.0

Table 4: The human evaluation results (%) of auto-labeled data in different iterations.

Manual Evaluation

To perform a fine-grained evaluation for the quality of the dataset constructed with our trigger-based instance discovery strategy and adversarial training strategy, we manually evaluate the precision of the constructed dataset. To be specific, we randomly select 150 instances from the newly constructed dataset and recruit four well-trained annotators to annotate the instances independently. We ask the annotators to label an instance as correct if and only if the trigger and event-type are both correct. We use the Fleiss' kappa (Fleiss, 1971) to measure the annotation consistency among these annotators. The results of the data distilled in different iterations during adversarial training are shown in Table 4. From the results, we can observe that the precision of the dataset constructed with our models is comparable to existing distant supervision methods (Chen et al., 2017; Zeng et al., 2018) using sophisticated human-designed rules and knowledge bases, and even outperforms them in the first iteration. It indicates that our models can distill informative instances with high precision.

Case Study

To further show the effectiveness of our models to improve the coverage of the dataset, we give an example in Table 5. The instance in the "In ACE-2005" row is a typical instance of the `Sue`

	Event-Type: `Justice` Subtype: `Sue`
In ACE-2005	Dell **sued** for ”bait and switch” and false promises.
Discovered	1. The lawyers for the four former state officials who have been **sued** told the jurors . . . 2. But **litigation** held up the project until . . . .

Table 5: The examples with highlighting triggers.

events, and the two instances in the “Discovered” row are sampled from the dataset constructed with our methods. In the “Discovered” row, the first instance is with an existing trigger in ACE-2005 but different in syntax, and the second instance is with a newly discovered trigger which is not contained in ACE-2005. In our extended dataset, there are 1.2% of the triggers are newly discovered. This demonstrates that our methods can not only find new instances from the unlabeled data which is similar to those instances in the labeled data, but also discover new triggers and extend the coverage of datasets substantially.

5 Conclusion and Future Work

In this paper, we take advantages of adversarial training and propose an effective method for weakly supervised ED. To be specific, our method is able to denoise and enhance distantly supervised ED models, as well as automatically construct more diverse and accurate training data for semi-supervised ED models. The experiments on two real-world datasets show that our method achieves the state-of-the-art results on the settings of both distant supervision and semi-supervision. In the future, we plan to explore the following directions: (1) We will extend our method to further extract event arguments and perform event extraction. (2) We will develop a large-scale and clean dataset for ED based on our method, which will benefit further research in this field.

Abstract

Extreme classification is a classification task on an extremely large number of labels (tags). User generated labels for any type of online data can be sparing per individual user but intractably large among all users. It would be useful to automatically select a smaller, standard set of labels to represent the whole label set. We can then solve efficiently the problem of multi-label learning with an intractably large number of interdependent labels, such as automatic tagging of Wikipedia pages. We propose a submodular maximization framework with linear cost to find informative labels which are most relevant to other labels yet least redundant with each other. A simple prediction model can then be trained on this label subset. Our framework includes both label-label and label-feature dependencies, which aims to find the labels with the most representation and prediction ability. In addition, to avoid information loss, we extract and predict outlier labels with weak dependency on other labels. We apply our model to four standard natural language data sets including Bibsonomy entries with users assigned tags, web pages with user assigned tags, legal texts with EUROVOC descriptors(A topic hierarchy with almost 4000 categories regarding different aspects of European law) and Wikipedia pages with tags from social bookmarking as well as news videos for automated label detection from a lexicon of semantic concepts. Experimental results show that our proposed approach improves label prediction quality, in terms of precision and nDCG, by 3% to 5% in three of the 5 tasks and is competitive in the others, even with a simple linear prediction model. An ablation study shows how different data sets benefit from different aspects of our model, with all aspects contributing substantially to at least one data set.

1 Introduction

Multi-label learning has recently attracted attention in the research community due to an increase in applications such as semantic labeling of images and videos, bio-informatics, genetic functions, and music categorization. In addition, multi-label learning can address machine learning problems in web data mining, including recommender systems, multimedia sharing websites, and ranking (Zhang and Zhang, 2010).

An important application of extreme multi-label learning is automatic tagging and social tagging of large information collections such as Wikipedia or the Web. A user can add their own keywords to a text, as if they were the keywords they would use to look for the article in a search engine. Since tags use an open vocabulary, the number of tags is increasing continually in order to adjust to the needs of new information. Moreover, different users can assign different tags to the same resource, resulting in a great diversity of tags for that resource.

The biggest challenge of extreme multi-label learning is the dimension of the output space. As the number of output labels increases, the number of output states increases exponentially. In order to overcome this exponential growth, it is necessary to use label dependencies to simplify the problem (Zhang and Zhang, 2010; Tsoumakas et al., 2010).

We propose a submodular maximization approach with a linear cost to find an informative set of labels. In contrast to the other similar approaches (Balasubramanian and Lebanon, 2012; Bi and Kwok, 2013) which consider only label-label dependencies, we also consider label-feature dependencies and outlier labels that are highly independent of other labels. Solving the problem using the selected (smaller number of) labels leads to minimizing both representation and training error.

Proceedings of NAACL-HLT 2019, pages 1009–1018
Minneapolis, Minnesota, June 2 - June 7, 2019.

Representation ability is equivalent to the power of the selected subset to reconstruct the remaining labels, and prediction ability is equivalent to training accuracy leading to less error propagation from predicted label subset to the remaining labels during reconstruction.

Submodular maximization approaches have proved very effective in many applications, such as finding the most influential nodes in social networks to maximize the spread of information (for applications such as advertising and marketing (Kempe et al., 2003; Ohsaka et al., 2014)) and video and image collection summarization (Gygli et al., 2015; Tschiatschek et al., 2014). There are many effective algorithms such as (Mirzasoleiman et al., 2015) to make submodular optimization approaches much faster or do them in a distributed way (Mirrokni and Zadimoghaddam, 2015) to perform faster parallel processing for very large scale datasets.

2 Related Work

Many of the early proposed multi-label learning approaches struggle with large-scale applications, as they learn each label separately or investigate the label dependencies in a way that leads to a costly and complicated model (Tsoumakas et al., 2010).

The other research trends is to transform the label space to a smaller space and map back the predicted results in the compressed space to the original space. Hsu et al. (2009) presented the first approach targeting label space compression based on compressed sensing, which assumes sparsity of the label space. An expensive optimisation problem has to be solved in the prediction step. Tai and Lin (2012); Chen and Lin (2012); Yu et al. (2014), and (Lin et al., 2014) used orthogonal projections and low-rank assumptions to extract a label matrix decomposition and find a low-dimensional embedding space. In (Bhatia et al., 2015b), the authors perform local embedding of the label vectors. To achieve stronger locality, they cluster the data into smaller regions, which is unstable and costly for high-dimensional spaces and one needs an ensemble of the learners to overcome this instability and achieve a good prediction accuracy.

Although the previously proposed approaches make the embedding space smaller and more tractable, they may lead to loss of information as a result of transforming the label space to lower-dimensional spaces. Many of these approaches rely on low-rank assumptions which transform the sparse label space to a new dense embedding space resulting in even lower accuracy, with a higher prediction cost in the new complicated space (Bhatia et al., 2015a).

Balasubramanian and Lebanon (2012) and Bi and Kwok (2013) proposed to select a subset of the labels, and solve the problem in the original label space, based on structure sparsity optimization and SVD decomposition, correspondingly. However, these methods are not tractable for large scale data and not compatible for the real application data. In addition, they have ignored the training error in the label selection step which can lead to selection of the labels that are hard to predict resulting in training error propagation through the next steps.

Another recent thread of research includes the methods that partition the data into smaller groups: In the framework proposed by Barezi et al. (2017), the label space is divided into smaller independent groups, while Agrawal et al. (2013); Prabhu and Varma (2014); Prabhu et al. (2018) propose tree-based methods which partition the data into tree-structured hierarchical groups. These partitioning-based approaches avoid information loss from dimension reduction. However, finding a partitioning tree is a very complicated and time-consuming problem and these approaches require solving a complicated optimization problem to perform partitioning at each node, which is expensive and needs many training samples. In addition, the tree-based approaches suffer from error propagation through the hierarchy and need many training samples to avoid under-fitting in the lower levels of the partitioning tree (Liu et al., 2005).

Instead of making the structural assumption on the relation between the labels, Yen et al. (2016) assume the label space is highly sparse and has a strong correlation with the feature space. They ignore the label space correlation information. Yen et al. (2017) proposed the parallel version of (Yen et al., 2016).

3 Methodology

In this paper, we propose a landmark selection framework for selecting the most informative labels and to solve the multi-label learning problem with these labels. As an example, consider predicting the commercial impact of a new event on some global organizations (equivalent to the labels in our problem) given a history of the impact of previous events (equivalent to the features and training data in our problem). Instead of predicting the impact on each organization individually, we predict only the impact on a small number of organizations which are both easier to predict and analyze according to available data as well as being more indicative of the economy and the other organizations. Being indicative means that if we know the impact of the new event on these organizations, it can help us to predict the reaction of the other organizations. More formally, we optimize the above set function $f(S)$ in Equation 1.

The proposed method includes both label-label and label-feature dependencies in order to minimize both representation and training error. Previous similar methods ignore label-feature dependencies in the subset selection step, allowing the training error for the selected subset of the labels to be propagated to the reconstructed labels and affecting the final predictions. In addition, to avoid information loss, we also extract and predict outlier labels with weak dependency on other labels and treat them separately.

Our construction results in a monotone submodular function of label sets allowing us to use a maximization framework that benefits from a good theoretical bound by a fast greedy approach with linear cost (Nemhauser et al., 1978). We use a method based on Alternating Direction Method of Multipliers (ADMM) (Boyd, 2011) optimization to learn a linear mapping back to original label space. Therefore, during training, we can select and learn the most informative label subset using a submodular maximization framework of linear cost. During the prediction time, we can use the selected subset to represent the remaining labels using a linear equation with a linear cost in number of the labels.

3.1 Overview of the Submodular Maximization Theorem

Submodular functions have a natural diminishing property which makes them suitable for many applications. A submodular function is a set function with the property that as the size of the selected subset increases, the incremental value of the function by adding a new element to the selected subset does not increase.

The formal definition of a submodular function is as follows:

Definition 1. *For a set function* $f(S) : 2^V \rightarrow R$ *defined for a finite ground set* $V = 1, 2, ...n$*, the marginal gain of adding each new member can be computed as* $\Delta_f(e|S) = f(e \cup S) - f(S)$*. The function* $f(.)$ *is submodular, if for each* $A \subseteq B \subseteq V$*,* $e \in V \backslash A \cap V \backslash B$*, then* $\Delta_f(e|A) \geq \Delta_f(e|B)$*. Equivalently, the function* $f(S) : 2^V \rightarrow R$ *is submodular if for any two sets* A*,* $B \in V$*,* $f(A \cup B) + f(A \cap B) \leq f(A) + f(B)$*.*

Monotony of sunmodular functions is a useful property which means that the value of the function would not decrease by adding each new member to the input set, and can be defined as following.

Definition 2. *A submodular function* $f(.)$ *is monotone (non-decreasing) if for every* $T \subseteq S$*, we have that* $f(T) \leq f(S)$*.*

A simple example of a submodular function is the setup cost in a factory. Suppose that a factory is capable of making any one of a large finite set V of products. In order to produce product $e \in V$, it is necessary to set up the machines needed to manufacture e, and this costs money. The setup cost is non-linear, and it depends on which other products you choose to produce. For example, if you are already producing iPhones, then the setup cost for also producing iPads is small, but if you are not producing iPhones, the setup cost for producing iPads is large.

We can find a good approximation of the optimum answer for a monotone submodular maximization problems by using the greedy approach and considering the selected subset size constraint. More formally:

Theorem 3. *(Nemhauser et al., 1978) For a non-negative, monotone submodular function* f*, let* S *be a set of size* k *obtained by the greedy strategy similar to Algorithm 1. Then,* $f(S) \geq (1 - 1/e)f(S^*)$*, where* S^* *is the optimum solution, and* e *is Euler's constant approximately equal to* 2.71828

3.2 Submodularity for Label Subset Selection

We propose two submodular functions, aiming to select the most informative subset of the labels. The first function is a penalized version of the graph cut function. It scores label sets with correlation to the other labels and penalizes their similarity to the previously selected labels (f_{pen} in

$$\begin{aligned} f(S) &= (How\ members\ of\ set\ S\ are\ individually\ predictable) + \\ &\quad (How\ members\ of\ set\ S\ can\ represent\ the\ members\ not\ included\ in\ S) \\ &= (Prediction\ ability) + (Representation\ ability) \\ &= (Label - Feature\ dependency) + (Label - Label\ dependency) \end{aligned} \tag{1}$$

Algorithm 1 $argmax_S\ f(S)\ s.t.\ \|S\| = k$.

```
Input: $V = 1, 2, ...n$
Initialization: $S = \emptyset$.
Repeat:
    1: $a^\star = argmax_{a \in V \setminus S} f(S \cup \{a\}) - f(S)$
    2: $S = S \cup \{a^\star\}$
Until $|S| = k$.
Output: $S$.
```

Equation 3). The graph is constructed using the labels as nodes and label correlations as weights for the graph edges. The second function scores the predictability of labels with respect to problem input features (f_{score} in Equation 5). Our final function for identifying the optimal subset of labels is a weighted sum of these (Equation 6).

We consider the label correlations as graph weights w. The graph cut function $f_{cut}(.)$ aims to find a subset of the graph nodes (labels) with the highest weights (strongest dependencies) to the remaining nodes (labels). This captures strong correlation of a label set to the other labels and thus its ability to reconstruct the other labels. The penalised version $f_{pen}(.)$ adds one more term to increase the diversity of the selected labels and avoid choosing similar labels.

$$f_{cut}(S) = \sum_{i \in V \setminus S} \sum_{j \in S} w_{i,j} \tag{2}$$

$$f_{pen}(S) = f_{cut}(S) - \lambda \sum_{\substack{i,j \in S \\ i \neq j}} w_{i,j}\ ,\ \lambda \geq 0 \tag{3}$$

Theorem 4. *$f_{cut}(S)$ is a submodular function and it is monotone for non-large values of $|S|$ (Nemhauser et al., 1978).*

Theorem 5. *$f_{pen}(S)$ is a submodular function and it is monotone for non-large values of λ (Lin et al., 2009).*

The proofs for Theorem 4 and 5 is provided in supplementary Section.

It is important also to consider predictability, which is the training error for the selected subset of the labels, in order to avoid the prediction error of labels with high training error being propagated to the whole label space.

As an estimate of predictability we use either a G^2 or χ^2 independence test for the discrete data, and Fishers Z or t test for the continuous data in order to reject or accept the null hypothesis of independence (Tsamardinos and Borboudakis, 2010). Since, this measures include an implicit normalization, the frequency of the classes in training data does not affect the sampling step.

A higher dependency score for each label and the input feature space means a stronger correlation of the label with the feature space and higher predictability. Given label predictability scores f_{ij} for label i and input feature j and D input features, we calculate dependency scores f_i of the i-th label and the input features:

$$f_i = \sum_{j=1}^{D} f_{ij} \tag{4}$$

Note that $f_i \geq 0$. We then define the following set function, which also is monotone and submodular (Theorem 6):

$$f_{score}(S) = \sum_{i \in S} f_i \tag{5}$$

Theorem 6. *$f_{score}(S)$ is a submodular monotone function.*

Proof. For w_i = the sum over the dependency scores of the i-th label and the feature space, $f(S) = \sum_{i \in S} w_i$ is a linear function with $w_i \geq 0$. Any linear function of the form $f(S) = \sum_{i \in S} w_i$ is a submodular function. If $S \subset R$, $\Delta_f(k|S) - \Delta_f(k|R) = 0 \Rightarrow \Delta_f(k|S) \geq \Delta_f(k|R)$.
Additionally, if $\forall i\, w_i \geq 0$, then f is monotone, because $f(S \cup k) - f(S) = w_k,\ w_k \geq 0$.
$max_{|S|=k} f(S) = max \sum_{i \in S} w_i$. Therefore $f(S)$ is a monotone submodular function. □

Since, any sum of submodular functions with positive coefficients is a submodular function, we can combine $f_{pen}(.)$, and $f_{score}(.)$ by positive weights, which results in a new submodular function that includes both representation ability and prediction ability of the selected labels. We choose a model parameter $\gamma > 0$ giving us our final submodular function:

$$f(S) = f_{pen}(S) + \gamma . f_{score}(S) \tag{6}$$

3.3 Landmark Information Propagation

The main step of our proposed framework is to propagate the predicted value for the selected label subset to the full set of labels in order to recover the original space. Therefore, we aim to find a linear relation including the dependency of the selected labels and all the other labels. In the prediction step, this linear function obtains the full label set by combining the subset (Y_s) and outlier predictions (E) predicted by the regression functions discussed in next section 3.4. Given 1-hot representations Y_s over the reduced set of labels and Y the full set of labels, we seek matrices Z and E that recover the original labels:

$$Y = Y_s Z + E \tag{7}$$

To find optimal Z and E, we solve the optimization problem Equation 8, where Y and Y_s are matrices populated with our training data. Note that $\|E\|_{2,1}$ is the L_1 norm of the L_2 norms of the columns of E.

$$\begin{aligned} \underset{Z,E}{\text{argmin}} \quad & (\|Z\|_1 + \alpha \|E\|_{2,1}) \\ \text{s.t.} \quad & Y = Y_s Z + E \end{aligned} \tag{8}$$

The sparse matrix Z is a $k \times L$ matrix which includes a few representative labels (due to the sparsity constraint $\|Z\|_1$) for each label ($Y = Y_k Z$). The Z matrix includes the dependency information and performs propagation of the predicted label subset to the full label set, while nonzero columns of matrix E show the outlier and tail labels set O, which cannot be computed perfectly through their relation to the other labels. The index set of the nonzero columns of matrix E indicates the outlier labels. α is a model parameter.

The alternating direction method of multipliers (ADMM) method (Boyd, 2011; Nesterov, 2004; Beck and Teboulle, 2009) provides an efficient algorithm for solving this problem, achieving a convergence rate of $O(1/T^2)$ (where T is the number of iterations). ADMM solves the problem with more than one unknown variable, (Z and E in our case), by alternating between optimizing each variable using augmented Lagrangian. Please see the supplementary materials for more detail on the ADMM method and how it is applied in this case.

3.4 Prediction and Mapping Back to the Original Label Space

We now train a linear classifier to predict labels in the reduced label set $S \cup O$ and map back to the full label set. Given features of the training data X, corresponding labels from selected and outlier labels Y_S and Y_O, we learn linear regression parameters w_s, b_s for the selected labels and w_e, b_e for the outlier labels:

$$\begin{aligned} & \underset{w_s,b_s}{\text{argmin}} \quad \|Y_s - (X * w_s + b_s)\| + \tfrac{\lambda_1}{2}\|w_s\|^2 \\ & \underset{w_e,b_e}{\text{argmin}} \quad \|Y_o - (X * w_e + b_e)\| + \tfrac{\lambda_2}{2}\|w_e\|^2 \end{aligned} \tag{9}$$

Since all these training tasks are independent of each other, this step is highly parallelizable. The final values for the labels are computed by propagating the selected label subset through the linear relation 7:

$$\begin{aligned} \hat{Y}_s &= X * w_s + b_s \\ \hat{E} &= X * w_e + b_e \end{aligned} \tag{10}$$

$$\hat{Y} = \hat{Y}_s Z + \hat{E} \tag{11}$$

An overview of steps for training and prediction are shown in Algorithms 2 and 3.

Algorithm 2 Training Algorithm.

```
Input: Training Data $X$ and $Y$.
Find the best label subset by submodular optimization over function 6;
Find the linear propagation equation through ADMM optimization over problem 8.
Find the linear regression models over small subset of labels and outliers by Equation 9
Output: Label subset, outliers, propagation and regression models.
```

4 Experiments

4.1 Datasets

We used six different datasets in the experiments. The "Bibtex" dataset is a text dataset extracted from the BibSonomy website (Katakis et al., 2008)

```
Algorithm 3 Prediction Algorithm.
Input: prediction samples $X$.
  1: Predict candidate label subset and outlier labels using regression model 10.
  2: Use 11 to produce full set of labels from candidate subset and outlier labels.
Output: Full label set for input $X$.
```

contains metadata for the bibtex items like the title of the paper, the authors, etc and extracts the features according to the term frequency. The "Mediamill" dataset is extracted from the Mediamill contest datasets, which include low-level multimedia features (visual and textual features) extracted from 85 hours of international news videos from the TRECVID 2005/2006 benchmark datasets (Snoek et al., 2006) labeled using a lexicon of 101 semantic concepts, like commercials, nature, and baseball.

The "Eurlex" dataset includes 19,348 legal documents from European nations, containing several different types of documents, including treaties, legislation, case-law and legislative proposals, classified according to the EUROVOC descriptor using 3993 different classes, and 5000 features extracted using common TF-IDF term weighting (Mencia and Fürnkranz, 2008). The "Delicious" dataset is a text dataset extracted from the `del.icio.us` social bookmarking site on the 1st of April 2007 and contains textual data of web pages along with their user defined tags (Tsoumakas et al., 2008). The content of web pages was represented using the Boolean bag-of-words model. "Wiki10-31K" is a collection of social tags for given Wikipedia pages with TF-IDF features (Zubiaga, 2012). The statistics of these datasets are provided in Table 1.

4.2 Experimental Setup

For the small datasets, "Bibtex", "Mediamill", "Delicious", and "Eurlex", the reported results are the average of 10 different experiments for random partitions of each dataset. For the larger dataset, "Wiki10-31K", we did one experiment with the training and testing partition reported in Table 1.

For all experiments we chose a label subset size of 100, except for Mediamill where we chose 30 since 100 would represent all labels. Model tuning is done in two phases: first we tune α for group sparsity (Equation 8), and γ for weighting of the submodular functions (Equation 6), then we tune for λ_1 and λ_2, the regression parameters for mapping back to the original label set (Equation 9) with α and γ fixed. All parameters were chosen by measuring the precision of 10-fold cross validation and using a grid search over the values $\{0, 10^{-3,\ldots,+3}\}$ for each dataset.

The proposed method was compared with several state-of-the-art methods with diverse approaches. LEML (Yu et al., 2014), CPLST (Chen and Lin, 2012), CS (Hsu et al., 2009) and SLEEC (Bhatia et al., 2015b) which are embedding based approaches with a low-rank or sparse assumption in the label space. ML-CSSP (Bi and Kwok, 2013) which solves the problem in the original label space which ignores the training error in the subset selection step. FastXML (Prabhu and Varma, 2014), and PD-sparse (Yen et al., 2016) which do not use an embedding transformation and aim to solve the problem without using compression or sampling. We have used the reported results, if available, and otherwise tuned the parameters for the baseline algorithms by means of 10-fold cross validation.

5 Results and Discussion

Table 2 shows the average and standard deviation of Precision@k for the four small-scale datasets, "Bibtex", "Mediamill", "Delicious", and "Eurlex", and the large-scale dataset "Wiki10-31k". For "Wiki10-31k", results are reported only for those baselines that were tractable. The results for nDCG@k are included in supplementary Material, Table 5. Since the SLEEC and FastXML methods are ensemble-based, using multiple non-linear models, it is not fair to compare them with the single model methods such as our own. These methods partition the sample space into smaller tractable clusters and obtain separate classifiers for each partition. We compare our method with these in Table 3.

The proposed approach in most cases has significantly better results than other methods on both measures. The embedding based approaches suffer from accumulation of the embedding and training error (Balasubramanian and Lebanon, 2012), however in the proposed approach, we have removed the embedding step and considered the training error minimization at the label subset selection step. On the other hand, the non-embedding approaches such as PD-sparse (Yen et al., 2016) ignore the label space inter-

dependency information which can be useful to improve the prediction accuracy for the labels which are not easy to predict only from input features.

ML-CSSP (Bi and Kwok, 2013) and the work of Balasubramanian and Lebanon (2012) attempt, like us, to find the most informative labels in order to perform label subset selection. However, our approach improves on their results, supporting the idea that considering only the label space information (ignoring label-feature dependency information) in the label selection step can lead to label sets that are not easy to predict whose training error will be propagated through to final model predictions.

The SLEEC and FastXML methods are ensemble-based methods using multiple nonlinear models and can be expected to outperform single model methods such as ours. SLEEC aims to partition the sample space into smaller tractable clusters to obtain a nonlinear embedding and trained model for each partition. FastXML finds a partitioning tree by using nonlinear binary classifiers to partition the samples at each node, which is a very complicated and unstable problem for high-dimensional spaces. Therefore, for both SLEEC and FastXML methods, they need an ensemble of the learners in order to overcome this instability and achieve a good prediction accuracy. Table 3 shows that SLEEC performs best on the Mediamill and FastXML performs best on the Delicious dataset. This shows that finding a representative subset using a linear method is not a consistent assumption for these datasets than the low-rank and tree-based assumptions. However, for Bibtex dataset, our proposed method is competitive with the best results, and for Eurlex and Wiki10-31k, our method is substantially better than both SLEEC and FastXML, a notable achievement for a single model approach.

5.1 Ablation study

The ablation study results in Table 4 shows how different data sets benefit from different parts of our proposed framework, with all parts contributing substantially to at least one data set. We have reported the results by considering only label-label dependency information (f_{pen}), label-feature dependency information (f_{score}) and combining all 3 parts (f_{pen}, f_{score} and outlier information). The results support the assertions that considering only the label space information (ignoring label-feature dependency information) in the label selection step causes prediction error of labels with high training error to be propagated to the whole label space and that it is important to also select outlier labels that are hard to predict from other selected labels.

Table 4: Ablation Study. Bold indicates a difference of $\geq 0.8\%$

We also investigated the effect of changing the subset size S on the final prediction quality (we have ignored the outlier effect in these experiments). Figure 1 shows an initial marked increase in performance with subset size, however the results gets more stable when the subset size gets larger. This observation, which is consistent with the submodular property, provides a clue that using a more complicated training model, like a nonlinear model, for a smaller selected set of labels may lead to higher performance than increasing the subset size while using a linear model.

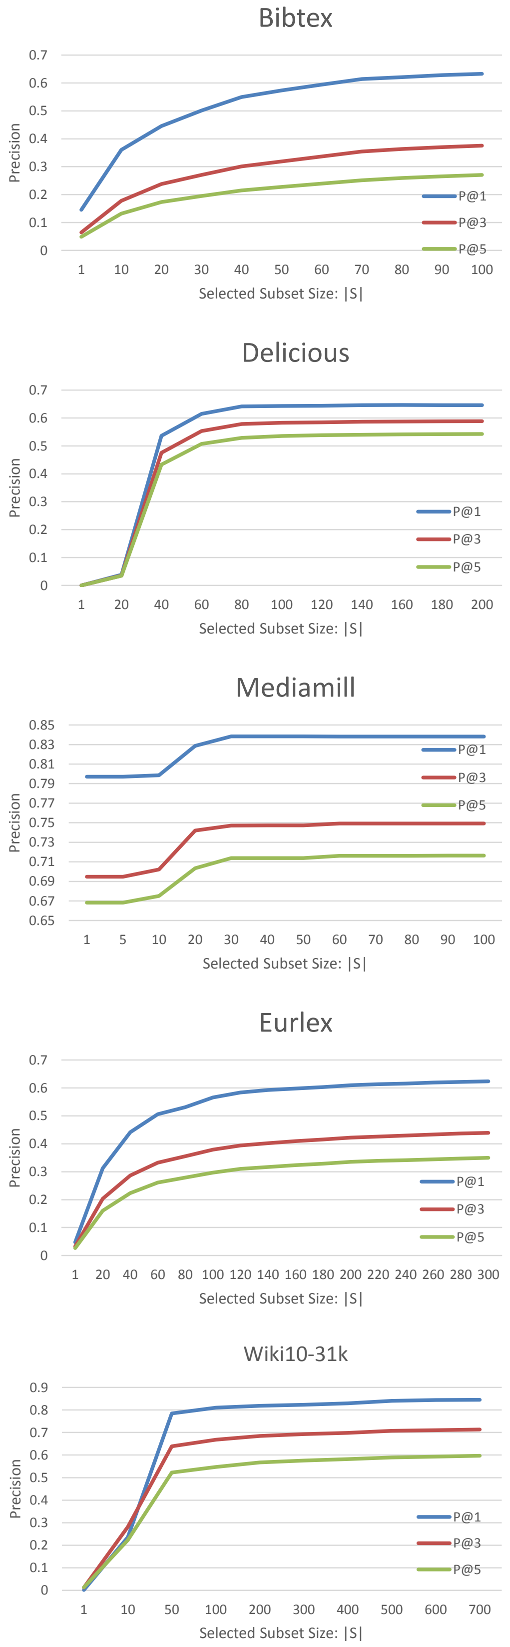

Figure 1: Precision score changes by subset size without outliers.

6 Conclusion and Future Work

We propose a novel approach for extreme multi-label classification that simplifies the problem by selecting an informative and easily modelled subset of labels and subsequently mapping back to the full set of labels. While the method is very well applicable to text datasets, it is applicable as a general ML method for different domains. Our novel label selection mechanism follows three principles: A new submodular maximisation framework that combines label-label dependencies and label training error together with a mechanism to identify outlier labels that are hard to reconstruct. Modelling only the most informative labels helps to avoid transforming the label space to a new embedding space leading to accumulation of training and embedding errors. We use a greedy approach for our monotone submodular framework with linear cost and good theoretical convergence. Extensive experiments using a linear prediction model on selected labels conducted on five standard real-world datasets demonstrate that our method achieves better performance than single model approaches, and better or comparable performance to ensemble based methods. In future, we can improve our model by using nonlinear training model instead of a simple linear regression model for the selected subset of the labels. Moreover, ablation study results suggest that a nonlinear propagation model to reconstruct the full label set may be of benefit.

Abstract

Distant supervision (DS) is an important paradigm for automatically extracting relations. It utilizes existing knowledge base to collect examples for the relation we intend to extract, and then uses these examples to automatically generate the training data. However, the examples collected can be very noisy, and pose significant challenge for obtaining high quality labels. Previous work has made remarkable progress in predicting the relation from distant supervision, but typically ignores the temporal relations among those supervising instances. This paper formulates the problem of relation extraction with temporal reasoning and proposes a solution to predict whether two given entities participate in a relation at a given time spot. For this purpose, we construct a dataset called WIKI-TIME[1] which additionally includes the valid period of a certain relation of two entities in the knowledge base. We propose a novel neural model to incorporate both the temporal information encoding and sequential reasoning. The experimental results show that, compared with the best of existing models, our model achieves better performance in both WIKI-TIME dataset and the well-studied NYT-10 dataset.

1 Introduction

As an important technique to automatically complete the knowledge base and reduce labeling efforts, distant supervision (DS) for relation extraction has drawn much attention. In DS, we align the entity pair $(head, tail)$ from a triple $\langle head, rel, tail\rangle$ extracted from a huge knowledge base (e.g., Freebase, Wikidata) with sentences from free texts (e.g., Wikipedia, New York Times) to obtain the training examples, and the label of such an example is the corresponding relation *rel*. Therefore, DS can automatically create a set of training data for each entity pair.

However, the noisy training data problem (Riedel et al., 2010) significantly affects the performance of DS. Therefore, most of the recent approaches (Riedel et al., 2010; Hoffmann et al., 2011; Zeng et al., 2015; Lin et al., 2016) follow a common assumption called the at-least-once assumption, which treats all aligned sentences of each entity pair as one training sample. We refer to a sentence as an instance and all sentences aligned to one entity pair as a mention set in the following, respectively.

The models in previous work (Zeng et al., 2015; Lin et al., 2016; Luo et al., 2017) generally include two parts, **encoding** and **fusion**. The former encodes each instance into a low-dimensional representation. The latter combines representation of each instance. Then, their combination is used to predict the relation.

Although the approaches mentioned above seem promising, they have the following limitations:

1. They all use a separate but identical encoding module among instances and introduce no difference temporally.
2. They only adopt single step of fusion and introduce no sentence-level reasoning.

We remark that the aforementioned approaches may be enough for the standard NYT-10 dataset (Riedel et al., 2010), because the dataset only extracts instances from New York Times corpus from the year 2005 to 2007 and consists of few mention sets with long time span. However, as one can easily imagine, ignoring temporal information may cause inaccurate predictions, especially when a mention set has a long time span and some

Proceedings of NAACL-HLT 2019, pages 1019–1030
Minneapolis, Minnesota, June 2 - June 7, 2019.

instances express different relations. For example, suppose we want to predict the relation between Angelina Jolie and Brad Pitt (using Wikidata). The knowledge base contains a factual relation of *spouse* between them with the valid period from August 2014 to September 2016. However, the extracted mention set contains instances about their marriage in 2014, as well as their divorce in 2016. Because existing models do not encode temporal information, the relation they extract is likely to be the one with highest confidence. In this example, their models may predict the relation of marriage since the instances may suggest a higher confidence for the relation of marriage. But the correct prediction should be divorce. As shown in the above example, we can see it is necessary to include temporal information in DS.

On the other hand, in fusion module, most existing work focused on denoising using methods such as attention or reinforcement learning. We want to argue that a sentence-level reasoning can also be useful since there are instances which are not direct positive examples for the given relation, but can provide supporting evidence. We call them remote instances. Consider the Jolie-Pitt example again. Suppose we are to predict their relation after their divorce. The instances about their marriage also indirectly help to infer their divorce since marriage is the premise of divorce. Hence, we need an algorithm that can incorporate temporal information and perform reasoning over remote instances.

In this paper, we address both limitations and extend the task to predict the relation of a particular entity pair at any specific time spot. The problem can be formulated as a sequence labeling problem (See § 2). We propose a novel relation extraction architecture that can address both aforementioned limitations. Our model follows the popular encoding-fusion architecture, but makes two crucial modifications. Firstly, we introduce temporal encoding to model the temporal information among the instances in the encoding. Secondly, we use the Memory Network (Sukhbaatar et al., 2015; Miller et al., 2016) to iteratively reason over temporally augmented encodings in the fusion part.

Moreover, we evaluate our model on the widely studied NYT-10 dataset (Riedel et al., 2010) and a new WIKI-TIME dataset. The construction of WIKI-TIME is similar to that of the NYT-10 dataset except for two important differences. One is that we only consider triples $\langle head, rel, tail\rangle$ with the valid period $(T1, T2)$. For example, the triple $\langle Jolie, married, Pitt\rangle$ has a valid period of $(2014.08, 2016.09)$. The other is that we extract contextual temporal information for each aligned instance. We use Wikidata (Vrandečić and Krötzsch, 2014) as knowledge base and Wikipedia as free corpus. Both automatic and manual evaluation are applied in the experiments. The experimental results show that, compared with existing models, our model can achieve comparable/better performance in both WIKI-TIME and standard NYT-10 datasets.

Our main contributions can be summarized as follows:

- We introduce a new task aiming to solve the problem of relation extraction with temporal information.
- We propose a novel relation extraction architecture, which encodes both the temporal and semantic information and includes remote instances for temporal reasoning.
- We construct a new WIKI-TIME dataset by aligning Wikidata to Wikipedia, which is specially designed for the task of relation extraction with temporal information.
- The experiment results show that, compared with the best of existing models, our model achieves comparable/better performance both in WIKI-TIME dataset and standart NYT-10 dataset.

2 Formulation

2.1 Traditional Distant Supervision (DS)

The traditional distant supervision (DS) task can be defined as:

Given two entities $\langle head, tail\rangle$ and their corresponding mention set $S = \{s_1, s_2, \cdots, s_T\}$, where s_i denotes the ith instance, the task aims to predict the probability for specific relation r of $\langle head, tail\rangle$:

$$P(r|S = \{s_1, s_2, \cdots, s_T\}). \tag{1}$$

The task can be seen as a multi-label multi-instance classification problem.

2.2 Distant Supervision with Temporal Reasoning

In distant supervision with temporal reasoning, our goal is to predict the relation between two entities at any specific time spot. Because modeling over any specific time spot is non-trivial, we relax the goal to predict the relation between two given entities at any mentioned time spots. Note that we can infer the relations at other time spots using prediction at mentioned ones. Formally, the relation r_t at $t \in (t_1, t_2]$ can be infered by r_{t_1}. Therefore, we can model the problem as a sequence labeling problem with noisy inputs.

Given two entities, we collect the chronologically sorted list of its mention instances and the time spot associated with each instance . We denote the list by $S = \{(s_1, t_1), \cdots, (s_T, t_T)\}$, where (s_i, t_i) is the ith instance and the associated time spot. Our goal is to predict the probability of relation r at time spot t_i:

$$P(r_{t_i}|S = \{(s_1, t_1), \cdots, (s_T, t_T)\}, t_i). \quad (2)$$

3 Methodology

3.1 Overview of TempMEM

Note that RNN-like models are not suitable for this sequence labeling problem, because the input sequence contains noisy sentences and lacks direct dependency between time steps. We propose a neural model called TempMEM which models the sequence labeling problem by creating query sequence based on each mentioned time spot.

TempMEM also follows the encoding-fusion framework (Zeng et al., 2015; Lin et al., 2016; Luo et al., 2017). However, we make two crucial modifications to the original framework. First, for the encoding part, we use time-aware encoding modules for instances instead of identical ones. Second, we use the memory network to iteratively reason over instances, which makes use of remote instances.

In the following sections, we introduce how to encode the temporal and semantic information and include remote instances for temporal reasoning.

3.2 Encoding

3.2.1 Sentence Encoding

For sentence encoding, here we apply the Convolutional Neural Network (CNN) and the Piecewise Convolutional Neural Network (PCNN) (Zeng et al., 2015). Note that, since TempMEM has no preferance over specific sentence encoding, other encoding modules like word memory (Feng et al., 2017) or self-attention can also be used here.

The inputs of convolution layers are word embeddings concatenated with position features. For a detailed description of the inputs, we refer the readers to (Zeng et al., 2015).

First, the convolution layer extracts local features with sliding window $\hat{w}$ over the input representation. Formally, the convolution operates on the concatenation of the input representations $\boldsymbol{X}_{k:k+\hat{w}}$ of instance j with the shared parameters $\boldsymbol{W}_c \in \mathbb{R}^{D*\hat{w}}$ and $b_c \in \mathbb{R}^1$:

$$o_{c,k} = \boldsymbol{W}_c \cdot \boldsymbol{X}_{k:k+\hat{w}} + b_c, \quad (3)$$

where $o_{c,k}$ is the kth output of channel c.

Then, we use the piece-wise max-pooling layer. It divides the outputs of filters into three parts $\{\boldsymbol{o}_{c,0:h}, \boldsymbol{o}_{c,h:t}, \boldsymbol{o}_{c,t:N}\}$ and performs max-pooling over each part:

$$\boldsymbol{o}_c = [\max_{0 \le k < h}(o_{c,k}), \max_{h \le k < t}(o_{c,k}), \max_{t \le k < N}(o_{c,k})], \quad (4)$$

where h and t denote the indices of the head and tail entities, respectively. The concatenation of the output of all channels c is considered as the convolutional representation of instance j:

$$\boldsymbol{O}_j = [\boldsymbol{o}_1, \boldsymbol{o}_2, \cdots, \boldsymbol{o}_C], \quad (5)$$

where C denotes the number of filters.

3.2.2 Temporal Encoding

In order to introduce temporal priorities among instances, it is necessary to inject temporal information into the encoding part. We want the temporal encoding to have the following characteristics:

- The temporal encodings should comply with the chronological order of instances.
- The difference between two time spots determines the similarity between two temporal encodings.

Since directly encoding the time spot value leads to huge difference among mention sets of the dataset, we propose an approximate approach with PE encoding (Vaswani et al., 2017) based on the rank (i.e. position of an instance in a mention set with chronological order):

$$\boldsymbol{PE(j)} = \begin{cases} sin(j/10000^{d/d_m}) & if\ d\%2 = 0 \\ cos(j/10000^{(d-1)/d_m}) & if\ d\%2 = 1 \end{cases}, \quad (6)$$

where j is the rank of instance s, d is the dimension, and d_m is the dimension of temporal encoding. Obviously, the PE encoding complies with the chronological order and the similarity between

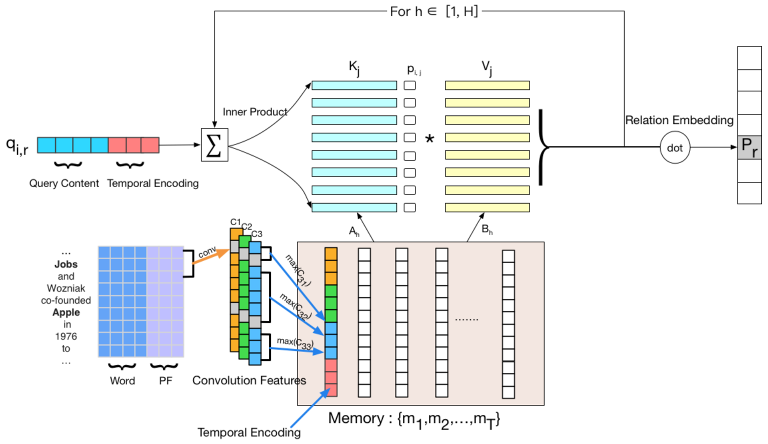

Figure 1: Overall TempMEM architecture

two PE encodings (by dot product) is determined by their rank difference.

Then, we concatenate the corresponding temporal encoding with the convolutional features of instance j to form the final representation of each instance with a learnable scale factor λ:

$$\boldsymbol{m}_j = [\boldsymbol{O}_j; \lambda \cdot \boldsymbol{PE(j)}]. \tag{7}$$

3.3 Fusion

In the fusion part, we use the Memory Network to perform temporal reasoning among different instances. Each encoded instance is considered to be a memory slot. Then, we construct a time specific query and iteratively compute the weighted attention over all instances. We detail the process in the following sections.

3.3.1 Query Construction

We construct each query with the guidance of the following intuition.

- Relation extraction within instances is equal to the query "what is the *relation* between *head* and *tail* at time spot t_i?".

So, we construct our queries based on four key variables, $(relation, head, tail, t_i)$.

Specifically, we combine the embeddings (pretrained by TransE (Bordes et al., 2013)) of *head* and *tail* and project the combination through an affine matrix $\boldsymbol{\Phi}_q \in \mathbb{R}^{D_e * D_r}$, where D_e and D_r denote the dimension of relation and entity embedding, respectively. After the projection, we add the randomly initialized relation embedding. The formal definition of a query is given below:

$$\boldsymbol{q}_r = \boldsymbol{R}_r + (\boldsymbol{E}_{head} + \boldsymbol{E}_{tail}) * \boldsymbol{\Phi}_q, \tag{8}$$

where $\boldsymbol{R}_r \in \mathbb{R}^{D_r}$ is the embedding of specific relation r and $\boldsymbol{E}_* \in \mathbb{R}^{D_e}$ is the entity embedding. Finally, we also concatenate the query with the same temporal encoding defined in § 3.2.2 to obtain the ith query:

$$\boldsymbol{q}_{r,i} = [\boldsymbol{q}_r; \lambda \cdot \boldsymbol{PE(i)}]. \tag{9}$$

3.3.2 Iterative Reasoning

In this part, we introduce how to use the queries to perform temporal reasoning. Two operations are involved, memory addressing and reading.

One of our key motivations is to consider the remote instances. So, instead of using single step attention computation as in previous work (Lin et al., 2016; Luo et al., 2017; Ji et al., 2017), we perform an overall H steps of memory addressing and reading to obtain the final prediction. Within each step (also called hop), we update the query value by adding the output of the previous step, which provides a gradual shift in attention. Next, we introduce the whole process in detail.

Memory Addressing In addressing, we compute the similarity between the query vector $\boldsymbol{q}_{i,r}$ and each candidate memory slot key $\boldsymbol{K}_j$. Note that the encoding output $\boldsymbol{m}_j$ is not in the same continuous space as the query vector. So, we adopt linear projections to both memory keys:

$$\boldsymbol{K}_j = \boldsymbol{A}_h^T \cdot \boldsymbol{m}_j, \tag{10}$$

where $\boldsymbol{A}_h \in \mathbb{R}^{D_m * D_r}$. Then, we compute the similarity score and importance probability using the bilinear form,

$$s_{i,j} = \boldsymbol{q}_{i,r}^T \cdot \boldsymbol{W}_a \cdot \boldsymbol{K}_j, \tag{11}$$

$$p_{i,j} = \frac{exp(s_{i,j})}{\sum_{\hat{j}=1}^{M} exp(s_{i,\hat{j}})}, \tag{12}$$

where $\boldsymbol{W}_a \in \mathbb{R}^{D_r * D_m}$ is the model parameter to be learned and i, j are the indices of queries and memory slots.

As for the addressing step, it worths noting that the query and memory slots are both concatenated with temporal encodings. If we define the embedding layer $\boldsymbol{A}$ as the identity matrix, each similarity score of a query-memory pair can be divided into two parts,

$$s_{i,j} = \boldsymbol{q}_i^T \cdot \boldsymbol{o}_j + \lambda^2 \cdot \boldsymbol{PE(i)}^T \cdot \boldsymbol{PE(j)}. \quad (13)$$

Each query can automatically attend to instances with either close encoding representations or close temporal encodings. This tradeoff also accords with our intuition, since the confidence of a relational factual statement decreases when the time span increases.

Memory reading The value of each memory slot, which is also projected by an affine matrix $\boldsymbol{B} \in \mathbb{R}^{D_m * D_r}$, is read by computing the weighted sum over all memory slots with the importance probability derived in the addressing step:

$$\hat{\boldsymbol{q}}_i = \sum_j p_{i,j} \boldsymbol{V}_j, \quad (14)$$

where $\boldsymbol{V}_j = \boldsymbol{B}_h^T \cdot \boldsymbol{m}_j$.

Iterative computation Here, we combine the above two operations as a single step for reasoning. We use $h \in [1, H]$ to denote a particular step, where H is the total step number. To achieve a step-by-step reasoning, we update the next step query q^{h+1} with the summation of the current step output $\hat{q}^h$ and the current query q^h:

$$\boldsymbol{q}^{h+1} = \boldsymbol{q}^h + \hat{\boldsymbol{q}}^h. \quad (15)$$

During training, we add dropout with probability p_b at the final query step. By combining the previous hop query and the output in this way, TempMEM can gain information from the last read output and shift addressing attention to remote instances.

3.3.3 Output

In the output module, we define the conditional probability $P(r|S, \theta)$ through a softmax layer as follows:

$$P(r|S, \theta) = \frac{exp(\boldsymbol{R}_r^T \cdot \boldsymbol{q}_r^H)}{\sum_{\hat{r}=1}^{N_r} exp(\boldsymbol{R}_{\hat{r}}^T \cdot \boldsymbol{q}_r^H)}, \quad (16)$$

where N_r is the total amount of pre-defined relations. Also, since we construct and predict relations using the same relation embedding in the query construction part, we remove the original query from the last hop query q^H to keep the prediction unbiased.

3.4 Optimization

Here we introduce the learning and optimization details of TempMEM. We use query-level CrossEntropy loss as our objective function:

$$J(\theta) = \sum_{s=1}^{N_s} \sum_{i=1}^{T} y_t \cdot \log p(\hat{y}_t | S_s, \theta, t_i), \quad (17)$$

where N_s is the number of sets and T is the length of query sequence.

We use stochastic gradient descent (SGD) to minimize our objective function. For the exploration of optimization, we add small white noise to the gradients (Neelakantan et al., 2015). We also anneal the learning rate l by $0 < \rho < 1$ (i.e., $l \leftarrow \rho \cdot l$) for every τ epochs.

4 Experiment

4.1 Dataset

We evaluate our model on two datasets, the widely used NYT-10 dataset which is developed by (Riedel et al., 2010) and the WIKI-TIME dataset we created.

4.1.1 NYT-10

This dataset is generated by aligning Freebase entities to New York Times corpus (NYT) of years from 2005 to 2007. There are 53 pre-defined relations including a particular relation NA which indicates no relation between *head* and *tail*. The training data contains 522,611 sentences, 281,270 entity pairs, and 18,252 of them are relational facts. The testing data contains 172,448 sentences, 96,678 entity pairs, and 1,950 of them are relational facts.

4.1.2 WIKI-TIME

Similar to NYT-10, the WIKI-TIME dataset is also generated by aligning knowledge base entities to free corpus, except that we choose Wikidata and Wikipedia instead of Freebase and NYT news.

The motivation of creating WIKI-TIME is to generate a time aligned dataset that can support temporal reasoning. Hence, we filter knowledge base entities that participate in relations with informative temporal features, such as start time, end time. Besides, we tag the aligned sentences with their time expressions in contexts. Then, we align the contextual time expressions with the valid period of each relation to achieve labeling. For example, sentence like:

"On September 19, 2016, Jolie filed for divorce from Pitt, citing irreconcilable differences."

is labeled with no relation (NA).

The dataset contains 57 relations. The training set contains 97,616 sentences and 20,085 entity pairs. The test set contains 39,990 sentences and 8,641 entity pairs. [2]

4.2 Experiment Details

Hyper-Parameter Settings For WIKI-TIME experiments, we construct query over each appeared time spot in the mention set. On the other hand, for NYT-10 experiments, we adopt a single query without temporal encoding to compare results with other baseline methods since the dataset only contains one label for each mention set.

Among all experiments, we use 230 convolution kernels with windows size 3. The dropout probability p_d is set to 0.5. We try various max hops values H (from 1 to 5) to test how reasoning works in our model. We train the models with 20 epochs and 50 epochs for NYT-10 dataset and WIKI-TIME dataset and report the best performance.

As for optimization step, we adopt SGD with gradient plus Gaussian noise with standard deviation of 0.01, which helps to better generalize. Also, we apply gradient decay of rate $(\rho = 0.5)$ over every $\tau = 10$ epochs. The learning rates for NYT-10 and WIKI-TIME experiments are set to 0.001 and 0.01, respectively.

4.2.1 Input Vectors

With regard to inputs, we use 50-d Glove (Pennington et al., 2014) word embeddings pretrianed on Wikipedia and Gigaword and 5-d postion embedding. The temporal encodings are either initialized with random 50-d vectors, which are learned during training, or set directly with PE. For entity embeddings, we use the TransE (Bordes et al., 2013) entity vectors pretrained on Wikidata released by the OpenKE platform.

4.2.2 Evaluation Metric

The performance of comparative experiment is reported by precision-recall (PR) curve. Specifically, we sort the prediction scores of the model in descending order (without NA relation) and compute the precision with threshold for each recall value. Also, we report the $P@N$ values which indicate the precision over N predictions with the highest confidence scores.

4.3 Performance of iterative reasoning

To test the effect of iterative reasoning over instances, we implement the neural models proposed in previous work (Zeng et al., 2015; Lin et al., 2016), from the source code released by authors. Since the previous models perform prediction in bag-level, the label is given by the latest relation appeared in KB. As for our models, we fix the number of hops $H = 2$ and set the encoding to CNN. [3] The notations of the experiments are shown in Table 1.

As shown in Figure 2 and Table 2, we have the following observations: (1) All TempMEM models achieve better performance compared with the previous neural models (CNN_ONE, CNN_ATT).

---

[2] The details of construction of WIKI-TIME can be found in *Appendix A*.

[3] The PCNN encoding is not used in WIKI-TIME dataset. The detailed explanation is given in *Appendix A*.

Method	P@N_100	P@N_200	P@N_300
CNN_ATT	67.33	67.66	66.45
CNN_ONE	70.3	68.66	65.78
TempMEM	81.18	**82.09**	**78.41**
TempMEM+R	79.21	78.61	75.42
TempMEM+P	**81.19**	79.1	77.41

Table 2: Comparison with previous models. P@N_100/200/300 refers to the precision for the highest 100, 200 and 300 predictions in WIKI-TIME.

Method	Bag-level F1	Query-level F1
CNN_ATT	39.66	-
CNN_ONE	40.15	-
TempMEM	47.88	54.75
TempMEM+R	46.76	47.83
TempMEM+P	**54.86**	**60.01**

Table 3: Manual evaluation of Bag-level and Query-level F1 scores in WIKI-TIME.

Recall that the hop number is set to 2. This can be seen as an ablation experiment. The results suggest that the remote instances can generally help relation extraction task. (2) TempMEM + P clearly outperforms TempMEM + R, which proves that the properly chosen temporal encodings help the performance.

Note that, in the columns "P@N_200" and "P@N_300" of Table 2, we find that the pure TempMEM outperforms TempMEM + P and TempMEM + R. Based on the results in Table 3, their drop of performance comes from the noisy labeling problem of distant supervision.

Also, TempMEM can catch relation changes through the timeline of two entities. We refer the readers to the case study in *Appendix B*.

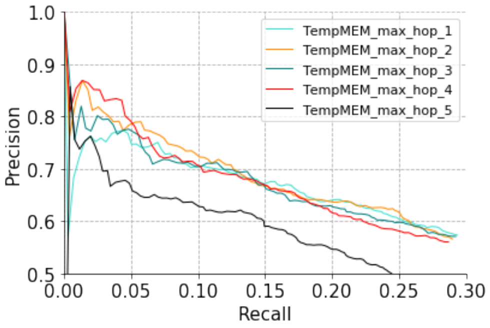

Figure 3: Number-of-hops experiment on WIKI-TIME. Best viewed in color.

4.4 Manual Evaluation on WIKI-TIME

Since the WIKI-TIME is distantly collected, we want to obtain a more precise view of how the models perform. So, we apply the manual evaluation to verify our experimental results. We randomly pick 200 mention sets in the test set of WIKI-TIME and ask two annotators to label the relation for each instance. The annotation rule is to label the instance with the relation that can be inferred from the instance itself or previous instances. As shown in Table 3, the manual evaluated F1 scores are basically consistent with the PR curves in Figure 2, which indirectly proves the WIKI-TIME's quality. Also, we find that the TempMEM + P achieves the best performance and shows obvious advantages in both query-level and bag-level F1 scores over the naive TempMEM (i.e., with no temporal encodings). This proves the effectiveness of our temporal encodings.

4.5 Effect of the Number of Hops

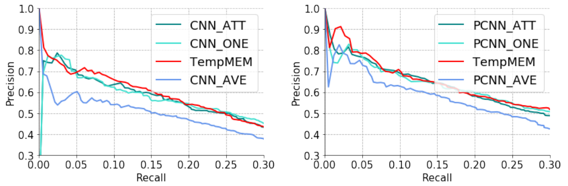
In this section, we discuss the effect of different number of hops in TempMEM. We change the hop value from 1 to 5 and evaluate the precision and recall of our models in query-level. The hyperparameters are fixed. The temporal encoding is set to PE and each model is trained for 30 epochs.

The results of the hop number experiment are depicted in Figure 3. From the results, we can observe that models show better performance with hop number 2 and 4. Most of the improvement of the model with hop number 4 resides in the recall range [0, 0.05], but the performance remains in the similar trend with other models in the recall range [0.05, 0.2]. In addition, we notice that the performance of the models fluctuates with the increase in the number of hops and the model with even hop number generally perform better than its predecessor, e.g. models with hop number 4 and 5. We believe that the reason might lie in the distribution of the hop distance between origin instance and useful remote instance.

4.6 Performance on NYT-10 Dataset

In this section, we report our results on the well-studied NYT-10 dataset. By evaluating our model in the NYT-10 dataset, our objective is to prove the power of reasoning among remote instances.

Note that, in the NYT-10 dataset, there is no temporal information for each instance, so we only use one query for each mention set and there's no



(a) Results with CNN encoding. (b) Results with PCNN encoding.

Figure 4: Precison-Recall curve on **NYT-10**. Best viewed in color.

temporal encoding for each instance. Also, we do not use the entity embedding for the NYT-10 experiments.

The results are shown in Figure 4. For both CNN and PCNN models, We can see that our models exceed the performance of all other models (CNN_ATT, CNN_ONE, CNN_AVE, PCNN_ATT, PCNN_ONE, PCNN_AVE) in the range of low recall values. In the high recall range, our models also have results about the same as the best model among others. This suggests that even without the temporal encoding, reasoning over remote instances is indeed useful in relation extraction task.

5 Related Work

5.1 Distant Supervision

Distant supervision for relation extraction is an important, automatic method of completing knowledge base.

(Riedel et al., 2010) made the at-least-once assumption that led the distant supervision for relation extraction to multi-instance learning. (Hoffmann et al., 2011) and (Surdeanu et al., 2012) tried to model the task with a multi-instance, multi-label setting using the classical graph model.

Recently, some work focused on applying deep neural network to the DS task. (Zeng et al., 2014) was the first trial to apply deep learning in relation extraction by solving a classification problem with fully supervised approach. (Zeng et al., 2015) moved a step further and introduced the multi-instance learning paradigm by using only the most important instance to predict relation. (Lin et al., 2016; Liu et al., 2017; Ji et al., 2017) improved the previous work by adding attention mechanism to instances and automatically reducing the weights of noisy instances. There are other approaches that tried to reduce the impact of noise in DS by using active learning (Sterckx et al., 2014) and reinforcement learning (Feng et al., 2018).

However, previous work focused on denoising but ignored the exploration of the remote instances and introduced no temporal information to support relation extraction. In this paper, we introduce temporal information into DS and combine it with the memory network to perform reasoning over instances.

(Feng et al., 2017) also used the memory network in the context of distant supervision. Their work performed word-level and relation-level reasoning to model the importance of words and dependency between relations. Their motivation was to gain better sentence encoding and relation modeling, while in our model, we apply the sentence-level memory network to understand the inference process among instances.

5.2 Temporal Relation Extraction

Also, this work is related to temporal relation extraction. (Dligach et al., 2017) was the first approach to use neural models for temporal relation extraction. (Tourille et al., 2017) used a Bi-LSTM to identify narrative containers between events and time expressions. (Cheng and Miyao, 2017) introduced dependency paths and used a "common-root" to solve the cross-sentence dependency. (Meng and Rumshisky, 2018) leveraged the Neural Turing Machine to enhance context-awareness of the temporal relation extraction model.

Previous work in temporal relation extraction was dedicated to event timelining and focused on dealing with relations between event and time expression. In constrast, our model aims to solve general entity to entity relation extraction by instance-level temporal reasoning based on a coarse-grained timelining.

5.3 Temporal Slot Filling

Another related research aspect is the temporal slot filling (TSF) task introduced in knowledge base population (Surdeanu, 2013; Ji et al., 2014). Distant supervision approaches (Garrido et al., 2013; Cucerzan and Sil, 2013; Sil and Cucerzan, 2014) (from Freebase and Wikipedia infoboxes) are widely applied to address the lack of supervising data. (Reinanda and De Rijke, 2014) performed the prior-sampling on distant supervision data to correct the mismatch of distributions.

The TSF task is similar to the task defined in this paper in the sense that TSF also asks the model to identify the start and end date of one knowledge triple $\langle head, rel, tail\rangle$. The difference is that the TSF task's objective is to predict validity period given the *head*, *rel* and *tail*, while in our setting, we predict *rel* between two entities in different periods.

6 Conclusion

In this paper, we formulate the task of distant supervision with temporal relation reasoning by modeling it as a sequence labeling problem. Following the DS paradigm, we created a new dataset called WIKI-TIME which is designed for the temporal relation extraction task. In addition, we propose an encoding-fusion model, TempMEM, which combines both encoding and reasoning temporally. At each computation step, our model can automatically attend information with either close representation or close temporal encoding. In experiments, we compare our model with the existing methods in both the well-known NYT-10 dataset and our WIKI-TIME dataset. Both automatic and manual evaluation are applied in the experiments. The experimental results show that our model not only realizes better performance in relation extraction by introducing instance-level reasoning but also improves the reasoning by bringing the temporal information in.

In the future, we plan to further explore the effect of different encoding modules like Bi-LSTM or self-attention and try to model temporal information with more sophisticated choices.

A Appendix A : WIKI-TIME Construction

Here we illustrate the construction process of WIKI-TIME dataset in detail. The construction of WIKI-TIME follows common distant supervision framework. In distant supervision, we align the knowledge base to free corpus. The chosen knowledge base and free corpus are Wikidata and Wikipedia, respectively.

As depicted in Figure 5, the construction of WIKI-TIME consists of the following procedures.

1. We extract the relations with the valid period (i.e., $\langle t_s, t_e \rangle$) that appeared in WikiData.
2. Based on the extracted relation set, we further extract entity pairs that participate in any relation in the set. Here, each extracted triple should have a valid period (i.e., $\langle E_1, rel, E_2 \rangle : \langle t_s, t_e \rangle$).
3. We tag each sentence in Wikipedia corpus using either time expression appeared in

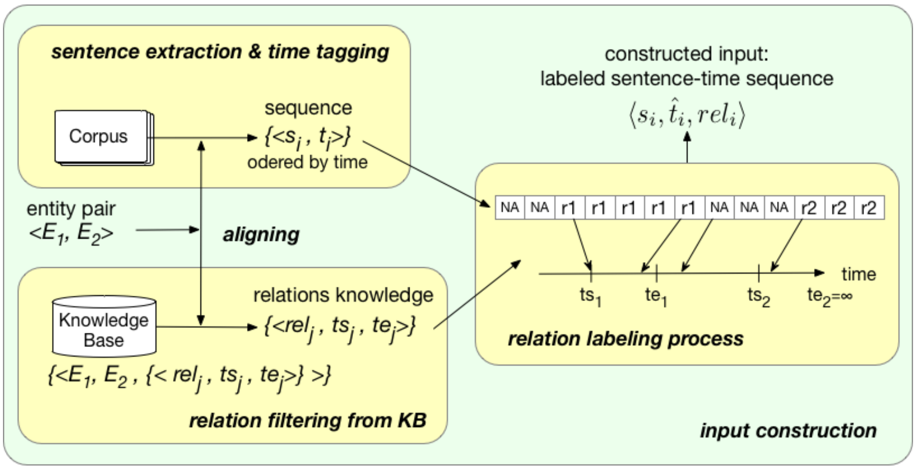

Figure 5: Preprocess of inputs

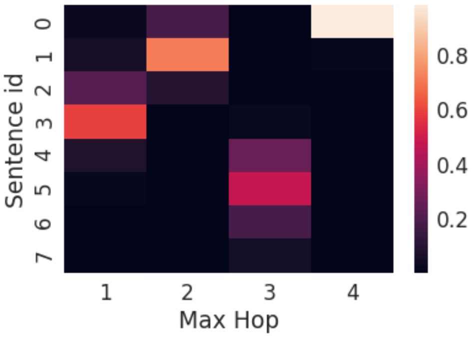
the sentence or last appeared time expression. We implement our own time expression recognition on the basis of NLTK-contrib's timex tool [4] with some modification according to our needs. Each tagged sentence is denoted by tuple $\langle s_i, \hat{t}_i \rangle$.

4. We align the extracted entity pairs to tagged corpus to retrieve our final mention set. Note that we additionally take sentences mentioning entity E_2 in the wiki page of entity E_1 as training sentences for (E_1, E_2) to obtain a larger dataset. In this case, the position of E_1 may not exist in our dataset. Because PCNN splits sentences by positions of entities, it is unclear how to apply it directly to our WIKI-TIME dataset.
5. We order the extracted sentences $\{\langle s_1, \hat{t}_1 \rangle, \cdots \langle s_m, \hat{t}_m \rangle\}$ into a timeline and align them with the corresponding knowledge triple for sentence-level relation $\langle s_i, \hat{t}_i, rel_i \rangle$.

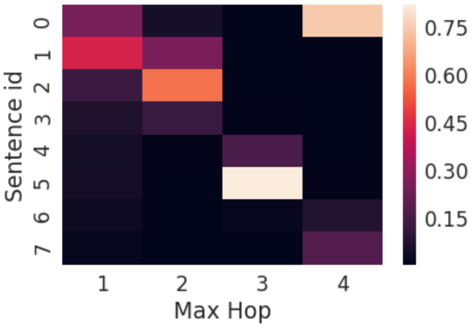
The final dataset contains 57 relations. The training set contains 97,616 sentences and 20,085 entity pairs. The test set contains 39,929 sentences and 8,641 entity pairs. The train/test split is done on entity pair level, so there is no overlap between train and test set.

B Appendix B : Case Study

Table 4 shows an example of our tagged data. For each sentence, we show the corresponding time slot and its relation. Also, the mentions of the entity are highlighted with the bold font and each sentence is indexed by *id* for clearness.



(a) q_3 over relation *Spouse*



(b) q_0 over relation *Spouse*

Figure 6: Attention weights for queries with $H = 4$

For each query, we show its corresponding heat map of attention values over different hops. The case we choose is $\langle Stelios \quad Kazantzidis, spouse, Marinella \rangle$. In Figure 6 (a), the attention of q_3 focuses on sentences with *id* 2 and 3 which support the relation *spouse* a lot. Then in the next hop, its attention shifts to sentences with *id* 0 and 1, which are the "remote" instances. Then in the third hop, its attention shifts again toward another part

id	Relation	Time Spot	Sentence
0	NA	1957-01-01	Her early career was marked by her collaboration with singer **Stelios Kazantzidis**.
1	NA	1960-01-01	... instances of **Marinella** in films of Greek cinema, from the 1960 by 1966 with **Stelios Kazantzidis** ...
2	Spouse	1964-05-07	**Marinella** married **Stelios Kazantzidis** on 7 May 1964 ...
3	Spouse	1964-05-07	**Stelios Kazantzidis** married **Marinella** on 7 May 1964 ...
4	NA	1966-09-01	In September 1966 he divorced **Marinella**...
5	NA	1968-01-01	Following **Marinella**'s departure Litsa Diamandi ...
6	NA	1968-01-01	**Marinella** sang on some songs ...
7	NA	1968-01-01	**Marinella** had an ”answer back” to that latter song ...

Table 4: Aligned sentences of ⟨ Stelios Kazantzidis , Marinella ⟩

of the sentence set (*id* 4 to 6), which contains sentences related to divorce, departure and so on. These findings prove the claim that our model can achieve more accurate relation extraction by exploitation of remote instances.

Also, we demonstrate that the model has different attentions for queries at different time spots. In Figure 6 (b), we still observe the case of ⟨ *Stelios Kazantzidis, spouse, Marinella* ⟩. But, the attention of query q_0 focuses on a different path compared with query q_3. It first focuses on the remote instances with *id* 0 and 1. Then the model shifts to the supporting sentences. After that, it highly focuses on sentence 5, which supports two entities' departure. All these findings show that the temporal encodings significantly affect the result of attention.

The differences between the attentions of quries q_0 and q_3 show that the temporal encodings significantly affect the result of attention.

Integrating Semantic Knowledge to Tackle Zero-shot Text Classification

Abstract

Insufficient or even unavailable training data of emerging classes is a big challenge of many classification tasks, including text classification. Recognising text documents of classes that have never been seen in the learning stage, so-called *zero-shot text classification*, is therefore difficult and only limited previous works tackled this problem. In this paper, we propose a two-phase framework together with data augmentation and feature augmentation to solve this problem. Four kinds of semantic knowledge (word embeddings, class descriptions, class hierarchy, and a general knowledge graph) are incorporated into the proposed framework to deal with instances of unseen classes effectively. Experimental results show that each and the combination of the two phases achieve the best overall accuracy compared with baselines and recent approaches in classifying real-world texts under the zero-shot scenario.

1 Introduction

As one of the most fundamental problems in machine learning, automatic classification has been widely studied in several domains. However, many approaches, proven to be effective in traditional classification tasks, cannot catch up with a dynamic and open environment where new classes can emerge after the learning stage (Romera-Paredes and Torr, 2015). For example, the number of topics on social media is growing rapidly, and the classification models are required to recognise the text of the new topics using only general information (e.g., descriptions of the topics) since labelled training instances are unfeasible to obtain for each new topic (Lee et al., 2011). This scenario holds in many real-world domains such as object recognition and medical diagnosis (Xian et al., 2017; World Health Organization, 1996).

Zero-shot learning (ZSL) for text classification aims to classify documents of classes which are absent from the learning stage. Although it is challenging for a machine to achieve, humans are able to learn new concepts by transferring knowledge from known to unknown domains based on high-level descriptions and semantic representations (Thrun and Pratt, 1998). Therefore, without labelled data of unseen classes, a zero-shot learning framework is expected to exploit supportive semantic knowledge (e.g., class descriptions, relations among classes, and external domain knowledge) to generally infer the features of unseen classes using patterns learned from seen classes.

So far, three main types of semantic knowledge have been employed in general zero-shot scenarios (Fu et al., 2018). The most widely used one is semantic attributes of classes such as visual concepts (e.g., colours, shapes) and semantic properties (e.g., behaviours, functions) (Lampert et al., 2009; Zhao et al., 2018). The second type is concept ontology, including class hierarchy and knowledge graphs, which represents relationships among classes and features (Wang et al., 2018; Fergus et al., 2010). The third type is semantic word embeddings which capture implicit relationships between words thanks to a large training text corpus (Socher et al., 2013; Norouzi et al., 2013). Nonetheless, concerning ZSL in text classification particularly, there are few studies exploiting one of these knowledge types and none has considered the combinations of them (Pushp and Srivastava, 2017; Dauphin et al., 2013). Moreover, some previous works used different datasets to train and test, but there is similarity between classes in the training and testing set. For example, in (Dauphin et al., 2013), the class "imdb.com" in the training set naturally corresponds to the class "Movies" in

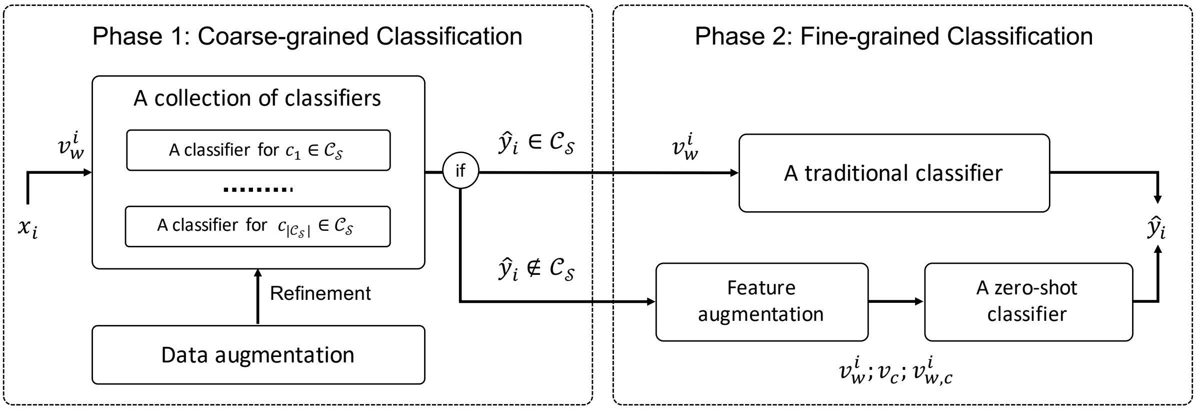

Figure 1: The overview of the proposed framework with two phases. The coarse-grained phase judges if an input document x_i comes from seen or unseen classes. The fine-grained phase finally decides the class $\hat{y}_i$. All notations are defined in section 2.1-2.2.

the testing set. Hence, these methods are not working under a strict zero-shot scenario.

To tackle the zero-shot text classification problem, this paper proposes a novel two-phase framework together with data augmentation and feature augmentation (Figure 1). In addition, four kinds of semantic knowledge including word embeddings, class descriptions, class hierarchy, and a general knowledge graph (ConceptNet) are exploited in the framework to effectively learn the unseen classes. Both of the two phases are based on convolutional neural networks (Kim, 2014). The first phase called **coarse-grained classification** judges if a document is from seen or unseen classes. Then, the second phase, named **fine-grained classification**, finally decides its class. Note that all the classifiers in this framework are trained using labelled data of seen classes (and augmented text data) only. None of the steps learns from the labelled data of unseen classes.

The contributions of our work can be summarised as follows.

- We propose a novel deep learning based two-phase framework, including coarse-grained and fine-grained classification, to tackle the zero-shot text classification problem. Unlike some previous works, our framework does not require semantic correspondence between classes in a training stage and classes in an inference stage. In other words, the seen and unseen classes can be clearly different.
- We propose a novel data augmentation technique called topic translation to strengthen the capability of our framework to detect documents from unseen classes effectively.
- We propose a method to perform feature augmentation by using integrated semantic knowledge to transfer the knowledge learned from seen to unseen classes in the zero-shot scenario.

In the remainder of this paper, we firstly explain our proposed zero-shot text classification framework in section 2. Experiments and results, which demonstrate the performance of our framework, are presented in section 3. Related works are discussed in section 4. Finally, section 5 concludes our work and mentions possible future work.

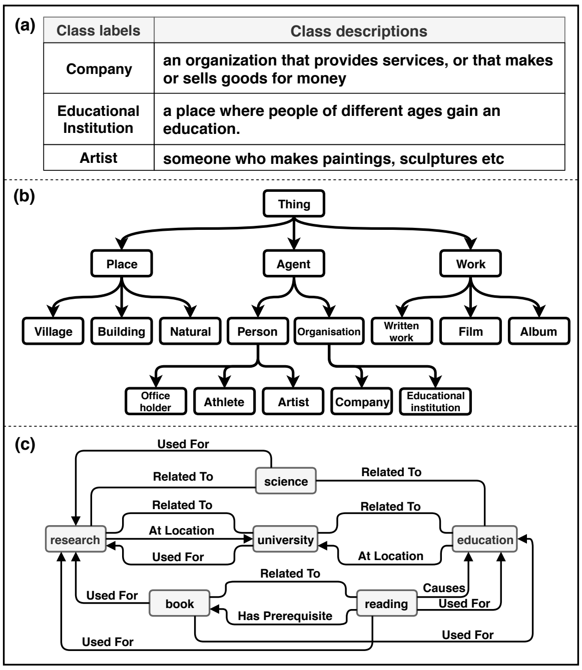
2 Methodology

2.1 Problem Formulation

Let $\mathcal{C}_S$ and $\mathcal{C}_U$ be disjoint sets of seen and unseen classes of the classification respectively. In the learning stage, a training set $\{(x_1, y_1), \ldots, (x_n, y_n)\}$ is given where x_i is the i-th document containing a sequence of words $[w_1^i, w_2^i, \ldots, w_t^i]$ and $y_i \in \mathcal{C}_S$ is the class of x_i. In the inference stage, the goal is to predict the class of each document, $\hat{y}_i$, in a testing set which has the same data format as the training set except that y_i comes from $\mathcal{C}_S \cup \mathcal{C}_U$. Note that *(i)* every class comes with a class label and a class description (Figure 2a); *(ii)* a class hierarchy showing superclass-subclass relationships is also provided (Figure 2b); *(iii)* the documents from unseen classes cannot be observed to train the framework.

2.2 Overview and Notations

As discussed in the Introduction, our proposed classification framework consists of two phases



(a)

Class labels	Class descriptions
Company	an organization that provides services, or that makes or sells goods for money
Educational Institution	a place where people of different ages gain an education.
Artist	someone who makes paintings, sculptures etc

Figure 2: Illustrations of semantic knowledge integrated into our framework: (a) class labels and class descriptions (b) class hierarchy and (c) a subgraph of the general knowledge graph (ConceptNet).

(Figure 1). The first phase, coarse-grained classification, predicts whether an input document comes from seen or unseen classes. We also apply a data augmentation technique in this phase to help the classifiers be aware of the existence of unseen classes without accessing their real data. Then the second phase, fine-grained classification, finally specifies the class of the input document. It uses either a traditional classifier or a zero-shot classifier depending on the coarse-grained prediction given by Phase 1. Also, feature augmentation based on semantic knowledge is used to provide additional information which relates the document and the unseen classes to generalise the zero-shot reasoning.

We use the following notations in Figure 1 and throughout this paper.

- The list of embeddings of each word in the document x_i is denoted by $v_w^i = [v_{w_1}^i, v_{w_2}^i, \ldots, v_{w_t}^i]$.
- The embedding of each class label c is denoted by v_c, $\forall c \in \mathcal{C_S} \cup \mathcal{C_U}$. It is assumed that each class has a one-word class label. If the class label has more than one word, a similar one-word class label is provided to find v_c.
- As augmented features, the relationship vector $v_{w_j,c}^i$ shows the degree of relatedness between the word w_j and the class c according to semantic knowledge. Hence, the list of relationship vectors between each word in x_i and each class $c \in \mathcal{C_S} \cup \mathcal{C_U}$ is denoted by $v_{w,c}^i = [v_{w_1,c}^i, v_{w_2,c}^i, \ldots, v_{w_t,c}^i]$. We will explain the construction method in section 2.4.1.

2.3 Phase 1: Coarse-grained Classification

Given a document x_i, Phase 1 performs a binary classification to decide whether $\hat{y}_i \in \mathcal{C_S}$ or $\hat{y}_i \notin \mathcal{C_S}$. In this phase, each seen class $c_s \in \mathcal{C_S}$ has its own CNN classifier (with a subsequent dense layer and a sigmoid output) to predict the confidence that x_i comes from the class c_s, i.e., $p(\hat{y}_i = c_s | x_i)$. The classifier uses v_w^i as an input and it is trained using a binary cross entropy loss with all documents of its class in the training set as positive examples and the rest as negative examples.

For a test document x_i, this phase computes $p(\hat{y}_i = c_s | x_i)$ for every seen class c_s in $\mathcal{C_S}$. If there exists a class c_s such that $p(\hat{y}_i = c_s | x_i) > \tau_s$, it predicts $\hat{y}_i \in \mathcal{C_S}$; otherwise, $\hat{y}_i \notin \mathcal{C_S}$. τ_s is a classification threshold for the class c_s, calculated based on the threshold adaptation method from (Shu et al., 2017).

2.3.1 Data Augmentation

During the learning stage, the classifiers in Phase 1 use negative examples solely from seen classes, so they may not be able to differentiate the positive class from unseen classes. Hence, when the names of unseen classes are known in the inference stage, we try to introduce them to the classifiers in Phase 1 via augmented data so they can learn to reject the instances likely from unseen classes. We do data augmentation by translating a document from its original seen class to a new unseen class using analogy. We call this process *topic translation*.

In the word level, we translate a word w in a document of class c to a corresponding word w' in the context of a target class c' by solving an analogy question "c:w :: c':?". For example, solving the analogy "company:firm :: village:?" via word embeddings (Mikolov et al., 2013), we know that the word "firm" in a document of class "company" can be translated into the word "hamlet" in the context of class "village". Our framework adopts the 3CosMul method by Levy and Goldberg (2014) to solve the analogy question and find candidates of w':

$$w' = \underset{x \in V}{\operatorname{argmax}} \frac{\cos(x, c') \cos(x, w)}{\cos(x, c) + \epsilon}$$

where V is a vocabulary set and $\cos(a, b)$ is a cosine similarity score between the vectors of word a and word b. Also, ϵ is a small number (i.e., 0.001) added to prevent division by zero.

In the document level, we follow Algorithm 1 to translate a document of class c into the topic of another class c'. To explain, we translate all nouns, verbs, adjectives, and adverbs in the given document to the target class, word-by-word, using the word-level analogy. The word to replace must have the same part of speech as the original word and all the replacements in one document are 1-to-1 relations, enforced by replace_dict in Algorithm 1. With this idea, we can create augmented documents for the unseen classes by topic-translation from the documents of seen classes in the training dataset. After that, we can use the augmented documents as additional negative examples for all the CNNs in Phase 1 to make them aware of the tone of unseen classes.

Algorithm 1: Document-level topic translation

```
Input : a document $x_i = [w_1^i, w_2^i, \ldots, w_t^i]$,
        an original class label $c$, a target class label $c'$
Output: a translated document $x'_i$
replace_dict = dict(); $x'_i$ = [];
foreach $w \in x_i$ do
    if is_valid_pos($w$) then
        if $w \notin$ replace_dict then
            cands = solve_analogy($w$, $c$, $c'$,
              top_k=20);
            for $j$ = 0 to len(cands)-1 do
                if cands[$j$] $\notin$ replace_dict.values() $\wedge$
                  pos_of($w$) $\in$ pos_list(cands[$j$])
                  then
                    replace_dict[$w$] = cands[$j$];
                    break;
            if $j$ == len(cands) then
                $x'_i$.append($w$);
                continue;
        $x'_i$.append(replace_dict[$w$]);
    else
        $x'_i$.append($w$);
return $x'_i$
```

2.4 Phase 2: Fine-grained Classification

Phase 2 decides the most appropriate class $\hat{y}_i$ for x_i using two CNN classifiers: a traditional classifier and a zero-shot classifier as shown in Figure 1. If $\hat{y}_i \in \mathcal{C_S}$ predicted by Phase 1, the traditional classifier will finally select a class $c_s \in \mathcal{C_S}$ as $\hat{y}_i$. Otherwise, if $\hat{y}_i \notin \mathcal{C_S}$, the zero-shot classifier will be used to select a class $c_u \in \mathcal{C_U}$ as $\hat{y}_i$.

The traditional classifier and the zero-shot classifier have an identical CNN-based structure followed by two dense layers but their inputs and outputs are different. The traditional classifier is a multi-class classifier ($|\mathcal{C_S}|$ classes) with a softmax output, so it requires only the word embeddings v_w^i as an input. This classifier is trained using a cross entropy loss with a training dataset whose examples are from seen classes only.

In contrast, the zero-shot classifier is a binary classifier with a sigmoid output. Specifically, it takes a text document x_i and a class c as inputs and predicts the confidence $p(\hat{y}_i = c | x_i)$. However, in practice, we utilise v_w^i to represent x_i, v_c to represent the class c, and also augmented features $v_{w,c}^i$ to provide more information on how intimate the connections between words and the class c are. Altogether, for each word w_j, the classifier receives the concatenation of three vectors (i.e., $[v_{w_j}^i; v_c; v_{w_j,c}^i]$) as an input. This classifier is trained using a binary cross entropy loss with a training data from seen classes only, but we expect this classifier to work well on unseen classes thanks to the distinctive patterns of $v_{w,c}^i$ in positive examples of every class. This is how we transfer knowledge from seen to unseen classes in ZSL.

2.4.1 Feature Augmentation

The relationship vector $v_{w_j,c}$ contains augmented features we input to the zero-shot classifier. $v_{w_j,c}$ shows how the word w_j and the class c are related considering the relations in a general knowledge graph. In this work, we use ConceptNet providing general knowledge of natural language words and phrases (Speer and Havasi, 2013). A subgraph of ConceptNet is shown in Figure 2c as an illustration. Nodes in ConceptNet are words or phrases, while edges connecting two nodes show how they are related either syntactically or semantically.

We firstly represent a class c as three sets of nodes in ConceptNet by processing the class hierarchy, class label, and class description of c. (1) ***the_class_nodes*** is a set of nodes of the class label c and any tokens inside c if c has more than one word. (2) ***superclass_nodes*** is a set of nodes of all the superclasses of c according to the class hierarchy. (3) ***description_nodes*** is a set of nodes of all nouns in the description of the class c. For example, if c is the class "Educational Institution", according to Figure 2a-2b, the three sets of Con-

ceptNet nodes for this class are:
(1) educational_institution, educational, institution
(2) organization, agent
(3) place, people, ages, education.

To construct $v_{w_j,c}$, we consider whether the word w_j is connected to the members of the three sets above within K hops by particular types of relations or not[1]. For each of the three sets, we construct a vector with $3K+1$ dimensions.

- $v[0]=1$ if w_j is a node in that set; otherwise, $v[0]=0$.
- for $k=0,\dots,K-1$:
  - $v[3k+1]=1$ if there is a node in the set whose shortest path to w_j is $k+1$. Otherwise, $v[3k+1]=0$.
  - $v[3k+2]$ is the number of nodes in the set whose shortest path to w_j is $k+1$.
  - $v[3k+3]$ is $v[3k+2]$ divided by the total number of nodes in the set.

Thus, the vector associated to each set shows how w_j is semantically close to that set. Finally, we concatenate the constructed vectors from the three sets to become $v_{w_j,c}$ with $3\times(3K+1)$ dimensions.

3 Experiments

3.1 Datasets

We used two textual datasets for the experiments. The vocabulary size of each dataset was limited by 20,000 most frequent words and all numbers were excluded. (1) **DBpedia** ontology dataset (Zhang et al., 2015) includes 14 non-overlapping classes and textual data collected from Wikipedia. Each class has 40,000 training and 5,000 testing samples. (2) The **20newsgroups** dataset [2] has 20 topics each of which has approximately 1,000 documents. 70% of the documents of each class were randomly selected for training, and the remaining 30% were used as a testing set.

3.2 Implementation Details [3]

In our experiments, two different rates of unseen classes, 50% and 25%, were chosen and the corresponding sizes of $\mathcal{C}_\mathcal{S}$ and $\mathcal{C}_\mathcal{U}$ are shown in Table 1. For each dataset and each unseen rate, the random selection of ($\mathcal{C}_\mathcal{S}$, $\mathcal{C}_\mathcal{U}$) were repeated ten times and these ten groups were used by all the experiments with this setting for a fair comparison. All documents from $\mathcal{C}_\mathcal{U}$ were removed from the training set accordingly. Finally, the results from all the ten groups were averaged.

In Phase 1, the structure of each classifier was identical. The CNN layer had three filter sizes [3, 4, 5] with 400 filters for each filter size and the subsequent dense layer had 300 units. For data augmentation, we used gensim with an implementation of 3CosMul (Řehůřek and Sojka, 2010) to solve the word-level analogy (line 5 in Algorithm 1). Also, the numbers of augmented text documents per unseen class for every setting (if used) are indicated in Table 1. These numbers were set empirically considering the number of available training documents to be translated.

In Phase 2, the traditional classifier and the zero-shot classifier had the same structure, in which the CNN layer had three filter sizes [2, 4, 8] with 600 filters for each filter size and the two intermediate dense layers had 400 and 100 units respectively. For feature augmentation, the maximum path length K in ConceptNet was set to 3 to create the relationship vectors[4]. The DBpedia ontology[5] was used to construct a class hierarchy of the DBpedia dataset. The class hierarchy of the 20newsgroups dataset was constructed based on the namespaces initially provided by the dataset. Meanwhile, the classes descriptions of both datasets were picked from Macmillan Dictionary[6] as appropriate.

For both phases, we used 200-dim GloVe vectors[7] for word embeddings v_w and v_c (Pennington et al., 2014). All the deep neural networks were implemented with TensorLayer (Dong et al., 2017a) and TensorFlow (Abadi et al., 2016).

Dataset	Unseen rate	$\mid\mathcal{C}_\mathcal{S}\mid$	$\mid\mathcal{C}_\mathcal{U}\mid$	#Augmented docs per c_u
DBpedia (14 classes)	25%	11	3	12,000
	50%	7	7	8,000
20news (20 classes)	25%	15	5	4,000
	50%	10	10	3,000

Table 1: The rates of unseen classes and the numbers of augmented documents (per unseen class) in the experiments

---

[1] In this paper, we only consider the most common types of positive relations which are *RelatedTo*, *IsA*, *PartOf*, and *AtLocation*. They cover ~60% of all edges in ConceptNet.

3.3 Baselines and Evaluation Metrics

We compared each phase and the overall framework with the following approaches and settings.

Phase 1: Proposed by (Shu et al., 2017), **DOC** is a state-of-the-art open-world text classification approach which classifies a new sample into a seen class or “reject” if the sample does not belong to any seen classes. The DOC uses a single CNN and a 1-vs-rest sigmoid output layer with threshold adjustment. Unlike DOC, the classifiers in the proposed Phase 1 work individually. However, for a fair comparison, we used DOC only as a binary classifier in this phase ($\hat{y}_i \in \mathcal{C}_S$ or $\hat{y}_i \notin \mathcal{C}_S$).

Phase 2: To see how well the augmented feature $v_{w,c}$ work in ZSL, we ran the zero-shot classifier with **different combinations of inputs**. Particularly, five combinations of v_w, v_c, and $v_{w,c}$ were tested with documents from unseen classes only (traditional ZSL).

The whole framework: (1) **Count-based model** selected the class whose label appears most frequently in the document as $\hat{y}_i$. (2) **Label similarity** (Sappadla et al., 2016) is an unsupervised approach which calculates the cosine similarity between the sum of word embeddings of each class label and the sum of word embeddings of every n-gram ($n = 1, 2, 3$) in the document. We adopted this approach to do single-label classification by predicting the class that got the highest similarity score among all classes. (3) **RNN AutoEncoder** was built based on a Seq2Seq model with LSTM (512 hidden units), and it was trained to encode documents and class labels onto the same latent space. The cosine similarity was applied to select a class label closest to the document on the latent space. (4) **RNN+FC** refers to the architecture 2 proposed in (Pushp and Srivastava, 2017). It used an RNN layer with LSTM (512 hidden units) followed by two dense layers with 400 and 100 units respectively. (5) **CNN+FC** replaced the RNN in the previous model with a CNN, which has the identical structure as the zero-shot classifier in Phase 2. Both RNN+FC and CNN+FC predicted the confidence $p(\hat{y}_i = c|x_i)$ given v_w and v_c. The class with the highest confidence was selected as $\hat{y}_i$.

For Phase 1, we used the accuracy for binary classification ($y, \hat{y}_i \in \mathcal{C}_S$ or $y, \hat{y}_i \notin \mathcal{C}_S$) as an evaluation metric. In contrast, for Phase 2 and the whole framework, we used the multi-class classification accuracy ($\hat{y}_i = y_i$) as a metric.

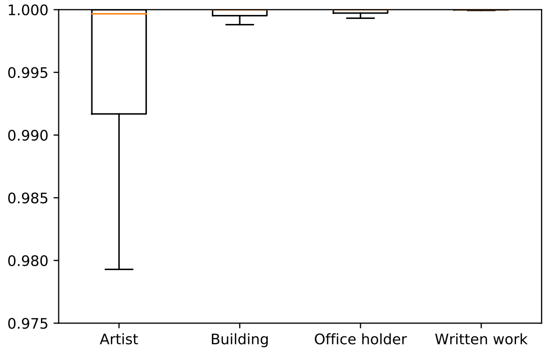

Figure 3: The distributions of confidence scores of positive examples from four seen classes of DBpedia in Phase 1.

3.4 Results and Discussion

The evaluation of Phase 1 (coarse-grained classification) checks if each x_i was correctly delivered to the right classifier in Phase 2. Table 3 shows the performance of Phase 1 with and without augmented data compared with DOC. Considering test documents from seen classes only, our framework outperformed DOC on both datasets. In addition, the augmented data improved the accuracy of detecting documents from unseen classes clearly and led to higher overall accuracy in every setting. Despite no real labelled data from unseen classes, the augmented data generated by topic translation helped Phase 1 better detect documents from unseen classes. Table 4 shows some examples of augmented data from the DBpedia dataset. Even if they are not completely understandable, they contain the tone of the target classes.

Although Phase 1 provided confidence scores for all seen classes, we could not use them to predict $\hat{y}_i$ directly since the distribution of scores of positive examples from different CNNs are different. Figure 3 shows that the distribution of confidence scores of the class “Artist” had a noticeably larger variance and was clearly different from the class “Building”. Hence, even if $p(\hat{y}_i =$ “Building”$|x_i) > p(\hat{y}_i =$ “Artist”$|x_i)$, we cannot conclude that x_i is more likely to come from the class “Building”. This is why **a traditional classifier in Phase 2 is necessary**.

Regarding Phase 2, fine-grained classification is in charge of predicting $\hat{y}_i$ and it employs two classifiers which were tested separately. Assuming Phase 1 is perfect, the classifiers in Phase 2 should be able to find the right class. The purpose of Table 5 is to show that **the traditional CNN classifier in Phase 2** was highly accurate.

Table 6: The accuracy of the zero-shot classifier in Phase 2 given documents from unseen classes only.

Besides, given test documents from unseen classes only, the performance of **the zero-shot classifier in Phase 2** is shown in Table 6. Based on the construction method, $v_{w,c}$ quantified the relatedness between words and the class but, unlike v_w and v_c, it did not include detailed semantic meaning. Thus, the classifier using $v_{w,c}$ only could not find out the correct unseen class and neither $[v_w; v_{w,c}]$ and $[v_c; v_{w,c}]$ could do. On the other hand, the combination of $[v_w; v_c]$, which included semantic embeddings of both words and the class label, increased the accuracy of predicting unseen classes clearly. However, the zero-shot classifier fed by the combination of all three types of inputs $[v_w; v_c; v_{w,c}]$ achieved the highest accuracy in all settings. It asserts that the integration of semantic knowledge we proposed is an effective means for knowledge transfer from seen to unseen classes in the zero-shot scenario.

Last but most importantly, we compared **the whole framework** with four baselines as shown in Table 2. First, the count-based model is a rule-based model so it failed to predict documents from seen classes accurately and resulted in unpleasant overall results. This was similar to the label similarity approach even though it had higher degree of flexibility. Next, the RNN Autoencoder was trained without any supervision since $\hat{y}_i$ was predicted based on the cosine similarity. We believe the implicit semantic relatedness between classes caused the failure of the RNN Autoencoder. Besides, the CNN+FC and RNN+FC had same inputs and outputs and it was clear that CNN+FC performed better than RNN+FC in the experiment. However, neither CNN+FC nor RNN+FC was able to transfer the knowledge learned from seen to unseen classes. Finally, our two-phase framework has competitive prediction accuracy on unseen classes while maintaining the accuracy on seen classes. This made it achieve the highest overall accuracy on both datasets and both unseen rates. In conclusion, by using integrated semantic knowledge, the proposed two-phase framework with data and feature augmentation is a promising step to tackle this challenging zero-shot problem.

Furthermore, another benefit of the framework is high flexibility. As the modules in Figure 1 has less coupling to one another, it is flexible to improve or customise each of them. For example, we can deploy an advanced language understanding model, e.g., BERT (Devlin et al., 2018), as a traditional classifier. Moreover, we may replace ConceptNet with a domain-specific knowledge graph to deal with medical texts.

4 Related Work

4.1 Zero-shot Text Classification

There are a few more related works to discuss besides recent approaches we compared with in the experiments (explained in section 3.3). Dauphin et al. (2013) predicted semantic utterance of texts by mapping class labels and text samples into the same semantic space and classifying each sample to the closest class label. Nam et al. (2016) learned the embeddings of classes, documents, and words jointly in the learning stage. Hence, it can perform well in domain-specific classification, but this is possible only with a large amount of training data. Overall, most of the previous works exploited semantic relationships between classes and documents via embeddings. In contrast, our proposed framework leverages not only the word embeddings but also other semantic knowledge. While word embeddings are used to solve analogy for data augmentation in Phase 1, the other semantic knowledge sources (in Figure 2) are integrated into relationship vectors and used as augmented features in Phase 2. Furthermore, our framework does not require any semantic correspondences between seen and unseen classes.

4.2 Data Augmentation in NLP

In the face of insufficient data, data augmentation has been widely used to improve generalisation of deep neural networks especially in computer vision (Krizhevsky et al., 2012) and multimodality (Dong et al., 2017b), but it is still not a common practice in natural language processing. Recent works have explored data augmentation in NLP tasks such as machine translation and text classification (Saito et al., 2017; Fadaee et al., 2017; Kobayashi, 2018), and the algorithms were designed to preserve semantic meaning of an original document by using synonyms (Zhang and LeCun, 2015) or adding noises (Xie et al., 2017), for example. In contrast, our proposed data augmentation technique translates a document from one meaning (its original class) to another meaning (an unseen class) by analogy in order to substitute unavailable labelled data of the unseen class.

4.3 Feature Augmentation in NLP

Apart from improving classification accuracy, feature augmentation is also used in domain adaptation to transfer knowledge between a source and a target domain (Pan et al., 2010b; Fang and Chiang, 2018; Chen et al., 2018). An early research paper applying feature augmentation in NLP is Daume III (2007) which targeted domain adaptation on sequence labelling tasks. After that, feature augmentation was used in several NLP tasks such as cross-domain sentiment classification (Pan et al., 2010a), multi-domain machine translation (Clark et al., 2012), semantic argument classification (Batubara et al., 2018), etc. Our work is different from previous works not only that we applied this technique to zero-shot text classification but also that we integrated many types of semantic knowledge to create the augmented features.

5 Conclusion and Future Work

To tackle zero-shot text classification, we proposed a novel CNN-based two-phase framework together with data augmentation and feature augmentation. The experiments show that data augmentation by topic translation improved the accuracy in detecting instances from unseen classes, while feature augmentation enabled knowledge transfer from seen to unseen classes for zero-shot learning. Thanks to the framework and the integrated semantic knowledge, our work achieved the highest overall accuracy compared with all the baselines and recent approaches in all settings. In the future, we plan to extend our framework to do multi-label classification with a larger amount of data, and also study how semantic units defined by linguists can be used in the zero-shot scenario.

Word-Node2Vec: Improving Word Embedding with Document-Level Non-Local Word Co-occurrences

Abstract

Standard word embedding algorithms, such as `word2vec` and `Glove`, make a restrictive assumption that words are likely to be semantically related only if they co-occur locally within a window of fixed size. However, this restrictive assumption may not capture the semantic association between words that co-occur frequently but non-locally within documents. To alleviate this restriction, in this paper, we propose a graph-based word embedding method, named 'word-node2vec'. By relaxing the strong constraint of locality, our method is able to capture both local and non-local co-occurrences. Word-node2vec constructs a weighted graph, where each node represents a word and the weight of an edge between two nodes represents a combination of both local (e.g. word2vec) and document-level co-occurrences. Our experiments show that word-node2vec outperforms word2vec and glove on a range of different tasks, such as word-pair similarity prediction, word analogy and concept categorization.

1 Introduction

Word embedding, the process of obtaining vector representations of words, is a first step towards addressing language semantics, in which discrete entities, such as words, are embedded as vectors over a continuous space of reals. This not only facilitates to obtain semantic similarities between words to improve tasks such as semantic search (Ganguly et al., 2015; Roy et al., 2016), but is also useful in a number of down-stream NLP tasks including concept categorization (Jastrzebski et al., 2017), information retrieval (Guo et al., 2016), sentence similarity prediction (Mueller and Thyagarajan, 2016), sentiment analysis (Faruqui et al., 2015) and POS tagging (Tsvetkov et al., 2016) etc.

Word embedding approaches such as `word2vec` (Mikolov et al., 2013a) and `Glove` (Pennington et al., 2014) rely on a large corpus to learn the association between words. The architecture of existing word embedding approaches mimics the process of human cognition of word association by learning the representation of each word with an objective of maximizing the likelihood of predicting the words around its *local* context (defined by a fixed length word window). A limitation of existing word embedding approaches, such as word2vec and glove, is that they use a strong constraint that words are likely to be semantically related to each other only if one occurs within a local context of the another, where the local context is given by a word window of specified length.

On the other hand, non-local or document-level co-occurrences between words have been widely used to estimate semantic similarities between words. More specifically, the latent semantic analysis (LSA) method proposed by Deerwester et al. (1990) uses a spectral analysis (method of principal component analysis) of the term-document matrix of a collection to obtain the most informative *concepts* (word classes), and then expresses each document as a linear combination of these principal components. Blei et al. (2003) estimate a generative model from a given collection by assuming that documents are mixtures of a preset number of topics, where each topic represents a word distribution over the vocabulary. This is largely similar to decomposing a term-document matrix as a product of matrices with non-negative components, a process commonly known as non-negative matrix factorization (NMF) (Gaussier and Goutte, 2005). The underlying common idea among all these approaches is to make use of the frequent document-level word co-occurrences to identify likely semantic association between words.

Despite the presence of a vast volume of lit-

Minneapolis, Minnesota, June 2 - June 7, 2019.

erature on document-level (non-local) word co-occurrences, word embedding approaches do not utilize this information to derive the word representations. In this paper, we propose to augment the document-level non-local word co-occurrence information with the local co-occurrence information that methods such as word2vec and glove use. More specifically, we propose a graph-based word embedding method, named `word-node2vec`, that by relaxing the strong constraint of locality, is able to capture both the local and non-local co-occurrences. To represent the local dependencies, each node, representative of a word (hence the name 'word-node'), is initialized with a vector representation obtained with a standard method, e.g. word2vec. We then define the weight of the edge between a pair of word-nodes to reflect their likelihood of non-local co-occurrence, computed with the help of the global term-document matrix for the whole collection.

The rest of the paper is organized as follows. In Section 2, we survey existing literature on word embedding. In Section 3, we revisit the skip-gram approach and propose a graph-based view of the skip-gram objective as a pre-cursor to developing our model. In Section 4, we extend the skip-gram graph model with non-local document-level co-occurrence information. Section 5 describes our experimental setup. Section 6 reports the results of our new embedding approach against a number of baselines. Finally, Section 7 concludes the paper with directions for future work.

2 Related Work

The word2vec (Mikolov et al., 2013a) embedding model shifts a window of a predefined size (a parameter) across the text of a collection of documents in order to train a linear classifier for each word to predict itself given its context (continuous bag-of-words), or its context given the word (skip-gram). The parameter vector transforming a word to its context (or vice-versa) gives its embedded representation. In addition to making use of the words in the context as positive samples, word2vec also relies on the use of words randomly sampled from the collection (outside the current context) as negative examples. Levy and Goldberg (2014) showed that the negative sampling based skip-gram (SGNS) objective function of `word2vec` is mathematically equivalent to factorizing a positive point-wise mutual information gain (PPMI) matrix shifted by $log(k)$, where k is the number of negative samples.

The key idea behind the glove algorithm proposed in (Pennington et al., 2014) is to make use of the ratio of the co-occurrence probabilities between word pairs to better distinguish semantically related words from non-related ones. The study ultimately shows that factorizing the log of the co-occurrence matrix leads to effective embedded representation of words. The co-occurrences in both word2vec and glove are essentially local in nature. In contrast, our proposed algorithm leverages both local and non-local co-occurrences.

More recently, Peters et al. (2018) proposed `ELMO`, a deep contextualized word representation with layers of stacked bi-directional LSTMs to model both a) complex characteristics of word use (e.g., syntax and semantics), and b) their diversity across various linguistic contexts. A limitation of ELMO is that a word representation may effectively be learned mainly in the presence of an associated context, as a result of which the method is likely to find applications mostly in downstream tasks, e.g. question answering and sentiment analysis. However, in contrast, our proposed method can learn the representation of a word in isolation, which means that, similar to word2vec and Glove, word vectors obtained using our method can be applied directly to (and is also likely to work well for) word similarity and word analogy tasks. We included ELMO as of our baseline approaches in our experiments.

Grover and Leskovec (2016) proposed a skip-gram based objective function to embed each node of a graph. Analogous to skip-gram based word embedding, each node vector is given as input to a linear classifier to predict the context vector around a node. The context vector around a node, in this case, consists of a sequence of nodes visited by a random walk starting from that node. In our method, we use a similar graph-based construction to train vector representations of a node (each node a word). However, we use a stratified sampling approach within a maximum distance (hop-count) of 2, instead of allowing the random walk to proceed along in a combined depth-first and breadth-first manner, as in (Grover and Leskovec, 2016). Through our experiments, we find that larger hop-counts (i.e. longer transitive dependencies) introduce noise in the document-level word co-occurrence estimation process.

3 Generalized Word Embedding

In this section, we propose a general word embedding framework based on the skip-gram objective function of word2vec. Our proposed method relies on a general construction of the *context* around a word. We modify the skip-gram objective function of word2vec to take into account this general context of words. Before describing our proposed approach, we revisit the objective function of negative sampling based skip-gram word2vec (SGNS).

Skip-gram. In word2vec, the context of a word comprises words occurring within a window of a fixed size (say k) pivoted at a particular instance of w in the collection. More formally, let $\Lambda(w)$ denote the set of indexes where the word w occurs in a collection $C = \{t_1, \ldots, t_T\}$, T denoting the total number of tokens in the collection C, i.e.

$$\Lambda(w) = \{i : t_i = w\}. \tag{1}$$

We then construct the context $c(w)$ of a word as

$$c(w) = \cup_{i \in \Lambda(w)} \cup_{\substack{j=-k \\ j \neq 0}}^{k} t_{i+j} \tag{2}$$

Let Ω denote the set of all observed word-context pairs $(w, c(w))$, i.e.

$$\Omega^{+} = \cup_{w \in V} \{w, c(w)\}, \tag{3}$$

where V denotes the vocabulary set, and Ω^{-} denote the set of negative samples of word-context pairs, i.e.

$$\Omega^{-} = \cup_{w \in V} \{w, \cup\{v : v \sim (V - c(w))\}\}, \tag{4}$$

where words v's in the negative context set are randomly sampled from the complement set $c(w)$.

Let y be an indicator random variable denoting semantic relatedness of a word with its context. For a word w and its context $c(w)$ (as defined in Equation 2, the SGNS algorithm seeks to maximize the objective function

$$\begin{aligned} J(\theta) = & \sum_{w,c(w) \in \Omega^{+}} p(y = 1 | \mathbf{w}, \mathbf{c_w}) + \\ & \sum_{w,c(w) \in \Omega^{-}} p(y = 0 | \mathbf{w}, \mathbf{c_w})), \end{aligned} \tag{5}$$

where $p(.)$ is the log-likelihood function, and $\theta \in \mathbb{R}^{d \times |V|}$ represents the trainable matrix of parameters, each d dimensional column vector of the matrix θ denoting the vector representation of word w, i.e. $\mathbf{w} = \theta_w$. Note that the vector for a set of context words $c(w)$ is obtained by some aggregation function (sum or average) over the constituent words, i.e.

$$\mathbf{c}(\mathbf{w}) = \sum_{u \in c(w)} \mathbf{u}. \tag{6}$$

In order to optimize $J(\theta)$, the word2vec approach shifts a window of size k pivoted around a word $w = t_i$ (token positioned at offset i in the corpus), and applies stochastic gradient descent (SGD) to update the parameters for the corresponding word w and its context vector $c(w)$.

A Graph Formulation of SGNS. We now propose a general framework that allows contexts to be defined in a more general way. The solution relies on defining a graph $G = (\mathcal{V}, \mathcal{E})$, where each node corresponds to a word from the vocabulary of the given collection, i.e.

$$\mathcal{V} = \{x_w : w \in V\}. \tag{7}$$

In general, an edge $(x_u, x_v) \in \mathcal{E}$ represents a *relation* between two words u and v of weight $w(x_u, x_v) \in \mathbb{R}$. For example, in order to define the context of SGNS (Equation 2), the edge set is defined as

$$\mathcal{E} = \{(x_w, x_u) : u \in \cup_{i \in \Lambda(w)} \cup_{\substack{j=-k \\ j \neq 0}}^{k} t_{i+j}\}. \tag{8}$$

Learning the vector representations for each node of the graph G leads to learning the vector representation for each word, because there is a one-one mapping between the set of nodes $\mathcal{V}$ and the set of words V (henceforth we refer to a node of this general class of graphs, defined as per Equation 7, as a *word-node*). The objective of the embedding is to learn vector representations of nodes such that two nodes are close in the embedded space if, as per the edge relations of the graph, these nodes are within a κ-adjacency neighborhood of each other. The κ-adjacency neighborhood of a graph is the set

$$N_\kappa(x_w) = \{x_u \in \mathcal{V} : h(x_w, x_u) \leq \kappa\}, \tag{9}$$

where $h(u, v)$ denotes the hop-count or adjacency number between nodes u and v. In the general formulation, the set of $N_\kappa(x_w)$, constituting the set of nodes reachable from paths of length at most k starting at x_w, act as positive examples to learn the embedding of node x_w. This is because these positive examples seek to make the vector representation of x_w similar to the vector representations of nodes in $N_\kappa(x_w)$. More formally,

$$\begin{aligned}\Omega^+ &= \cup_{x_w \in \mathcal{V}}\{x_w, N_\kappa(x_w)\},\\ \Omega^- &= \cup_{x_w \in \mathcal{V}}\{x_w, \cup\{x_u : u \sim \mathcal{V} - N_\kappa(x_w)\}\}.\end{aligned} \tag{10}$$

Instead of iterating over the words in a corpus, the SGNS equivalent is then achieved by iterating over the set of nodes and maximizing the same objective function of Equation 5 using the definitions of the positive and negative example sets from Equation 10. Note that to achieve the SGNS objective the value of κ is set to 1 in the definition of Ω^+ in Equation 10, i.e. the set of context for a word-node comprises one-hop neighbours as defined by the edge relations of Equation 8.

4 Extending the Graph Model for Non-Local Co-occurrences

The graph based approach of Section 3 allows alternative ways to define the context and learn the objective function to obtain word-node representations. In this section, we describe how to augment the non-local document-level co-occurrence information in the graph-based framework.

Co-occurrence Weights. The first step to include non-local co-occurrences is to modify the edge relations of SGNS (Equation 8) to accommodate weighted document-level co-occurrences. Instead of considering the collection $C = \{t_1, \ldots, t_T\}$ as a stream of words, we consider C as a set of M documents $\{D_i\}_{i=1}^M$.

First, we make provision to include weighted edges of the form $(x_w, x_u, \omega(x_w, x_u))$ in the edge construction process of Equation 8. The weight $\omega(x_w, x_u)$ between word-nodes x_w and x_u is intended to represent a measure of association between these words.

Next, we describe how to compute the non-local co-occurrence weight between a pair of words. First, we compute the co-occurrence probability of two words w and u as

$$P(w,u) = \frac{\sum_{i=1}^M \mathbb{I}(w,u,D_i)}{\sum_{i=1}^M \mathbb{I}(w,D_i)\sum_{i=1}^M \mathbb{I}(u,D_i)}, \tag{11}$$

where the numerator denotes the total number of times that the words w and u co-occur in the collection of all documents, and the denominator denotes the number of times each occur independently. In our approach, we use a generalized form of Equation 11, where analogous to the Jelinek-Mercer smoothing method (Ponte and Croft, 1998), we take into account the informativeness of the co-occurrences by linearly combining the frequencies with the global statistics of inverse collection frequency. More specifically,

$$P_\alpha(w,u) = \alpha P(w,u) + \frac{(1-\alpha)T^2}{|\Lambda(w)||\Lambda(u)|}, \tag{12}$$

where $P(w,u)$ represents the maximum likelihood estimate computed by Equation 11 and the denominator denotes the product of the collection frequencies of the terms (as per the notation of Equation 1). It can be seen that Equation 12 allows relative weighting of the term frequency and the informativeness components.

Combination with Local Co-occurrences. The next step in our word-node2vec method is to augment the non-local co-occurrence information computed as per Equation 12 with the local co-occurrence of SGNS as defined in Equation 8. For this, analogous to (Pennington et al., 2014), we compute the probability of co-occurrence between a word pair restricted within a window of size k over the whole collection. More formally,

$$P_k(w,u) = \frac{1}{|\Lambda(w)|}\sum_{i\in\Lambda(w)} \mathbb{I}(t_{i+j} = u)_{j=-k}^{k} \tag{13}$$

Next, we assign weight to an edge by combining the local and non-local co-occurrence probabilities estimated from Equations 13 and 12 respectively. Formally speaking,

$$\omega(x_w, x_u) = P_\alpha(w,u)P_k(w,u). \tag{14}$$

Context with Weighted Edges. Constructing the context of a node x_w (Section 3), requires a modification aimed to take into account the edge weights while selecting the neighboring nodes of x_w. Instead of defining the context as the entire set of κ-neighborhood $N_\kappa(x_w)$ of a node x_w, we define a κ-neighbourhood of length (hop-count), l, which is a subset of l samples drawn from the overall neighbourhood.

The likelihood of sampling a node x_u from the neighbourhood set is proportional to the weight of the edge (x_w, x_u), i.e., $\omega(x_w, x_u)$. This way of defining the context allows the algorithm to make use of the edge weights (local and non-local co-occurrences) in learning the node representations, i.e. assigning more importance to associations with higher weights in seeking to embed the current word-node close to them.

Our idea, in general, is to use stratified sampling, where each stratum corresponds to a neighbourhood of particular length. The priors assigned to the strata in increasing sequence of adjacency length form a decreasing sequence, which means that the most emphasis is put on direct co-occurrence evidence (i.e. the 1-adjacent neighborhood), than to the 2-adjacent nodes and so on.

Stratified sampling requires the strata to be mutually disjoint of each other. This means that the κ-neighbourhood of Equation 9 needs to be redefined to ensure that any node belongs to exactly one of the partitions (defined by its hop-count). To state this formally, we define the set of nodes of (*not up to*) hop-count j as

$$H_j(x_w) = \cup\{x_u : h(x_w, x_u) = j\} \qquad (15)$$

The κ-neighbourhood is then defined as

$$N_\kappa(x_w) = \cup_{j=1}^{\kappa}(H_j(x_w) - \cup_{j'=1}^{j-1} H_{j'}(x_w)). \qquad (16)$$

A subset of size l, comprised of stratified samples from $N_\kappa(x_w)$, is then sampled with decreasing priors $\beta_1, \ldots, \beta_\kappa$, i.e., $\beta_j < \beta_{j-1} \forall j = 2, \ldots, \kappa$ and $\sum_{j=1}^{\kappa} \beta_j = 1$.

Putting things together, the probability of sampling a node from the set $N_\kappa(x_w)$ defined as per Equation 16 is then given by

$$P(x_u|N_\kappa(x_w)) = \beta_j P(x_u|H_j(x_w)) = \beta_j \frac{\omega(x_w, x_u)}{\omega(x_w, .)}, \qquad (17)$$

where $\omega(x_w, x_u)$ are edge weights computed with Equation 14 and $\omega(x_w, .)$ denotes the sum of edges emanating from node x_w.

As a point of note, for our experiments, we obtained optimal results by using $\kappa = 2$. Consequently, to simplify the description of our experiments, we name the parameter β_1 as β (the parameter β_2 is then identical to $1 - \beta$). We would also mention at this point that our proposed way of constructing the context by sampling neighboring nodes is different from the one proposed in (Grover and Leskovec, 2016), which uses a combination of breadth-first (BFS) and depth-first (DFS) traversals, with parameters p and q respectively.

#Documents	4,641,754
#Avg. Doc Length (#words)	43.23
#Vocabulary size	461,572
#Tokens	202,575,916

Table 1: Dataset characteristics of DBPedia-2014.

Our experiments reveal that our sampling strategy outperforms that of Grover and Leskovec (2016) (treated as a baseline).

5 Experimental Setup

In this section, we describe our experimental setup to evaluate our new word embedding method.

5.1 Dataset

A word embedding algorithm requires a collection to learn word representations. To compare the various word embedding approaches (i.e. our method and the baselines), we use the DBPedia (2014) corpus, which is a collection of abstracts of Wikipedia pages crawled in 2014[1]. Dataset characteristics are outlined in Table 1. As part of preprocessing, we removed words with collection frequency less than 10 and also removed stopwords[2].

5.2 Baselines and Implementation

The objective of our experiments is two-fold. First, to show that a combination of local and global approaches is likely to yield effective embedded representations of word vectors, and second that our proposed graph-based formalism is likely to work better than a trivial black-box way of combining the two sources of information.

Local Co-occurrence approaches. As approaches that use local co-occurrence information, we use three state-of-the-art embedding approaches namely skip-gram word2vec with negative sampling (SGNS) (Mikolov et al., 2013a), Glove (Pennington et al., 2014) and Fasttext (Joulin et al., 2016). All these methods rely only on co-occurrences (at the level of words for the first two and at the level of character n-grams for the last one) within a word or character n-gram window of specified length k (acting as a parameter). Fasttext learns the vector representation of each word by aggregating (vector sum) the vector representations of its constituent n-grams.

---

[1] `http://downloads.dbpedia.org/2014/en/long_abstracts_en.ttl.bz2`

[2] `http://www.lextek.com/manuals/onix/stopwords2.html`

Additionally, we also employ a more recent approach, namely ELMO (Peters et al., 2018), which relies on a pre-trained model (comprised of stacked bidirectional LSTMs) to infer vectors for a given context (typically a sequence of words). For our experiments,

Document-level Co-occurrence approaches. Although not an embedding approach, the LDA topic modeling algorithm outputs two matrices, namely $\theta \in \mathbb{R}^{M \times d}$ and $\phi \in \mathbb{R}^{d \times V}$, representing the document-topic and topic-words distribution respectively (Blei et al., 2003). LDA uses document-level word co-occurrences to estimate both these matrices. In principle, one can then use the ϕ matrix as a substitute for the word embedding parameter matrix of SGNS (see Equation 5). This gives d dimensional vectors for each word purely with a global co-occurrence based approach.

Although it is possible to choose other non-local co-occurrence approaches as baselines, e.g. PLSA (Hofmann, 1999) or LSA, (Deerwester et al., 1990), it was shown in (Blei et al., 2003) that LDA outperforms each of these. Consequently, we use the stronger baseline of LDA in our experiments.

Combination of Local and Non-local Co-occurrences. To empirically demonstrate the effectiveness of our proposed graph-based word-node embedding, we employ an additional baseline that is a linear combination of the word vectors obtained individually with the local and non-local approaches. More formally, the vector of each word w is given as

$$\mathbf{w} = \lambda \mathbf{w}_{\text{Local}} + (1 - \lambda) \mathbf{w}_{\text{LDA}}, \qquad (18)$$

where $\mathbf{w}_{\text{Local}}$ is the vector representation of word w obtained by a local co-occurrence baseline, i.e. SGNS and Glove, whereas $\mathbf{w}_{\text{LDA}}$ represents the vector for the word w obtained with LDA.

Additionally, we employ the node2vec approach as a baseline. In particular, we use node2vec to learn the word-node representations of the graph constructed as per Section 4. The purpose of this baseline is to show that our way of defining the contexts around word-nodes is more suitable for our task of word embedding than a general-purpose graph node embedding approach.

5.3 Evaluation Tasks and Datasets

To compare the relative performance of word-node2vec with the baselines, we use a number of datasets, each corresponding to one of the following three evaluation tasks.

Dataset	Composition	Example
MSR	Syntactic	good:better rough:X
Google	Syntactic and Semantic	Athens:Greece Berlin:X
SemEval	Syntactic and Semantic	dog:bone bird:X

Table 2: Word analogy datasets overview.

Word Similarity. A standard way to measure the effectiveness of embedded words is to measure how well the similarity between a pair of words correlates with human judgments. Two such standard datasets that we use for our experiments are the WSIM-353 (Finkelstein et al., 2014) and the MEN (Bruni et al., 2014) datasets. Both comprise a list of word pairs, with an associated human judged similarity value. This similarity value is expected to be high for semantically similar words, such as 'morning' and 'sunrise' (human assigned score of 49 out of 50), and low for semantically unrelated words, such as 'angel' and 'gasoline' (score of 1 out of 50), both examples being taken from the MEN dataset.

Word Analogy. The word analogy task consists of templates of the form "A:B as C:X", where A, B, and C are given words, whereas X is unknown. Using a vector representation of words this analogy task is solved by retrieving the vector most similar to that of $\mathbf{B} + \mathbf{C} - \mathbf{A}$. A word embedding is considered effective if it finds a greater number of correct answers (resulting in higher accuracy).

We employed three different analogy datasets, namely, the Google Analogy (Mikolov et al., 2013a), the MSR Analogy (Mikolov et al., 2013b) and the SemEval-2012 task 2 (Jurgens et al., 2012) datasets. The MSR dataset contains syntactic questions only involving morphological variations. The Google dataset on the other hand contains both syntactic and semantic questions.

Given an analogy 'A:B as C:D', the Semeval-2012 task requires prediction of the degree to which the semantic relations between A and B are similar to those between C and D. In our experiments, we treat the given entity D as unknown and seek to predict D, similar to the MSR and Google analogy datasets. Table 2 provides an overview of examples from these datasets.

Concept Categorization Task. The concept categorization task requires classifying nouns into a concept type derived from an ontology. For this task, we employ the AP (Almuhareb and Poesio, 2005), BLESS (Baroni and Lenci, 2011) and ESSL_{2b} (Marco Baroni and Lenci, 2008) datasets. The AP dataset contains 402 nouns from 21 WordNet classes, e.g., nouns such as 'ceremony', 'feast', and 'graduation' belong to the class 'Social Occasion'. The BLESS dataset, designed for the evaluation of distributional semantic models, contains 200 distinct English concrete nouns as target concepts. These nouns are categorized into 17 broad classes.

Evaluation Metrics and Pipeline. The word similarity prediction effectiveness is measured with the help of Spearman's rank correlation coefficient ρ. This measures the rank correlation (higher is better) between the list of word pairs sorted in decreasing order of inter-similarity values as predicted by a word embedding algorithm and the reference list of human judged word pairs. For the analogy and the concept categorization tasks, we report the accuracy in predicting the reference word and that of the class, respectively.

Parameters and Settings. In our experiments, for all the methods, except ELMO, we set the number of dimensions to 200. To find optimal settings for each method (except ELMO), we use the MEN dataset as a development set for tuning the parameters of each method. Each method with the optimal parameter settings is then applied for the rest of the datasets and tasks.

Since we used a pre-trained model for ELMO, the number of dimensions corresponds to the size of the output layer of the network, the value of which in the default configuration of the Python implementation[3] is 1024.

The parameters of SGNS are window size (k) and the number of negative samples (NS). For the baseline approach SGNS, we varied k from 5 to 40 in steps of 5 and found that the best results are obtained when $k = 10$ and $NS = 5$. Similarly, for Glove we chose the optimal settings by varying k within the same range of $[5, 40]$ and found that the optimal ρ for the MEN dataset is obtained for $k = 20$. We obtain the LDA results by setting the number of topics to 200 (so as to match with the dimensionality). As LDA hyper-parameters, we use settings as prescribed in (Griffiths and Steyvers, 2004), i.e., $\beta = 0.1$ and $\alpha = 0.25$ $(50/(\#topics = 200))$.

Method	Spearman's ρ	
	MEN	WSIM
SGNS ($k = 10, NS = 5$)	0.7432	0.6977
Glove ($k = 20$)	0.7066	0.6706
FastText	0.7307	0.6518
ELMO	0.4225	0.4631
LDA	0.4933	0.4074
SGNS-LDA ($\lambda = 0.9$)	0.7367	0.6548
Node2vec ($p = 0.5, q = 0.5, l = 40$)	0.7440	0.6988
Word-node2vec ($\alpha = 0.5, \beta = 0.7, l = 20$)	**0.7491**	**0.7032**

Table 3: Word similarity prediction results.

Since we found that SGNS performed significantly better than Glove, we use SGNS vectors for the linear combination method (Equation 1), which we call `SGNS-LDA` from hereon. The parameter λ was varied within a range of $[0.1, 0.9]$ in steps of 0.1 ($\lambda = 0$ and $\lambda = 1$ degenerate to that of LDA and SGNS respectively). We found that the best results are obtained for $\lambda = 0.9$.

For node2vec baseline approach of word-node embedding, we varied the parameters p and q (BFS and DFS parameters) within a range of $[0.1, 5]$ and found that the best results on the MEN dataset are given for $p = 1$ and $q = 1$ (Grover and Leskovec, 2016). Another parameter in node2vec is the random walk length, l, for which the optimal value was found to be 80.

For word-node2vec, in addition to window size (k) and number of negative samples (NS), three more parameters are: i) α, i.e., the importance of the presence of a term relative to its informativeness (Equation 12, ii) β, the prior assigned to sampling from the 1-adjacent neighborhood, and iii) the size of the context sampled from the neighborhood, l (this is analogous to the random walk length parameter of node2vec). Instead of separately optimizing the parameters common to SGNS, we directly use the optimal values of $k = 10$ and $NS = 5$ for word-node2vec. The optimal results of the additional parameters, tuned on the MEN dataset, are shown in Table 3.

6 Results

Word Similarity Prediction. Table 3 shows the results obtained by the competing methods on the word similarity prediction task. It can be seen that Glove turns out to be relatively ineffective in modeling the semantic representations of words

as compared to human judgments. SGNS performs significantly better and the settings trained on MEN dataset generalize well on the WSIM-353 dataset as well. LDA performs rather poorly indicating that only global co-occurrences can lead to noisy representations of words. FastText performs worse as compared to SGNS. It is worth mentioning that the performance of ELMO is disappointing on this task of semantic similarity prediction, because of the most likely reason that it better learns vector representations of word in the presence of a context.

A linear combination of SGNS and LDA (Equation 1 with $\lambda = 0.9$) does not perform better than SGNS, which means that a simple way of combining the embedded representations obtained individually with local and non-local approaches does not work well.

The node2vec approach of embedding nodes of the word-nodes graph constructed as per the description of Section 4 relies on a random walk based construction of the context of a word node. This random walk based context construction is only able to improve the SGNS results slightly, indicating that random walks can introduce noise in the contexts of word-nodes.

The word-node based graph construction (incorporating local and non-local co-occurrences in a principled way) works particularly well in conjunction with the stratified sampling based approach of selecting context words from the κ-neighborhood. The optimal value of $\alpha = 0.5$ suggests that document-level co-occurrences should be computed by assigning equal importance to term presence and informativeness. A value of $\beta = 0.7$ confirms the hypothesis that more emphasis should be put on direct co-occurrences.

Word Analogy and Concept Categorization. Similar trends are observed in the word analogy and concept categorization tasks in Tables 4 and 5 respectively. Relatively higher improve-

Rank	SGNS		word-node2vec	
1	albums	0.929	albums	0.926
2	selftitled	0.885	selftitled	0.883
3	rerecorded	0.868	rerecorded	0.863
4	promotional	0.815	**released**	0.852
5	reissue	0.790	**song**	0.810

Table 6: Nearest neighbors of the word ‘album’ obtained by SGNS and word-node2vec.

ments with word-node2vec are noted for the MSR analogy task (comprised of syntactic categories). Among the baseline approaches, both node2vec and SGNS-LDA work well on the concept categorization task. However, the performance improvements are inconsistent across datasets, e.g. SGNS-LDA performs well on ESSLI$_{2b}$ and poorly on AP. Our proposed method configured on the MEN dataset works consistently well across all datasets, which indicates that word-node2vec can generalize well for different tasks.

As a side observation, we note that ELMO performs well for the analogy and concept categorization tasks (yielding the best results in particular on the Google analogy dataset). Although the results are not directly comparable because of differences in the dimensionality of the vectors and also in the collection of documents used in the pretrained ELMO vectors (Billion word benchmark as against DBPedia in our case), it could possibly be reasoned that the additional contextual information of the ELMO vectors turns out to be useful for in the analogy task.

Embedding Examples. Table 6 shows an example of the change in the neighbourhood of a sample word in the embedded space obtained by SGNS and word-node2vec. It can be seen from the table that word-node2vec is able to push relevant words, such as ‘released’ and ‘song’ within the top 5-NN of the word ‘album’. Although the words ‘promotional’ and ‘reissue’ are related to ‘album’, the semantic association of ‘released’ and ‘song’ with ‘album’ is apparently higher. We found that the word ‘song’ occurs in the local context of the word ‘album’ only $133,494$ number of times out of a total number of $177,487$ instances of the word ‘album’. This means that a significant percentage of times (almost 25%), ‘song’ co-occurs with ‘album’ at a document-level. Our embedding algorithm is able to leverage this information by making the vector for ‘song’ closer to ‘album’.

Sensitivity Analysis. Tables 3-5 show word-node2vec results with optimal parameter settings. We now investigate the effect of varying these parameters on each individual evaluation task. We observe that both term presence and term informativeness are important to model document-level co-occurrences as seen from the fact that the ρ and accuracy values decrease as α gets close to 0 or 1 (the 1st and 3rd plots from the left of Figure 1). Similarly, it can be seen that the results tend to improve with higher values of β, which confirms that direct associations between words in the word-node graph are more important than transitive ones (2nd plot from the left and the rightmost plot of Figure 1). However, second-order transitive associations are still important because the results tend to decrease for β close to 1.

7 Conclusions and Future work

We proposed a word embedding approach that leverages document-level non-local co-occurrences, in addition to the window-based local co-occurrences. We proposed a graph-based framework, in which words are represented as nodes and the edges between a pair of words reflect the degree of association between them. This association is a function of both the local and the document-level co-occurrences, which enables our approach to achieve ‘the best of both worlds’ in word embedding. Experiments show that our proposed method outperforms local approaches, namely word2vec, Glove and FastText, on a number of different tasks. Our approach also outperforms a naive black-box combination of embeddings obtained separately by local and document-level approaches. This proves the importance of addressing both these sources of information jointly in an embedding objective.

In future, we would like to explore ways of applying a similar graph based formalism for learning vectors for documents.

Abstract

In traditional Distributional Semantic Models (DSMs) the multiple senses of a polysemous word are conflated into a single vector space representation. In this work, we propose a DSM that learns multiple distributional representations of a word based on different topics. First, a separate DSM is trained for each topic and then each of the topic-based DSMs is aligned to a common vector space. Our unsupervised mapping approach is motivated by the hypothesis that words preserving their relative distances in different topic semantic sub-spaces constitute robust *semantic anchors* that define the mappings between them. Aligned cross-topic representations achieve state-of-the-art results for the task of contextual word similarity. Furthermore, evaluation on NLP downstream tasks shows that multiple topic-based embeddings outperform single-prototype models.

1 Introduction

Word-level representation learning algorithms adopt the *distributional hypothesis* (Harris, 1954), presuming a correlation between the distributional and the semantic relationships of words. Typically, these models encode the contextual information of words into dense feature vectors—often referred to as *embeddings*—of a k-dimensional space, thus creating a Vector Space Model (VSM) of lexical semantics. Such embeddings have been successfully applied to various natural language processing applications, including information retrieval (Manning et al., 2008), sentiment analysis (Tai et al., 2015), and machine translation (Amiri et al., 2016; Sharaf et al., 2017).

Despite their popularity, traditional DSMs rely solely on models where each word is uniquely represented by one point in the vector space. From a linguistic perspective, these models cannot capture the distinct meanings of polysemous words (e.g., *bank* or *cancer*), resulting in conflated word representations of diverse contextual semantics.

To alleviate this problem, DSMs with multiple representations per word have been proposed in the literature, based on clustering local contexts of individual words (Reisinger and Mooney, 2010; Tian et al., 2014; Neelakantan et al., 2014). An alternative way to train multiple representation DSMs is to utilize semantic lexical resources (Rothe and Schütze, 2015; Pilehvar and Collier, 2016). Christopoulou et al. (2018), based on the assumption that typically words appear with a specific sense in each topic, proposed a topic-based semantic mixture model that exploits a combination of similarities estimated on topic-based DSMs for the computation of semantic similarity between words. Their model performs well for a variety of semantic similarity tasks; however, it lacks a unified representation of multiple senses in a common semantic space. The problem of defining transformations between embeddings—trained independently under different corpora—has been previously examined in various works, such as machine translation (Mikolov et al., 2013b; Xing et al., 2015; Artetxe et al., 2016), induction of historical embeddings (Hamilton et al., 2016) and lexical resources enrichment (Prokhorov et al., 2017).

Following this line of research, we induce the creation of multiple cross-topic word embeddings by projecting the semantic representations of topic-based DSMs to a unified semantic space. We investigate different ways to perform the mappings from the topic sub-spaces to the unified semantic space, and propose a completely unsupervised approach to extract *semantic anchors* that define those mappings. Furthermore, we claim that polysemous words change their meaning in different topic domains; this is reflected in rela-

Minneapolis, Minnesota, June 2 - June 7, 2019.

tive shifts of their distributional representations in different topic-based DSMs. On the other hand, semantic anchors should have consistent semantic relationships regardless of the domain they reside in. Hence, their distributions of similarity values should also be similar across different domains. Finally, we apply a smoothing technique to each word's set of topic embeddings, resulting in representations with fine-grained semantics.

To our knowledge, this is the first time that mappings between semantic spaces are applied to the problem of learning multiple embeddings for polysemous words. Our multi-topic word representations are evaluated on the contextual semantic similarity task and yield state-of-the-art performance compared to other unsupervised multi-prototype word embedding approaches. We further perform experiments on two NLP downstream tasks: text classification and paraphrase identification and demonstrate that our learned word representations consistently provide higher performance than single-prototype word embedding models. The code of the present work is publicly available[1].

2 Related Work

Methods that assign multiple distributed representations per word can be grouped into two broad categories.[2] Unsupervised methods induce multiple word representations without leveraging semantic lexical resources. Reisinger and Mooney (2010) were the first to create a multi-prototype DSM with a fixed number of vectors assigned to each word. In their model, the centroids of context-dependent clusters were used to create a set of "sense-specific" vectors for each target word. Based on similar clustering approaches, follow-up works introduced neural network architectures that incorporated both local and global context in a joint training objective (Huang et al., 2012), as well as methods that jointly performed word sense clustering and embedding learning as in Neelakantan et al. (2014); Li and Jurafsky (2015). A probabilistic framework was introduced by Tian et al. (2014), where the Skip-Gram model of Word2Vec was modified to learn multiple embedding vectors. Furthermore, latent topics were integrated into the Skip-Gram model, resulting in topical word embeddings which modeled the semantics of a word under different contexts (Liu et al., 2015b,a; Nguyen et al., 2017). Another topic-related embedding creation approach was proposed in Christopoulou et al. (2018) where a mixture of topic-based semantic models was extracted by topical adaptation of in-domain corpora. Other approaches used autoencoders (Amiri et al., 2016), convolutional neural networks designed to produce context representations that reflected the order of words in a context (Zheng et al., 2017) and reinforcement learning (Lee and Chen, 2017; Guo et al., 2018).

Supervised approaches, based on prior knowledge acquired by sense inventories (e.g., WordNet) along with word sense disambiguation algorithms, were also introduced for sense-specific representations extraction (Chen et al., 2014; Iacobacci et al., 2015). In other works, pre-trained word embeddings have been extended to embeddings of lexemes and synsets (Rothe and Schütze, 2015) or were de-conflated into their constituent sense representations (Pilehvar and Collier, 2016) by exploiting semantic lexical resources.

3 Unified Multi-Topic DSM (UTDSM)

Our system follows a four-step approach:

1. **Global Distributional Semantic Model.** Given a large collection of text data we train a DSM that encodes the contextual semantics of each word into a single representation, also referred to as Global-DSM.

2. **Topic-based Distributional Semantic Models.** Next, a topic model is trained using the same corpus. The topic model splits the corpus into K (possibly overlapping) sub-corpora. A DSM is then trained from each sub-corpus resulting in K topic-based DSMs (TDSMs). The topical adaptation of the semantic space takes into account the contextual variations a word exhibits under different thematic domains and therefore leads to the creation of "topic-specific" vectors (topic embeddings).

3. **Mappings of topic embeddings.** Next, we map the vector space of each topic-based DSM to the shared space of the Global-DSM, using a list of anchor words selected through

---

[1] `https://github.com/Elbria/utdsm_naacl2018`

[2] We limit our discussion to related works that use monolingual DSMs and corpora.

an unsupervised self-learning scheme. In the unified semantic space each word is represented by a set of topic embeddings that were previously isolated in distinct vector spaces, thus creating a Unified multi-Topic DSM (UTDSM).

4. **Smoothing of topic embeddings.** As an optional step, we employ a smoothing approach in order to cluster a word's topic embeddings into N Gaussian distributions via a Gaussian Mixture Model (GMM). This step lessens the noise introduced to our system through the semantic mappings and sparse training data.

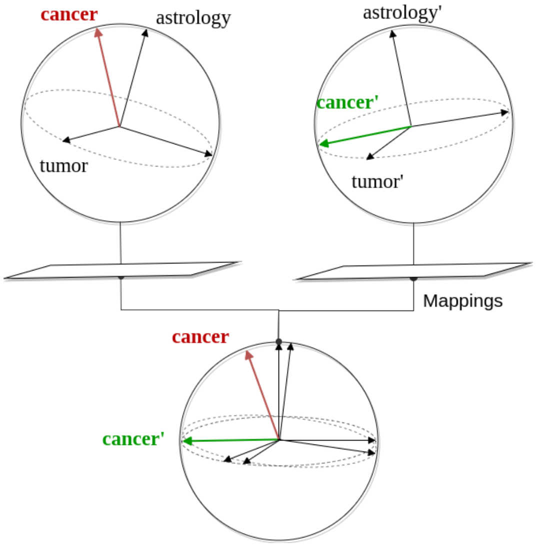

Figure 1: Simplified depiction summarizing the intuition behind the alignment process of topic embeddings. In the unified vector space, the polysemous word *cancer* is represented by two topic vectors that capture different semantic properties of the word under a zodiacal and a medical topic. Words *astrology* and *tumor* are examples of *semantic anchors* that define the mappings.

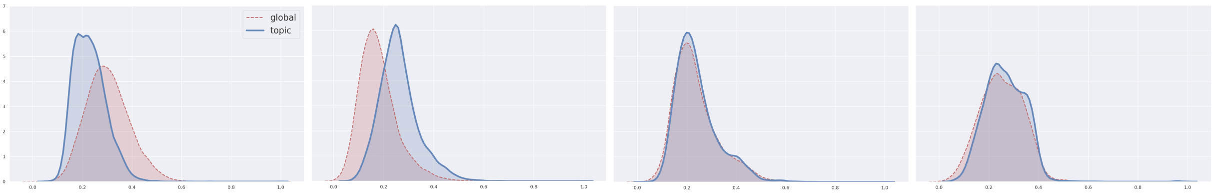
3.1 Topic-Based Distributional Semantic Models

The first step towards the thematic adaptation of the semantic space is the induction of in-domain corpora, using the Latent Dirichlet Algorithm (LDA) (Blei et al., 2003). LDA is a generative probabilistic model of a corpus. Its core idea is that documents are represented as random mixtures over topics; where each topic is defined as a probability distribution over a collection of words. Given as input a corpus of documents, LDA trains a topic model and creates a distribution of words for each topic in the corpus. Using the trained LDA model, we infer a topic distribution for each sentence in the corpus. Afterward, following a soft clustering scheme each sentence is included in a topic-specific corpus when the posterior probability for the corresponding topic exceeds a predefined threshold. The resulting topic sub-corpora are then used to train topic-based DSMs. Any of the DSM training algorithms proposed in the literature can be used for this purpose; in this paper, we opt for the Word2Vec model (Mikolov et al., 2013a).

3.2 Mappings Of Topic Embeddings

The intrinsic non-determinism of the Word2Vec algorithm leads to the creation of continuous vector spaces that are not naturally aligned to a unified semantic reference space, precluding the comparison between words of different thematic domains. To circumvent this limitation, we need to map the word representations of TDSMs to a shared vector space. In particular, we hypothesize that TDSMs capture meaningful variations in usage of polysemous words, while the relative semantic distance between monosemous words is preserved. This hypothesis motivated us to think of monosemous words as *anchors* between semantic spaces, as illustrated in Figure 1. One way to retrieve the list of anchors is to extract monosemous words from lexical resources such as WordNet (Prokhorov et al., 2017). However, this method is restricted to languages where such lexical resources exist and depends on the lexical coverage and quality of such resources.

To overcome the above limitations, we propose a fully unsupervised method for semantic anchor induction. Although the embeddings of the topic and global semantic vector spaces are not aligned, their corresponding similarity matrices (once normalized) are. Based on this observation, we compute the similarity between a given word and every other word in the vocabulary (similarity distribution) for the different topic and global spaces. Then, we assume that good semantic anchors should have similar similarity distributions across the topic-specific and the global space, as illustrated in Figure 2. Artetxe et al. (2018) was based on a similar observation to align vector semantic spaces in bilingual machine translation context.



view crater professor october

Figure 2: Similarity distributions of four different words (corresponding to the smoothed density estimates of the similarity matrices) in topic domain space as defined in Equation 1 and global space s_g^i. Selected anchors ("professor" and "october") have more similar distributions in the global and topic spaces, when compared to unselected ones ("view" and "crater"). We observe that the selected anchors are less ambiguous, while the not selected ones are expected to have diverse contextual semantics.

Let V be the intersection of the Global-DSM and the K TDSMs vocabularies and d the embedding dimension. We then define $X_k \in \mathbb{R}^{|V| \times d}$ as the embedding matrix of the k-th TDSM, and $Y \in \mathbb{R}^{|V| \times d}$ as the embedding matrix of the global DSM, where the i-th row of each matrix corresponds to the unit normalized representation of a word in V. Then, we define $S_k = X_k X_k^T$, $S_g = YY^T \in \mathbb{R}^{|V| \times |V|}$ to be the similarity distribution matrices for the k-th TDSM and the global-DSM, respectively. Then our objective is to extract a list of semantic anchors A that minimizes the Euclidean distance between the two different similarity distributions. Specifically, for every word i we calculate the average semantic distribution across all topics:

$$< s_k^i >_k = \frac{1}{K} \sum_{k=1}^{K} s_k^i \tag{1}$$

$$\| < s_k^i >_k - s_g^i \|_2 , \quad \forall\, i = 1, \ldots, |V| \tag{2}$$

where s_g^i, s_k^i is the i-th row of the S_g and S_k similarity matrix, respectively, representing the similarity distribution between word i and every other word in the vocabulary V. We then choose $|A|$ anchors as the words with the smallest values according to criterion 2. Furthermore, we assume that there exists an orthogonal transformation matrix between the topic embeddings of the extracted semantic anchors of each TDSM (source space) and the corresponding representations of the global-DSM (target space). The orthogonality constraint on the transformation matrix is widely adopted by the literature for various semantic space alignment tasks (Xing et al., 2015; Artetxe et al., 2016; Hamilton et al.). Assume $\alpha_k^j \in \mathbb{R}^d$ is the vector representation of the j-th *anchor* word in the source space and $\alpha_g^j \in \mathbb{R}^d$ is its corresponding vector representation in the target space. The transformation matrix $M_k \in \mathbb{R}^{d \times d}$ that projects the first space to the latter is learned via solving the following constraint optimization problem:[3]

$$\min_{M_k} \sum_{j=1}^{|A|} \| M_k \alpha_k^j - \alpha_g^j \|_2^2, \quad \text{s.t. } M_k M_k^T = \mathbb{I} \tag{3}$$

The induction of multiple topic embeddings in the unified vector space is achieved via applying Equation 3 to each TDSM. Specifically, given a word and its k-th topic distributed representation $x_k \in \mathbb{R}^d$, we compute its projected representation $x'_k \in \mathbb{R}^d$ as follows:

$$x'_k = M_k x_k \tag{4}$$

3.3 Smoothing Of Topic Embeddings

Starting from the set of aligned topic embeddings $\{x'_k\}_{k=1}^K$ for each word, we learn a Gaussian Mixture Model with N components, where closely positioned topic embeddings are assigned to the same component. This step operates as an implicit way of segmenting the space of topic embeddings for each word in order to capture more useful hyper-topics—union of topics—which better represent their different meanings. We suggest that each Gaussian distribution forms a semantically coherent unit that corresponds to closely related semantics of the target word. Subsequently, the mean vector of each Gaussian distribution is used as a representative vector of each component, leading to a new set of *smoothed* topic embeddings $\{x_n^*\}_{n=1}^N$ for each word, where $x_n^* \in \mathbb{R}^d$.

---

[3] This problem is known as the orthogonal Procrustes problem and it has a closed form solution as proposed in (Schönemann, 1966).

4 Experimental Setup

4.1 DSM Settings

As our initial corpus we used the English Wikipedia, containing 8.5 million articles (Turney, 2012). During the training of the topic model, we used the articles found in the Wikipedia corpus and employed the Gensim implementation of LDA (Rubenstein and Goodenough, 1965) setting the number of topics K to 50. Using a threshold of 0.1, we followed a soft-clustering approach, to bootstrap the creation of topic sub-corpora, using our trained topic model. Finally, we used Gensim's implementation of Word2Vec and Continuous Bag-of-Words method to train both the global-DSM and the TDSMs. The context window parameter of Word2Vec is set to 5, while the dimensionality d of all the constructed DSMs is equal to 300 or 500.[4]

4.2 Semantic Anchors

The number of *semantic anchors* that determine the mappings between our source and target spaces is set to $|A| = 5\,000$ [5] according to our unsupervised approach (criterion 2). Those are selected from the common set of words that are represented in all semantic spaces with $|V| \sim 12\,000$.

As a second experiment, we randomly sample $|A|$ words from the vocabulary of each TDSM to define its transformation matrix. We repeat this experiment 10 times, every time sampling a different list from the corresponding vocabulary and report average performance results.

4.3 Gaussian Mixture Model

To apply the smoothing technique on the set of a word's topic embeddings we use the Scikit-learn implementation of Gaussian Mixture Model clustering algorithm (Pedregosa et al., 2011). We initialize the mean vector of each component using k-means algorithm and the parameters of the model are estimated using Expectation-Maximization (EM) algorithm.

4.4 Contextual Semantic Similarity

To estimate the semantic similarity between a pair of words provided in sentential context, we use the standard evaluation Stanford Contextual Word Similarity (SCWS) (Huang et al., 2012) dataset which consists of 2 003 word-pairs with assigned semantic similarity scores computed as the average estimations of several human annotators. Following the evaluation guidelines proposed in literature, we employ the $\mathrm{AvgSimC}$ and $\mathrm{MaxSimC}$ contextual metrics, firstly discussed in Reisinger and Mooney (2010). In particular, given the word-pair (w, w'), and their provided contexts (c, c') we define:

$$\mathrm{AvgSimC}(w, w') = \frac{1}{K^2}\sum_{j=1}^{K}\sum_{k=1}^{K}\mathrm{p}(j|w,c)\mathrm{p}(k|w',c')\mathrm{d}(x'_j(w), x'_k(w')), \tag{5}$$

$$\mathrm{MaxSimC}(w, w') = \mathrm{d}(\hat{x}'(w), \hat{x}'(w')), \tag{6}$$

Following the notation used in 3.2, K is the number of topics returned by the trained LDA model, x'_j is the word embedding trained on the sub-corpus corresponding to the j-th topic after being projected to the unified vector space, $\mathrm{p}(j|w,c)$ denotes the posterior probability of topic j returned by LDA given as input the context c of word w, d denotes the cosine similarity between the two input representations and finally $\hat{x}'(w) = u_{\mathrm{argmax}_{1\leq j\leq K}\,\mathrm{p}(j|w,c)}(w)$ is the vector representation of word w that corresponds to the topic with the maximum posterior for c. Intuitively, a higher score in $\mathrm{MaxSimC}$ indicates the existence of more robust multi-topic word representations. On the other hand, $\mathrm{AvgSimC}$ provides a topic-based smoothed result across different embeddings.

4.5 Downstream NLP Tasks

Besides the standard evaluation benchmark of contextual word similarity, we also investigate the effectiveness of our mapped cross-topic embeddings on document and sentence level downstream NLP tasks: text classification and paraphrase identification. We report weighted-averaging precision, recall, F1-measure and accuracy performance metrics.

Text classification. We used the 20NewsGroup[6] dataset, which consists of about 20 000 documents. Our goal is to classify each document into one of the 20 different newsgroups based on its content.

---

[4] Any parameter not mentioned is set to default values of the corresponding implementations (e.g., Word2Vec, Gensim LDA).

[5] We have experimented with different values of anchors from $\{1\,000, 2\,000, 3\,000, 4\,000, 5\,000\}$ and report results for the best setup.

[6] http://qwone.com/ jason/20Newsgroups/

Paraphrase Identification. For this task we aimed at identifying whether two given sentences can be considered paraphrases or not, using the Microsoft Paraphrase dataset (Dolan et al., 2004).

Document and Sentence level representations. Given a document or a sentence D, where w_d corresponds to the d-th word in D, we extract its feature representation using three different ways:

$$\mathrm{AvgC_D} = \frac{1}{|D|}\sum_{d=1}^{|D|}\sum_{k=1}^{K} \mathrm{p}(k|D) x'_k(w_d), \tag{7}$$

$$\mathrm{Avg_D} = \frac{1}{|D|}\sum_{d=1}^{|D|}\sum_{k=1}^{K} \frac{1}{K} x'_k(w_d), \tag{8}$$

$$\mathrm{MaxC_D} = \frac{1}{|D|}\sum_{w=1}^{|D|} x'_m(w_d) \tag{9}$$

$$\text{s.t.} \quad m = \operatorname*{argmax}_{k=1,..,K}\{\mathrm{p}(k|D)\},$$

where $\mathrm{p}(k|D)$ denotes the posterior probability of topic k returned by LDA given as input the sentence/document D and $x'_k(w_d)$ is the mapped representation of word w_d for topic k. For the case of paraphrase identification, we extract a single feature vector for each sentence-pair via concatenating the features of the individual sentences.

After feature extraction, we train a linear Support Vector Classifier (SVM) (Pedregosa et al., 2011) using the proposed train/test sets for both tasks. We report the best results for each experimental configuration after tuning the SVM's penalty parameter of the error term using 500-dimensional word embeddings.

5 Results

In Table 1 we compare our model (UTDSM) with our baseline (Global-DSM) and other state-of-the-art multi-prototype approaches for the contextual semantic similarity task. It is clear that all different setups of UTDSM perform better than the baseline for both contextual semantic similarity metrics. Using a single Gaussian distribution (UTDSM + GMM (1)) at the smoothing step of our method produces similar results to the baseline model. This is anticipated as both methods provide a centroid representation of a word's diverse semantics. In terms of $\mathrm{MaxSimC}$ the model consistently yields higher performance when the list of semantic anchors is induced via our unsupervised method instead of using randomly selected anchor words (UTDSM Random). We also observe that random anchoring performs slightly worse than UTDSM with respect to $\mathrm{AvgSimC}$. This result validates our hypothesis that the representations of words, which share consistent similarity distributions across different topic domains, constitute informative *semantic anchors* that determine the mappings between semantic vector spaces.

Method	AvgSimC	MaxSimC
Liu et al. (2015a)	67.3	68.1
Liu et al. (2015b)	69.5	67.9
Amiri et al. (2016)	70.9	-
Lee and Chen (2017)	68.7	67.9
Guo et al. (2018)	69.3	68.2
300-dimensions		
Global-DSM	67.1	67.1
UTDSM Random	69.1 ± 0.1	66.4 ± 0.2
UTDSM	**69.6**	67.1
UTDSM + GMM (1)	67.4	67.4
UTDSM + GMM (2)	68.4	**68.3**
UTDSM + GMM (3)	68.9	**68.3**
UTDSM + GMM (8)	69.1	68.0
UTDSM + GMM (10)	69.0	67.8
500-dimensions		
Global-DSM	67.6	67.6
UTDSM Random	69.4 ± 0.1	66.5 ± 0.3
UTDSM	**70.2**	68.0
UTDSM + GMM (1)	67.6	67.6
UTDSM + GMM (2)	68.8	**68.6**
UTDSM + GMM (3)	69.0	68.5
UTDSM + GMM (8)	69.5	68.5
UTDSM + GMM (10)	69.2	68.0

Table 1: Performance comparison between different state-of-the-art approaches on SCWS, in terms of Spearman's correlation. UTDSM refers to the projected cross-topic representation, UTDSM Random refers to the case when random words served as anchors and GMM (c) corresponds to GMM smoothing with c components.

Furthermore, we observe that GMM smoothing has a different effect on the $\mathrm{MaxSimC}$ and $\mathrm{AvgSimC}$ metrics. Specifically, for $\mathrm{AvgSimC}$ we consistently report lower results when GMM smoothing is applied for different number of components. We attribute this behavior to a possible loss of model capacity—decrease in the number of topic embeddings—that is capable of capturing additional topic information. At the same time, our smoothing technique highly improves the performance of $\mathrm{MaxSimC}$ for all possible configurations. Given that this metric is more sensitive to noisy word representations, this result indicates that our technique lessens the noise introduced to our system and captures finer-grained topic senses of words.

Overall, the performance of our model is highly competitive to the state-of-the-art models in terms of $\mathrm{AvgSimC}$, for 500-dimensional topic embeddings. We also achieve state-of-the-art performance for the $\mathrm{MaxSimC}$ metric, using smoothed topic embeddings of 300 or 500 dimensions with 2 or 3 Gaussian components.

Method	Precision	Recall	F1-score	Accuracy
LDA	39.7	41.8	38.8	41.8
Global-DSM	62.9	63.3	62.9	63.3
$\mathrm{MaxC_D}$	61.9	63.0	62.0	63.0
$\mathrm{Avg_D}$	63.5	64.6	63.3	64.3
$\mathrm{AvgC_D}$	**64.6**	**65.5**	**64.5**	**65.5**

Table 2: Evaluation results of multi-class text classification.

Evaluation results on text classification are presented in Table 2. We observe that our model performs better than the baseline across all metrics for both averaging approaches ($\mathrm{AvgC_D}$, $\mathrm{Avg_D}$), while the usage of dominant topics appears to have lower performance ($\mathrm{MaxC_D}$). Specifically, we get an improvement of $2 - 2.5\%$ on topic-based average and $0.5 - 1\%$ on simple average combination compared to using Global-DSM.

Method	Precision	Recall	F1-score	Accuracy
Global-DSM	68.6	69.2	62.0	69.2
$\mathrm{MaxC_D}$	**69.0**	69.3	62.1	69.3
$\mathrm{Avg_D}$	67.7	**69.4**	**64.0**	**69.4**
$\mathrm{AvgC_D}$	68.8	69.4	62.6	69.4

Table 3: Evaluation results on paraphrase detection task.

Results for the paraphrase identification task are presented in Table 3. $\mathrm{Avg_D}$ yields the best results especially in F1 metric showing that cross-topic representations are semantically richer than single embeddings baseline (Global-DSM). Although we apply the topic distributions $\mathrm{p}(k|D)$ extracted from LDA (document-level model) to a sentence-level task, improvements over the baseline are also shown in the $\mathrm{AvgC_D}$ and $\mathrm{MaxC_D}$ cases.

Overall, the proposed UTDSM model outperforms the baseline Global-DSM model on both semantic similarity and downstream tasks.[7]

6 Cross-Domain Semantic Analysis

Finally, we carry out a cross-domain semantic analysis to detect the variations of a word's meaning in different topic domains. To that end, we use a list of known polysemous words and measure the semantic similarity between different topic representations of the same ambiguous word. The ultimate goal of this analysis is to validate that our model captures known thematic variations in semantics of polysemous words.

Table 4 includes examples of our analysis. The most probable words of the topics (second column) give an intuitive sense of their major contexts, while their nearest neighbors (third column) infer the sense of the target word in the corresponding topic domain. For example, the word *drug* is mostly related to "medication" in a broad medical domain; it experiences though a slight shift from this meaning when it resides in a topic about "illegal substances". Furthermore, the highly polysemous word *act* shifts from meaning "statute" to meaning "performance" under the corresponding law and art topics. Similar semantic variations are observed for words *python*, *rock* and *nursery*.

Moreover, in Figure 3 we visualize the topic embeddings of seven words before and after projecting the topic-based DSMs to the unified space, using principal component analysis. We additionally depict the Gaussian distribution learned from the topic representations of each word reflecting the uncertainty of their meanings. The center of each distribution is specified by the mean vector and contour surface by the covariance matrix. On the left, we depict the position of words prior to applying the unsupervised mapping approach where the topic sub-spaces are unaligned. In the unaligned space, words demonstrate similar area coverage regardless of their polysemy. After the mappings, we see on the right that the area under a word's distribution is indicative of its degree of polysemy. Specifically, we observe that the variance of the learned representations becomes larger for the cases of polysemous words such as

---

[7] Similar results were obtained for each metric using smoothed word embeddings. Also, there are no standard evaluation approaches for comparison of previous works on downstream tasks.

[8] Note that a topic domain is described as a distribution over words in our model.

Word	Topic Words	Nearest Neighbors	Similarity
drug	health, medical, cancer, treatment, disease	insulin, therapy, heparin, chemotherapy, vaccines	0.61
	drug, health, marijuana, alcohol, effects	meth, cocaine, methamphetamine, mdma, heroin	
act	law, court, legal, tax, state	bylaw, legislature, complying, entities, entitlement	0.39
	music, guitar, piano, dance, theatre	touring, pantomime, weekend, shakespeare, musical	
python	garden, plant, fish, bird, animal	macaw, crocodile, hamster, albino, rattlesnake	0.27
	software, forum, download, windows, web	algorithm, parser, notepad, gui, tutorial	
rock	mountain, river, park, road, trail	geology, slab, limestone, waterfalls, canyon	0.43
	music, guitar, piano, dance, theatre	touring, acoustic, americana, songwriter, combo	
nursery	garden, plant, tree, flower, gardening	camellias, succulents, greenhouse, ornamental, grower	0.46
	university, school, college, education, program	prep, montessori, grammar, preschool, infant	

Table 4: Examples of polysemous words and the change of meaning between different topic domains. First column lists the example target words. Second column includes the most probable words of the topic domains[8] these words are assigned to. Each row corresponds to a different topic domain. Third column shows the nearest monosemous neighbors of the target word in the corresponding topic domain. The last column corresponds to the cosine similarity between the two topic representations of the target word.

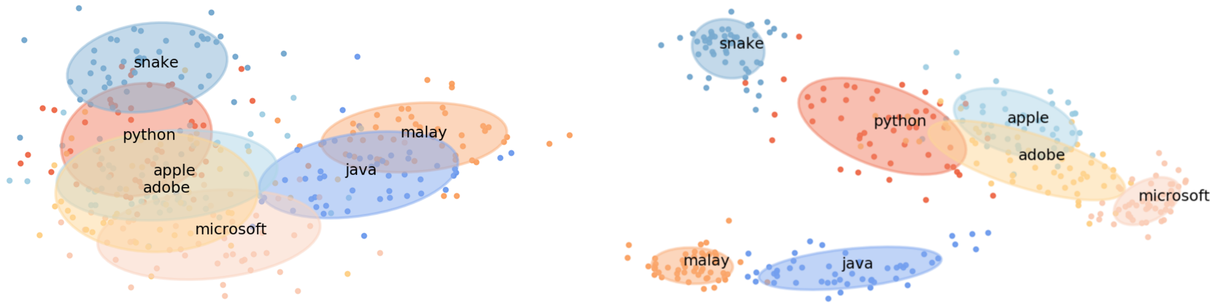


Figure 3: A 2-dimensional projection of the latent semantic space encoded in our unified vector space model, depicting the topic word representations of 7 words before (left) and after (right) mapping the TDSMs to the global semantic space.

"python", "java", "adobe" in order to assign some probability to their diverse meanings. Monosemous words such as "snake", "microsoft" and "malay" have smaller variances. Furthermore, we observe that the semantic relationships between words are much better captured by their corresponding positions in the aligned space.

7 Conclusion

We present an unsupervised approach of mapping multiple topic-based DSMs to a unified vector space in order to capture different contextual semantics of words. We assume that words having consistent similarity distributions regardless of the domain they exist in could be considered informative semantic anchors that determine the mappings between semantic spaces. The projected word embeddings yield state-of-the-art results on contextual similarity compared to previously proposed unsupervised approaches for multiple word embeddings creation, while they also outperform single vector representations in downstream NLP tasks. In addition, we provide insightful visualizations and examples that demonstrate the capability of our model to capture variations in topic semantics of words.

As future work, one can hypothesize that the area a word covers in the mapped space reveals its semantic range. In this direction, a refinement of the semantic anchor selection approach could be explored in an iterative way assuming that the variance of a word's Gaussian distribution denotes its degree of polysemy (Vilnis and McCallum, 2015). Moreover, we would like to explore a more sophisticated smoothing technique where the number of Gaussian components is adapted for each word. Given that Gaussian mixture embeddings could capture the uncertainty of a word's representation in the semantic space one could also investigate different metrics for measuring the semantic relationship between word pairs that go beyond their point-wise comparison. Finally, it may be helpful to investigate non-linear mappings between semantic spaces using deep neural network architectures.

What just happened? Evaluating retrofitted distributional word vectors

Abstract

Recent work has attempted to enhance vector space representations using information from structured semantic resources. This process, dubbed retrofitting Faruqui et al. (2015), has yielded improvements in word similarity performance. Research has largely focused on the retrofitting algorithm, or on the kind of structured semantic resources used, but little research has explored why some resources perform better than others. We conducted a fine-grained analysis of the original retrofitting process, and found that the utility of different lexical resources for retrofitting depends on two factors: the coverage of the resource and the evaluation metric. Our assessment suggests that the common practice of using correlation measures to evaluate increases in performance against full word similarity benchmarks 1) obscures the benefits offered by smaller resources, and 2) overlooks incremental gains in word similarity performance. We propose root-mean-square error (RMSE) as an alternative evaluation metric, and demonstrate that correlation measures and RMSE sometimes yield opposite conclusions concerning the efficacy of retrofitting. This point is illustrated by word vectors retrofitted with novel treatments of the FrameNet data (Fillmore and Baker, 2010).

1 Introduction

One of the most challenging tasks in the field of Natural Language Processing (NLP) is accurately encoding meaning into a computational system. Currently, the predominant approach is to represent the meanings of linguistic units, such as words or phrases, as vectors in a high-dimensional space. Vector embeddings are trained over large text corpora using machine-learning techniques, and have proven useful for a wide range of applications, such as named entity recognition (Turian et al., 2010), semantic role labeling (Collobert et al., 2011), sentiment analysis (Socher et al., 2013), and machine translation (Zou et al., 2013).

Word vectors are typically trained solely on the distributional information from text corpora. Recent work has attempted to improve word vectors by infusing them with information from semantic resources in a post-processing step. This technique, referred to as *retrofitting*, was introduced by Faruqui et al. (2015). They adjusted pre-trained embeddings based on lexical relations in WordNet (Miller, 1995), FrameNet (Fillmore and Baker, 2010), and the Paraphrase Database (Ganitkevitch et al., 2013). In some cases, this method yielded gains in word similarity performance.

Retrofitting has been extended in a variety of ways. Briefly, these include 1) adding word-to-word relations to encompass more than just similarity relations, such as by directly introducing antonymy relations (Mrkšić et al., 2016), or by explicitly modeling the pairwise relations between items (Lengerich et al., 2017); 2) increasing the size of the output vocabulary (Speer et al., 2017), or extending the process to affect the word vectors of words outside of the semantic resource (Glavaš and Vulić, 2018); and 3) constructing sense-specific word vectors using a word sense ontology (Jauhar et al., 2015), or word sense information learned from parallel text corpora (Ettinger et al., 2016).

However, while Faruqui et al. (2015) has certainly spawned a productive line of research into improving pre-trained word vectors, the original study contained a puzzling finding: retrofitting with certain semantic resources actually appeared to harm the quality of the word embeddings. This seems counter-intuitive. In principle, if semantic resources contain information that is not already captured by the word vectors, then retrofitting should always improve them.

Proceedings of NAACL-HLT 2019, pages 1062–1072
Minneapolis, Minnesota, June 2 - June 7, 2019.

In order to understand why some semantic resources appear better suited for retrofitting word vectors, we conducted a fine-grained analysis of Faruqui et al.'s original technique. Given their popularity, we focused on word similarity evaluations. We observe that the perceived usefulness of a semantic resource depends on its coverage of the words in the evaluation benchmark. Furthermore, we report that the choice of evaluation metric can lead to different conclusions. We note that some gains in performance are not captured by correlation measures, and propose that root-mean-square error (RMSE) is more appropriate for measuring changes in word similarity performance.

2 Methods

2.1 Retrofitting

The original retrofitting algorithm from Faruqui et al. (2015) is described below. The process essentially moves the word vectors of related words closer together. A semantic resource can be regarded as a graph which covers a vocabulary $V = \{w_1, ..., w_n\}$ and denotes relations between them as edges $(w_i, w_j) \in E$. Given a set of pre-trained distributional vectors $\hat{\vec{W}} = \{\hat{\vec{w_1}}, ..., \hat{\vec{w_d}}\}$ and a semantic resource with edges E, the goal is to learn a new set of vectors $\vec{W} = \{\vec{w_1}, ..., \vec{w_d}\}$. Here $\vec{w_i}$ is the word vector corresponding to vocabulary item w_i. The objective function to be minimized is the following:

$$\sum_{w_i}^{V} \left(\alpha_i ||\vec{w_i} - \hat{\vec{w_i}}||^2 + \sum_{(w_i,w_j)}^{E} \beta_{ij} ||\vec{w_i} - \vec{w_j}||^2 \right) \quad (1)$$

The first term of the inner sum ensures that the vectors do not stray too far away from their original representations (controlled by α), while the second term compels the vectors to move closer to their neighbors in the semantic resource (controlled by β). In Faruqui et al.'s experiments, all $\alpha_i = 1$, and all $\beta_{ij} = \frac{1}{degree(w_i)}$, where $degree(w_i)$ refers to the number of neighbors w_i had in the resource. This is equivalent to specifying that half of the new retrofitted vector will come from the distributional data while the other half will be an average of its neighbors' word vectors. They allowed the process to run for 10 iterations. We retained these settings in our experiments.

Resource	Terms	Groupings
`WordNet+`	147,306	117,659
`PPDB`	84,467	102,899
`FrameNet`	8,483	1,074
`FrameNet-Anno`	37,855	7,146

Table 1: Number of word forms and word groupings per semantic resource.

2.2 Semantic resources

We employed three semantic resources in our analyses. Table 1 shows the number of terms and groupings in each resource after removing terms containing numbers or punctuation.[1]

WordNet. WordNet (Miller, 1995) is a large lexical database of English words. The resource is composed of synsets, groupings of synonyms. Synsets are linked together through a small number of semantic relations. We follow Faruqui et al. (2015) and link each word form to its synonyms, hypernyms, and hyponyms (`WN+`). For instance, the word *dog* is linked to *canine* (synonym), *corgi* (hyponym) and *domestic_animal* (hypernym). In order to faithfully replicate Faruqui et al., we collapsed part of speech and sense distinctions, meaning that a word form was linked to all of its related words through all of its synsets. For instance, *dog*'s neighbors include *corgi* through the noun *dog* (e.g. "Sam pet the dog.") and *track* through the verb *to dog* (e.g. "The task dogged me.") Although the word vectors and evaluations used in this study are insensitive to part of speech and sense distinctions, the number and order of groupings affects the retrofitting procedure. In particular, as noted by Speer and Chin (2016), the results depend on the order in which the groupings are iterated over. Though we attempted to group words by their synsets, this appeared to lead to poorer performance and we do not report those results here.

PPDB. The paraphrase database (Ganitkevitch et al., 2013) contains millions of English paraphrases automatically extracted from bilingual parallel corpora. The core idea is that if a non-English phrase translates to two distinct English strings, then these may be considered paraphrases of each other. For instance, since German *festgenommen* translates to both "thrown into jail"

---

[1] The number of groupings for PPDB is approximate, taken as the number of unique sets of words in Faruqui et al.'s pre-processed lexicon file.

and "imprisoned", the latter two are listed as paraphrases. Faruqui et al. (2015) used the XL lexical pack from PPDB 1.0. Since this version is no longer publically available, we used their preprocessed file (`PPDB`).

FrameNet. FrameNet (Fillmore and Baker, 2010) is a highly-interconnected lexical database of English containing sense-annotated sentences. The basic units of FrameNet are semantic frames, which specify the conceptual structure necessary to understand sets of lexical units (LUs). For instance, the frame Attack contains LUs such as *attack.v*, *attack.n* and *offensive.a*, which can be understood in light of the frame elements (FEs) *Assailant* and *Victim*. We performed two experiments with the FrameNet data. In the first, we grouped words together if they shared a frame (`FN`). Note that this differs from the treatment of WordNet because the frame groupings retain part of speech and sense distinctions. Although this method follows Faruqui et al. (2015), we located a bug in their code which led to a loss of about 1/3 of the data: the original code did correctly handle polysemy, which is widespread in FrameNet.

For our second experiment, we grouped words together based on the FEs that they filled (`FN-ANNO`). All of the FrameNet FEs were used in this task (i.e. both core and non-core FEs). Since FEs are defined with respect to their frames, each semantic role is frame-specific. The rationale is that words which can occupy the same semantic role should be more similar. We created groupings from the last nouns which appeared in the FE fillers in the annotation data. To illustrate, since the annotation data linked to the FE *Assailant* of the Attack frame included the nouns *enemy*, *troop*, *terrorist* and *forces*, their corresponding word vectors were moved closer together. Note that all of our retrofitting analyses ignored the frequency of a word's neighbor: even if *enemy* filled the FE *Assailant* 100 times, its effect on its neighbors would be identical to if it had only filled the FE once.

We recognize that the last noun heuristic is simplistic. However, we estimate that around 73% of the syntactic heads of FE fillers are nouns. Of these, 68% contain only one noun, and 18% contain only two nouns. Taken together, this implies that a more sophisticated approach is unlikely to alter the results. In addition to the last noun heuristic, we considered grouping the first nouns in the FE fillers, all of the nouns in the FE fillers, and the nouns from FE fillers which contained only one noun. All of these experiments yielded similar results, so we only report the last noun condition here. Nouns were identified using the default NLTK (Bird and Loper, 2004) English part-of-speech tagger.

2.3 Word vectors

Our analyses included two popular pre-trained word vector embeddings.

SG. `word2vec` (Mikolov et al., 2013) is widely-used to learn vector representations from distributional information. In the continuous skip-gram architecture (SG), the target word is fed into a log-linear classifier to predict surrounding words within a given context window. The available vectors were trained on about 100 billion words from the Google News dataset.

GloVe. Global Vectors for Word Representation (Pennington et al., 2014) is a global log-bilinear regression model which captures both global and local word co-occurrence statistics. We use the 300 dimension vectors trained on 6 billion words from Wikipedia and the English Gigaword corpus.

2.4 Word similarity

Word similarity judgments are the most widely-used method of intrinsic evaluation. We chose four commonly used word similarity datasets comprised of nouns, verbs and adjectives.

MEN3K (Bruni et al., 2012) contains 3,000 pairs of words from a set of labels for an image database. Interestingly, although Bruni et al. claim that their dataset "contains 3,000 pairs of randomly selected words that occur [as labels]", it only contains 751 unique words.[2] Therefore, as an additional evaluation of high-frequency words, we included MTURK-771 (Halawi et al., 2012), a crowd-sourced dataset of 771 word-pairs consisting of 1,113 unique words which we will refer to as **MT771**. The Stanford Rare Words (**RW**) dataset (Luong et al., 2013) is comprised of 2,034 word-pairs formed from 2,951 unique words. **SL999** (Hill et al., 2015) explicitly quantifies semantic similarity between pairs of words. The dataset contains 999 word pairs from 1,028 unique words. The word pairs in SL999 were chosen to cover the full range of concreteness within each part of speech category. We included RW

---

[2] By our calculations, the expected number of unique words obtained from 3,000 random pairs drawn from 20,515 labels (the number in their image database) is around 5,200.

and SL999 to examine whether the results of our analyses would differ for benchmarks containing common vs. rare words and for those capturing association and relatedness vs. similarity only.

3 Evaluation procedure

The standard approach to evaluate the performance of word vectors on word similarity judgments is to compute the cosine similarity values between each pair of words in the dataset and then calculate the correlation between these values and the similarity scores collected from human raters. A similar technique is used to assess the utility of different semantic resources in retrofitting word vectors: increases in correlation are taken to be indicative that information from the resource has been successfully injected into the word vectors. For both types of evaluations, Spearman correlation has become the preferred correlation measure.

However, there are several reasons that this method may be misleading. The first concerns the issue of the relative coverage of each resource. Simply put, not every resource contains all of the words in the evaluation dataset. If a resource lacks the words for a particular similarity judgment, then the predicted score will be the same for both the baseline and retrofitted vectors. This may have important consequences on the evaluation metric: the fixed scores can throw off the global ranking of the predicted scores, which is measured by the Spearman correlation.

For every word pair in a word similarity dataset, a resource can contain 1) both words, 2) one of the words, or 3) neither of the words. If the goal of the evaluation is to determine whether the knowledge of particular semantic resources can be added to word vectors, then it seems reasonable to only evaluate the resource on the word pairs it covers. In this case, the resource will either group the two words together or place them in separate groups, which can be interpreted as explicitly indicating whether the two words are semantically related or not. Conversely, it is obvious that retrofitting will not improve the vectors for the word pairs for which neither word is in the semantic resource.

The situation where only one word is present is more complicated. For example, imagine that a resource contained the word *view* but not the word *skyline*. Following retrofitting the vector for *view* will move while the vector for *skyline* will stay the same. The relationship between *view* and *skyline* will either become more accurate or less accurate, but this change does not directly stem from the semantic resource. If the goal of the retrofitting evaluation is to assess the usefulness of particular semantic resources, then including these kinds of word pairs is misleading, since the observed changes are incidental and do not reflect the semantic groupings in the resource.

In our analyses, "all pairs" shows the performance of the word vectors using all of the word similarity judgments, and "pairs in resource" shows their performance using only the subset comprised of judgments for which both words were contained in the semantic resource.

Our more radical proposal is to consider an entirely different evaluation metric altogether. Measures of correlation indicate how well word vectors are able to predict the similarity judgments. Spearman correlation specifically measures how well word vectors are able to predict the correct rankings of similarity judgments. For example, according to the MEN3K dataset, *brick* and *construction* should be ranked as less similar than *town* and *village*. Another conceivable way to test the word vectors ability to capture word similarity knowledge would be to directly compare the word vectors' predicted score with the human score. According to MEN3K, the average rated similarity for *town* and *village* was 43 out of 50. Taken literally, after normalizing the original scores the cosine similarity should be exactly 0.86. We operationalized this by evaluating word vectors using root-mean-square error (RMSE). This approach seems particularly appealing for measuring the effects of retrofitting because each similarity judgment contributes independently to the RMSE score.

One may wonder whether Pearson correlation, which measures linear association, might serve as a better comparison to RMSE. To address this concern, we employed the harmonic mean of the Pearson and Spearman correlations as our correlation measure. This blends the linear measure (Pearson) with the standardly-employed measure (Spearman). However, we note that the resulting baseline and retrofitted scores were very similar across correlation measures, and so our conclusions regarding the choice of evaluation metric were unaffected by this decision.

In the analysis that follows, we considered the effect of resource coverage and evaluation metric

	NB	GloVe	SG
MT771	**0.80 / 0.35**	0.65 / 0.36	0.66 / 0.39
MEN3K	**0.85** / 0.28	0.75 / 0.27	0.78 / **0.27**
RW	**0.54 / 0.37**	0.35 / 0.55	0.45 / 0.45
SL999	**0.66 / 0.21**	0.38 / 0.26	0.45 / 0.25

Table 2: Baseline word vector similarity performance. Scores are listed in the form "Correlation/RMSE". Bold face indicates the best-performing set of vectors for each similarity dataset for their correlation score and for their RMSE score. Recall that lower RMSE is better.

on the results of retrofitting. There were four conditions: 1) Correlation, all word pairs in the benchmark, 2) Correlation, only those pairs in which both words were in resource, 3) RMSE, all word pairs in the benchmark, and 4) RMSE, only those pairs in which both words were in resource. If one of the words in a word pair was missing from the word vectors, then it was assigned a predicted cosine similarity of zero. (This only occurred with the RW dataset, and was limited to the all pairs conditions.)

4 Results

Table 2 shows the baseline word similarity performance according to the harmonic mean of the correlation measures and RMSE. As a reference, we include the NumberBatch (NB) vectors, which recently demonstrated state-of-the-art word similarity performance (Speer et al., 2017). Correlation and RMSE give similar baseline results among the vector sets and their ability to predict the four similarity benchmarks: NB performs the best. The exception is that SG scores a slightly better RMSE score on the MEN3K dataset.

4.1 All word pairs

Figure 1 shows the measured improvements in correlation due to retrofitting. This mirrors Faruqui et al. (2015)'s original finding that the PPDB offers the most improvements, and that grouping words by FrameNet frames (`FN`) usually leads to worse performance. Note that this finding is observed after correcting for the issue from Faruqui et al. which omitted data from FrameNet. This plot also suggests that using FrameNet frame elements (`FN-ANNO`) to group words is very detrimental to word vectors.

As shown in Figure 2, simply switching the evaluation metric to RMSE paints a much different picture. (Since RMSE measures error rather than improvement, the y-axis has been inverted so that improvement is still in the upward direction.) The most obvious difference is that according to RMSE all of the semantic resources appear to help. Compared to Figure 1, there is a noticeable boost in performance for `WN+`, especially when evaluated against RW. Remarkably, `FN-ANNO` almost completely flips polarity. The result is especially dramatic against the evaluation sets containing common words (i.e. MT771 and MEN3K): `FN-ANNO` goes from being the worst-performing resource to one of the best-performing resources.

4.2 Word pairs in resource

Figure 3 shows the measured improvements in correlation when considering only the word pairs in which both words were present in resources. The ranked order of the semantic resources is virtually the same. Note, however, that the measured performance of the relatively low-coverage resource, FrameNet (`FN`), has jumped considerably: in the RW with GloVe condition, it overtakes PPDB as the resource providing the best improvement.

Figure 4 measures the change of RMSE for the word pairs covered by the resources. FrameNet (`FN`) appears to yield a substantial gain in performance for the subset of the similarity judgments that it covers, and again emerges as the highest-performance resource when evaluated against RW. A direct comparison of the "all pairs" to "pairs in resource" figures shows that the scores of the other resources change very little. The difference is attenuated because these resources are much larger and therefore cover most of the words in the similarity datasets.

We interpret the jumps in performance from the "all pairs" to "pairs in resource" condition as evidence that evaluating a resource on word pairs containing a mixture of words within and outside of its vocabulary may obscure its benefits. Of course, low coverage is problematic if the goal is to improve word vectors on a large number of word judgments. The "pairs in resource" assessment is particularly antithetical to the spirit of RW, which is often employed to assess word vector coverage, and we admit that `FN` only contains 6.3% of the RW word pairs. However, we

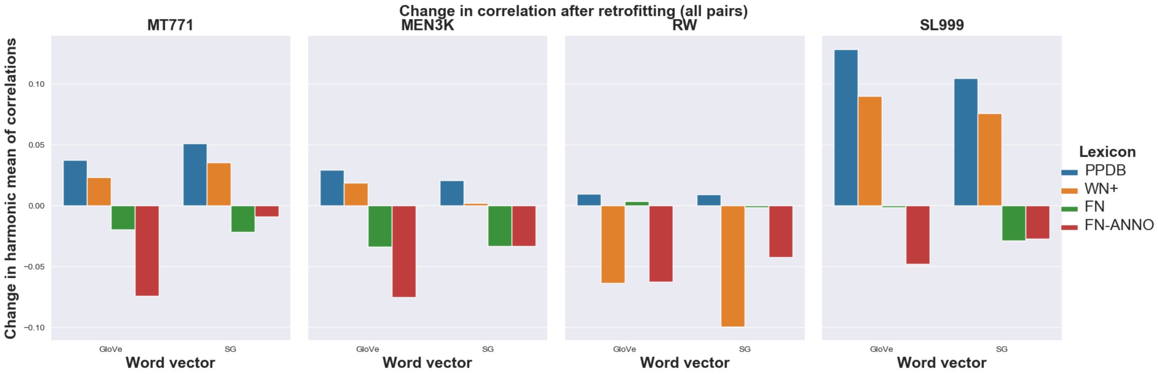

Figure 1: Change in correlation after retrofitting, considering all word pairs

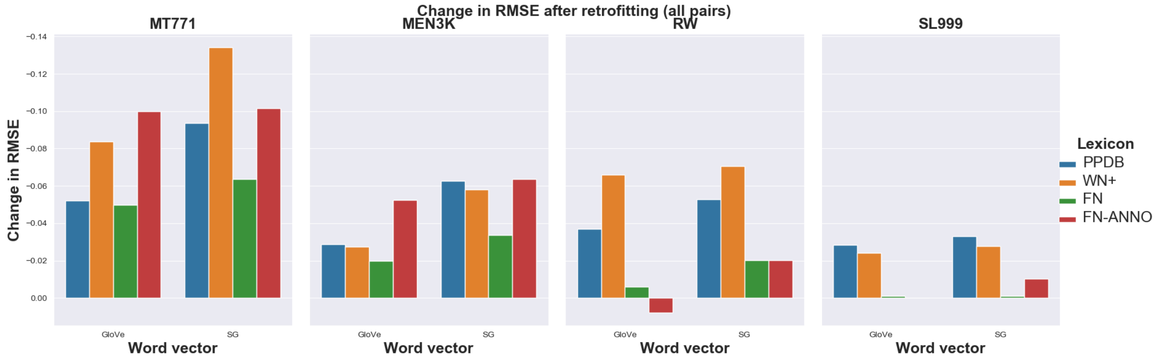

Figure 2: Change in Root-mean-square error after retrofitting, considering all word pairs

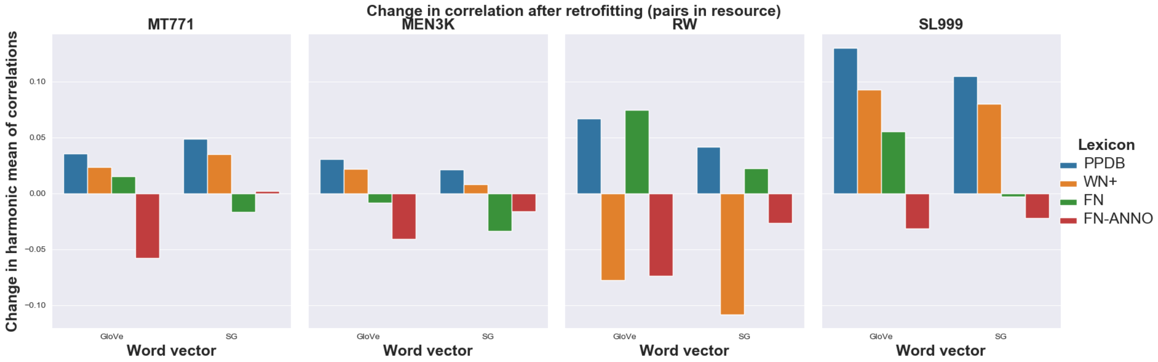

Figure 3: Change in correlation after retrofitting, considering only the word pairs in each resource

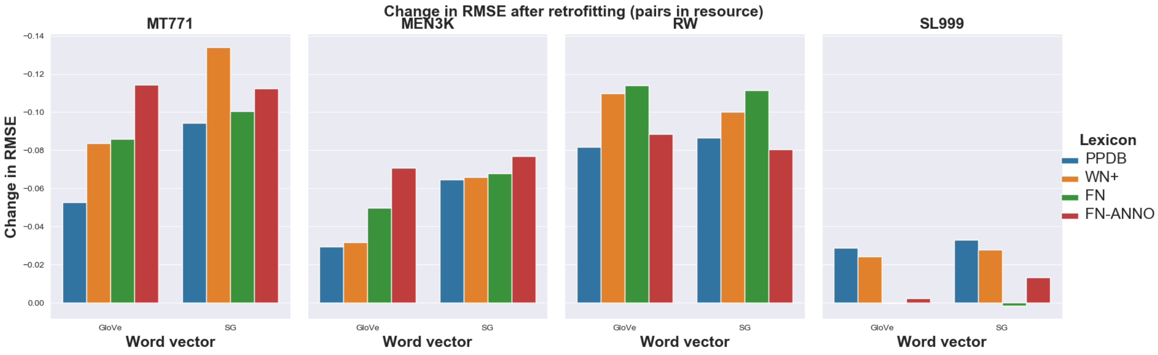

Figure 4: Change in Root-mean-square error after retrofitting, considering only the word pairs in each resource

would argue that there is an important difference between concluding that a semantic resource does not yield gains in retrofitting vs. concluding that the resource improves the quality of the vectors it covers.

4.3 SimLex

We note that our four conditions yield similar conclusions according to the SL999 evaluation set. `PPDB` and `WN+` consistently offer strong improvements, in contrast to `FN` and `FN-ANNO`. This is not surprising, and follows from the design principles underlying each resource: while PPDB and WordNet specifically group synonyms, FrameNet groups words which evoke the same semantic frame. In particular, some frames intentionally contain antonyms. As discussed above, the FrameNet groupings still appear useful in improving against MT771, MEN3K and RW, which have been argued to conflate association and similarity (Hill et al., 2015).

4.4 Further analysis

Our most striking finding is that correlation measures and RMSE occasionally yield opposite conclusions regarding the utility of semantic resources. How can the retrofitted data simultaneously show a drop in correlation and a gain in RMSE? To examine this further, we plotted the effects of retrofitting GloVe with `FN-ANNO` against the MT771 benchmark (Figure 5). Vector cosine similarity (x-axis) is plotted against the human similarity judgments (y-axis). The left and right panels compare the vector performance before and after retrofitting. Each point represents a single word pair in the MT771 dataset. The dashed line corresponds to a model which perfectly predicts the gold standard. Points are color-coded with respect to this line: green points mark word pairs whose computed cosine similarity moved closer to the human judgments, while red points indicate word pairs who moved in the opposite direction. A small number of blue points indicate predictions which were unaffected by retrofitting because the word pairs were not present in the resource.

The color-coding in Figure 5 helps illustrate how both Spearman correlation (a measure of goodness) and RMSE (a measure of error) decrease. Most of the points are green, which means that from the perspective of individual word pairs, the predictions from the retrofitted vectors are more in line with the gold standard. This is directly reflected in RMSE. However, while most of the mass moves closer to the dashed line, retrofitting increases the scatter of the points, resulting in a worse association between the vector cosine similarity human similarity judgments.

Three points are labeled in Figure 5 to show the effect of retrofitting on individual word similarity predictions. The diamond marks the word pair *find & occurrence*, which yields the most improvement according to MT771, with its absolute residual (i.e. distance from the human judgment) dropping 0.25. In comparison, the worst-performing word pair is *occasion & second*, marked with an X, whose residual increases by 0.14. This point is part of a noticeable band of red points located near the dotted line. Interestingly, for these points the predicted scores for the baseline word vectors were nearly correct, and retrofitting pushed them to overpredict similarity. The square marks *film & movie*, whose residual drops an almost imperceptible 0.003.

The reason that retrofitting may lead to a worse correlation but a better RMSE score stems from how these measures are computed from the data. Each word pair contributes independently to the RMSE score. Whether a word pair improves or decreases in performance, it is simply tallied onto the running RMSE score. In this case, it is irrelevant whether retrofitting leads to a large increase in scatter. In contrast, correlation measures are anchored to the sample means of the two variables. After retrofitting, there may be an increase in the scatter in the predicted cosine similarity values. Since on average the word pairs will be further away from the sample mean, there will be a drop in correlation. Put another way, a word pair's contribution to the correlation score depends on the positions of the all of the other word pairs.

The particularly large drop in correlation for `FN-ANNO` likely stems from the unusual heterogeneity of its groupings. For example, the word *film* occurs in the annotation data of 108 distinct FEs in FrameNet, and is grouped with dozens of varied words, such as *book*, *movie*, but also *DNA* and *meeting*. Each of the 108 retrofitting adjustments introduces some scatter. In contrast, the neighbors in other resources can be straightforwardly interpreted as related words, and each word will appear in a small number of groupings.

We note that while it may be instructive to track the performance of individual word pairs, it is dif-

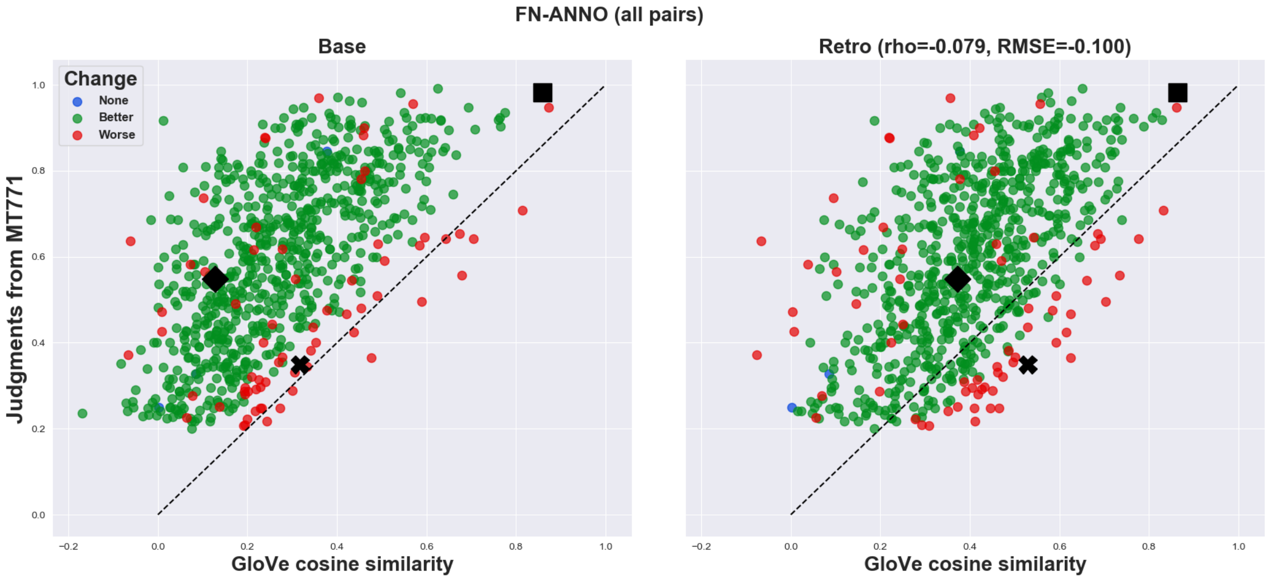

Figure 5: Effects of retrofitting GloVe by grouping nouns filling the same frame element in the FrameNet annotation data, considering all word pairs. Vector-computed similarity is plotted against the MT771 gold standard judgments using the original word vectors (left panel) and the retrofitted vectors (right panel). The dashed line illustrates a model which exactly predicts the human judgments. Predicted scores which moved closer to that line are colored green, while points which moved away from the line are colored red. Blue points represent word pairs which were not present in the resource, and so were unaffected by retrofitting. The changes in Spearman correlation and RMSE are shown above the right panel. The symbols are discussed in the text.

ficult to pinpoint the exact source of the change. For instance, in Figure 5 the words corresponding to the square (little change) and the X (worse change) are paired together, while the word pair linked to the diamond (best change) are not.

5 Related work

Faruqui et al. (2015) attributed FrameNet's comparatively poor performance to the fact that it groups words according to abstract concepts, noting that *push* and *grow* are in the same frame. Such an argument might explain why FrameNet does not yield gains in performance against SL999, which was designed to capture true similarity judgments. However, we have shown that conclusions on the other similarity benchmarks rest on the evaluation metric and on the types of word pairs considered. In the RMSE and "pairs in resource" condition, grouping words by FrameNet frames appears at least as useful as PPDB and WordNet. Alternatively, FrameNet can be interpreted as a useful resource for retrofitting the vectors of the words it contains as lexical units.

Our novel treatment of FrameNet groups nouns using its collection of sense-annotated sentences. Although all of the frame elements in these sentences were annotated by hand, the words filling the FEs are not, adding a component of randomness. Especially with more semantically general frames, frame elements can be realized by a large number of words. This contrasts with FrameNet frames, in which the placement of word senses are painstakingly deliberated, and a particular sense can only be put into one frame.

PropBank (Bonial et al., 2014) is a large semantically-annotated corpus. The semantic roles ("rolesets") in PropBank are defined with respect to individual verb and noun word senses. The types of words that fill these roles are presumably less varied than those that fill the semantically broader FrameNet frame elements. Additionally, PropBank is considerably larger than FrameNet. Consequently, we might predict that retrofitting word vectors to PropBank would yield stronger gains in word similarity judgment than to the FrameNet annotation data. We leave this task for future research.

Grouping nouns using the FrameNet annotation data led to large drops in correlation against word similarity benchmarks. However, these same data yielded large gains in RMSE performance. It might be inferred that semantic resources which have a similar stochastic component may result lower correlation. The PPDB is automatically generated, introducing a similar element of randomness, but this is curtailed by its conservative criteria: paraphrases must be attested as translation equivalents.

BabelNet (Navigli and Ponzetto, 2012) and ConceptNet (Speer et al., 2017) are knowledge resources derived from a number of collaboratively-constructed sources, such as Wikipedia and Wiktionary. Though their collaborative nature likely makes them less accurate than hand-curated resources such as WordNet, they have potential in improving the quality of word vectors (e.g. Speer and Chin, 2016). As we observed with `FN-ANNO`, RMSE may be a more informative measure of comparison than correlation in future retrofitting experiments involving heterogeneous resources.

More generally, there does not seem to be a strong theoretical reason to prefer correlation-based measures over residual-based ones. Although the current practice is to report the Spearman's rank correlation coefficient between the vector cosine similarities and human word similarity judgments, for over a decade the standard was to report Pearson product-moment correlation coefficient. When Resnik (1995) pioneered the technique of comparing computed measures of similarity with human similarity ratings, he used (Pearson) correlation as "one reasonable way to judge [computational measures of semantic similarity]".

The switch to Spearman correlation appears to have occurred in Gabrilovich and Markovitch (2007), who employed it without comment. Agirre et al. (2009) did provide a justification, saying, "In our belief Pearson is less informative, as the Pearson correlation suffers much when the scores of two systems are not linearly correlated, something which happens often due to the different nature of the techniques applied." Unfortunately, Agirre et al. (2009) mischaracterized the popularity of Spearman correlation by claiming that all researchers have used Spearman in evaluating WordSim-353 dataset (Finkelstein et al., 2002). This likely stems from a misinterpretation of Gabrilovich and Markovitch's Table 4, which compares their methodology with earlier studies using Spearman correlation. The latter authors apparently recomputed word relatedness with the associated algorithms, as the cited studies report Pearson correlation values.

Willmott (1981; 1982) specifically argues that Pearson correlation should not be used to evaluate model performance, and that RMSE is superior at comparing observed and simulated data.[3] However, as far as we know, no previous work has seriously considered evaluating the performance of computed word similarity scores using RMSE. Reliance on Spearman correlation may lead to incorrect conclusions regarding the quality of word vectors.

6 Conclusion

Retrofitting distributional word vectors using relational information in semantic resources can yield improvements in word similarity performance. Our fine-grained analysis of the original retrofitting process shows that 1) the evaluation metric matters: root-mean-square error (RMSE) is more sensitive to gains in performance than correlation measures; and 2) coverage matters: improvements offered by resources are highly dependent on their coverage of the evaluation benchmark. Future attempts to improve word vectors can only succeed if gains in word vector performance are inspected carefully.

Abstract

Contextual word representations derived from large-scale neural language models are successful across a diverse set of NLP tasks, suggesting that they encode useful and transferable features of language. To shed light on the linguistic knowledge they capture, we study the representations produced by several recent pretrained contextualizers (variants of ELMo, the OpenAI transformer language model, and BERT) with a suite of sixteen diverse probing tasks. We find that linear models trained on top of frozen contextual representations are competitive with state-of-the-art task-specific models in many cases, but fail on tasks requiring fine-grained linguistic knowledge (e.g., conjunct identification). To investigate the transferability of contextual word representations, we quantify differences in the transferability of individual layers within contextualizers, especially between recurrent neural networks (RNNs) and transformers. For instance, higher layers of RNNs are more task-specific, while transformer layers do not exhibit the same monotonic trend. In addition, to better understand what makes contextual word representations transferable, we compare language model pretraining with eleven supervised pretraining tasks. For any given task, pretraining on a closely related task yields better performance than language model pretraining (which is better on average) when the pretraining dataset is fixed. However, language model pretraining on *more data* gives the best results.

1 Introduction

Pretrained word representations (Mikolov et al., 2013; Pennington et al., 2014) are a key component of state-of-the-art neural NLP models. Traditionally, these word vectors are static—a single vector is assigned to each word. Recent work has explored *contextual* word representations (henceforth: CWRs), which assign each word a vector that is a function of the entire input sequence; this enables them to model the use of words in context. CWRs are typically the outputs of a neural network (which we call a *contextualizer*) trained on tasks with large datasets, such as machine translation (McCann et al., 2017) and language modeling (Peters et al., 2018a). CWRs are extraordinarily effective—using them in place of traditional static word vectors within the latest models leads to large gains across a variety of NLP tasks.

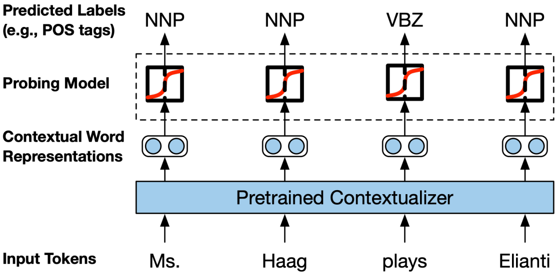

Figure 1: An illustration of the probing model setup used to study the linguistic knowledge within contextual word representations.

The broad success of CWRs indicates that they encode useful, transferable features of language. However, their *linguistic knowledge* and *transferability* are not yet well understood.

Recent work has explored the linguistic knowledge captured by language models and neural machine translation systems, but these studies often focus on a single phenomenon, e.g., knowledge of hierarchical syntax (Blevins et al., 2018) or morphology (Belinkov et al., 2017a). We extend prior work by studying CWRs with a diverse set of sixteen probing tasks designed to assess a wide array of phenomena, such as coreference, knowledge of semantic relations, and entity information, among

Minneapolis, Minnesota, June 2 - June 7, 2019.

others. The result is a broader view of the linguistic knowledge encoded within CWRs.

With respect to transferability, pretraining contextualizers on the language modeling task has had the most empirical success, but we can also consider pretraining contextualizers with other supervised objectives and probing their linguistic knowledge. We examine how the pretraining task affects the linguistic knowledge learned, considering twelve pretraining tasks and assessing transferability to nine target tasks.

Better understanding the linguistic knowledge and transferability of CWRs is necessary for their principled enhancement through new encoder architectures and pretraining tasks that build upon their strengths or alleviate their weaknesses (Linzen, 2018). This paper asks and answers:

1. What features of language do these vectors capture, and what do they miss? (§4)
2. How and why does transferability vary across representation layers in contextualizers? (§5)
3. How does the choice of pretraining task affect the vectors' learned linguistic knowledge and transferability? (§6)

We use probing models[1] (Shi et al., 2016b; Adi et al., 2017; Hupkes et al., 2018; Belinkov and Glass, 2019) to analyze the linguistic information within CWRs. Concretely, we generate features for words from pretrained contextualizers and train a model to make predictions from those features alone (Figure 1). If a simple model can be trained to predict linguistic information about a word (e.g., its part-of-speech tag) or a pair of words (e.g., their semantic relation) from the CWR(s) alone, we can reasonably conclude that the CWR(s) encode this information.

Our analysis reveals interesting insights such as:

1. Linear models trained on top of frozen CWRs are competitive with state-of-the-art task-specific models in many cases, but fail on tasks requiring fine-grained linguistic knowledge. In these cases, we show that *task-trained contextual features* greatly help with encoding the requisite knowledge.
2. The first layer output of long short-term memory (LSTM) recurrent neural networks is consistently the most transferable, whereas it is the middle layers for transformers.
3. Higher layers in LSTMs are more task-specific (and thus less general), while the transformer layers do not exhibit this same monotonic increase in task-specificity.
4. Language model pretraining yields representations that are more transferable *in general* than eleven other candidate pretraining tasks, though pretraining on related tasks yields the strongest results for individual end tasks.

2 Probing Tasks

We construct a suite of sixteen diverse English probing tasks and use it to better understand the linguistic knowledge contained within CWRs. In contrast to previous studies that analyze the properties and task performance of sentence embeddings (Adi et al., 2017; Conneau et al., 2018, *inter alia*), we specifically focus on understanding the CWRs of individual or pairs of words. We release this analysis toolkit to support future work in probing the contents of representations.[2] See Appendix A for details about task setup.

2.1 Token Labeling

The majority of past work in probing the internal representations of neural models has examined various token labeling tasks, where a decision is made independently for each token (Belinkov et al., 2017a,b; Blevins et al., 2018, *inter alia*). We synthesize these disparate studies and build upon them by proposing additional probing tasks.

The **part-of-speech tagging (POS)** task assesses whether CWRs capture basic syntax. We experiment with two standard datasets: the Penn Treebank (PTB; Marcus et al., 1993) and the Universal Dependencies English Web Treebank (UD-EWT; Silveira et al., 2014).

The **CCG supertagging (CCG)** task assesses the vectors' fine-grained information about the syntactic roles of words in context. It is considered "almost parsing" (Bangalore and Joshi, 1999), since a sequence of supertags maps a sentence to a small set of possible parses. We use CCGbank (Hockenmaier and Steedman, 2007), a conversion of the PTB into CCG derivations.

The **syntactic constituency ancestor tagging** tasks are designed to probe the vectors' knowledge of hierarchical syntax. For a given word, the probing model is trained to predict the constituent la-

bel of its parent **(Parent)**, grandparent **(GParent)**, or great-grandparent **(GGParent)** in the phrase-structure tree (from the PTB).

In the **semantic tagging** task (**ST**), tokens are assigned labels that reflect their semantic role in context. These semantic tags assess lexical semantics, and they abstract over redundant POS distinctions and disambiguate useful cases within POS tags. We use the dataset of Bjerva et al. (2016); the tagset has since been developed as part of the Parallel Meaning Bank (Abzianidze et al., 2017).

Preposition supersense disambiguation is the task of classifying a preposition's lexical semantic contribution (the function; **PS-fxn**) and the semantic role or relation it mediates (the role; **PS-role**). This task is a specialized kind of word sense disambiguation, and examines one facet of lexical semantic knowledge. In contrast to the tagging tasks above, the model is trained and evaluated on single-token prepositions (rather than making a decision for every token in a sequence). We use the STREUSLE 4.0 corpus (Schneider et al., 2018); example sentences appear in Figure 2.

The **event factuality (EF)** task involves labeling phrases with the factuality of the events they describe (Saurí and Pustejovsky, 2009, 2012; de Marneffe et al., 2012). For instance, in the following example reproduced from Rudinger et al. (2018), "(1a) conveys that the leaving didn't happen, while the superficially similar (1b) does not".

(1) a. Jo didn't remember to **leave**.
b. Jo didn't remember **leaving**.

We use the Universal Decompositional Semantics It Happened v2 dataset (Rudinger et al., 2018), and the model is trained to predict a (non)factuality value in the range $[-3, 3]$. Unlike the tagging tasks above, this task is treated as a regression problem, where a prediction is made only for tokens corresponding to events (rather than every token in a sequence). Performance is measured using Pearson correlation (r); we report ($r \times 100$) so metrics for all tasks fall between 0 and 100.

2.2 Segmentation

Several of our probing tasks involve segmentation using BIO or IO tags. Here the model is trained to predict labels from *only* a single word's CWR.

Syntactic chunking (Chunk) tests whether CWRs contain notions of spans and boundaries; the task is to segment text into shallow constituent chunks. We use the CoNLL 2000 shared task dataset (Tjong Kim Sang and Buchholz, 2000).

Named entity recognition (NER) examines whether CWRs encode information about entity types. We use the CoNLL 2003 shared task dataset (Tjong Kim Sang and De Meulder, 2003).

Grammatical error detection (GED) is the task of identifying tokens which need to be edited in order to produce a grammatically correct sentence. Given that CWRs are extracted from models trained on large amounts of grammatical text, this task assesses whether embeddings encode features that indicate anomalies in their input (in this case, ungrammaticality). We use the First Certificate in English (Yannakoudakis et al., 2011) dataset, converted into sequence-labeling format by Rei and Yannakoudakis (2016).

The **conjunct identification (Conj)** task challenges the model to identify the tokens that comprise the conjuncts in a coordination construction. Doing so requires highly specific syntactic knowledge. The data comes from the coordination-annotated PTB of Ficler and Goldberg (2016).

2.3 Pairwise Relations

We also design probing tasks that examine whether relationships *between* words are encoded in CWRs. In these tasks, given a word pair w_1, w_2, we input $[w_1, w_2, w_1 \odot w_2]$ into the probing model; it is trained to predict information about the relation between the tokens (Belinkov, 2018).

We distinguish between **arc prediction** and **arc classification** tasks. Arc prediction is a binary classification task, where the model is trained to identify *whether* a relation exists between two tokens. Arc classification is a multiclass classification task, where the model is provided with two tokens that are linked via some relationship and trained to identify *how* they are related.

For example, in the **syntactic dependency arc prediction** task, the model is given the representations of two tokens (w_a, w_b) and trained to predict whether the sentence's syntactic dependency parse contains a dependency arc with w_a as the head and w_b as the modifier. The **syntactic dependency arc classification** task presents the model with the representations of two tokens (w_{head}, w_{mod}), where w_{mod} is the modifier of w_{head}, and the model is trained to predict the type of syntactic relation that link them (the label on that dependency arc). We use the PTB (converted to UD) and the UD-EWT.

Similarly, **semantic dependency arc prediction** trains the model to predict whether two tokens are connected by a semantic dependency arc, while the **semantic dependency arc classification** task trains models to classify the semantic relations between tokens. We use the dataset from the SemEval 2015 shared task (Oepen et al., 2015) with the DELPH-IN MRS-Derived Semantic Dependencies (DM) target representation.

The syntactic and semantic dependency arc prediction and classification tasks are closely related to state-of-the-art models for semantic and syntactic dependency parsing, which score pairs of CWRs to make head attachment and arc labeling decisions (Dozat and Manning, 2016, 2018).

To generate negative examples for the dependency arc prediction tasks, we take each positive example (w_{head}, w_{mod}) and generate a new negative example (w_{rand}, w_{mod}). w_{rand} is a random token in the sentence that is not the head of w_{mod}. Thus, the datasets used in these tasks are balanced.

We also consider a **coreference arc prediction** task, where the model is trained to predict whether two entities corefer from their CWRs. We use the dataset from the CoNLL 2012 shared task (Pradhan et al., 2012). To generate negative examples, we follow a similar procedure as the dependency arc prediction tasks: given a positive example (w_a, w_b), where w_b occurs after w_a and the two tokens share a coreference cluster, we create a negative example (w_{random_entity}, w_b), where w_{random_entity} is a token that occurs before w_b and belongs to a different coreference cluster.

3 Models

Probing Model We use a linear model as our probing model; limiting its capacity enables us to focus on what information can be *easily* extracted from CWRs. See Appendix B for probing model training hyperparameters and other details.

Contextualizers We study six publicly-available models for contextualized word representation in English.

ELMo (Peters et al., 2018a) concatenates the output of two contextualizers independently trained on the bidirectional language modeling (biLM) task. **ELMo (original)** uses a 2-layer LSTM for contextualization. We also study two variations from Peters et al. (2018b): **ELMo (4-layer)** uses a 4-layer LSTM, and **ELMo (transformer)** uses a 6-layer transformer (Vaswani et al., 2017). Each of these models is trained on 800M tokens of sentence-shuffled newswire text (the 1 Billion Word Benchmark; Chelba et al., 2014).

The **OpenAI transformer** (Radford et al., 2018) is a left-to-right 12-layer transformer language model trained on 800M tokens of contiguous text from over 7,000 unique unpublished books (BookCorpus; Zhu et al., 2015).

BERT (Devlin et al., 2018) uses a bidirectional transformer jointly trained on a masked language modeling task and a next sentence prediction task. The model is trained on BookCorpus and the English Wikipedia, a total of approximately 3300M tokens. We study **BERT (base, cased)**, which uses a 12-layer transformer, and **BERT (large, cased)**, which uses a 24-layer transformer.

4 Pretrained Contextualizer Comparison

To better understand the linguistic knowledge captured by pretrained contextualizers, we analyze each of their layers with our set of probing tasks. These contextualizers differ in many respects, and it is outside the scope of this work to control for all differences between them. We focus on probing the models that are available to us, leaving a more systematic comparison of training regimes and model architectures to future work.

4.1 Experimental Setup

Our probing models are trained on the representations produced by the individual layers of each contextualizer. We also compare to a linear probing model trained on noncontextual vectors (300-dimensional GloVe trained on the cased Common Crawl; Pennington et al., 2014) to assess the gains from contextualization.

Pretrained Representation			POS						Supersense ID		
	Avg.	CCG	PTB	EWT	Chunk	NER	ST	GED	PS-Role	PS-Fxn	EF

Table 1: Performance of the best layerwise linear probing model for each contextualizer compared against a GloVe-based linear probing baseline and the previous state of the art. The best contextualizer for each task is bolded. Results for all layers on all tasks, and papers describing the prior state of the art, are given in Appendix D.

4.2 Results and Discussion

Table 1 compares each contextualizer's best-performing probing model with the GloVe baseline and the previous state of the art for the task (excluding methods that use pretrained CWRs).[3,4]

With just a linear model, we can readily extract much of the information needed for high performance on various NLP tasks. In all cases, CWRs perform significantly better than the noncontextual baseline. Indeed, we often see probing models rivaling or exceeding the performance of (often carefully tuned and task-specific) state-of-the-art models. In particular, the linear probing model surpasses the published state of the art for grammatical error detection and preposition supersense identification (both role and function).

Comparing the ELMo-based contextualizers, we see that ELMo (4-layer) and ELMo (original) are essentially even, though both recurrent models outperform ELMo (transformer). We also see that the OpenAI transformer significantly underperforms the ELMo models and BERT. Given that it is also the only model trained in a unidirectional (left-to-right) fashion, this reaffirms that bidirectionality is a crucial component for the highest-quality contextualizers (Devlin et al., 2018). In addition, the OpenAI transformer is the only model trained on lowercased text, which hinders its performance on tasks like NER. BERT significantly improves over the ELMo and OpenAI models.

Our probing task results indicate that current methods for CWR do not capture much transferable information about entities and coreference phenomena in their input (e.g., the NER results in Table 1 and the coreference arc prediction results in Appendix D). To alleviate this weakness, future work could augment pretrained contextualizers with explicit entity representations (Ji et al., 2017; Yang et al., 2017; Bosselut et al., 2017).

Probing Failures While probing models are at or near state-of-the-art performance across a number of tasks, they also do not perform as well on several others, including NER, grammatical error detection, and conjunct identification. This may occur because (1) the CWR simply does not encode the pertinent information or any predictive correlates, or (2) the probing model does not have the capacity necessary to extract the information or predictive correlates from the vector. In the former case, learning *task-specific contextual features* might be necessary for encoding the requisite task-specific information into the CWRs. Learning task-specific contextual features with a contextual probing model also helps with (2), but we would expect the results to be comparable to increasing the probing model's capacity.

To better understand the failures of our probing model, we experiment with (1) a contextual probing model that uses a task-trained LSTM (unidirectional, 200 hidden units) before the linear output layer (thus adding task-specific contextualization) or (2) replacing the linear probing model with a multilayer perceptron (MLP; adding more parameters to the probing model: a single 1024d hidden layer activated by ReLU). These alternate probing models have nearly the same number of parameters (LSTM + linear has slightly fewer).

We also compare to a full-featured model to

---

[3] See Appendix C for references to the previous state of the art (without pretraining).

[4] For brevity, in this section we omit probing tasks that cannot be compared to prior work. See Appendix D for pretrained contextualizer performance for all layers and all tasks.

Probing Model	NER	GED	Conj	GGParent
Linear	82.85	29.37	38.72	67.50
MLP (1024d)	87.19	47.45	55.09	78.80
LSTM (200d) + Linear	**88.08**	**48.90**	**78.21**	**84.96**
BiLSTM (512d) + MLP (1024d)	90.05	48.34	87.07	90.38

Table 2: Comparison of different probing models trained on ELMo (original); best-performing probing model is bolded. Results for each probing model are from the highest-performing contextualizer layer. Enabling probing models to learn task-specific contextual features (with LSTMs) yields outsized benefits in tasks requiring highly specific information.

estimate an upper bound on performance for our probing setup. In this model, the CWRs are inputs to a 2-layer BiLSTM with 512 hidden units, and the output is fed into a MLP with a single 1024-dimensional hidden layer activated by a ReLU to predict a label. A similar model, augmented with a conditional random field (CRF; Lafferty et al., 2001), achieved state-of-the-art results on the CoNLL 2003 NER dataset (Peters et al., 2018a). We remove the CRF, since other probing models have no global context.

For this experiment, we focus on the ELMo (original) pretrained contextualizer. Table 2 presents the performance of the best layer within each alternative probing model on the two tasks with the largest gap between the linear probing model and state-of-the-art methods: NER and grammatical error detection. We also include great-grandparent prediction and conjunct identification, two tasks that require highly specific syntactic knowledge. In all cases, we see that adding more parameters (either by replacing the linear model with a MLP, or using a contextual probing model) leads to significant gains over the linear probing model. On NER and grammatical error detection, we observe very similar performance between the MLP and LSTM + Linear models—this indicates that the probing model simply needed more capacity to extract the necessary information from the CWRs. On conjunct identification and great-grandparent prediction, two tasks that probe syntactic knowledge unlikely to be encoded in CWRs, adding parameters as a task-trained component of our probing model leads to large gains over simply adding parameters to the probing model. This indicates that the pretrained contextualizers do not capture the information necessary for the task, since such information is learnable by a task-specific contextualizer.

This analysis also reveals insights about contextualizer fine-tuning, which seeks to specialize the CWRs for an end task (Howard and Ruder, 2018; Radford et al., 2018; Devlin et al., 2018). Our results confirm that task-trained contextualization is important when the end task requires specific information that may not be captured by the pretraining task (§4). However, such end-task–specific contextualization can come from either fine-tuning CWRs or using fixed output features as inputs to a task-trained contextualizer; Peters et al. (2019) begins to explore when each approach should be applied.

5 Analyzing Layerwise Transferability

We quantify the transferability of CWRs by how well they can do on the range of probing tasks—representations that are more transferable will perform better than alternatives across tasks. When analyzing the representations produced by each layer of pretrained contextualizers, we observe marked patterns in layerwise transferability (Figure 3). The first layer of contextualization in recurrent models (original and 4-layer ELMo) is consistently the most transferable, even outperforming a scalar mix of layers on most tasks (see Appendix D for scalar mix results). Schuster et al. (2019) see the same trend in English dependency parsing. By contrast, transformer-based contextualizers have no single most-transferable layer; the best performing layer for each task varies, and is usually near the middle. Accordingly, a scalar mix of transformer layers outperforms the best individual layer on most tasks (see Appendix D).

Pretraining encourages the model to encode pretraining-task–specific information; they learn transferable features incidentally. We hypothesize that this is an inherent trade-off—since these models used fixed-sized vector representations, task-specificity comes at the cost of generality and transferability. To investigate the task-specificity of the representations generated by each contextualizer layer, we assess how informative each layer of representation is for the pretraining task, essentially treating it as a probe.

5.1 Experimental Setup

We focus on the ELMo-based models, since the authors have released code for training their con-

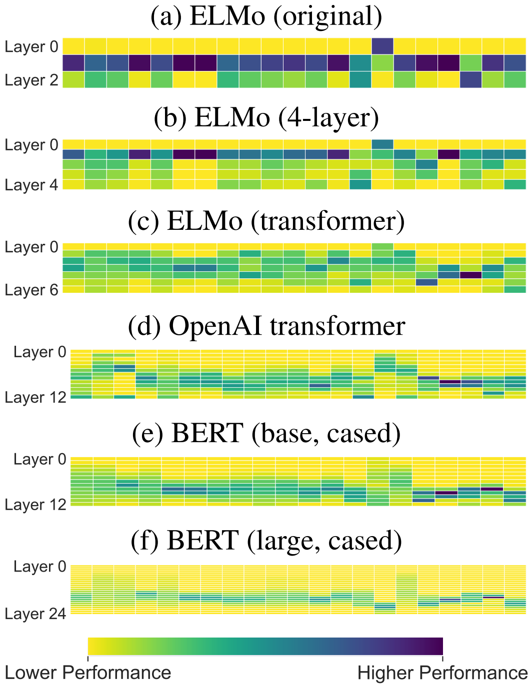

Figure 3: A visualization of layerwise patterns in task performance. Each column represents a probing task, and each row represents a contextualizer layer.

textualizers. Furthermore, the ELMo-based models facilitate a controlled comparison—they only differ in the contextualizer architecture used.

We evaluate how well CWR features perform the pretraining task—bidirectional language modeling. Specifically, we take the pretrained representations for each layer and relearn the language model softmax classifiers used to predict the next and previous token. The ELMo models are trained on the Billion Word Benchmark, so we retrain the softmax classifier on similar data to mitigate any possible effects from domain shift. We split the held-out portion of the Billion Word Benchmark into train (80%, 6.2M tokens) and evaluation (20%, 1.6M tokens) sets and use this data to retrain and evaluate the softmax classifiers. We expect that biLM perplexity will be lower when training the softmax classifiers on representations from layers that capture more information about the pretraining task.

5.2 Results and Discussion

Figure 4 presents the performance of softmax classifiers trained to perform the bidirectional language modeling task, given just the CWRs as input. We notice that higher layers in recurrent models consistently achieve lower perplexities. Interestingly, we see that layers 1 and 2 in the 4-layer ELMo model have very similar performance—this warrants further exploration. On the other hand, the layers of the ELMo (transformer) model do not exhibit such a monotonic increase. While the topmost layer is best (which we expected, since this is the vector originally fed into a softmax classifier during pretraining), the middle layers show varying performance. Across all models, the representations that are better-suited for language modeling are also those that exhibit worse probing task performance (Figure 3), indicating that contextualizer layers trade off between encoding general and task-specific features.

These results also reveal a difference in the layerwise behavior of LSTMs and transformers; moving up the LSTM layers yields more task-specific representations, but the same does not hold for transformers. Better understanding the differences between transformers and LSTMs is an active area of research (Chen et al., 2018; Tang et al., 2018), and we leave further exploration of these observations to future work.

These observations motivate the gradual unfreezing method of Howard and Ruder (2018), where the model layers are progressively unfrozen (starting from the final layer) during the fine-tuning process. Given our observation that higher-level LSTM layers are less general (and more pretraining task-specific), they likely have to be fine-tuned a bit more in order to make them appropriately task specific. Meanwhile, the base layer of the LSTM already learns highly transferable features, and may not benefit from fine-tuning.

6 Transferring Between Tasks

Successful pretrained contextualizers have used self-supervised tasks such as bidirectional language modeling (Peters et al., 2018a) and next sentence prediction (Devlin et al., 2018), which enable the use of large, unannotated text corpora. However, contextualizers can also be pretrained on explicitly supervised objectives, as done in pretrained *sentence* embedding methods (Conneau et al., 2017). To better understand how the choice of pretraining task affects the linguistic knowledge within and transferability of CWRs, we compare pretraining on a range of different explicitly-supervised tasks with bidirectional language model pretraining.

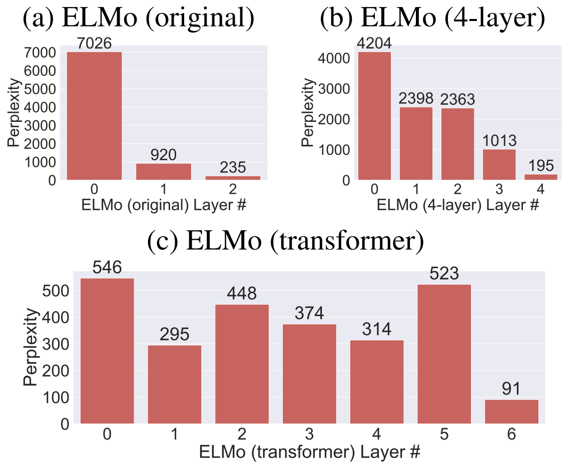

Figure 4: Bidirectional language modeling as a probe: average of forward and backward perplexity (lower is better) of each ELMo contextualizer layer. We see a monotonic decrease in BiLM perplexity when trained on the outputs of higher LSTM layers, but transformer layers do not exhibit the same pattern.

Pretraining Task	Layer Average Target Task Performance

Table 3: Performance (averaged across target tasks) of contextualizers pretrained on a variety of tasks.

6.1 Experimental Setup

To ensure a controlled comparison of different pretraining tasks, we fix the contextualizer's architecture and pretraining dataset. All of our contextualizers use the ELMo (original) architecture, and the training data from each of the pretraining tasks is taken from the PTB. Each of the (identical) models thus see the same tokens, but the supervision signal differs.[5] We compare to (1) a noncontextual baseline (GloVe) to assess the effect of contextualization, (2) a randomly-initialized, untrained ELMo (original) baseline to measure the effect of pretraining, and (3) the ELMo (original) model pretrained on the Billion Word Benchmark to examine the effect of training the bidirectional language model on more data.

6.2 Results and Discussion

Table 3 presents the average target task performance of each layer in contextualizers pretrained on twelve different tasks (biLM and the eleven tasks from §2 with PTB annotations). Bidirectional language modeling pretraining is the most effective on average. However, the settings that achieve the highest performance for individual target tasks often involve transferring between related tasks (not shown in Table 3; see Appendix E). For example, when probing CWRs on the syntactic dependency arc classification (EWT) task, we see the largest gains from pretraining on the task itself, but with a different dataset (PTB). However, pretraining on syntactic dependency arc prediction (PTB), CCG supertagging, chunking, the ancestor prediction tasks, and semantic dependency arc classification all give better performance than bidirectional language model pretraining.

Although related task transfer is beneficial, we naturally see stronger results from training on more data (the ELMo original BiLM trained on the Billion Word Benchmark). This indicates that the transferability of pretrained CWRs relies on pretraining on large corpora, emphasizing the utility and importance of self-supervised pretraining.

Furthermore, layer 0 of the BiLM is the highest-performing single layer among PTB-pretrained contextualizers. This observation suggests that lexical information is the source of the language model's initial generalizability, since layer 0 is the output of a character-level convolutional neural network with no token-level contextual information.

7 Related Work

Methodologically, our work is most similar to Shi et al. (2016b), Adi et al. (2017), and Hupkes et al. (2018), who use the internal representations of neural models to predict properties of interest. Conneau et al. (2018) construct probing tasks to study the linguistic properties of sentence embed-

---

[5] We omit the OpenAI transformer and BERT from this comparison, since code for pretraining these contextualizers is not publicly available.

ding methods. We focus on contextual word representations, which have achieved state-of-the-art results on a variety of tasks, and examine a broader range of linguistic knowledge.

In contemporaneous work, Tenney et al. (2019) evaluate CoVe (McCann et al., 2017), ELMo (Peters et al., 2018a), the OpenAI Transformer (Radford et al., 2018), and BERT (Devlin et al., 2018) on a variety of sub-sentence linguistic analysis tasks. Their results also suggest that the aforementioned pretrained models for contextualized word representation encode stronger notions of syntax than higher-level semantics. They also find that using a scalar mix of output layers is particularly effective in deep transformer-based models, aligned with our own probing results and our observation that transformers tend to encode transferable features in their intermediate layers. Furthermore, they find that ELMo's performance cannot be explained by a model with access to only local context, indicating that ELMo encodes linguistic features from distant tokens.

Several other papers have examined how architecture design and choice of pretraining task affect the quality of learned CWRs. Peters et al. (2018b) study how the choice of neural architecture influences the end-task performance and qualitative properties of CWRs derived from bidirectional language models (ELMo). Bowman et al. (2018) compare a variety of pretraining tasks and explore the the impact of multitask learning.

Prior work has employed a variety of other methods to study the learned representations in neural models, such as directly examining the activations of individual neurons (Karpathy et al., 2015; Li et al., 2015; Shi et al., 2016a, *inter alia*), ablating components of the model and dataset (Kuncoro et al., 2017; Gaddy et al., 2018; Khandelwal et al., 2018), or interpreting attention mechanisms (Bahdanau et al., 2015); see Belinkov and Glass (2019) for a recent survey. One particularly relevant line of work involves the construction of synthetic tasks that a model can only solve if it captures a particular phenomenon (Linzen et al., 2016; Jumelet and Hupkes, 2018; Wilcox et al., 2018; Futrell and Levy, 2019, *inter alia*). Zhang and Bowman (2018) compare the syntactic knowledge of language models and neural machine translation systems. We widen the range of pretraining tasks and target probing model tasks to gain a more complete picture. We also focus on a stronger contextualizer architecture, ELMo (original), that has produced state-of-the-art results.

Several studies have sought to intrinsically evaluate noncontextual word representations with word similarity tasks, such as analogies (Mikolov et al., 2013). These methods differ from our approach in that they require no extra parameters and directly assess the vectors, while our probing models must be trained. In this regard, our method is similar to QVEC (Tsvetkov et al., 2015).

8 Conclusion

We study the linguistic knowledge and transferability of contextualized word representations with a suite of sixteen diverse probing tasks. The features generated by pretrained contextualizers are sufficient for high performance on a broad set of tasks. For tasks that require specific information not captured by the contextual word representation, we show that learning task-specific contextual features helps to encode the requisite knowledge. In addition, our analysis of patterns in the transferability of contextualizer layers shows that the lowest layer of LSTMs encodes the most transferable features, while transformers' middle layers are most transferable. We find that higher layers in LSTMs are more task-specific (and thus less general), while transformer layers do not exhibit this same monotonic increase in task-specificity. Prior work has suggested that higher-level contextualizer layers may be expressly encoding higher-level semantic information. Instead, it seems likely that certain high-level semantic phenomena are incidentally useful for the contextualizer's pretraining task, leading to their presence in higher layers. Lastly, we find that bidirectional language model pretraining yields representations that are more transferable *in general* than eleven other candidate pretraining tasks.

Acknowledgments

We thank Johannes Bjerva for sharing the semantic tagging dataset used in Bjerva et al. (2016). We also thank the members of the Noah's ARK group at the University of Washington, the researchers at the Allen Institute for Artificial Intelligence, and the anonymous reviewers for their valuable feedback. Appendices

A Probing Task Setup Details

Syntactic Constituency Ancestor Tagging We remove the top-level ROOT node in each sentence. For words that do not have a parent, grandparent, or great-grandparent, we set the label to ”None”. The example is then treated as any other, and the probing model is required to predict this ”None” label during training and evaluation.

Preposition Supersense Disambiguation Since we focus on the linguistic knowledge within individual or pairs of CWRs, we train and evaluate our probing models on only single-word adpositions.

Conjunct Identification Our probing models are only trained and evaluated on sentences with a coordination construction in them.

B Probing Model Training Details

Our probing models are trained with Adam (Kingma and Ba, 2015), using a learning rate of 0.001. We train for 50 epochs, using early stopping with a patience of 3. Our models are implemented in the AllenNLP framework (Gardner et al., 2018).

For contextualizers that use subword representations (e.g., the OpenAI transformer and BERT), we aggregate subword representations into token representations by taking a token's representation to be the representation of its final subword.

C References to State-of-the-Art Task-Specific Models (Without Pretraining)

POS (EWT)	95.82 (Yasunaga et al., 2018)
Chunk	95.77 (Hashimoto et al., 2017)
NER	91.38 (Hashimoto et al., 2017)
ST	95.15 (Bjerva et al., 2016)
GED	39.83 (Rei and Sogaard, 2019)
PS-Role	66.89 (Schneider et al., 2018)
PS-Fxn	78.29 (Schneider et al., 2018)
EG	77.10 (Rudinger et al., 2018)

Table 4: Performance of prior state of the art models (without pretraining) for each task.

Note that the performance reported in this paper for the preposition supersense identification models of Schneider et al. (2018) differs from their published result. Their published result is the accuracy on all adpositions; since we only train and evaluate our model on single-word adpositions, the number we report in this paper is the performance of the Schneider et al. (2018) model on only single-word adpositions.

Mutual Information Maximization for Simple and Accurate Part-Of-Speech Induction

Karl Stratos
Toyota Technological Institute at Chicago
`stratos@ttic.edu`

Abstract

We address part-of-speech (POS) induction by maximizing the mutual information between the induced label and its context. We focus on two training objectives that are amenable to stochastic gradient descent (SGD): a novel generalization of the classical Brown clustering objective and a recently proposed variational lower bound. While both objectives are subject to noise in gradient updates, we show through analysis and experiments that the variational lower bound is robust whereas the generalized Brown objective is vulnerable. We obtain strong performance on a multitude of datasets and languages with a simple architecture that encodes morphology and context.

1 Introduction

We consider information theoretic objectives for POS induction, an important unsupervised learning problem in computational linguistics (Christodoulopoulos et al., 2010). The idea is to make the induced label syntactically informative by maximizing its mutual information with respect to local context. Mutual information has long been a workhorse in the development of NLP techniques, for instance the classical Brown clustering algorithm (Brown et al., 1992). But its role in today's deep learning paradigm is less clear and a subject of active investigation (Belghazi et al., 2018; Oord et al., 2018).

We focus on fully differentiable objectives that can be plugged into an automatic differentiation system and efficiently optimized by SGD. Specifically, we investigate two training objectives. The first is a novel generalization of the Brown clustering objective obtained by relaxing the hard clustering constraint. The second is a recently proposed variational lower bound on mutual information (McAllester, 2018).

A main challenge in optimizing these objectives is the difficulty of stochastic optimization. Each objective involves entropy estimation which is a nonlinear function of all data and does not decompose over individual instances. This makes the gradients estimated on minibatches inconsistent with the true gradient estimated from the entire dataset. To our surprise, in practice we are able to optimize the variational objective effectively but not the generalized Brown objective. We analyze the estimated gradients and show that the inconsistency error is only logarithmic in the former but linear in the latter.

We validate our approach on POS induction by attaining strong performance on a multitude of datasets and languages. Our simple architecture that encodes morphology and context reaches up to 80.1 many-to-one accuracy on the 45-tag Penn WSJ dataset and achieves 4.7% absolute improvement to the previous best result on the universal treebank. Unlike previous works, our model does not rely on computationally expensive structured inference or hand-crafted features.

2 Background

2.1 Information Theory

Mutual information. Mutual information between two random variables measures the amount of information gained about one variable by observing the other. Unlike the Pearson correlation coefficient which only captures the degree of linear relationship, mutual information captures any nonlinear statistical dependencies (Kinney and Atwal, 2014).

Formally, the mutual information between discrete random variables X, Y with a joint distribution p is the KL divergence between the joint distribution $p(x, y)$ and the product distribution

Proceedings of NAACL-HLT 2019, pages 1095–1104
Minneapolis, Minnesota, June 2 - June 7, 2019.

$p(x)p(y)$ over X, Y:

$$I(X,Y) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)}$$
$$= \mathop{\mathbf{E}}_{(x,y)\sim p} \left[\log \frac{p(x,y)}{p(x)p(y)} \right] \quad (1)$$

It is thus nonnegative and zero iff X and Y are independent. We assume that the marginals $p(x)$ and $p(y)$ are nonzero.

It is insightful to write mutual information in terms of entropy. The entropy of X is

$$H(X) = -\sum_x p(x) \log p(x) = \mathop{\mathbf{E}}_{x\sim p} \left[\log \frac{1}{p(x)} \right]$$

corresponding to the number of bits for encoding the behavior of X under p.[1] The entropy of X given the information that Y equals y is

$$H(X|Y=y) = -\sum_x p(x|y) \log p(x|y)$$

Taking expectation over Y yields the conditional entropy of X given Y:

$$H(X|Y) = \sum_y p(y) \left(-\sum_x p(x|y) \log p(x|y) \right)$$
$$= \mathop{\mathbf{E}}_{(x,y)\sim p} \left[\log \frac{1}{p(x|y)} \right] \quad (2)$$

By manipulating the terms in mutual information, we can write

$$I(X,Y) = \mathop{\mathbf{E}}_{x\sim p} \left[\log \frac{1}{p(x)} \right] - \mathop{\mathbf{E}}_{(x,y)\sim p} \left[\log \frac{1}{p(x|y)} \right]$$
$$= H(X) - H(X|Y)$$

which expresses the amount of information on X gained by observing Y. Switching X and Y shows that $I(X,Y) = H(Y) - H(Y|X)$.

Cross entropy. If p and q are full-support distributions over the same discrete set, the cross entropy between p and q is the asymmetric quantity

$$H(p,q) = -\sum_x p(x) \log q(x) = \mathop{\mathbf{E}}_{x\sim p} \left[\log \frac{1}{q(x)} \right]$$

corresponding to the number of bits for encoding the behavior of X under p by using q. It is revealing to write entropy in terms of KL divergence. Multiplying the term inside the log by $p(x)/p(x)$ we derive

$$H(p,q) = \mathop{\mathbf{E}}_{x\sim p} \left[\log \frac{1}{p(x)} \right] + \mathop{\mathbf{E}}_{x\sim p} \left[\log \frac{p(x)}{q(x)} \right]$$
$$= H(p) + D_{\mathrm{KL}}(p||q)$$

Thus $H(p,q) \geq H(p)$ with equality iff $p = q$.

2.2 Brown Clustering

Our primary inspiration comes from Brown clustering (Brown et al., 1992), a celebrated word clustering technique that had been greatly influential in unsupervised and semi-supervised NLP long before continuous representations based on neural networks were popularized. It finds a clustering $C : V \to [m]$ of the vocabulary V into m classes by optimizing the mutual information between the clusters of a random bigram (X, Y). Given a corpus of N words $(x_1 \ldots x_N)$, it assumes a uniform distribution over consecutive word pairs (x_{i-1}, x_i) and optimizes the following empirical objective

$$\max_{C:V\to[m]} \sum_{c,c'\in[m]} \frac{\#(c,c')}{N} \log \left(\frac{\#(c,c')N}{\#(c)\#(c')} \right) \quad (3)$$

where $\#(c, c')$ denotes the number of occurrences of the cluster pair (c, c') under C. While this optimization is intractable, Brown et al. (1992) derive an effective heuristic that 1. initializes m most frequent words as singleton clusters and 2. repeatedly merges a pair of clusters that yields the smallest decrease in mutual information. The resulting clusters have been useful in many applications (Koo et al., 2008; Owoputi et al., 2013) and has remained a strong baseline for POS induction decades later (Christodoulopoulos et al., 2010). But the approach is tied to highly nontrivial combinatorial optimization tailored for the specific problem and difficult to scale/generalize.

3 Objectives

In the remainder of the paper, we assume discrete random variables $(X, Y) \in \mathcal{X} \times \mathcal{Y}$ with a joint distribution D that represent naturally co-occurring observations. In POS induction experiments, we will set D to be a context-word distribution where Y is a random word and X is the surrounding context of Y (thus $\mathcal{Y}$ is the vocabulary and $\mathcal{X}$ is the space of all possible contexts). Let m be the number of labels to induce. We introduce a pair of trainable classifiers that define conditional label distributions $p(z|x)$ and $q(z|y)$ for all $x \in \mathcal{X}$,

---

[1] The paper will always assume log base 2 to accommodate the bit interpretation.

$y \in \mathcal{Y}$, and $z \in [m]$. For instance, $p(\cdot|y)$ can be the output of a softmax layer on some transformation of y.

Our goal is to learn these classifiers without observing the latent variable z by optimizing an appropriate objective. For training data, we assume N iid samples $(x_1, y_1) \dots (x_N, y_N) \sim D$.

3.1 Generalized Brown Objective

Our first attempt is to maximize the mutual information between the predictions of p and q. Intuitively, this encourages p and q to agree on some annotation scheme (up to a permutation of labels), modeling the dynamics of inter-annotator agreement (Artstein, 2017). It can be seen as a differentiable generalization of the Brown clustering objective. To this end, define

$$\begin{aligned} p(z) &= \mathop{\mathbf{E}}_{x \sim D}\left[p(z|x)\right] & \forall z \in [m] \\ q(z) &= \mathop{\mathbf{E}}_{y \sim D}\left[q(z|y)\right] & \forall z \in [m] \end{aligned}$$

The mutual information between the predictions of p and q on a single sample (x, y) is then

$$J^{\text{mi}}_{x,y} = \sum_{z,z'} p(z|x) q(z'|y) \log \frac{p(z|x) q(z'|y)}{p(z) q(z')}$$

and the objective (to maximize) is

$$J^{\text{mi}} = \mathop{\mathbf{E}}_{(x,y) \sim D}\left[J^{\text{mi}}_{x,y}\right]$$

Note that this becomes exactly the original Brown objective (3) if (X, Y) is defined as a random bigram and p and q are tied and constrained to be a hard clustering.

Empirical objective. In practice, we work with the value of empirical mutual information $\widehat{J}^{\text{mi}}$ estimated from the training data:

$$\begin{aligned} \hat{p}(z) &= \frac{1}{N} \sum_{i=1}^{N} p(z|x_i) & \forall z \in [m] \\ \hat{q}(z) &= \frac{1}{N} \sum_{i=1}^{N} q(z|y_i) & \forall z \in [m] \\ \widehat{J}^{\text{mi}}_i &= \sum_{z,z'} p(z|x_i) q(z'|y_i) \log \frac{p(z|x_i) q(z'|y_i)}{\hat{p}(z) \hat{q}(z')} \\ \widehat{J}^{\text{mi}} &= \frac{1}{N} \sum_{i=1}^{N} \widehat{J}^{\text{mi}}_i & (4) \end{aligned}$$

Our task is to maximize (4) by taking gradient steps at random minibatches. Note, however, that the objective cannot be written as a sum of local objectives because we take log of the estimates $\hat{q}(z)$ and $\hat{p}(z)$ computed from all samples. This makes the stochastic gradient estimator biased (i.e., it does not match the gradient of (4) in expectation) and compromises the correctness of SGD. This bias is investigated more closely in Section 4.

3.2 Variational Lower Bound

The second training objective we consider can be derived in a rather heuristic but helpful manner as follows. Since X, Y are always drawn together, if $q(z|y)$ is the target label distribution for the pair (x, y), then we can train $p(z|x)$ by minimizing the cross entropy between q and p over samples

$$H(q, p) = \mathop{\mathbf{E}}_{(x,y) \sim D}\left[-\sum_{z} q(z|y) \log p(z|x)\right]$$

which is minimized to zero at $p = q$. However, q is also untrained and needs to be trained along with p. Thus this loss alone admits trivial solutions such as setting $p(1|x) = p(1|y) = 1$ for all (x, y). This undesirable behavior can be prevented by simultaneously maximizing the entropy of q. Let Z denote a random label from q with distribution $q(z) = \mathop{\mathbf{E}}_{y \sim D}\left[q(z|y)\right]$ (thus Z is a function of q). The entropy of Z is

$$H(Z) = -\sum_{z} q(z) \log q(z)$$

Putting together, the objective (to maximize) is

$$J^{\text{var}} = H(Z) - H(q, p)$$

Variational interpretation. The reason this objective is named a variational lower bound is due to McAllester (2018) who shows the following. Consider the mutual information between Z and the raw signal X:

$$I(X, Z) = H(Z) - H(Z|X) \qquad (5)$$

Because Z is drawn from q conditioning on Y, which is co-distributed with X, we have a Markov chain $X \to Y \xrightarrow{q} Z$. Thus maximizing $I(X, Z)$ over the choice of q is a reasonable objective that enforces "predictive coding": the label predicted by q from Y must be as informative of X as possible. It can be seen as a special case of the objective underlying the information bottleneck method (Tishby et al., 2000).

So what is the problem with optimizing (5) directly? The problem is that the conditional entropy under the model

$$H(Z|X) = \mathop{\mathbf{E}}_{\substack{(x,y)\sim D \\ z\sim q(\cdot|y)}} \left[\log \frac{1}{\pi(z|x)} \right] \tag{6}$$

involves the posterior probability of z given x

$$\pi\left(z|x\right) = \frac{\sum_y D(x,y)q(z|y)}{\sum_{y,z} D(x,y)q(z|y)}$$

This *conditional* marginalization is generally intractable and cannot be approximated by sampling since the chance of seeing a particular x is small. However, we can introduce a variational distribution $p(z|x)$ to model $\pi\left(z|x\right)$. Plugging this into (6) we observe that

$$\mathop{\mathbf{E}}_{\substack{(x,y)\sim D \\ z\sim q(\cdot|y)}} \left[\log \frac{1}{p(z|x)} \right] = H(q,p)$$

Moreover,

$$\begin{aligned} &\mathop{\mathbf{E}}_{\substack{(x,y)\sim D \\ z\sim q(\cdot|y)}} \left[\log \frac{1}{p(z|x)} \right] \\ &\quad = \mathop{\mathbf{E}}_{\substack{(x,y)\sim D \\ z\sim q(\cdot|y)}} \left[\log \frac{\pi\left(z|x\right)}{\pi\left(z|x\right)p(z|x)} \right] \\ &\quad = H(Z|X) + D_{\mathrm{KL}}(\pi||p) \end{aligned}$$

Thus $H(q,p)$ is an upper bound on $H(Z|X)$ for any p with equality iff p matches the true posterior distribution π. This in turn means that $J^{\mathrm{var}} = H(Z) - H(q,p)$ is a lower bound on $I(X,Z)$, hence the name.

Empirical objective. As with the generalized Brown objective, the variational lower bound can be estimated from the training data as

$$\begin{aligned} \widehat{H}(Z) &= -\sum_z \hat{q}(z)\log\hat{q}(z) \\ \widehat{H}(q,p) &= \frac{1}{N}\sum_{i=1}^{N}\left(-\sum_z q(z|y_i)\log p(z|x_i)\right) \\ \widehat{J}^{\mathrm{var}} &= \widehat{H}(Z) - \widehat{H}(q,p) \end{aligned} \tag{7}$$

where $\hat{q}(z)$ is defined as in Section 3.1. Our task is again to maximize this empirical objective (7) by taking gradient steps at random minibatches. Once again, it cannot be written as a sum of local objectives because the entropy term involves log of $\hat{q}(z)$ computed from all samples. Thus it is not clear if stochastic optimization will be effective.

4 Analysis

The discussion of the two objectives in the previous section is incomplete because the stochastic gradient estimator is biased under both objectives. In this section, we formalize this issue and analyze the bias.

4.1 Setting

Let $B_1 \ldots B_K$ be a partition of the N training examples $(x_1, y_1) \ldots (x_N, y_N)$ into K (iid) minibatches. For simplicity, assume $|B_k| = M$ for all k and $N = MK$. We will adopt the same notation in Section 3 for $\hat{p}(z)$ and $\hat{q}(z)$ estimated from all N samples. Define analogous estimates based on the k-th minibatch by

$$\begin{aligned} \hat{p}_k(z) &= \frac{1}{M}\sum_{x\in B_k} p(z|x) \qquad \forall z \in [m] \\ \hat{q}_k(z) &= \frac{1}{M}\sum_{y\in B_k} q(z|y) \qquad \forall z \in [m] \end{aligned}$$

If l_N denotes an objective function computed from all N samples in the training data and l_k denotes the same objective computed from B_k, a condition on the correctness of SGD is that the gradient of l_k (with respect to model parameters) is consistent with the gradient of l_N on average:

$$\nabla l_N = \frac{1}{K}\sum_{k=1}^{K}\nabla l_k + \epsilon \tag{8}$$

where ϵ denotes the bias of the stochastic gradient estimator. In particular, any loss of the form $l_N = (1/K)\sum_k l_k$ that decomposes over independent minibatches (e.g., the cross-entropy loss for supervised classification) satisfies (8) with $\epsilon = 0$. The bias is nonzero for the unsupervised objectives considered in this work due to the issues discussed in Section 3.

4.2 Result

The following theorem precisely quantifies the bias for the empirical losses associated with the variational bound and the generalized Brown objectives. We only show the result with the gradient with respect to q, but the result with the gradient with respect to p is analogous and omitted for brevity.

Theorem 4.1. *Assume the setting in Section 4.1 and the gradient is taken with respect to the pa-*

rameters of q*. For* $l_N = -\widehat{J}^{\text{var}}$ *defined in* (7)*,*

$$\epsilon = \frac{1}{K}\sum_{k=1}^{K}\sum_{z}\log\frac{\hat{q}(z)}{\hat{q}_k(z)}\nabla\hat{q}_k(z)$$

On the other hand, for $l_N = -\widehat{J}^{\text{mi}}$ *defined in* (4)*,*

$$\epsilon = \frac{1}{N}\sum_{k=1}^{K}\sum_{z,z'}\Bigg(\epsilon_k(z,z')\nabla\hat{q}_k(z') + \log\frac{\hat{p}(z)\hat{q}(z')}{\hat{p}_k(z)\hat{q}_k(z')}\sum_{(x,y)\in B_k}p(z|x)\nabla q(z'|y)\Bigg)$$

where

$$\epsilon_k(z,z') = \frac{1}{K}\sum_{i=1}^{N}\frac{p(z|x_i)q(z'|y_i)}{\hat{q}(z')} - \sum_{(x,y)\in B_k}\frac{p(z|x)q(z'|y)}{\hat{q}_k(z')}$$

A proof can be found in the appendix. We see that both biases go to zero as $\hat{p}_k$ and $\hat{q}_k$ approach $\hat{p}$ and $\hat{q}$. However, the bias is logarithmic in the ratio $\hat{q}(z)/\hat{q}_k(z)$ for the variational lower bound but roughly linear in the difference between $\frac{1}{\hat{q}(z')}$ and $\frac{1}{\hat{q}_k(z')}$ for the generalized Brown objective. In this sense, the variational lower bound is exponentially more robust to noise in minibatch estimates than the generalized Brown objective. This is confirmed in experiments: we are able to optimize $\widehat{J}^{\text{var}}$ with minibatches as small as 80 examples but unable to optimize $\widehat{J}^{\text{mi}}$ unless minibatches are prohibitively large.

5 Experiments

We demonstrate the effectiveness of our training objectives on the task of POS induction. The goal of this task is to induce the correct POS tag for a given word in context (Merialdo, 1994). As typical in unsupervised tasks, evaluating the quality of induced labels is challenging; see Christodoulopoulos et al. (2010) for an in-depth discussion. To avoid complications, we follow a standard practice (Berg-Kirkpatrick et al., 2010; Ammar et al., 2014; Lin et al., 2015; Stratos et al., 2016) and adopt the following setting for all compared methods.

- We use many-to-one accuracy as a primary evaluation metric. That is, we map each induced label to the most frequently coinciding ground-truth POS tag in the annotated data and report the resulting accuracy. We also use the V-measure (Rosenberg and Hirschberg, 2007) when comparing with CRF autoencoders to be consistent with reported results (Ammar et al., 2014; Lin et al., 2015).
- We use the number of ground-truth POS tags as the value of m (i.e., number of labels to induce). This is a data-dependent quantity, for instance 45 in the Penn WSJ and 12 in the universal treebank. Fixing the number of tags this way obviates many evaluation issues.
- Model-specific hyperparameters are tuned on the English Penn WSJ dataset. This configuration is then fixed and used for all other datasets: 10 languages in the universal treebank[2] and 7 languages from CoNLL-X and CoNLL 2007.

5.1 Setting

We set D to be a uniform distribution over context-word pairs in the training corpus. Given N samples $(x_1, y_1) \ldots (x_N, y_N) \sim D$, we optimize the variational objective (7) or the generalized Brown objective (4) by taking gradient steps at random minibatches. This gives us conditional label distributions $p(z|x)$ and $q(z|y)$ for all contexts x, words y, and labels z. At test time, we use

$$z^* = \arg\max_z q(z|y)$$

as the induced label of word y. We experimented with different inference methods such as taking $\arg\max_z p(z|x)q(z|y)$ but did not find it helpful.

5.2 Definition of (X, Y)

Let V denote the vocabulary. We assume an integer $H \geq 1$ that specifies the width of local context. Given random word $y \in V$, we set $x \in V^{2H}$ to be an ordered list of H left and H right words of y. For example, with $H = 2$, a typical context-target pair $(x, y) \sim D$ may look like

$$x = (\text{“had”}, \text{“these”}, \text{“in”}, \text{“my”})$$
$$y = \text{“keys”}$$

We find this simple fixed-window definition of observed variables to be the best inductive bias for POS induction. The correct label can be inferred from either x or y in many cases: in the above example, we can infer that the correct POS tag is plural noun by looking at the target or the context.

---

[2] https://github.com/ryanmcd/uni-dep-tb

5.3 Architecture

We use the following simple architecture to parameterize the label distribution $p(\cdot|x)$ conditioned on context $x \in V^H$ and the label distribution $q(\cdot|y)$ conditioned on word $y \in V$.

Context architecture. The parameters of p are word embeddings $e_w \in \mathbb{R}^d$ for all $w \in V$ and matrices $W_j \in \mathbb{R}^{m\times d}$ for all $j = 1 \ldots 2H$. Given $2H$ ordered contextual words $x = (w_j)_{j=1}^{2H}$, we define

$$p\left(\cdot|x\right) = \mathrm{softmax}\left(\sum_{j=1}^{2H} W_j e_{w_j}\right)$$

Word architecture. The parameters of q are the same word embeddings $e_w \in \mathbb{R}^d$ shared with p, character embeddings $e_c \in \mathbb{R}^{d/2}$ for all distinct characters c, two single-layer LSTMs with input/output dimension $d/2$, and matrices $W_c, W_w \in \mathbb{R}^{m\times d}$. Given the word y with character sequence $c_1 \ldots c_T$, we define

$$\begin{aligned}(f_1 \ldots f_T) &= \mathrm{LSTM}_f(e_{c_1} \ldots e_{c_T})\\ (b_1 \ldots b_T) &= \mathrm{LSTM}_b(e_{c_T} \ldots e_{c_1})\\ q(\cdot|y) &= \mathrm{softmax}\left(W_c \begin{bmatrix} f_T \\ b_T \end{bmatrix} + W_w e_y\right)\end{aligned}$$

The overall architecture is illustrated in Figure 1. Our hyperparameters are the embedding dimension $d = 200$, the context width $H = 2$, the learning rate of the Adam optimizer $r = 0.001$, and the minibatch size $B = 80$.[3] Their values are tuned on the 45-tag Penn WSJ dataset to maximize accuracy.

5.4 Baselines

We focus on comparing with the following models which are some of the strongest baselines in the literature we are aware of. Berg-Kirkpatrick et al. (2010) extend a standard hidden Markov Model (HMM) to incorporate linguistic features. Stratos et al. (2016) develop a factorization-based algorithm for learning a constrained HMM. Ammar et al. (2014) propose a CRF autoencoder that reconstructs words from a structured label sequence. Lin et al. (2015) extend Ammar et al. (2014) by switching a categorical reconstruction distribution with a Gaussian distribution. In addition to these baselines, we also report results with Brown clustering (Brown et al., 1992), the Baum-Welch algorithm (Baum and Petrie, 1966), and k-means clustering of 300-dimensional GloVe vectors (Pennington et al., 2014).

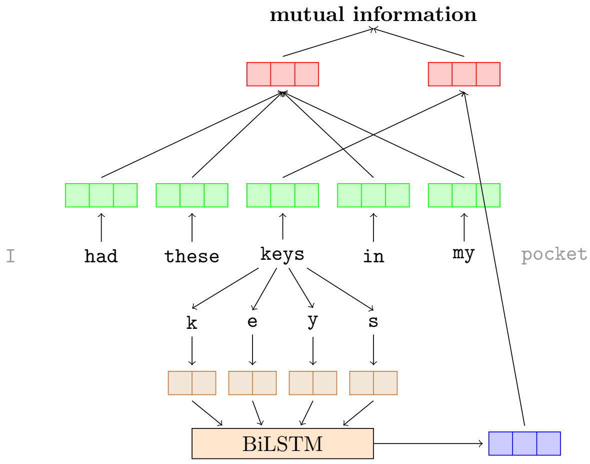

Figure 1: Architecture illustrated on the example text "had these keys in my" with target Y = "keys".

5.5 Results

The 45-tag Penn WSJ dataset. The 45-tag Penn WSJ dataset is a corpus of around one million words each tagged with one of $m = 45$ tags. It is used to optimize hyperparameter values for all compared methods. Table 1 shows the average accuracy over 10 random restarts with the best hyperparameter configurations; standard deviation is given in parentheses (except for deterministic methods Stratos et al. (2016) and Brown clustering).

Our model trained with the variational objective (7) outperforms all baselines.[4] We also observe that our model trained with the generalized Brown objective (4) does not work. We have found that unless the minibatch size is as large as 10,000 the gradient steps do not effectively increase the true data-wide mutual information (4). This supports our bias analysis in Section 4. While it may be possible to develop techniques to resolve the difficulty, for instance keeping a moving average of estimates to stabilize estimation, we leave this as future work and focus on the variational objective in the remainder of the paper.

Table 2 shows ablation experiments on our best

---

[3] An implementation is available at: `https://github.com/karlstratos/mmi-tagger`.

[4] We remark that Tran et al. (2016) report a single number 79.1 with a neuralized HMM. We also note that the concurrent work by He et al. (2018) obtains 80.8 by using word embeddings carefully pretrained on one billion words.

Method	Accuracy
Variational $\widehat{J}^{\text{var}}$ (7)	**78.1** ($\pm$0.8)
Generalized Brown $\widehat{J}^{\text{mi}}$ (4)	48.8 ($\pm$0.9)
Berg-Kirkpatrick et al. (2010)	74.9 ($\pm$1.5)
Stratos et al. (2016)	67.7
Brown et al. (1992)	65.6
Baum-Welch	62.6 ($\pm$1.1)
k-MEANS	32.6 ($\pm$0.7)

Table 1: Many-to-one accuracy on the 45-tag Penn WSJ with the best hyperparameter configurations. The average accuracy over 10 random restarts is reported and the standard deviation is given in parentheses (except for deterministic methods).

Configuration	Accuracy
Best	80.1
$H = 3$	75.9
$H = 1$	75.9
Sentence-level batching	72.4
GloVe initialization	67.6
No character encoding	65.6

Table 2: Ablation of the best model on Penn WSJ.

model (accuracy 80.1) to better understand the sources of its strong performance. Context size $H = 2$ is a sizable improvement over $H = 3$ or $H = 1$. Random sampling is significantly more effective than sentence-level batching (i.e., each minibatch is the set of context-word pairs within a single sentence as done in McAllester (2018)). GloVe initialization of word embeddings e_w is harmful. As expected for POS tagging, morphological modeling with LSTMs gives the largest improvement.

While it may be surprising that GloVe initialization is harmful, it is well known that pretrained word embeddings do not necessarily capture syntactic relationships (as evident in the poor performance of k-means clustering). Consider the top ten nearest neighbors of the word "made" under GloVe embeddings (840B.300d, within PTB vocab) shown in Table 3. The neighbors are clearly not in the same syntactic category. The embeddings can be made more syntactic by controlling the context window. But we found it much more effective (and simpler) to start from randomly initialized embeddings and let the objective induce appropriate representations.

0.6514	came
0.6494	but
0.6486	even

Table 3: Nearest neighbors of "made" under GloVe embeddings (840B.300d, within PTB vocab).

The 12-tag universal treebank. The universal treebank v2.0 is a corpus in ten languages tagged with $m = 12$ universal POS tags (McDonald et al., 2013). We use this corpus to be compatible with existing results. Table 4 shows results on the dataset, using the same setting in the experiments on the Penn WSJ dataset. Our model significantly outperforms the previous state-of-the-art, achieving an absolute gain of 4.7 over Stratos et al. (2016) in average accuracy.

Comparison with CRF autoencoders. Table 5 shows a direct comparison with CRF autoencoders (Ammar et al., 2014; Lin et al., 2015) in many-to-one accuracy and the V-measure. We compare against their reported numbers by running our model once on the same datasets using the same setting in the experiments on the Penn WSJ dataset. The data consists of the training portion of CoNLL-X and CoNLL 2007 labeled with 12 universal tags. Our model is competitive with all baselines.

6 Related Work

Information theory, in particular mutual information, has played a prominent role in NLP (Church and Hanks, 1990; Brown et al., 1992). It has intimate connections to the representation learning capabilities of neural networks (Tishby and Zaslavsky, 2015) and underlies many celebrated modern approaches to unsupervised learning such as generative adversarial networks (GANs) (Goodfellow et al., 2014).

There is a recent burst of effort in learning continuous representations by optimizing various lower bounds on mutual information (Belghazi et al., 2018; Oord et al., 2018; Hjelm et al., 2018). These representations are typically eval-

uated on extrinsic tasks as features. In contrast, we learn discrete representations by optimizing a novel generalization of the Brown clustering objective (Brown et al., 1992) and a variational lower bound on mutual information proposed by McAllester (2018). We focus on intrinsic evaluation of these representations on POS induction. Extrinsic evaluation of these representations in downstream tasks is an important future direction.

The issue of biased stochastic gradient estimators is a common challenge in unsupervised learning (e.g., see Wang et al., 2015). This arises mainly because the objective involves a nonlinear transformation of all samples in a training dataset, for instance the whitening constraints in deep canonical correlation analysis (CCA) (Andrew et al., 2013). In this work, the problem arises because of entropy. This issue is not considered in the original work of McAllester (2018) and the error analysis we present in Section 4 is novel. Our finding is that the feasibility of stochastic optimization greatly depends on the size of the bias in gradient estimates, as we are able to effectively optimize the variational objective while not the generalized Brown objective.

Our POS induction system has some practical advantages over previous approaches. Many rely on computationally expensive structured inference or pre-optimized features (or both). For instance, Tran et al. (2016) need to calculate forward/backward messages and is limited to truncated sequences by memory constraints. Berg-Kirkpatrick et al. (2010) rely on extensively hand-engineered linguistic features. Ammar et al. (2014), Lin et al. (2015), and He et al. (2018) rely on carefully pretrained lexical representations like Brown clusters and word embeddings. In contrast, the model presented in this work requires no expensive structured computation or feature engineering and uses word/character embeddings trained from scratch. It is easy to implement using a standard neural network library and outperforms these previous works in many cases.

Acknowledgments

The author thanks David McAllester for many insightful discussions, and Sam Wiseman for helpful comments. The Titan Xp used for this research was donated by the NVIDIA Corporation.

A Proof of Theorem 4.1

We first analyze the variational loss

$$\widehat{H}(q,p) - \widehat{H}(Z)$$

Note that the cross entropy term decomposes over samples and causes no bias. Thus we focus on the negative entropy term

$$-\widehat{H}(Z) = \sum_z \hat{q}(z) \log \hat{q}(z)$$

whose gradient with respect to q is

$$\begin{aligned} &\sum_z \left(1 + \log \hat{q}(z)\right) \nabla \hat{q}(z) \\ &= \frac{1}{K} \sum_{k=1}^{K} \sum_z \left(1 + \log \hat{q}(z)\right) \nabla \hat{q}_k(z) \qquad (9) \end{aligned}$$

where we expand $\nabla \hat{q}(z)$ by the identity

$$\nabla \hat{q}(z) = \frac{1}{N} \sum_{i=1}^{N} \nabla q(z|y_i) = \frac{1}{K} \sum_{k=1}^{K} \nabla \hat{q}_k(z) \tag{10}$$

In contrast, the gradient of the negative entropy term averaged over minibatches is

$$\frac{1}{K} \sum_{k=1}^{K} \sum_z \left(1 + \log \hat{q}_k(z)\right) \nabla \hat{q}_k(z) \tag{11}$$

Hence the difference between (9) and (11) is

$$\frac{1}{K} \sum_{k=1}^{K} \sum_z \log \frac{\hat{q}(z)}{\hat{q}_k(z)} \nabla \hat{q}_k(z)$$

This shows the first result. Now we analyze the generalized Brown loss

$$\frac{1}{N} \sum_{i=1}^{N} \sum_{z,z'} p(z|x_i) q(z'|y_i) \log \frac{\hat{p}(z)\hat{q}(z')}{p(z|x_i) q(z'|y_i)}$$

When we expand the log fraction, we see that the denominator decomposes over samples and causes no bias. Thus we focus on the numerator term

$$\frac{1}{N} \sum_{z,z'} \log \left(\hat{p}(z)\hat{q}(z')\right) \sum_{i=1}^{N} p(z|x_i) q(z'|y_i)$$

By the product rule, its gradient with respect to q is a sum of two terms. The first term is (using (10) again)

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \left(\frac{1}{K} \sum_{i=1}^{N} \frac{p(z|x_i) q(z'|y_i)}{\hat{q}(z')} \right) \nabla \hat{q}_k(z') \tag{12}$$

The second term is (as a sum over batches)

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \log \left(\hat{p}(z)\hat{q}(z')\right) \sum_{(x,y)\in B_k} p(z|x) \nabla q(z'|y) \tag{13}$$

In contrast, the numerator term estimated as an average over minibatches is

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \log \left(\hat{p}_k(z)\hat{q}_k(z')\right) \sum_{(x,y)\in B_k} p(z|x) q(z'|y)$$

and the two terms of its gradient with respect to q (corresponding to (12) and (13)) are

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \left(\sum_{(x,y)\in B_k} \frac{p(z|x) q(z'|y)}{\hat{q}_k(z')} \right) \nabla \hat{q}_k(z') \tag{14}$$

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \log \left(\hat{p}_k(z)\hat{q}_k(z')\right) \sum_{(x,y)\in B_k} p(z|x_i) \nabla q(z'|y) \tag{15}$$

Thus the difference between (12) and (14) is

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \epsilon_k(z,z') \nabla \hat{q}_k(z')$$

where

$$\begin{aligned} \epsilon_k(z,z') = &\frac{1}{K} \sum_{i=1}^{N} \frac{p(z|x_i) q(z'|y_i)}{\hat{q}(z')} \\ &- \sum_{(x,y)\in B_k} \frac{p(z|x) q(z'|y)}{\hat{q}_k(z')} \end{aligned}$$

The difference between (13) and (15) is

$$\frac{1}{N} \sum_{k=1}^{K} \sum_{z,z'} \log \frac{\hat{p}(z)\hat{q}(z')}{\hat{p}_k(z)\hat{q}_k(z')} \sum_{(x,y)\in B_k} p(z|x) \nabla q(z'|y)$$

Adding these differences gives the second result.

Unsupervised Recurrent Neural Network Grammars

Abstract

Recurrent neural network grammars (RNNG) are generative models of language which jointly model syntax and surface structure by incrementally generating a syntax tree and sentence in a top-down, left-to-right order. Supervised RNNGs achieve strong language modeling and parsing performance, but require an annotated corpus of parse trees. In this work, we experiment with unsupervised learning of RNNGs. Since directly marginalizing over the space of latent trees is intractable, we instead apply amortized variational inference. To maximize the evidence lower bound, we develop an inference network parameterized as a neural CRF constituency parser. On language modeling, unsupervised RNNGs perform as well their supervised counterparts on benchmarks in English and Chinese. On constituency grammar induction, they are competitive with recent neural language models that induce tree structures from words through attention mechanisms.

1 Introduction

Recurrent neural network grammars (RNNGs) (Dyer et al., 2016) model sentences by first generating a nested, hierarchical syntactic structure which is used to construct a context representation to be conditioned upon for upcoming words. Supervised RNNGs have been shown to outperform standard sequential language models, achieve excellent results on parsing (Dyer et al., 2016; Kuncoro et al., 2017), better encode syntactic properties of language (Kuncoro et al., 2018), and correlate with electrophysiological responses in the human brain (Hale et al., 2018). However, these all require annotated syntactic trees for training. In this work, we explore unsupervised learning of recurrent neural network grammars for language modeling and grammar induction.

The standard setup for unsupervised structure learning is to define a generative model $p_\theta(\mathbf{x}, \mathbf{z})$ over observed data $\mathbf{x}$ (e.g. sentence) and unobserved structure $\mathbf{z}$ (e.g. parse tree, part-of-speech sequence), and maximize the log marginal likelihood $\log p_\theta(\mathbf{x}) = \log \sum_{\mathbf{z}} p_\theta(\mathbf{x}, \mathbf{z})$. Successful approaches to unsupervised parsing have made strong conditional independence assumptions (e.g. context-freeness) and employed auxiliary objectives (Klein and Manning, 2002) or priors (Johnson et al., 2007). These strategies imbue the learning process with inductive biases that guide the model to discover meaningful structures while allowing tractable algorithms for marginalization; however, they come at the expense of language modeling performance, particularly compared to sequential neural models that make no independence assumptions.

Like RNN language models, RNNGs make no independence assumptions. Instead they encode structural bias through operations that compose linguistic constituents. The lack of independence assumptions contributes to the strong language modeling performance of RNNGs, but make unsupervised learning challenging. First, marginalization is intractable. Second, the biases imposed by the RNNG are relatively weak compared to those imposed by models like PCFGs. There is little pressure for non-trivial tree structure to emerge during unsupervised RNNG (URNNG) learning.

In this work, we explore a technique for handling intractable marginalization while also injecting inductive bias. Specifically we employ amortized variational inference (Kingma and Welling, 2014; Rezende et al., 2014; Mnih and Gregor, 2014) with a *structured* inference network. Variational inference lets us tractably optimize a lower bound on the log marginal likelihood, while employing a structured inference network encourages non-trivial structure. In particular, a con-

ditional random field (CRF) constituency parser (Finkel et al., 2008; Durrett and Klein, 2015), which makes significant independence assumptions, acts as a guide on the generative model to learn meaningful trees through regularizing the posterior (Ganchev et al., 2010).

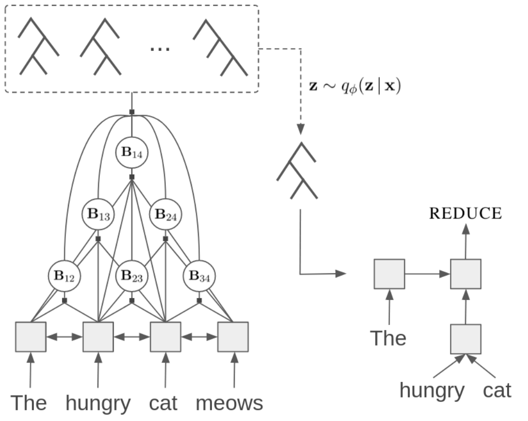
We experiment with URNNGs on English and Chinese and observe that they perform well as language models compared to their supervised counterparts and standard neural LMs. In terms of grammar induction, they are competitive with recently-proposed neural architectures that discover tree-like structures through gated attention (Shen et al., 2018). Our results, along with other recent work on joint language modeling/structure learning with deep networks (Shen et al., 2018, 2019; Wiseman et al., 2018; Kawakami et al., 2018), suggest that it is possible learn generative models of language that model the underlying data well (i.e. assign high likelihood to held-out data) and at the same time induce meaningful linguistic structure.

2 Unsupervised Recurrent Neural Network Grammars

We use $\mathbf{x} = [x_1, \dots, x_T]$ to denote a sentence of length T, and $\mathbf{z} \in \mathcal{Z}_T$ to denote an unlabeled binary parse tree over a sequence of length T, represented as a a binary vector of length $2T - 1$. Here 0 and 1 correspond to SHIFT and REDUCE actions, explained below.[1] Figure 1 presents an overview of our approach.

2.1 Generative Model

An RNNG defines a joint probability distribution $p_\theta(\mathbf{x}, \mathbf{z})$ over sentences $\mathbf{x}$ and parse trees $\mathbf{z}$. We consider a simplified version of the original RNNG (Dyer et al., 2016) by ignoring constituent labels and only considering binary trees. The RNNG utilizes an RNN to parameterize a stack data structure (Dyer et al., 2015) of partially-completed constituents to incrementally build the parse tree while generating terminals. Using the current stack representation, the model samples an action (SHIFT or REDUCE): SHIFT generates a terminal symbol, i.e. word, and shifts it onto the stack,[2] REDUCE pops the last two elements off the stack, composes them, and shifts the composed representation onto the stack.



Inference Network $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ Generative Model $p_\theta(\mathbf{x}, \mathbf{z})$

Figure 1: Overview of our approach. The inference network $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ (left) is a CRF parser which produces a distribution over binary trees (shown in dotted box). $\mathbf{B}_{ij}$ are random variables for existence of a constituent spanning i-th and j-th words, whose potentials are the output from a bidirectional LSTM (the global factor ensures that the distribution is only over valid binary trees). The generative model $p_\theta(\mathbf{x}, \mathbf{z})$ (right) is an RNNG which consists of a stack LSTM (from which actions/words are predicted) and a tree LSTM (to obtain constituent representations upon REDUCE). Training involves sampling a binary tree from $q_\phi(\mathbf{z} \,|\, \mathbf{x})$, converting it to a sequence of shift/reduce actions, and optimizing the log joint likelihood $\log p_\theta(\mathbf{x}, \mathbf{z})$.

Formally, let $S = [(\mathbf{0}, \mathbf{0})]$ be the initial stack. Each item of the stack will be a pair, where the first element is the hidden state of the stack LSTM, and the second element is an input vector, described below. We use $\text{top}(S)$ to refer to the top pair in the stack. The push and pop operations are defined imperatively in the usual way. At each time step, the next action z_t (SHIFT or REDUCE) is sampled from a Bernoulli distribution parameterized in terms of the current stack representation. Letting $(\mathbf{h}_{\text{prev}}, \mathbf{g}_{\text{prev}}) = \text{top}(S)$, we have

$$z_t \sim \text{Bernoulli}(p_t), \qquad p_t = \sigma(\mathbf{w}^\top \mathbf{h}_{\text{prev}} + b).$$

Subsequent generation depend on z_t:

- If $z_t = 0$ (SHIFT), the model first generates a terminal symbol via sampling from a categorical distribution whose parameters come from an affine transformation and a softmax,

  $$x \sim \text{softmax}(\mathbf{W}\mathbf{h}_{\text{prev}} + \mathbf{b}).$$

  Then the generated terminal is shifted onto the stack using a stack LSTM,

  $$\mathbf{h}_{\text{next}} = \text{LSTM}(\mathbf{e}_x, \mathbf{h}_{\text{prev}}),$$
  $$\text{push}(S, (\mathbf{h}_{\text{next}}, \mathbf{e}_x)),$$

  where $\mathbf{e}_x$ is the word embedding for x.

---

[1] The cardinality of $\mathcal{Z}_T \subset \{0, 1\}^{2T-1}$ is given by the $(T-1)$-th Catalan number, $|\mathcal{Z}_T| = \frac{(2T-2)!}{T!(T-1)!}$.

[2] A better name for SHIFT would be GENERATE (as in Dyer et al. (2016)), but we use SHIFT to emphasize similarity with the shift-reduce parsing.

- If $z_t = 1$ (REDUCE), we pop the last two elements off the stack,
$$(\mathbf{h}_r, \mathbf{g}_r) = \text{pop}(S), \quad (\mathbf{h}_l, \mathbf{g}_l) = \text{pop}(S),$$
and obtain a new representation that combines the left/right constituent representations using a tree LSTM (Tai et al., 2015; Zhu et al., 2015),
$$\mathbf{g}_{\text{new}} = \text{TreeLSTM}(\mathbf{g}_l, \mathbf{g}_r).$$
Note that we use $\mathbf{g}_l$ and $\mathbf{g}_r$ to obtain the new representation instead of $\mathbf{h}_l$ and $\mathbf{h}_r$.[3] We then update the stack using $\mathbf{g}_{\text{new}}$,
$$\begin{aligned}&(\mathbf{h}_{\text{prev}}, \mathbf{g}_{\text{prev}}) = \text{top}(S),\\ &\mathbf{h}_{\text{new}} = \text{LSTM}(\mathbf{g}_{\text{new}}, \mathbf{h}_{\text{prev}}),\\ &\text{push}(S, (\mathbf{h}_{\text{new}}, \mathbf{g}_{\text{new}})).\end{aligned}$$

The generation process continues until an end-of-sentence symbol is generated. The parameters θ of the generative model are $\mathbf{w}, b, \mathbf{W}, \mathbf{b}$, and the parameters of the stack/tree LSTMs. For a sentence $\mathbf{x} = [x_1, \ldots, x_T]$ of length T, the binary parse tree is given by the binary vector $\mathbf{z} = [z_1, \ldots, z_{2T-1}]$.[4] The joint log likelihood decomposes as a sum of terminal/action log likelihoods,

$$\log p_\theta(\mathbf{x}, \mathbf{z}) = \underbrace{\sum_{t=1}^{T} \log p_\theta(x_t \,|\, \mathbf{x}_{<t}, \mathbf{z}_{<n(t)})}_{\log p_\theta(\mathbf{x} \,|\, \mathbf{z})} + \underbrace{\sum_{j=1}^{2T-1} \log p_\theta(z_j \,|\, \mathbf{x}_{<m(j)}, \mathbf{z}_{<j})}_{\log p_\theta(\mathbf{z} \,|\, \mathbf{x}_{<\mathbf{z}})}, \quad (1)$$

where $\mathbf{z}_{<n(t)}$ refers to all actions before generating the t-th word, and similarly $\mathbf{x}_{<m(j)}$ refers to all words generated before taking the j-th action. For brevity, from here on we will use $\log p_\theta(\mathbf{x} \,|\, \mathbf{z})$ to refer to the first term (terminal log likelihood) and $\log p_\theta(\mathbf{z} \,|\, \mathbf{x}_{<\mathbf{z}})$ to refer to the second term (action log likelihood) in the above decomposition.[5]

In the supervised case where ground-truth $\mathbf{z}$ is available, we can straightforwardly perform gradient-based optimization to maximize the joint log likelihood $\log p_\theta(\mathbf{x}, \mathbf{z})$. In the unsupervised case, the standard approach is to maximize the log marginal likelihood,

$$\log p_\theta(\mathbf{x}) = \log \sum_{\mathbf{z}' \in \mathcal{Z}_T} p_\theta(\mathbf{x}, \mathbf{z}').$$

However this summation is intractable because z_t fully depends on all previous actions $[z_1, \ldots, z_{t-1}]$. Even if this summation were tractable, it is not clear that meaningful latent structures would emerge given the lack of explicit independence assumptions in the RNNG (e.g. it is clearly not context-free). We handle these issues with amortized variational inference.

2.2 Amortized Variational Inference

Amortized variational inference (Kingma and Welling, 2014) defines a trainable inference network ϕ that parameterizes $q_\phi(\mathbf{z} \,|\, \mathbf{x})$, a variational posterior distribution, in this case over parse trees $\mathbf{z}$ given the sentence $\mathbf{x}$. This distribution is used to form an evidence lower bound (ELBO) on the log marginal likelihood,

$$\text{ELBO}(\theta, \phi; \mathbf{x}) = \mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}\left[\log \frac{p_\theta(\mathbf{x}, \mathbf{z})}{q_\phi(\mathbf{z} \,|\, \mathbf{x})}\right].$$

We maximize the ELBO with respect to both model parameters θ and inference network parameters ϕ. The ELBO is still intractable to calculate exactly, but this formulation will allow us to obtain unbiased gradient estimators based on Monte Carlo sampling.

Observe that rearranging the ELBO gives the following optimization problem,

$$\max_{\theta, \phi} \; \log p_\theta(\mathbf{x}) - \text{KL}[q_\phi(\mathbf{z} \,|\, \mathbf{x}) \,\|\, p_\theta(\mathbf{z} \,|\, \mathbf{x})].$$

Thus, ϕ is trained to match the variational posterior $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ to the true posterior $p_\theta(\mathbf{z} \,|\, \mathbf{x})$, but θ is *also* trained to match the true posterior to the variational posterior. Indeed, there is some evidence to suggest that generative models trained with amortized variational inference (i.e. variational autoencoders) learn posterior distributions that are close to the variational family (Cremer et al., 2018).

We can use this to our advantage with an inference network that injects inductive bias. We propose to do this by using a context-free model for the inference network, in particular, a neural CRF parser (Durrett and Klein, 2015). This choice

---

[3] The update equations for the tree LSTM (and the stack LSTM) also involve *cell* states in addition to the hidden states. To reduce notational clutter we do not explicitly show the cell states and instead subsume them into $\mathbf{g}$. If one (or both) of the inputs to the tree LSTM is a word embedding, the associated cell state is taken to be zero. See Tai et al. (2015) for the exact parameterization.

[4] As it stands, the support of $\mathbf{z}$ is $\{0, 1\}^{2T-1}$, all binary vectors of length $2T - 1$. To restrict our distribution to $\mathcal{Z}_T$ (binary vectors which describe valid trees), we constrain z_t to be valid at each time step, which amounts to deterministically choosing $z_t = 0$ (SHIFT) if there are fewer than two elements (not counting the initial zero tuple) on the stack.

[5] The action log likelihood is the sum of log *conditional* priors, which is obviously different from the unconditional log prior $\log p_\theta(\mathbf{z}) = \log \sum_{\mathbf{x}} p_\theta(\mathbf{x}, \mathbf{z})$.

can seen as a form of posterior regularization that limits posterior flexibility of the overly powerful RNNG generative model.[6,7]

The parameterization of span scores is similar to recent works (Wang and Chang, 2016; Stern et al., 2017; Kitaev and Klein, 2018): we add position embeddings to word embeddings and run a bidirectional LSTM over the input representations to obtain the forward $[\overrightarrow{\mathbf{h}}_1, \dots, \overrightarrow{\mathbf{h}}_T]$ and backward $[\overleftarrow{\mathbf{h}}_1, \dots, \overleftarrow{\mathbf{h}}_T]$ hidden states. The score $s_{ij} \in \mathbb{R}$ for a constituent spanning x_i to x_j is given by,

$$s_{ij} = \text{MLP}([\overrightarrow{\mathbf{h}}_{j+1} - \overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_{i-1} - \overleftarrow{\mathbf{h}}_j]).$$

Letting $\mathbf{B}$ be the binary matrix representation of a tree ($\mathbf{B}_{ij} = 1$ means there is a constituent spanning x_i and x_j), the CRF parser defines a distribution over binary trees via the Gibbs distribution,

$$q_\phi(\mathbf{B} \,|\, \mathbf{x}) = \frac{1}{Z_T(\mathbf{x})} \exp\Big(\sum_{i \le j} \mathbf{B}_{ij} s_{ij}\Big),$$

where $Z_T(\mathbf{x})$ is the partition function,

$$Z_T(\mathbf{x}) = \sum_{\mathbf{B}' \in \mathcal{B}_T} \exp\Big(\sum_{i \le j} \mathbf{B}'_{ij} s_{ij}\Big),$$

and ϕ denotes the parameters of the inference network (i.e. the bidirectional LSTM and the MLP). Calculating $Z_T(\mathbf{x})$ requires a summation over an exponentially-sized set $\mathcal{B}_T \subset \{0, 1\}^{T \times T}$, the set of all binary trees over a length T sequence. However we can perform the summation in $O(T^3)$ using the inside algorithm (Baker, 1979), shown in Algorithm 1. This computation is itself differentiable and amenable to gradient-based optimization. Finally, letting $f : \mathcal{B}_T \to \mathcal{Z}_T$ be the bijection between the binary tree matrix representation and a sequence of SHIFT/REDUCE actions, the inference network defines a distribution over $\mathcal{Z}_T$ via $q_\phi(\mathbf{z} \,|\, \mathbf{x}) \triangleq q_\phi(f^{-1}(\mathbf{z}) \,|\, \mathbf{x})$.

```
procedure INSIDE($s$)                              ▷ scores $s_{ij}$ for $i \le j$
    for $i := 1$ to $T$ do                          ▷ length-1 spans
        $\beta[i, i] = s_{ii}$
    for $\ell := 1$ to $T - 1$ do                   ▷ span length
        for $i := 1$ to $T - \ell$ do               ▷ span start
            $j = i + \ell$                          ▷ span end
            $\beta[i, j] = \sum_{k=i}^{j-1} s_{ij} \cdot \beta[i, k] \cdot \beta[k + 1, j]$
    return $\beta[1, T]$              ▷ return partition function $Z_T(\mathbf{x})$
```

2.3 Optimization

For optimization, we use the following variant of the ELBO,

$$\mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}[\log p_\theta(\mathbf{x}, \mathbf{z})] + \mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})],$$

where $\mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})] = \mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}[-\log q_\phi(\mathbf{z} \,|\, \mathbf{x})]$ is the entropy of the variational posterior. A Monte Carlo estimate for the gradient with respect to θ is

$$\nabla_\theta \, \text{ELBO}(\theta, \phi; \mathbf{x}) \approx \frac{1}{K} \sum_{k=1}^{K} \nabla_\theta \log p_\theta(\mathbf{x}, \mathbf{z}^{(k)}),$$

with samples $\mathbf{z}^{(1)}, \dots, \mathbf{z}^{(K)}$ from $q_\phi(\mathbf{z} \,|\, \mathbf{x})$. Sampling uses the intermediate values calculated during the inside algorithm to sample split points recursively (Goodman, 1998; Finkel et al., 2006), as shown in Algorithm 2. The gradient with respect to ϕ involves two parts. The entropy term $\mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$ can be calculated exactly in $O(T^3)$, again using the intermediate values from the inside algorithm (see Algorithm 3).[8] Since each step of this dynamic program is differentiable, we can obtain the gradient $\nabla_\phi \mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$ using automatic differentation.[9] An estimator for the gradient with respect to $\mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}[\log p_\theta(\mathbf{x}, \mathbf{z})]$ is obtained via the score function gradient estimator (Glynn, 1987; Williams, 1992),

$$\begin{aligned}
&\nabla_\phi \mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}[\log p_\theta(\mathbf{x}, \mathbf{z})] \\
&\quad = \mathbb{E}_{q_\phi(\mathbf{z} \,|\, \mathbf{x})}[\log p_\theta(\mathbf{x}, \mathbf{z}) \nabla_\phi \log q_\phi(\mathbf{z} \,|\, \mathbf{x})] \\
&\quad \approx \frac{1}{K} \sum_{k=1}^{K} \log p_\theta(\mathbf{x}, \mathbf{z}^{(k)}) \nabla_\phi \log q_\phi(\mathbf{z}^{(k)} \,|\, \mathbf{x}).
\end{aligned}$$

---

[6] While it has a similar goal, this formulation differs the from posterior regularization as formulated by Ganchev et al. (2010), which constrains the distributional family via linear constraints on posterior expectations. In our case, the conditional independence assumptions in the CRF lead to a *curved* exponential family where the vector of natural parameters has fewer dimensions than the vector of sufficient statistics of the full exponential family. This curved exponential family is a subset of the marginal polytope of the full exponential family, but it is an intersection of both linear and nonlinear manifolds, and therefore cannot be characterized through linear constraints over posterior expectations.

[7] In preliminary experiments, we also attempted to learn latent trees with a transition-based parser (which does not make explicit independence assumptions) that looks at the entire sentence. However we found that under this setup, the inference network degenerated into a local minimum whereby it always generated left-branching trees despite various optimization strategies. Williams et al. (2018) observe a similar phenomenon in the context of learning latent trees for classification tasks. However Li et al. (2019) find that it is possible use a transition-based parser as the inference network for dependency grammar induction, if the inference network is constrained via posterior regularization (Ganchev et al., 2010) based on universal syntactic rules (Naseem et al., 2010).

[8] We adapt the algorithm for calculating tree entropy in PCFGs from Hwa (2000) to the CRF case.

[9] $\nabla_\phi \mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$ can also be computed using the inside-outside algorithm and a second-order expectation semiring (Li and Eisner, 2009), which has the same asymptotic runtime complexity but generally better constants.

Algorithm 2 Top-down sampling a tree from $q_\phi(\mathbf{z} \,|\, \mathbf{x})$

```
procedure SAMPLE($\beta$)                    ▷ $\beta$ from running INSIDE(s)
  $\mathbf{B} = \mathbf{0}$                  ▷ binary matrix representation of tree
  $Q = [(1, T)]$                             ▷ queue of constituents
  while $Q$ is not empty do
    $(i, j) = \text{pop}(Q)$
    $\tau = \sum_{k=i}^{j-1} \beta[i, k] \cdot \beta[k+1, j]$
    for $k := i$ to $j - 1$ do               ▷ get distribution over splits
      $w_k = (\beta[i, k] \cdot \beta[k+1, j])/\tau$
    $k \sim \text{Cat}([w_i, \dots, w_{j-1}])$   ▷ sample a split point
    $\mathbf{B}_{i,k} = 1,\ \mathbf{B}_{k+1,j} = 1$   ▷ update B
    if $k > i$ then                          ▷ if left child has width > 1
      push($Q$, $(i, k)$)                    ▷ add to queue
    if $k + 1 < j$ then                      ▷ if right child has width > 1
      push($Q$, $(k+1, j)$)                  ▷ add to queue
  $\mathbf{z} = f(\mathbf{B})$               ▷ $f : \mathcal{B}_T \to \mathcal{Z}_T$ maps matrix representation of tree to sequence of actions.
  return z
```

The above estimator is unbiased but typically suffers from high variance. To reduce variance, we use a control variate derived from an average of the other samples' joint likelihoods (Mnih and Rezende, 2016), yielding the following estimator,

$$\frac{1}{K}\sum_{k=1}^{K}(\log p_\theta(\mathbf{x}, \mathbf{z}^{(k)}) - r^{(k)})\nabla_\phi \log q_\phi(\mathbf{z}^{(k)} \,|\, \mathbf{x}),$$

where $r^{(k)} = \frac{1}{K-1}\sum_{j \neq k} \log p_\theta(\mathbf{x}, \mathbf{z}^{(j)})$. This control variate worked better than alternatives such as estimates of baselines from an auxiliary network (Mnih and Gregor, 2014; Deng et al., 2018) or a language model (Yin et al., 2018).

3 Experimental Setup

3.1 Data

For English we use the Penn Treebank (Marcus et al., 1993, PTB) with splits and preprocessing from Dyer et al. (2016) which retains punctuation and replaces singleton words with Berkeley parser's mapping rules, resulting in a vocabulary of 23,815 word types.[10] Notably this is much larger than the standard PTB LM setup from Mikolov et al. (2010) which uses 10K types.[11] Also different from the LM setup, we model each sentence separately instead of carrying information across sentence boundaries, as the RNNG is a generative model of sentences. Hence our perplexity numbers are not comparable to the PTB LM results (Melis et al., 2018; Merity et al., 2018; Yang et al., 2018).

Since the PTB is rather small, and since the URNNG does not require annotation, we also test our approach on a subset of the one billion word corpus (Chelba et al., 2013). We randomly sample 1M sentences for training and 2K sentences for validation/test, and limit the vocabulary to 30K word types. While still a subset of the full corpus (which has 30M sentences), this dataset is two orders of magnitude larger than PTB. Experiments on Chinese utilize version 5.1 of the Chinese Penn Treebank (CTB) (Xue et al., 2005), with the same splits as in Chen and Manning (2014). Singleton words are replaced with a single ⟨UNK⟩ token, resulting in a vocabulary of 17,489 word types.

Algorithm 3 Calculating the tree entropy $\mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$

```
procedure ENTROPY($\beta$)                   ▷ $\beta$ from running INSIDE(s)
  for $i := 1$ to $T$ do                     ▷ initialize entropy table
    $H[i, i] = 0$
  for $l := 1$ to $T - 1$ do                 ▷ span length
    for $i := 1$ to $T - l$ do               ▷ span start
      $j = i + l$                            ▷ span end
      $\tau = \sum_{u=i}^{j-1} \beta[i, u] \cdot \beta[u+1, j]$
      for $u := i$ to $j - 1$ do
        $w_u = (\beta[i, u] \cdot \beta[u+1, j])/\tau$
      $H[i, j] = \sum_{u=i}^{j-1}(H[i, u] + H[u+1, j]$
                    $- \log w_u) \cdot w_u$
  return $H[1, T]$                           ▷ return tree entropy $\mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$
```

3.2 Training and Hyperparameters

The stack LSTM has two layers with input/hidden size equal to 650 and dropout of 0.5. The tree LSTM also has 650 units. The inference network uses a one-layer bidirectional LSTM with 256 hidden units, and the MLP (to produce span scores s_{ij} for $i \leq j$) has a single hidden layer with a ReLU nonlinearity followed by layer normalization (Ba et al., 2016) and dropout of 0.5. We share word embeddings between the generative model and the inference network, and also tie weights between the input/output word embeddings (Press and Wolf, 2016).

Optimization of the model itself required standard techniques for avoiding posterior collapse in VAEs.[12] We warm-up the ELBO objective by linearly annealing (per batch) the weight on the conditional prior $\log p_\theta(\mathbf{z} \,|\, \mathbf{x}_{<\mathbf{z}})$ and the entropy $\mathbb{H}[q_\phi(\mathbf{z} \,|\, \mathbf{x})]$ from 0 to 1 over the first two epochs (see equation (1) for definition of $\log p_\theta(\mathbf{z} \,|\, \mathbf{x}_{<\mathbf{z}})$). This is analogous to KL-annealing in VAEs with continuous latent variables (Bowman et al., 2016; Sønderby et al., 2016). We train for 18 epochs (enough for convergence for all models) with a batch size of 16 and $K = 8$ samples for the Monte Carlo gradient estimators. The generative model is optimized with SGD with learning rate equal to 1,

---

[10] https://github.com/clab/rnng

[11] Both versions of the PTB data can be obtained from http://demo.clab.cs.cmu.edu/cdyer/ptb-lm.tar.gz.

[12] Posterior collapse in our context means that $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ always produced trivial (always left or right branching) trees.

except for the affine layer that produces a distribution over the actions, which has learning rate 0.1. Gradients of the generative model are clipped at 5. The inference network is optimized with Adam (Kingma and Ba, 2015) with learning rate 0.0001, $\beta_1 = 0.9, \beta_2 = 0.999$, and gradient clipping at 1. As Adam converges significantly faster than SGD (even with a much lower learning rate), we stop training the inference network after the first two epochs. Initial model parameters are sampled from $\mathcal{U}[-0.1, 0.1]$. The learning rate starts decaying by a factor of 2 each epoch after the first epoch at which validation performance does not improve, but this learning rate decay is not triggered for the first eight epochs to ensure adequate training. We use the same hyperparameters/training setup for both PTB and CTB. For experiments on (the subset of) the one billion word corpus, we use a smaller dropout rate of 0.1. The baseline RNNLM also uses the smaller dropout rate.

All models are trained with an end-of-sentence token, but for perplexity calculation these tokens are not counted to be comparable to prior work (Dyer et al., 2016; Kuncoro et al., 2017; Buys and Blunsom, 2018). To be more precise, the inference network does not make use of the end-of-sentence token to produce parse trees, but the generative model is trained to generate the end-of-sentence token after the final REDUCE operation.

3.3 Baselines

We compare the unsupervised RNNG (URNNG) against several baselines: (1) RNNLM, a standard RNN language model whose size is the same as URNNG's stack LSTM; (2) Parsing Reading Predict Network (PRPN) (Shen et al., 2018), a neural language model that uses gated attention layers to embed soft tree-like structures into a neural network (and among the current state-of-the-art in grammar induction from words on the full corpus); (3) RNNG with trivial trees (left branching, right branching, random); (4) supervised RNNG trained on unlabeled, binarized gold trees.[13] Note that the supervised RNNG also trains a discriminative parser $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ (alongside the generative model $p_\theta(\mathbf{x}, \mathbf{z})$) in order to sample parse forests for perplexity evaluation (i.e. importance sampling). This discriminative parser has the same architecture as URNNG's inference network. For all models, we perform early stopping based on validation perplexity.

Model	PTB PPL	PTB F_1	CTB PPL	CTB F_1
RNNLM	93.2	–	201.3	–
PRPN (default)	126.2	32.9	290.9	32.9
PRPN (tuned)	96.7	41.2	216.0	36.1
Left Branching Trees	100.9	10.3	223.6	12.4
Right Branching Trees	93.3	34.8	203.5	20.6
Random Trees	113.2	17.0	209.1	17.4
URNNG	90.6	40.7	195.7	29.1
RNNG	88.7	68.1	193.1	52.3
RNNG → URNNG	85.9	67.7	181.1	51.9
Oracle Binary Trees	–	82.5	–	88.6

Table 1: Language modeling perplexity (PPL) and grammar induction F_1 scores on English (PTB) and Chinese (CTB) for the different models. Note that our PTB setup from Dyer et al. (2016) differs considerably from the usual language modeling setup (Mikolov et al., 2010) since we model each sentence independently and use a much larger vocabulary (see §3.1).

4 Results and Discussion

4.1 Language Modeling

Table 1 shows perplexity for the different models on PTB/CTB. As a language model URNNG outperforms an RNNLM and is competitive with the supervised RNNG.[14] The left branching baseline performs poorly, implying that the strong performance of URNNG/RNNG is not simply due to the additional depth afforded by the tree LSTM composition function (a left branching tree, which always performs REDUCE when possible, is the "deepest" model). The right branching baseline is essentially equivalent to an RNNLM and hence performs similarly. We found PRPN with default hyperparameters (which obtains a perplexity of 62.0 in the PTB setup from Mikolov et al. (2010)) to not perform well, but tuning hyperparameters improves performance.[15] The supervised RNNG performs well as a language model, despite being trained on the joint (rather than marginal) likelihood objective.[16] This indicates that explicit

---

[13] We use right branching binarization—Matsuzaki et al. (2005) find that differences between various binarization schemes have marginal impact. Our supervised RNNG therefore differs the original RNNG, which trains on non-binarized trees and does not ignore constituent labels.

[14] For RNNG and URNNG we estimate the log marginal likelihood (and hence, perplexity) with $K = 1000$ importance-weighted samples, $\log p_\theta(\mathbf{x}) \approx \log\left(\frac{1}{K}\sum_{k=1}^{K} \frac{\log p(\mathbf{x},\mathbf{z}^{(k)})}{q_\phi(\mathbf{z}^{(k)} \,|\, \mathbf{x})}\right)$. During evaluation only, we also flatten $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ by dividing span scores s_{ij} by a temperature term 2.0 before feeding it to the CRF.

[15] Using the code from https://github.com/yikangshen/PRPN, we tuned model size, initialization, dropout, learning rate, and use of batch normalization.

[16] RNNG is trained to maximize $\log p_\theta(\mathbf{x}, \mathbf{z})$ while URNNG is trained to maximize (a lower bound on) the language modeling objective $\log p_\theta(\mathbf{x})$.

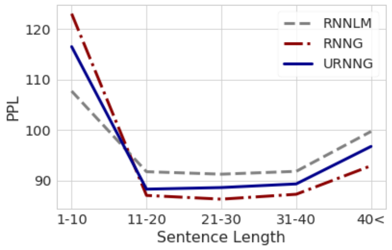

Figure 2: Perplexity of the different models grouped by sentence length on PTB.

modeling of syntax helps generalization even with richly-parameterized neural models. Encouraged by these observations, we also experiment with a hybrid approach where we train a supervised RNNG first and continue fine-tuning the model (including the inference network) on the URNNG objective (RNNG → URNNG in Table 1).[17] This approach results in nontrivial perplexity improvements, and suggests that it is potentially possible to improve language models with supervision on parsed data. In Figure 2 we show perplexity by sentence length. We find that a standard language model (RNNLM) is better at modeling short sentences, but underperforms models that explicitly take into account structure (RNNG/URNNG) when the sentence length is greater than 10. Table 2 (top) compares our results against prior work on this version of the PTB, and Table 2 (bottom) shows the results on a 1M sentence subset of the one billion word corpus, which is two orders of magnitude larger than PTB. On this larger dataset URNNG still improves upon the RNNLM. We also trained an RNNG (and RNNG → URNNG) on this dataset by parsing the training set with the self-attentive parser from Kitaev and Klein (2018).[18] These models improve upon the RNNLM but not the URNNG, potentially highlighting the limitations of using predicted trees for supervising RNNGs.

PTB	PPL
KN 5-gram (Dyer et al., 2016)	169.3
RNNLM (Dyer et al., 2016)	113.4
Original RNNG (Dyer et al., 2016)	102.4
Stack-only RNNG (Kuncoro et al., 2017)	101.2
Gated-Attention RNNG (Kuncoro et al., 2017)	100.9
Generative Dep. Parser (Buys and Blunsom, 2015)	138.6
RNNLM (Buys and Blunsom, 2018)	100.7
Sup. Syntactic NLM (Buys and Blunsom, 2018)	107.6
Unsup. Syntactic NLM (Buys and Blunsom, 2018)	125.2
PRPN† (Shen et al., 2018)	96.7
This work:	
RNNLM	93.2
URNNG	90.6
RNNG	88.7
RNNG → URNNG	85.9
1M Sentences	**PPL**
PRPN† (Shen et al., 2018)	77.7
RNNLM	77.4
URNNG	71.8
RNNG‡	72.9
RNNG‡ → URNNG	72.0

Table 2: (Top) Comparison of this work as a language model against prior works on sentence-level PTB with preprocessing from Dyer et al. (2016). Note that previous versions of RNNG differ from ours in terms of parameterization and model size. (Bottom) Results on a subset (1M sentences) of the one billion word corpus. PRPN† is the model from Shen et al. (2018), whose hyperparameters were tuned by us. RNNG‡ is trained on predicted parse trees from Kitaev and Klein (2018).

4.2 Grammar Induction

Table 1 also shows the F_1 scores for grammar induction. Note that we induce latent trees directly from words on the full dataset.[19] For RNNG/URNNG we obtain the highest scoring tree from $q_\phi(\mathbf{z} \,|\, \mathbf{x})$ through the Viterbi inside (i.e. CKY) algorithm. We calculate unlabeled F_1 using `evalb`, which ignores punctuation and discards trivial spans (width-one and sentence spans).[20] Since we compare F_1 against the original, non-binarized trees (per convention), F_1 scores of models using oracle binarized trees constitute the upper bounds.

We confirm the replication study of Htut et al. (2018) and find that PRPN is a strong model for grammar induction. URNNG performs on par with PRPN on English but PRPN does better on Chinese; both outperform right branching baselines. Table 3 further analyzes the learned trees and shows the F_1 score of URNNG trees against

---

[17] We fine-tune for 10 epochs and use a smaller learning rate of 0.1 for the generative model.

[18] To parse the training set we use the `benepar_en2` model from https://github.com/nikitakit/self-attentive-parser, which obtains an F_1 score of 95.17 on the PTB test set.

[19] Past work on grammar induction usually train/evaluate on short sentences and also assume access to gold POS tags (Klein and Manning, 2002; Smith and Eisner, 2004; Bod, 2006). However more recent works do train directly words (Jin et al., 2018; Shen et al., 2018; Drozdov et al., 2019).

[20] Available at https://nlp.cs.nyu.edu/evalb/. We evaluate with `COLLINS.prm` parameter file and `LABELED` option equal to 0. We observe that the setup for grammar induction varies widely across different papers: lexicalized vs. unlexicalized; use of punctuation vs. not; separation of train/test sets; counting sentence-level spans for evaluation vs. ignoring them; use of additional data; length cutoff for training/evaluation; corpus-level F_1 vs. sentence-level F_1; and, more. In our survey of twenty or so papers, almost no two papers were identical in their setup. Such variation makes it difficult to meaningfully compare models across papers. Hence, we report grammar induction results mainly for the models and baselines considered in the present work.

Tree	PTB	CTB
Gold	40.7	29.1
Left	9.2	8.4
Right	68.3	51.2
Self	92.3	87.3
RNNG	55.4	47.1
PRPN	41.0	47.2

Label	URNNG	PRPN
SBAR	74.8%	28.9%
NP	39.5%	63.9%
VP	76.6%	27.3%
PP	55.8%	55.1%
ADJP	33.9%	42.5%
ADVP	50.4%	45.1%

Table 3: (Left) F_1 scores of URNNG against other trees. "Self" refers to another URNNG trained with a different random seed. (Right) Recall of constituents by label for URNNG and PRPN. Recall for a particular label is the fraction of ground truth constituents of that label that were identified by the model.

	F_1	+PP
PRPN-UP‡	39.8	45.4
PRPN-LM‡	42.8	42.4
ON-LSTM‡ (Shen et al., 2019)	49.4	–
DIORA‡ (Drozdov et al., 2019)	49.6	56.2
PRPN (tuned)	49.0	49.9
URNNG	52.4	52.4

Table 4: PTB F_1 scores using the same evaluation setup as Drozdov et al. (2019), which evaluates against binarized trees, counts punctuation and trivial spans, and uses sentence-level F_1. +PP indicates a post-processing heuristic which directly attaches trailing punctuation to the root. This does not change URNNG results since it learns to do so anyway. Results with ‡ are copied from Table 1 of Drozdov et al. (2019).

other trees (left), and the recall of URNNG/PRPN trees against ground truth constituents (right). We find that trees induced by URNNG and PRPN are quite different; URNNG is more sensitive to SBAR and VP, while PRPN is better at identifying NP. While left as future work, this naturally suggests a hybrid approach wherein the intersection of constituents from URNNG and PRPN is used to create a corpus of partially annotated trees, which can be used to guide another model, e.g. via posterior regularization (Ganchev et al., 2010) or semi-supervision (Hwa, 1999). Finally, Table 4 compares our results using the same evaluation setup as in Drozdov et al. (2019), which differs considerably from our setup.

4.3 Distributional Metrics

Table 5 shows some standard metrics related to the learned generative model/inference network. The "reconstruction" perplexity based on $\mathbb{E}_{q_\phi(\mathbf{z} \mid \mathbf{x})}[\log p_\theta(\mathbf{x} \mid \mathbf{z})]$ is much lower than regular perplexity, and further, the Kullback-Leibler divergence between the conditional prior and the variational posterior, given by

$$\mathbb{E}_{q_\phi(\mathbf{z} \mid \mathbf{x})}\left[\log \frac{q_\phi(\mathbf{z} \mid \mathbf{x})}{p_\theta(\mathbf{z} \mid \mathbf{x}_{<\mathbf{z}})}\right],$$

	PTB		CTB	
	RNNG	URNNG	RNNG	URNNG
PPL	88.7	90.6	193.1	195.7
Recon. PPL	74.6	73.4	183.4	151.9
KL	7.10	6.13	11.11	8.91
Prior Entropy	7.65	9.61	9.48	15.13
Post. Entropy	1.56	2.28	6.23	5.75
Unif. Entropy	26.07	26.07	30.17	30.17

Table 5: Metrics related to the generative model/inference network for RNNG/URNNG. For the supervised RNNG we take the "inference network" to be the discriminative parser trained alongside the generative model (see §3.3). Recon. PPL is the reconstruction perplexity based on $\mathbb{E}_{q_\phi(\mathbf{z} \mid \mathbf{x})}[\log p_\theta(\mathbf{x} \mid \mathbf{z})]$, and KL is the Kullback-Leibler divergence. Prior entropy is the entropy of the conditional prior $p_\theta(\mathbf{z} \mid \mathbf{x}_{<\mathbf{z}})$, and uniform entropy is the entropy of the uniform distribution over binary trees.

is highly nonzero. (See equation (1) for definitions of $\log p_\theta(\mathbf{x} \mid \mathbf{z})$ and $\log p_\theta(\mathbf{z} \mid \mathbf{x}_{<\mathbf{z}})$). This indicates that the latent space is being used in a meaningful way and that there is no posterior collapse (Bowman et al., 2016). As expected, the entropy of the variational posterior is much lower than the entropy of the conditional prior, but there is still some uncertainty in the posterior.

4.4 Syntactic Evaluation

We perform a syntactic evaluation of the different models based on the setup from Marvin and Linzen (2018): the model is given two minimally different sentences, one grammatical and one ungrammatical, and must identify the grammatical sentence by assigning it higher probability.[21] Table 6 shows the accuracy results. Overall the supervised RNNG significantly outperforms the other models, indicating opportunities for further work in unsupervised modeling. While the URNNG does slightly outperform an RNNLM, the distribution of errors made from both models are similar, and thus it is not clear whether the outperformance is simply due to better perplexity or learning different structural biases.

4.5 Limitations

There are several limitations to our approach. For one, the URNNG takes considerably more time/memory to train than a standard language model due to the $O(T^3)$ dynamic program in the inference network, multiple samples to obtain low-variance gradient estimators, and dynamic computation graphs that make efficient batching

---

[21] We modify the publicly available dataset from https://github.com/BeckyMarvin/LM_syneval to only keep sentence pairs that did not have any unknown words with respect to our vocabulary, resulting in 80K sentence pairs for evaluation.

	RNNLM	PRPN	RNNG	URNNG
PPL	93.2	96.7	88.7	90.6
Overall	62.5%	61.9%	69.3%	64.6%
Subj.	63.5%	63.7%	89.4%	67.2%
Obj. Rel.	62.6%	61.0%	67.6%	65.7%
Refl.	60.7%	68.8%	57.3%	60.5%
NPI	58.7%	39.5%	46.8%	55.0%

Table 6: Syntactic evaluation based on the setup from Marvin and Linzen (2018). Subj. is subject-verb agreement in sentential complement, across prepositional phrase/subjective relative clause, and VP coordination; Obj. Rel. refers to subject-verb agreement in/across an objective relative clause; Refl. refers to reflexive pronoun agreement with antecedent; NPI is negative polarity items.

nontrivial. The model is sensitive to hyperparameters and required various optimization strategies (e.g. separate optimizers for the inference network and the generative model) to avoid posterior collapse. Finally, the URNNG also seemed to rely heavily on punctuation to identify constituents and we were unable to improve upon a right-branching baseline when training the URNNG on a version of PTB where punctuation is removed.[22]

5 Related Work

There has been much work on incorporating tree structures into deep models for syntax-aware language modeling, both for unconditional (Emami and Jelinek, 2005; Buys and Blunsom, 2015; Dyer et al., 2016) and conditional (Yin and Neubig, 2017; Alvarez-Melis and Jaakkola, 2017; Rabinovich et al., 2017; Aharoni and Goldberg, 2017; Eriguchi et al., 2017; Wang et al., 2018; Gū et al., 2018) cases. These approaches generally rely on annotated parse trees during training and maximizes the joint likelihood of sentence-tree pairs. Prior work on combining language modeling and unsupervised tree learning typically embed soft, tree-like structures as hidden layers of a deep network (Cho et al., 2014; Chung et al., 2017; Shen et al., 2018, 2019). In contrast, Buys and Blunsom (2018) make Markov assumptions and perform exact marginalization over latent dependency trees. Our work is also related to the recent line of work on learning latent trees as part of a deep model through supervision on other tasks, typically via differentiable structured hidden layers (Kim et al., 2017; Bradbury and Socher, 2017; Liu and Lapata, 2018; Tran and Bisk, 2018; Peng et al., 2018; Niculae et al., 2018; Liu et al., 2018), policy gradient-based approaches (Yogatama et al., 2017; Williams et al., 2018; Havrylov et al., 2019), or differentiable relaxations (Choi et al., 2018; Maillard and Clark, 2018).

The variational approximation uses amortized inference (Kingma and Welling, 2014; Mnih and Gregor, 2014; Rezende et al., 2014), in which an inference network is used to obtain the variational posterior for each observed $\mathbf{x}$. Since our inference network is structured (i.e., a CRF), it is also related to CRF autoencoders (Ammar et al., 2014) and structured VAEs (Johnson et al., 2016; Krishnan et al., 2017), which have been used previously for unsupervised (Cai et al., 2017; Drozdov et al., 2019; Li et al., 2019) and semi-supervised (Yin et al., 2018; Corro and Titov, 2019) parsing.

6 Conclusion

It is an open question as to whether explicit modeling of syntax significantly helps neural models. Strubell et al. (2018) find that supervising intermediate attention layers with syntactic heads improves semantic role labeling, while Shi et al. (2018) observe that for text classification, syntactic trees only have marginal impact. Our work suggests that at least for language modeling, incorporating syntax either via explicit supervision or as latent variables does provide useful inductive biases and improves performance.

Finally, in modeling child language acquisition, the complex interaction of the parser and the grammatical knowledge being acquired is the object of much investigation (Trueswell and Gleitman, 2007); our work shows that apparently grammatical constraints can emerge from the interaction of a constrained parser and a more general grammar learner, which is an intriguing but underexplored hypothesis for explaining human linguistic biases.

[22] Many prior works that induce trees directly from words often employ additional heuristics based on punctuation (Seginer, 2007; Ponvert et al., 2011; Spitkovsky et al., 2013; Parikh et al., 2014), as punctuation (e.g. comma) is usually a reliable signal for start/end of constituent spans. The URNNG still has to *learn* to rely on punctuation, similar to recent works such as depth-bounded PCFGs (Jin et al., 2018) and DIORA (Drozdov et al., 2019). In contrast, PRPN (Shen et al., 2018) and Ordered Neurons (Shen et al., 2019) induce trees by directly training on corpus without punctuation. We also reiterate that punctuation is used during training but ignored during evaluation (except in Table 4).

Abstract

There has been considerable attention devoted to models that learn to jointly infer an expression's syntactic structure and its semantics. Yet, Nangia and Bowman (2018) has recently shown that the current best systems fail to learn the correct parsing strategy on mathematical expressions generated from a simple context-free grammar. In this work, we present a recursive model inspired by Choi et al. (2018) that reaches near perfect accuracy on this task. Our model is composed of two separated modules for syntax and semantics. They are cooperatively trained with standard continuous and discrete optimisation schemes. Our model does not require any linguistic structure for supervision, and its recursive nature allows for out-of-domain generalisation. Additionally, our approach performs competitively on several natural language tasks, such as Natural Language Inference and Sentiment Analysis.

1 Introduction

Standard linguistic theories propose that natural language is structured as nested constituents organised in the form of a tree (Partee et al., 1990). However, most popular models, such as the Long Sort-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997), process text without imposing a grammatical structure. To bridge this gap between theory and practice models that process linguistic expressions in a tree-structured manner have been considered in recent work (Socher et al., 2013; Tai et al., 2015; Zhu et al., 2015; Bowman et al., 2016). These tree-based models explicitly require access to the syntactic structure for the text, which is not entirely satisfactory.

Indeed, parse tree level supervision requires a significant amount of annotations from expert linguists. These trees have been annotated with different goals in mind than the tasks we are using them for. Such discrepancy may result in a deterioration of the performance of models relying on them. Recently, several attempts were made to learn these models without explicit supervision for the parser (Yogatama et al., 2016; Maillard et al., 2017; Choi et al., 2018). However, Williams et al. (2018a) has recently shown that the structures learned by these models cannot be ascribed to discovering meaningful syntactic structure. These models even fail to learn the simple context-free grammar of nested mathematical operations (Nangia and Bowman, 2018).

In this work, we present an extension of Choi et al. (2018), that successfully learns these simple grammars while preserving competitive performance on several standard linguistic tasks. Contrary to previous work, our model makes a clear distinction between the parser and the compositional function. These two modules are trained with different algorithms, cooperating to build a semantic representation that optimises the objective function. The parser's goal is to generate a tree structure for the sentence. The compositional function follows this structure to produce the sentence representation. Our model contains a continuous component, the compositional function, and a discrete one, the parser. The whole system is trained end-to-end with a mix of reinforcement learning and gradient descent. Drozdov and Bowman (2017) has noticed the difficulty of mixing these two optimisation schemes without one dominating the other. This typically leads to the "coadaptation problem" where the parser simply follows the compositional function and fails to produce meaningful syntactic structures. In this work, we show that this pitfall can be avoided by synchronising the learning paces of the two optimisation schemes. This is achieved by com-

Minneapolis, Minnesota, June 2 - June 7, 2019.

bining several recent advances in reinforcement learning. First, we use input-dependent control variates to reduce the variance of our gradient estimates (Ross, 1997). Then, we apply multiple gradient steps to the parser's policy while controlling for its learning pace using the Proximal Policy Optimization (PPO) of Schulman et al. (2017). The code for our model is publicly available[1].

2 Preliminaries

In this section, we present existing works on Recursive Neural Networks and their training in the absence of supervision on the syntactic structures.

2.1 Recursive Neural Networks

A Recursive Neural Network (RvNN) has its architecture defined by a directed acyclic graph (DAG) given alongside with an input sequence (Goller and Kuchler, 1996). RvNNs are commonly used in NLP to generate sentence representation that leverages available syntactic information, such as a constituency or a dependency parse trees (Socher et al., 2011).

Given an input sequence and its associated DAG, a RvNN processes the sequence by applying a transformation to the representations of the tokens lying on the lowest levels of the DAG. This transformation, or compositional function, merges these representations into representations for the nodes on the next level of the DAG. This process is repeated recursively along the graph structure until the top-level nodes are reached. In this work, we assume that the compositional function is the same for every node in the graph.

Tree-LSTM. We focus on a specific type of RvNNs, the tree-based long short-term memory network (Tree-LSTM) of Tai et al. (2015) and Zhu et al. (2015). Its compositional function generalizes the LSTM cell of Hochreiter and Schmidhuber (1997) to tree-structured topologies, i.e.,

$$\begin{bmatrix}\mathbf{z}\\\mathbf{i}\\\mathbf{f}_l\\\mathbf{f}_r\\\mathbf{o}\end{bmatrix} = \begin{bmatrix}\mathtt{tanh}\\\sigma\\\sigma\\\sigma\\\sigma\end{bmatrix}\left(\mathbf{R}\begin{bmatrix}\mathbf{h}_l\\\mathbf{h}_r\end{bmatrix}+\mathbf{b}\right),$$

$$\mathbf{c}_p = \mathbf{z}\odot\mathbf{i}+\mathbf{c}_l\odot\mathbf{f}_l+\mathbf{c}_r\odot\mathbf{f}_r,$$

$$\mathbf{h}_p = \mathtt{tanh}(\mathbf{c}_p)\odot\mathbf{o},$$

where σ and `tanh` are the sigmoid and hyperbolic tangent functions. Tree-LSTM cell is differentiable with respect to its recursion matrix $\mathbf{R}$, bias $\mathbf{b}$ and its input. The gradients of a Tree-LSTM can thus be computed with backpropagation through structure (BPTS) (Goller and Kuchler, 1996).

2.2 Learning with RvNNs

A tree-based RvNN is a function f_θ parameterized by a d dimensional vector θ that predicts an output y given an input x and a tree t. Given a dataset $\mathcal{D}$ of N triplets (x, t, y), the parameters of the RvNN are learned with the following minimisation problem:

$$\min_{\theta\in\mathbb{R}^d}\frac{1}{N}\sum_{(x,t,y)\in\mathcal{D}}\ell(f_\theta(x,t),y), \qquad (1)$$

where ℓ is a logistic regression function. These models need an externally provided parsing tree for each input sentence during both training and evaluation. Alternatives, such as the shift-reduce-based SPINN model of Bowman et al. (2016), learn an internal parser from the given trees. While these solutions do not need external trees during evaluation, they still require tree level annotations for training. More recent work has focused on learning a latent parser with no direct supervision.

2.3 Latent tree models

Latent tree models aim at jointly learning the compositional function f_θ and a parser without supervision on the syntactic structures (Yogatama et al., 2016; Maillard et al., 2017; Choi et al., 2018). The latent parser is defined as a parametric probability distribution over trees conditioned on the input sequence. The parameters of this tree distribution $p_\phi(.|x)$ are represented by a vector ϕ. Given a dataset $\mathcal{D}$ of pairs of input sequences x and outputs y, the parameters θ and ϕ are jointly learned by minimising the following objective function:

$$\min_{\theta,\phi}\mathcal{L}(\theta,\phi) = \frac{1}{N}\sum_{(x,y)}\ell(\mathbb{E}_\phi[f_\theta(x,t)],y), \qquad (2)$$

where $\mathbb{E}_\phi$ is the expectation with respect to the $p_\phi(.|x)$ distribution. Directly minimising this objective function is often difficult due to expensive marginalisation of the unobserved trees. Hence, when ℓ is a convex function (e.g. cross entropy of an exponential family) usually an upper bound of Eq. (2) can be derived by applying

---

[1] `https://github.com/facebookresearch/latent-treelstm`

Jensen's inequality:

$$\hat{\mathcal{L}}(\theta, \phi) = \frac{1}{N} \sum_{(x,y)} \mathbb{E}_\phi[\ell(f_\theta(x, t), y)]. \quad (3)$$

Learning a distribution over a set of discrete items involves a discrete optimisation scheme. For example, the RL-SPINN model of Yogatama et al. (2016) uses a mix of gradient descent for θ and REINFORCE for ϕ (Williams et al., 2018a). Drozdov and Bowman (2017) has recently observed that this optimisation strategy tends to produce poor parsers, e.g., parsers that only generate left-branching trees. The effect, called the coadaptation issue, is caused by both bias in the parsing strategy and a difference in convergence paces of continuous and discrete optimisers. Typically, the parameters θ are learned more rapidly than ϕ. This limits the exploration of the search space to parsing strategies similar to those found at the beginning of the training.

2.3.1 Gumbel Tree-LSTM

In their Gumbel Tree-LSTM model, Choi et al. (2018) propose an alternative parsing strategy to avoid the coadaptation issue. Their parser incrementally merges a pair of consecutive constituents until a single one remains. This strategy reduces the bias towards certain tree configurations observed with RL-SPINN.

Each word i of the input sequence is represented by an embedding vector. A leaf transformation maps this vector to pair of vectors $\mathbf{r}_i^0{=}(\mathbf{h}_i^0, \mathbf{c}_i^0)$. We considered three types of leaf transformations: affine transformation, LSTM and bidirectional LSTM. The resulting representations form the initial states of the Tree-LSTM. In the absence of supervision, the tree is built in a bottom-up fashion by recursively merging consecutive constituents $(i, i+1)$ based on merge-candidate scores. On each level k of the bottom-up derivation, the merge-candidate score of the pair $(i, i{+}1)$ is computed as follow:

$$s_k(i) = \langle \mathbf{q}, \texttt{Tree-LSTM}(\mathbf{r}_i^k, \mathbf{r}_{i+1}^k) \rangle,$$

where $\mathbf{q}$ is a trainable query vector and $\mathbf{r}_i^k$ is the constituent representation at position i after k mergings. We merge a pair (i^*, i^*+1) sampled from the Categorical distribution built on the merge-candidate scores. The representations of the constituents are then updated as follow:

$$\mathbf{r}_i^{k+1} = \begin{cases} \mathbf{r}_i^k, & i < i^*, \\ \texttt{Tree-LSTM}(\mathbf{r}_i^k, \mathbf{r}_{i+1}^k) & i = i^*, \\ \mathbf{r}_{i+1}^k & i > i^*. \end{cases}$$

This procedure is repeated until one constituent remains. Its hidden state is the input sentence representation. This procedure is non-differentiable. Choi et al. (2018) use an approximation based on the Gumbel-Softmax distribution (Maddison et al., 2016; Jang et al., 2016) and the reparametrization trick (Kingma and Welling, 2013).

This relaxation makes the problem differentiable at the cost of a bias in the gradient estimates (Jang et al., 2016). This difference between the real objective function and their approximation could explain why their method cannot recover simple context-free grammars (Nangia and Bowman, 2018). We investigate this question by proposing an alternative optimisation scheme that directly aims for the correct objective function.

3 Our model

We consider the problem defined in Eq. (3) to jointly learn a composition function and an internal parser. Our model is composed of the parser of Choi et al. (2018) and the Tree-LSTM for the composition function. As suggested in past work (Mnih et al., 2016; Schulman et al., 2017), we added an entropy $\mathcal{H}$ over the tree distribution to the objective function:

$$\min_{\theta,\,\phi} \hat{\mathcal{L}}(\theta, \phi) - \lambda \sum_x \mathcal{H}(t \mid x), \quad (4)$$

where $\lambda > 0$. This regulariser improves exploration by preventing early convergence to a suboptimal deterministic parsing strategy. The new objective function is differentiable with respect to θ, but not ϕ, the parameters of the parser. Learning θ follows the same procedure with BPTS as if the tree would be externally given.

In the rest of this section, we discuss the optimization of the parser and a cooperative training strategy to reduce the coadaptation issue.

3.1 Unbiased gradient estimation

We cast the training of the parser as a reinforcement learning problem. The parser is an agent whose reward function is the negative of the loss function defined in Eq. (3). Its action space is the space of binary trees. The agent's policy is a probability distribution over binary trees that decomposes as a sequence of K merging actions:

$$p_\phi(t|x) = \prod_{k=0}^{K} \pi_\phi(a_k^i|\mathbf{r}^k), \tag{5}$$

where $\mathbf{r}^k = (\mathbf{r}_0^k, \dots, \mathbf{r}_{K-k}^k)$. The loss function is optimised with respect to ϕ with REINFORCE (Williams, 1992). REINFORCE requires a considerable number of random samples to obtain a gradient estimate with a reasonable level of variance. This number is positively correlated with the size of the search space, which is exponentially large in the case of binary trees. We consider several extensions of REINFORCE to circumvent this problem.

Variance reduction. An alternative solution to increasing the number of samples is the control variates method (Ross, 1997). It takes advantage of random variables with known expected values and positive correlation with the quantity whose expectation is tried to be estimated. Given an input-output pair (x, y) and tree t sampled from $p_\phi(t|x)$, let's define the random variable G as:

$$G(t) = \ell(f_\theta(x,t), y)\frac{\partial \log p_\phi(t|x)}{\partial \phi}. \tag{6}$$

According to REINFORCE, calculating the gradient with respect to ϕ for the pair (x, y) is then equivalent to determining the unknown mean of the random variable $G(t)$[2]. Let's assume there is a control variate, i.e., a random variable $b(t)$ that positively correlates with G and has known expected value with respect to $p_\phi(.|x)$. Given N samples of the $G(t)$ and the control variate $b(t)$, the new gradient estimator is:

$$G_{\text{CV}} = \mathbb{E}_{p_\phi(t|x)}[b(t)] + \frac{1}{N}\left[\sum_{i=1}^{N}(G(t_i) - b(t_i))\right].$$

A popular control variate, or baseline, used in REINFORCE is the moving average of recent rewards multiplied by the score function (Ross, 1997):

$$b(t) = c\nabla_\phi \log p_\phi(t|x).$$

It has a zero mean under the $p_\phi(.|x)$ distribution and it positively correlates with $G(t)$.

Surrogate loss. REINFORCE often is implemented via a surrogate loss defined as follow:

$$\hat{\mathbb{E}}_t\left[r_\phi(t)\ell(f_\theta(x,t), y)\right], \tag{7}$$

where $\hat{\mathbb{E}}_t$ is the empirical average over a finite batch of samples and $r_\phi(t) = \frac{p_\phi(t|x)}{p_{\phi_{\text{old}}}(t|x)}$ is the probability ratio with ϕ_{old} standing for the parameters before the update.

Input-dependent baseline. The moving average baseline cannot detect changes in rewards caused by structural differences in the inputs. In our case, a long arithmetic expression is much harder to parse than a short one, systematically leading to their lower rewards. This structural differences in the rewards aggravate the credit assignment problem by encouraging REINFORCE to discard actions sampled for longer sequences even though there might be some subsequences of actions that produce correct parsing subtrees.

A solution is to make the baseline input-dependent. In particular, we use the self-critical training (SCT) baseline of Rennie et al. (2017), defined as:

$$b(t, x) = c_{\theta,\phi}(x)\nabla_\phi \log p_\phi(t \mid x),$$

where $c_{\theta,\phi}$ is the reward obtained with the policy used at test time, i.e., $\hat{t} = \arg\max p_\phi(t|x)$. This control variate has a zero mean under the $p_\phi(t|x)$ distribution and correlates positively with the gradients. Computing the $\arg\max$ of a policy among all possible binary trees has exponential complexity. We replace it with a simpler greedy decoding, i.e, a tree t is selected by following a sequence of greedy actions $\hat{a}_k$:

$$\hat{a}_k = \arg\max \pi_\phi(a_k \mid \hat{\mathbf{r}}^k).$$

This approximation is very efficient and computing the baseline requires only one additional forward pass.

Gradient normalization. We empirically observe significant fluctuations in the gradient norms. This creates instability that can not be reduced by additive terms, such as the input-dependent baselines. A solution is to divide the gradients by a coarse approximation of their norm, e.g., a running estimate of the reward standard deviation (Mnih and Gregor, 2014). This trick ensures that the rewards remain approximately in the unit ball, making the learning process less sensitive to steep changes in the loss.

---

[2] Note that while we are computing the gradients using ℓ, we could also directly optimise the parser with respect to downstream accuracy.

3.2 Synchronizing syntax and semantics learning with PPO

The gradients of the loss function from the Eq. (4) are calculated using two different schemes, BPST for the composition function parameters θ and REINFORCE for the parser parameters ϕ. Then, both are updated with SGD. The estimate of the gradient with respect to ϕ has higher variance compared to the estimate with respect to θ. Hence, using the same learning rate schedule does not necessarily correspond to the same real pace of learning. It is ϕ parameters that are harder to optimise, so to improve training stability and convergence it is reasonable to aim for such updates that does not change the policy too much or too little. A simple yet effective solution is the Proximal Policy Optimization (PPO) of Schulman et al. (2017). It considers the next surrogate loss:

$$\hat{\mathbb{E}}_t \left[\max \left\{ r_\phi(t) \ell \left(f_\theta(x,t), y \right), r^c_\phi(t) \ell \left(f_\theta(x,t), y \right) \right\} \right],$$

Where $r^c_\phi(t) = \texttt{clip}\left(r_\phi(t), 1-\epsilon, 1+\epsilon\right)$ and ϵ is a real number in $(0; 0.5]$. The first argument of the $\max$ is the surrogate loss for REINFORCE. The clipped ratio in the second argument disincentivises the optimiser from performing updates resulting in large tree probability changes. With this, the policy parameters can be optimised with repeated K steps of SGD to ensure a similar "pace" of learning between the parser and the compositional function.

4 Related work

Besides the works mentioned in Sec. 2 and Sec. 3, there is a vast literature on learning latent parsers. Early connectionist work in inferring context-free grammars proposed stack-augmented models and relied on explicit supervision on the strings that belonged to the target language and those that did not (Giles et al., 1989; Sun, 1990; Das et al., 1992; Mozer and Das, 1992). More recently, new stack-augmented models were shown to learn latent grammars from positive evidence alone (Joulin and Mikolov, 2015). In parallel to these, other statistical approaches were proposed to automatically induce grammars from unparsed text (Sampson, 1986; Magerman and Marcus, 1990; Carroll and Charniak, 1992; Brill, 1993; Klein and Manning, 2002). Our work departs from these approaches in that we aim at learning a latent grammar in the context of performing some given task.

Socher et al. (2011) uses a surrogate auto-encoder objective to search for a constituency structure, merging nodes greedily based on the reconstruction loss. Maillard et al. (2017) defines a relaxation of a CYK-like chart parser that is trained for a particular task. A similar idea is introduced in Le and Zuidema (2015) where an automatic parser prunes the chart to reduce the overall complexity of the algorithm. Another strategy, similar in nature, has been recently proposed by Corro and Titov (2018), where Gumbel noise is used with differentiable dynamic programming to generate dependency trees. In contrast, Yogatama et al. (2016) learns a Shift-Reduce parser using reinforcement learning. Maillard and Clark (2018) further proposes a beam search strategy to overcome learning trivial trees. On a different vein, Vlad Niculae (2018) proposes a quadratic penalty term over the posterior distribution of non-projective dependency trees to enforce sparsity of the relaxation. Finally, there is a large body of work in Reinforcement Learning that aims at discovering how to combine elementary modules to solve complex tasks (Singh, 1992; Chang et al., 2018; Sahni et al., 2017). Due to the limited space, we will not discuss them in further details.

5 Experiments

We conducted experiments on three different tasks: evaluating mathematical expressions on the ListOps dataset (Nangia and Bowman, 2018), sentiment analysis on the SST dataset (Socher et al., 2013) and natural language inference task on the SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018b) datasets.

Technical details. For ListOps, we follow the experimental protocol of Nangia and Bowman (2018), i.e., a 128 dimensional model and a ten-way softmax classifier. However, we replace their multi-layer perceptron (MLP) by a linear classifier. The validation set is composed of 1k examples randomly selected from the training set. For SST and NLI, we follow the setup of Choi et al. (2018): we initialise the word vectors with GloVe300D (Pennington et al., 2014) and train an MLP classifier on the sentence representations. The hyperparameters are selected on the validation set using 5 random seeds for each configuration. Our hyperparameters are the learning rate, weight decay, the regularisation parameter λ, the leaf transformations, variance reduction hyperpa-

rameters and the number of updates K in PPO. We use an adadelta optimizer (Zeiler, 2012).

5.1 ListOps

The ListOps dataset probes the syntax learning ability of latent tree models (Nangia and Bowman, 2018). It is designed to have a single correct parsing strategy that a model must learn in order to succeed. It is composed of prefix arithmetic expressions and the goal is to predict the numerical output associated with the evaluation of the expression. The sequences are made of integers in $[0, 9]$ and 4 operations: `MIN`, `MAX`, `MED` and `SUM_MOD`. The output is an integer in the range $[0, 9]$. For example, the expression `[MIN 2 [MAX 0 1] [MIN 6 3 ] 5 ]` is mapped to the output `1`. The ListOps task is thus a sequence classification problem with 10 classes. There are 90k training examples and 10k test examples. It is worth mentioning that the underlying semantic of operations and symbols is not provided. In other words, a model has to infer from examples that `[MIN 0 1] = 0`.

As shown in Table 2, the current leading latent tree models are unable to learn the correct parsing strategy on ListOps (Nangia and Bowman, 2018). They even achieve performance worse than purely sequential recurrent networks. On the other hand, our model achieves near perfect accuracy on this task, suggesting that our model is able to discover the correct parsing strategy. Our model differs in several ways from the Gumbel Tree-LSTM of Choi et al. (2018) that could explain this gap in performance. In the rest of this section, we perform an ablation study on our model to understand the importance of each of these differences.

Impact of the baseline and PPO. We report the impact of our design choices on the performance in Table 1. Our model without baseline nor PPO is vanilla REINFORCE. The baselines only improve performance when PPO is used. Furthermore, these ablated models without PPO perform on-par with the RL-SPINN model (see Table 2). This confirms our expectations for models that fail to synchronise syntax and semantics learning.

Interestingly, using PPO has a positive impact on both baselines, but accuracy remains low with the moving average baseline. The reduction of variance induced by the SCT baseline leads to a near-perfect recovery of the good parsing strategy in all five experiments. This shows the importance of this baseline for the stability of our approach.

Sensitivity to hyperparameters. Our model is relatively robust to hyperparameters changes when we use the SCT baseline and PPO. For example, changing the leaf transformation or dimensionality of the model has a minor impact on performance. However, we have observed that the choice of the optimiser has a significant impact. For example, the average performance drops to 73.0% if we replace Adadelta by Adam (Kingma and Ba, 2014). Yet, the maximum value out of 5 runs remains relatively high, 99.0%.

Untied parameters. As opposed to previous work, the parameters of the parser and the composition function are not tied in our model. Without this separation between syntax and semantics, it would be impossible to update one module with-

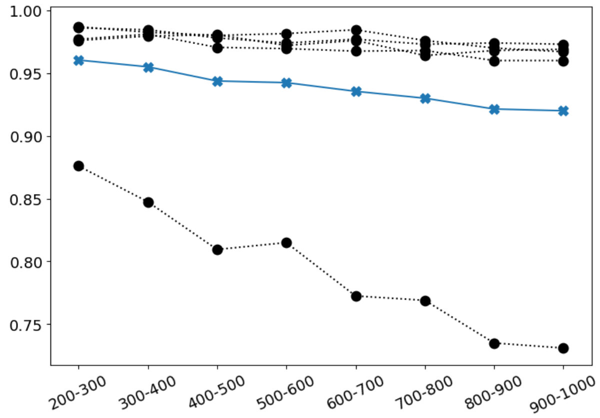

Figure 1: Blue crosses depict an average accuracy of five models on the test examples that have lengths within certain range. Black circles illustrate individual models.

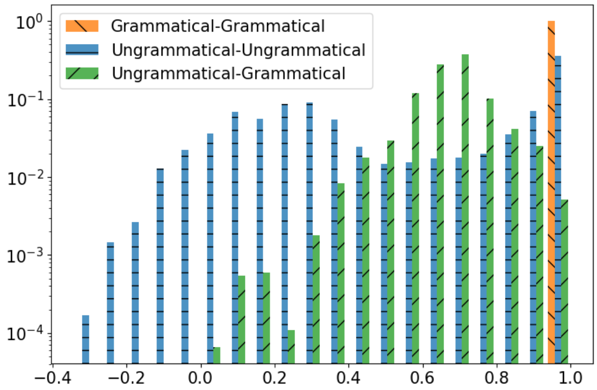

Figure 2: The distributions of cosine similarity for elements from the different sets of mathematical expressions. A logarithmic scale is used for y-axis.

out changing the other. The gradient direction is then dominated by the low variance signal from the semantic component, making it hard to learn the parser. We confirmed experimentally that our model with tied parameters fails to find the correct parser and its accuracy drops to 64.7%.

Extrapolation and Grammaticality. Recursive models have the potential to generalise to any sequence length. Our model was trained with sequences of length up to 130 tokens. We test the ability of the model to generalise to longer sequences by generating additional expressions of lengths 200 to 1000. As shown in Fig.1, our model has a little loss in accuracy as the length increases to ten times the maximum length seen during training.

On the other hand, we notice that final representations produced by the parser are very similar to each other. Indeed, the cosine similarity between these vectors for the test set has a mean value of 0.998 with a standard deviation of 0.002. There are two possible explanations for this observation: either our model assigns similar representations to valid expressions, or it produces a trivial uninformative representation regardless of the expression. To verify which explanation is correct, we generate ungrammatical expressions by removing either one operation token or one closing bracket symbol for each sequence in the test set. As shown in Figure 2, in contrast to grammatical expressions, ungrammatical ones tend to be very different from each other: "Happy families are all alike; every unhappy family is unhappy in its own way." The only exception, marked by a mode near 1, come from ungrammatical expressions that represent incomplete expressions because of missing a closing bracket at the end. This kind of sequences were seen by the parser during training and they indeed have to be represented by the same vector. These observations show that our model does not produce a trivial representation, but identifies the rules and constraints of the grammar. Moreover, vectors for grammatical sequences are so different from vectors for ungrammatical ones that you can tell them apart with 99.99% accuracy by simply measuring their cosine similarity to a randomly chosen grammatical vector from the training set. Interestingly, we have not observed a similar signal from the vectors generated by the composition function. Even learning a naive classifier between grammatical and ungrammatical expressions on top of these representations achieves an accuracy of only 75%. This suggests that most of the syntactic information is captured by the parser, not the composition function.

5.2 Natural Language Inference

We next evaluate our model on natural language inference using the Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) and MultiNLI (Williams et al., 2018b) datasets. Natural language inference consists in predicting the relationship between two sentences which can be either entailment, contradiction, or neutral. The task can be formulated as a three-way classification problem. The results are shown in Tables 3 and 4. When training the model on MultiNLI dataset we augment the training data with the SNLI data and use *matched* versions of the de-

velopment and test sets. Surprisingly, two out of four models for MultiNLI task collapsed to left-branching parsing strategies. This collapse can be explained by the absence of the entropy regularisation and the small number of PPO updates $K = 1$, which were determined to be optimal via hyperparameter optimisation. As with ListOps, using an Adadelta optimizer significantly improves the training of the model.

5.3 Sentiment Analysis

We evaluate our model on a sentiment classification task using the Stanford Sentiment Treebank (SST) of Socher et al. (2013). All sentences in SST are represented as binary parse trees, and each subtree of a parse tree is annotated with the corresponding sentiment score. There are two versions of the dataset, with either binary labels, “negative” or “positive”, (SST-2) or five labels, representing fine-grained sentiments (SST-5). As shown in Table 5, our results are in line with previous work, confirming the benefits of using latent syntactic parse trees instead of the predefined syntax.

We noticed that all models trained on NLI or sentiment analysis tasks have parsing policies with relatively high entropy. This indicates that the algorithm does not prefer any specific grammar. Indeed, generated trees are very similar to balanced ones. This result is in line with Shi et al. (2018) where they observe that binary balanced tree encoder gets the best results on most classification tasks.

We also compare with state-of-the-art sequence-based models. For the most part, these models are pre-trained on larger datasets and fine-tuned on these tasks. Nonetheless, they outperform recursive models by a significant margin. Performance on these datasets is more impacted by pre-training than by learning the syntax. It would be interesting to see if a similar pre-training would also improve the performance of recursive models with latent tree learning.

6 Conclusion

In this paper, we have introduced a novel model for learning latent tree parsers. Our approach relies on a separation between syntax and semantics. This allows dedicated optimisation schemes for each module. In particular, we found that it is important to have an unbiased estimator of the parser gradients and to allow multiple gradient steps with PPO. When tested on a CFG, our learned parser generalises to sequences of any length and distinguishes grammatical from ungrammatical expressions by forming meaningful representations for well-formed expressions. For natural language tasks, instead, the model prefers to fall back to trivial strategies, in line with what was previously observed by Shi et al. (2018). Additionally, our approach performs competitively on several real natural language tasks. In the future, we would like to explore further relaxation-based techniques for learning the parser, such as REBAR (Tucker et al., 2017) or ReLAX (Grathwohl et al., 2017). Finally, we plan to look into applying recursive approaches to language modelling as a pre-training step and measure if it has the same impact on downstream tasks as sequential models.

Acknowledgments

We would like to thank Alexander Koller, Ivan Titov, Wilker Aziz and anonymous reviewers for their helpful suggestions and comments.

Abstract

We introduce deep inside-outside recursive autoencoders (DIORA), a fully-unsupervised method for discovering syntax that simultaneously learns representations for constituents within the induced tree. Our approach predicts each word in an input sentence conditioned on the rest of the sentence and uses inside-outside dynamic programming to consider all possible binary trees over the sentence. At test time the CKY algorithm extracts the highest scoring parse. DIORA achieves a new state-of-the-art F1 in unsupervised binary constituency parsing (unlabeled) in two benchmark datasets, WSJ and MultiNLI.

1 Introduction

Syntactic parse trees are useful for downstream tasks such as relation extraction (Gamallo et al., 2012), semantic role labeling (Sutton and McCallum, 2005; He et al., 2018), machine translation (Aharoni and Goldberg, 2017; Eriguchi et al., 2017; Zaremoodi and Haffari, 2018), and text classification (Li and Roth, 2006; Tai et al., 2015). Traditionally, supervised parsers trained on datasets such as the Penn Treebank (Marcus et al., 1993) are used to obtain syntactic trees. However, the treebanks used to train these supervised parsers are typically small and restricted to the newswire domain. Unfortunately, models trained on newswire treebanks tend to perform considerably worse when applied to new types of data, and creating new domain specific treebanks with syntactic annotations is expensive and time-consuming.

Motivated by the desire to address the limitations of supervised parsing and by the success of large-scale unsupervised modeling such as ELMo and BERT (Peters et al., 2018a; Devlin et al., 2019), we propose a new deep learning method of unsupervised parser training that can extract both shallow parses (i.e., noun phrases or entities) and full syntactic trees from any domain or language automatically *without requiring any labeled training data*. In addition to producing parses, our model simultaneously builds representations for internal constituents that reflect syntactic and semantic regularities which can be leveraged by downstream tasks.

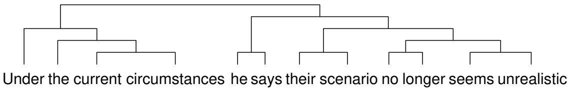

Figure 1: An unlabeled binary constituency parse from DIORA matching the ground truth.

Our model builds on existing work developing latent tree chart parsers (Socher et al., 2011b; Le and Zuidema, 2015; Yogatama et al., 2017; Maillard et al., 2017; Choi et al., 2018). These methods produce representations for all internal nodes in the tree (cells in the chart), each generated as a soft weighting over all possible sub-trees (§2). Unfortunately, they still require sentence-level annotations during training, as they are all trained to optimize a downstream task, typically natural language inference.

To address these limitations, we present deep inside-outside recursive autoencoders (DIORA) which enable unsupervised discovery and representation of constituents without requiring any supervised training data. DIORA incorporates the inside-outside algorithm (Baker, 1979; Lari and Young, 1990) into a latent tree chart parser. The bottom-up inside step calculates a representation for all possible constituents within a binary tree over the input sentence. This step is equivalent to the forward-pass of previous latent tree chart parsers (Maillard et al., 2017). These inside representations only encode the current subtree, ignor-

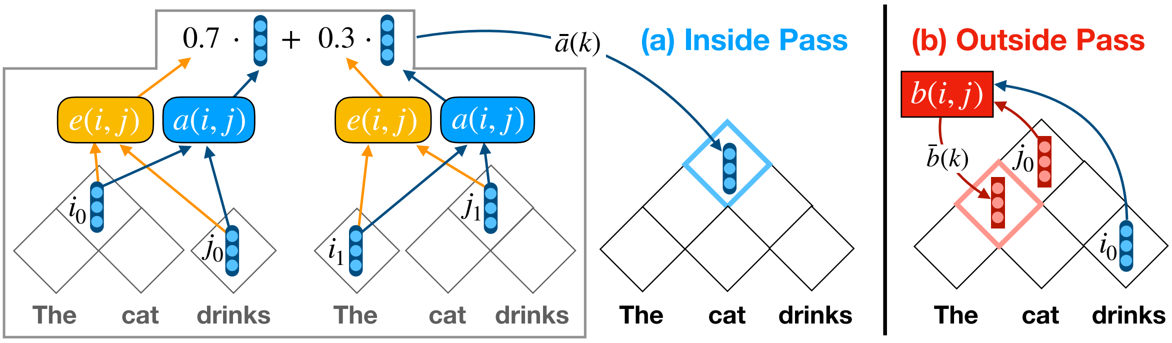

Figure 2: The illustrated inside and outside pass of DIORA operating over an input of length three, 'the cat drinks'. a) The inside pass: The inside vector $\bar{a}(k)$ for the phrase 'the cat drinks' is a weighted average of the compositions for the two possible segmentations - ((the cat), drinks) and (the, (cat drinks)). The scalar weights come from a learned compatibility function. b) The outside pass: The outside vector $\bar{b}(k)$ for the phrase 'the cat' is a function of the outside vector of its parent 'the cat drinks' and the inside vector of its sibling 'drinks'.

ing all outside context. Thus, we perform an additional top-down outside calculation for each node in the tree, providing external context into the subtree representations in each chart cell. The model is then trained with the objective that the outside representations of the leaf cells should reconstruct the corresponding leaf input word, analogous to masked language model (Devlin et al., 2019) pretraining, except by using dynamic programming we predict every word from a completely unmasked context. The single most likely tree can be recovered using the CKY algorithm and compatibility scores between constituents. Previous work either predict trees that are not well aligned with known treebanks (Yogatama et al., 2017; Choi et al., 2018), or has no mechanism for explicitly modeling phrases, requiring a complex procedure to extract syntactic structures (Shen et al., 2018).

To probe different properties of our model, we run experiments on unsupervised parsing, segment recall, and phrase representations. DIORA achieves multiple new state-of-the-art results for unsupervised constituency parsing (absolute improvements of **13.7%**, **11.5%**, and **7.8%** on WSJ, WSJ-40, and MultiNLI), has a greater recall on more constituent types than a strong baseline, and produces meaningful phrase representations.

2 DIORA: Deep Inside-Outside Recursive Autoencoders

Our goal is to design a model and unsupervised training procedure that learns structure from raw text. The design of DIORA is based on our hypothesis is that the most effective compression of a sentence will be derived from following the true syntactic structure of the underlying input. Our approach builds on previous latent tree chart parsers which are augmented with the inside-outside algorithm (Baker, 1979; Lari and Young, 1990) and trained to reproduce each input word from its outside context. Based on our hypothesis, loosely inspired by the linguistic "substitution principle" (Frege, 1960), the model will best reconstruct the input by discovering and exploiting syntactic regularities of the text.

The inside pass of our method recursively compresses the input sequence, at each step inputting the vector representations of the two children into a composition function (§2.1.1) that outputs an inside vector representation of the parent. This process continues up to the root of the tree, eventually yielding a single vector representing the entire sentence (Figure 2a). This is loosely analogous to the compression step of an autoencoder and equivalent to existing latent tree chart parsers forward pass (Maillard et al., 2017). Following this, we initiate the outside pass of our algorithm with a generic (root) representation that is learned as a separate parameter. As the outside step of the inside-outside algorithm (Figure 2b), we unfold until finally producing representations of the leaf nodes. These leaves are then optimized to reconstruct the input sentence as done in an autoencoder-based deep neural network.

2.1 Filling the Chart with Inside-Outside

Each inside representation is the root of a particularly sub-tree, and that representation is generated by considering only the descendant constituents within that sub-tree, ignoring any outside context. After the inside representations are calculated, we perform a top-down outside pass to compute outside representations. The outside representations are encoded by looking at only the context of a given sub-tree. Once the chart is filled, each constituent k (cell in the chart) is associated with an inside vector $\bar{a}(k)$, an outside vector $\bar{b}(k)$, inside compatibility score $\bar{e}(k)$ and outside compatibility score $\bar{f}(k)$.

The input to our model is a sentence $\boldsymbol{x}$ made up of T tokens, $x_0, x_1, ..., x_{T-1}$. Each token x_i has a corresponding pre-trained embedded vector v_i.

2.1.1 Inside Pass

For each pair of neighboring constituents i and j [1], we compute a *compatibility* score and a *composition* vector. The score and vector that represent a particular span k are computed using a soft weighting over all possible pairs of constituents, that together fully cover the span (we refer to this set of constituent pairs as $\{k\}$).

Vectors for spans of length 1 are initialized as a non-linear transformation [2] of the embedded input v_i, and the scores associated with these spans are set to 0:

$$\begin{bmatrix} x \\ o \\ u \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \tanh \end{bmatrix} (U_\psi v_k + b)$$
$$\bar{a}(k) = o + \tanh(x \odot u)$$
$$\bar{e}(k) = 0$$

Higher levels of the chart are computed as a weighted summation of constituent pairs:

$$\bar{a}(k) = \sum_{i,j \in \{k\}} e(i,j)\, a(i,j)$$
$$\bar{e}(k) = \sum_{i,j \in \{k\}} e(i,j)\, \hat{e}(i,j)$$

The compatibility function $\hat{e}$ is meant to produce a score for how likely a pair of neighboring cells are to be merged. We implement this as a bilinear function of the vectors from neighboring spans, using a learned parameter matrix S. We additionally add the individual scores from each two merging cells. Intuitively, these individual scores correspond to how likely each of the cells would exist in the final binary tree independently. The formula for the compatibility function (and its normalized form e) is defined as follows:

$$e(i,j) = \frac{\exp(\hat{e}(i,j))}{\sum_{\hat{i},\hat{j} \in \{k\}} \exp(\hat{e}(\hat{i},\hat{j}))}$$
$$\hat{e}(i,j) = \phi(\bar{a}(i), \bar{a}(j); S_\alpha) + \bar{e}(i) + \bar{e}(j)$$

Where the bilinear projection ϕ is defined as:

$$\phi(u, v; W) = u^\top W v$$

For the composition function a we used either a TreeLSTM (Tai et al., 2015) or a 2-layer MLP (see Appendix A.2 for more precise definitions on both methods). In order for the remainder of equations to remain agnostic to the choice of composition function, we refer to the function as Compose, which produces a hidden state vector h and, in the case of TreeLSTM, a cell state vector c, resulting in:

$$a(i,j) = \text{Compose}_\alpha(\bar{a}(i), \bar{a}(j))$$

2.1.2 Outside Pass

The outside computation is similar to the inside pass (depicted in Figure 2b).

The root node of the outside chart is learned as a bias. Descendant cells are predicted using a disambiguation over the possible outside contexts. Each component of the context consists of a sibling cell from the inside chart and a parent cell from the outside chart.

The function f is analogous to the function e. It is normalized over constituent pairs i, j for the span k, and is used to disambiguate among the many outside contexts. The function b generates a phrase representation for the missing sibling cell. Equations for the outside computation follow:

$$\bar{b}(k) = \sum_{i,j \in \{k\}} f(i,j)\, b(i,j)$$
$$\bar{f}(k) = \sum_{i,j \in \{k\}} f(i,j)\, \hat{f}(i,j)$$
$$b(i,j) = \text{Compose}_\beta(\bar{a}(i), \bar{b}(j))$$
$$\hat{f}(i,j) = \phi(\bar{a}(i), \bar{b}(j); S_\beta) + \bar{e}(i) + \bar{f}(j)$$

In the majority of our experiments, the Compose used in b shares parameters with a used in the inside pass, as do the compatibility functions $\hat{e}$ and $\hat{f}$ (see §3.4 for results on the effects of parameter sharing).

---

[1] The symbols i, j, and k are identifiers of spans from the input $\boldsymbol{x}$. The symbol i^* identifies a token from the set of negative examples $\{\boldsymbol{x}^*\}$.

[2] This function shares its bias term b with Compose_α, although U_ψ is not tied to any other weights.

2.2 Training Objective

To train our model we use an autoencoder-like language modeling objective. In a standard autoencoder, the entire input $\boldsymbol{x}$ is compressed into a single lower dimensional representation. This representation, $\boldsymbol{z}$, is then decompressed and trained to reconstruct $\boldsymbol{x}$. In our model, we never condition the reconstruction of $\boldsymbol{x}$ on a single $\boldsymbol{z}$ because the root's outside representation is initialized with a bias rather than the root's own inside vector. Instead, we reconstruct $\boldsymbol{x}$ conditioned on the many sub-tree roots, each of which is only a compression of a *subset* of the input.

To approximate this reconstruction we use a max-margin loss considering a set $\{\boldsymbol{x}^*\}$ of N negative examples that are sampled according to their frequency from the vocabulary (further details in Appendix A.1). The terminal outside vector $\bar{b}(i)$ is trained to predict its original input v_i.

The per-instance loss function is described in Equation 1:

$$L_{\boldsymbol{x}} = \sum_{i=0}^{T-1} \sum_{i^*=0}^{N-1} \max(0, 1 - \bar{b}(i) \cdot \bar{a}(i) + \bar{b}(i) \cdot \bar{a}(i^*)) \qquad (1)$$

The max-margin loss does not provide a gradient if the predicted vector is closer to its ground truth than the negative example by a margin greater than 1. For that reason, we also experimented with an objective based on cross-entropy, described in Equation 2:

$$Z^* = \sum_{i^*=0}^{N-1} \exp(\bar{b}(i) \cdot \bar{a}(i^*))$$

$$L_{\boldsymbol{x}} = -\sum_{i=0}^{T-1} \log \frac{\exp(\bar{b}(i) \cdot \bar{a}(i))}{\exp(\bar{b}(i) \cdot \bar{a}(i)) + Z^*} \qquad (2)$$

2.3 DIORA CKY Parsing

To obtain a parse with DIORA, we populate an inside and outside chart using the input sentence. We can extract the maximum scoring parse based on our single grammar rule using the CKY procedure (Kasami, 1966; Younger, 1967). The steps for this procedure are described in Algorithm 1 and its runtime complexity in Appendix A.4.

3 Experiments

To evaluate the effectiveness of DIORA, we run experiments on unsupervised parsing, unsupervised segment recall, and phrase similarity. The model has been implemented in PyTorch (Team, 2018) and the code is published online.[3] For training details, see Appendix A.1.

Algorithm 1 Parsing with DIORA

```
procedure CKY(chart)
    Initialize terminal values.
    for each $k \in$ chart | SIZE$(k) = 1$ do
        $x_k \leftarrow 0$
    Calculate a maximum score for each span,
    and record a backpointer.
    for each $k \in$ chart do
        $x_k \leftarrow \max_{i,j \in \{k\}} [x_i + x_j + e(i,j)]$
        $\pi_k^i, \pi_k^j \leftarrow \arg\max_{i,j \in \{k\}} [x_i + x_j + e(i,j)]$
    Backtrack to get the maximal tree.
    procedure BACKTRACK($k$)
        if SIZE$(k) = 1$ then
            return k
        $i \leftarrow$ BACKTRACK$(\pi_k^i)$
        $j \leftarrow$ BACKTRACK$(\pi_k^j)$
        return (i, j)
    return BACKTRACK($k \leftarrow$ root)
```

3.1 Unsupervised Parsing

We first evaluate how well our model predicts a full unlabeled constituency parse. We look at two data sets used in prior work (Htut et al., 2018), The Wall Street Journal (WSJ) section of Penn Treebank (Marcus et al., 1993), and the automatic parses from MultiNLI (Williams et al., 2018b). WSJ has gold human-annotated parses and MultiNLI contains automatic parses derived from a supervised parser (Manning et al., 2014).

In addition to PRPN (Shen et al., 2018),[4] we compare our model to deterministically constructed left branching, right branching, balanced, and random trees. We also compare to ON-LSTM (Shen et al., 2019), an extension of the PRPN model, RL-SPINN (Yogatama et al., 2017), an unsupervised shift-reduce parser, and ST-Gumbel (Choi et al., 2018), an unsupervised chart parser. The latter two of these models are trained to predict the downstream task of natural language inference (NLI).

---

[3] `https://github.com/iesl/diora`

[4] We consider the PRPN models using LM stopping criteria, which outperformed UP.

3.1.1 Binarized WSJ and MultiNLI results

For the full WSJ test set and MultiNLI datasets we follow the experimental setup of previous work (Williams et al., 2018a). We binarize target trees using Stanford CoreNLP (Manning et al., 2014) and do not remove punctuation (experiments in §3.1.2 do remove punctuation).

Latent tree models have been shown to perform particularly poorly on attachments at the beginning and end of the sequence (Williams et al., 2018a). To address this, we incorporate a post-processing heuristic (denoted as +PP in result tables)[5]. This heuristic simply attaches trailing punctuation to the root of the tree, regardless of its predicted attachment.

In Table 1, we see that DIORA^{+PP} achieves the highest average and maximum F1 from five random restarts. This model achieves a mean F1 7 points higher than ON-LSTM and an increase of over 6.5 max F1 points. We also see that DIORA exhibits much less variance between random seeds than ON-LSTM. Additionally, we find that PRPN-UP and DIORA benefit much more from the +PP heuristic than PRPN-LM. This is consistent with qualitative analysis showing that DIORA and PRPN-UP incorrectly attach trailing punctuation much more often than PRPN-LM.

On the MultiNLI dataset, PRPN-LM is the top performing model without using the +PP heuristic while DIORA matches PRPN-UP (Table 2. Using the heuristic, DIORA greatly surpasses both variants of PRPN. However, it is worth noting that this is not a gold standard evaluation and instead evaluates a model's ability to replicate the output of a trained parser (Manning et al., 2014). A second caveat is that SNLI (Bowman et al., 2015) and MultiNLI contain several non-newswire domains. Syntactic parsers often suffer significant performance drops when predicting outside of the newswire domain that the models were trained on.

Model	**F1**$_\mu$	**F1**$_{max}$	δ

PRPN-LM^{+PP}	-	50.4	5.1
DIORA^{+PP}	59.0	**59.1**	6.7

Table 2: NLI unsupervised unlabeled binary constituency parsing comparing to CoreNLP predicted parses. PRPN F1 was calculated using the parse trees and results provided by Htut et al. (2018). F1 median and max are calculated over five random seeds and the top F1 value in each column is bolded. Note that we use median rather than mean in order to compare with previous work.

3.1.2 WSJ-10 and WSJ-40 results

We also compare our models to two subsets of the WSJ dataset that were used in previous unsupervised parsing evaluations. WSJ-10 and WSJ-40 contain sentences up to length 10 and 40 respectively after punctuation removal. We do not binarize either of these two splits in order to compare to previous work (see Appendix A.3 for more details on WSJ split differences). Not binarizing the target trees sets an upper-bound on the performance of our models, denoted as UB in Table 3.

We compare against previous notable models for this task: CCM (Klein and Manning, 2002) uses the EM algorithm to learn probable nested

---

[5] We did not have access to predictions or an implementation of the concurrent ON-LSTM model and therefore could not apply the +PP heuristic.

bracketings over a sentence using gold or induced part-of-speech tags, and PRLG (Ponvert et al., 2011) performs constituent parsing through consecutive rounds of sentence chunking.

In Table 3, we see that DIORA outperforms the previous state of the art for WSJ-40, PRLG, in max F1. The WSJ-10 split has been difficult for latent tree parsers such as DIORA, PRPN, and ON-LSTM, none of which (including our model) are able to improve upon previous non-neural methods. However, when we compare trends between WSJ-10 and WSJ-40, we see that DIORA does a better job at extending to longer sequences.

3.2 Unsupervised Phrase Segmentation

In many scenarios, one is only concerned with extracting particular constituent phrases rather than a full parse. Common use cases would be identifying entities, noun phrases, or verb phrases for downstream analysis. To get an idea of how well our model can perform on phrase segmentation, we consider the maximum recall of spans in our predicted parse tree. We leave methods for cutting the tree to future work and instead consider the maximum recall of our model which serves as an upper bound on its performance. Recall here is the percentage of labeled constituents that appear in our predicted tree relative to the total number of constituents in the gold tree. These scores are separated by type and presented in Table 4.

In Table 4 we see the breakdown of constituent recall across the 10 most common types. DIORA achieves the highest recall across the most types and is the only model to perform effectively on verb-phrases. Interestingly, DIORA performs worse than PRPN-LM at prepositional phrases.

3.3 Phrase Similarity

One of the goals of DIORA is to learn meaningful representations for spans of text. Most language modeling methods focus only on explicitly modeling token representations and rely on ad-hoc post-processing to generate representations for longer spans, typically relying on simple arithmetic functions of the individual tokens.

To evaluate our model's learned phrase representations, we look at the similarity between spans of the same type within labeled phrase datasets. We look at two datasets. CoNLL 2000 (Tjong Kim Sang and Buchholz, 2000) is a shallow parsing dataset containing spans of noun phrases, verb phrases, etc. CoNLL 2012 (Pradhan et al., 2012) is a named entity dataset containing 19 different entity types.

	WSJ-10		**WSJ-40**

ON-LSTM‡	65.1 ±1.7	66.8	-	-
DIORA	67.7 ±0.7	68.5	60.6 ±0.2	**60.9**

Table 3: WSJ-10 and WSJ-40 unsupervised non-binary unlabeled constituency parsing with punctuation removed. † indicates that the model predicts a full, non-binary parse with additional resources. ‡ indicates model was trained on WSJ data and PRPN$_{NLI}$ was trained on MultiNLI data. CCM uses predicted POS tags while CCM$_{gold}$ uses gold POS tags. PRPN F1 was calculated using the parse trees and results provided by Htut et al. (2018). LB and RB are the left and right-branching baselines. UB is the upper bound attainable by a model that produces binary trees.

For each of the labeled spans with length greater than one, we first generate its phrase representation. We then calculate its cosine similarity to all other labeled spans. We then calculate if the label for that query span matches the labels for each of the K most similar other spans in the dataset. In Table 5 we report precision@K for both datasets and various values of K.

The first baseline we compare against produces phrase representations from averaging context-insensitive (CI) ELMo vectors of individual tokens with the span. The second uses sentence-insensitive (SI) ELMo vectors, running the full ELMo over only the relevant tokens and ignoring the rest of the sentence. We also look at ELMo's output when given the entire sentence. When analyzing our baselines that run the full ELMo, we follow the procedure described in (Peters et al., 2018b) and represent phrases as a function of its first and last hidden state. We extract these states from the final ELMo layer (3rd BiLSTM) as these consistently gave the best performance among other options. For DIORA, we use the concatenation of the inside and outside representations ($[\bar{a}; \bar{b}]$).

Table 4: Segment recall from WSJ separated by phrase type. The 10 most frequent phrase types are shown above, and the highest value in each row is bolded. P-UP=PRNP-UP, P-LM=PRPN-LM

For CoNLL 2000, we find that our model outperforms all baselines for all values of K. This demonstrates DIORA's ability to capture and represent syntactic information within phrases. For CoNLL 2012, we find that DIORA outperforms both ELMo$_{CI}$ and ELMo$_{SI}$ while ELMo performs best overall. ELMo$_{CI}$ is surprisingly effective on this dataset even though it performed more poorly on CoNLL 2000. These results indicate that DIORA is capturing syntax quite well, but still has room to improve on more fine-grained semantic representations.

3.4 Impact of Modeling Choices

To test the impact of our modeling choices, we compared the performance of two different losses and four different composition functions on the full WSJ validation set. The losses were covered in Equations 1 (Margin) and 2 (Softmax). The two primary methods of composition we considered were TreeLSTM (Tai et al., 2015) and MLP (a 2-hidden layer neural network). In addition, we experimented with a simple *kernel* of the MLP input $[x; y; x \odot y; x - y]$ and with a setting where both the inside and outside parameters are *shared*.

The results are shown in Table 6. We see that MLP composition consistently performs better than with TreeLSTM, that MLP benefits from the Softmax loss, and that the best performance comes from sharing parameters. All other experimental results use this highly performant setting unless otherwise specified.

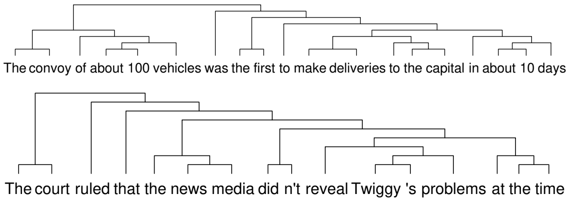

Figure 3: DIORA can match the ground truth exactly.

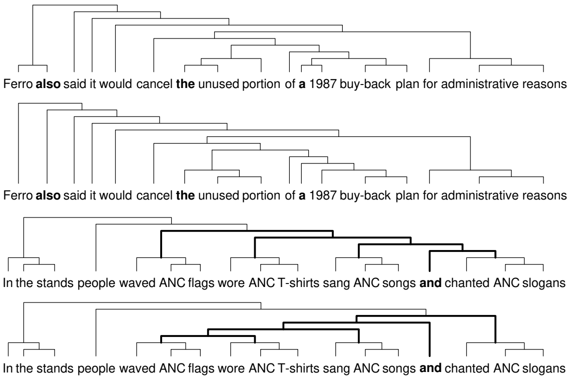

Figure 4: At times, DIORA exhibits contrary behavior to the ground truth inevitably leading to some error. DIORA's output is shown above the ground truth.[6]

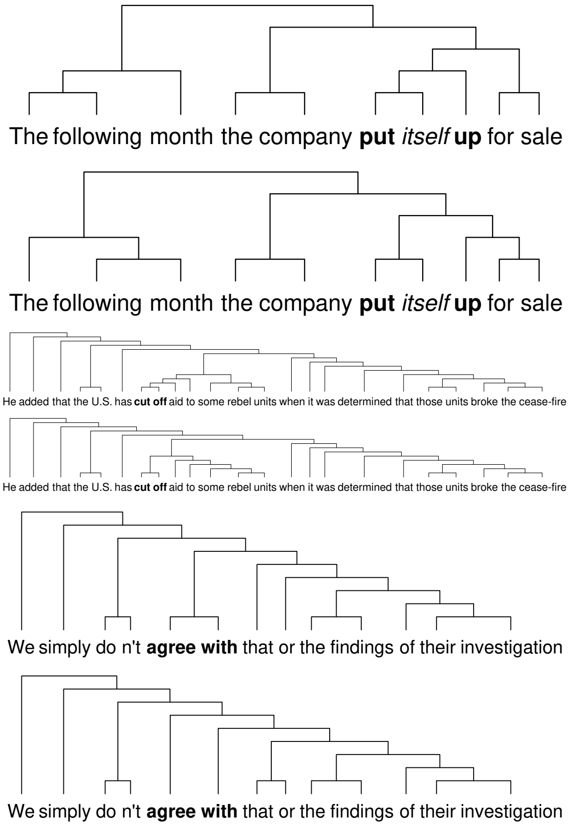

Figure 5: DIORA often groups verbs and particles (top), sometimes exactly as the ground truth (middle). Occasionally, errors are particle-like (bottom). DIORA's output is shown above the ground truth.[6]

---

[6] Ground truth parses are binarized unless otherwise specified. All examples of DIORA parses are already binary. Some punctuation has been removed for easier readability.

		CoNLL 2000			**CoNLL 2012**		
Model	Dim	P@1	P@10	P@100	P@1	P@10	P@100
Random	800	0.684	0.683	0.680	0.137	0.133	0.135
ELMo$_{CI}$	1024	0.962	0.955	0.957	0.708	0.643	0.544
ELMo$_{SI}$	4096	0.970	0.964	0.955	0.660	0.624	0.533
ELMo	4096	0.987	0.983	0.974	**0.896**	**0.847**	**0.716**
DIORA$_{In/Out}$	800	**0.990**	**0.985**	**0.979**	0.860	0.796	0.646

Table 5: P@1, P@10, and P@100 for labeled chunks from CoNLL-2000 and CoNLL 2012 datasets. For all metrics, higher is better. The top value in each column is bolded. Diora uses the concatenation of the inside and outside vector at each cell which performed better than either in isolation.

3.5 Qualitative Results

Looking at our model's output, we see that some trees are an exact replication of the binarized ground truth (Fig. 3), or very close (Fig. 4). For future work we intend to explore common patterns in DIORA's learned structure, although some patterns are already recognizable, such as the affinity to group particles and verbs (Fig. 5).

4 Related Work

Latent Tree Learning A brief survey of neural latent tree learning models was covered in (Williams et al., 2018a). The first positive result for neural latent tree parsing was shown in (Htut et al., 2018), which used a language modeling objective. The model in (Liu et al., 2018) uses an inside chart and an outside procedure to calculate marginal probabilities in order to align spans between sentences in entailment.

		F1$_\mu$	
Composition	**Loss**	∅	+PP
TreeLSTM	Margin	49.9	53.1
TreeLSTM	Softmax	52.0	52.9
MLP	Margin	49.7	54.4
MLP	Softmax	52.6	55.5
MLP$_{\text{Kernel}}$	Softmax	51.8	54.8
MLP$_{\text{Shared}}$	Softmax	50.8	56.7

Table 6: F1 for different model variants on the binary WSJ validation set with included punctuation. The binary trees are as-is (∅) or modified according to the post-processing heuristic (+PP). The mean F1 is shown across three random seeds.

Neural Inside-Outside Parsers The Inside-Outside Recursive Neural Network (IORNN) (Le and Zuidema, 2014) is closest to ours. It is a graph-based dependency parser that uses beam search and can reliably find accurate parses when retaining a k-best list. In contrast, our model produces the most likely parse given the learned compatibility of the constituents. The Neural CRF Parser (Durrett and Klein, 2015), similar to DIORA, performs exact inference on the structure of a sentence, although requires a set of grammar rules and labeled parse trees during training. DIORA, like Liu et al. (2018), has a single grammar rule that applies to any pair of constituents and does not use structural supervision.

Learning from Raw Text Unsupervised learning of syntactic structure has been an active research area (Brill et al., 1990), including for unsupervised segmentation (Ando and Lee, 2000; Goldwater et al., 2009; Ponvert et al., 2011) and unsupervised dependency parsing (Spitkovsky et al., 2013). Some models exploit the availability of parallel corpora in multiple languages (Das and Petrov, 2011; Cohen et al., 2011). Others have shown that dependency parsing can be used for unsupervised constituency parsing (Spitkovsky et al., 2013; Klein and Manning, 2004), or that it's effective to prune a random subset of possible trees (Bod, 2006). These approaches aren't necessarily orthogonal to DIORA. For instance, our model may benefit when combined with an unsupervised dependency parser.

5 Conclusion

In this work we presented DIORA, an unsupervised method for inducing syntactic trees and representations of constituent spans. We showed inside-outside representations constructed with a latent tree chart parser and trained with an autoencoder language modeling objective learns syntactic structure of language effectively. In experiments on unsupervised parsing, chunking, and phrase representations we show our model is comparable to or outperforms previous methods, achieving the state-of-the-art performance on unsupervised unlabeled constituency parsing for the full WSJ (with punctuation), WSJ-40, and NLI datasets. We also show our model obtains higher segment recall than a comparable model and outperforms strong baselines on phrase representations on a chunking dataset.

While the current model seems to focus primarily on syntax, future work can improve the model's ability to capture fine-grained semantics. Potential avenues include training larger models over much larger corpora, extra unsupervised or weakly-supervised phrase classification objectives, and other modeling enhancements. We are also eager to apply DIORA to other domains and languages which do not have rich linguistically annotated training sets.

A Appendices

A.1 Training Details

Training Data. Sentences of length ≤ 20 from the SNLI and MultiNLI training sets.
Optimization. We train our model using stochastic gradient descent with the Adam optimization algorithm (Kingma and Ba, 2014). Cells were normalized to have magnitude of 1, following Socher et al. (2011a). For instance, $\bar{a}(k) := \bar{a}(k)/\left\|\bar{a}(k)\right\|^2$. Gradients are clipped to a maximum L2-norm of 5.
Hyperparameters. Chosen using grid search over cell-dimension $\{400\text{D}, 800\text{D}\}$ and learning rate $\{2, 4, 8, 10, 20\} \cdot 10^{-4}$.
Early Stopping. Using unlabeled parsing F1 against the binarized WSJ validation set.
Vocabulary. The model is trained in an open-vocabulary setting using pre-trained context-insensitive character embeddings. The embedder is taken from ELMo (Peters et al., 2018a).
Batching. Batches were constructed such that they contained sentences of uniform length. Using batch size 128 for 400D and 64 for 800D.
Sampling. N negatives are sampled for each batch. All experiments use $N = 100$.
Training Steps. 1M parameter updates, taking 3 days using 4x Nvidia 1080ti.

A.2 Composition and Input Transform

TreeLSTM. The $\mathrm{TreeLSTM}$ (Tai et al., 2015) function produces a hidden state vector h and cell state vector c given two input vectors h_i and h_j.

$$\begin{bmatrix} x \\ f_i \\ f_j \\ o \\ u \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} \left(U \begin{bmatrix} h_i \\ h_j \end{bmatrix} + b + \begin{bmatrix} 0 \\ \omega \\ \omega \\ 0 \\ 0 \end{bmatrix} \right)$$

$$\begin{aligned} c &= c_i \odot f_i + c_j \odot f_j + x \odot u \\ h &= o + \tanh(c) \end{aligned}$$

The constant ω is set to 1 for the inside, 0 for the outside. U and b are learned.

MLP. MLP (Multi-Layer Perceptron) is a deep non-linear composition with the following form:

$$h = W_1 \left(W_0 \left\langle h_i, h_j \right\rangle + b \right) + b_1$$

The operator $\langle h_i, h_j \rangle$ is a concatenation $[h_i; h_j]$. For the MLP^{Kernel} $\langle h_i, h_j \rangle$ is more involved to support further interaction between the two input vectors $[h_i; h_j; h_i \odot h_j; h_i - h_j]$. The variables W_0, W_1, b, b_1 are learned and c is unused.

A.3 Reproducing Parsing Results

In Table 7, we've organized a reference for creating various splits of the WSJ for the purpose of evaluating unsupervised parsing. Some splits use only the test set (section 23), others use all of the training, validation, and test data. Optionally, punctuation is stripped and sentences greater than a specified length are ignored. Predictions can be compared to the full parse trees in the annotated data, or to a binarized version. The PARSEVAL specification calculated bracketing F1 considering all spans, although some previous work diverts from PARSEVAL and ignores spans that are trivially correct (ones over the entire sentence).

	WSJ	WSJ-10	WSJ-40
Split	Test	All	Test
w/ Punctuation	Yes	No	No
Max Length	∞	10	40
Binarized	Yes	No	No
Trivial Spans	Yes	No	No

Table 7: Settings for unlabeled binary bracketing evaluation for different splits of the WSJ corpus.

A.4 Runtime Complexity

The runtime complexities for DIORA's methods are shown in Table 8. The parallel column represents the complexity when the values for all constituent pairs are computed simultaneously, assuming that these computations are independent and do not depend on values that have yet to be computed. Linear complexity is theoretically feasible depending on batch size, input length, and number of computational cores. In practice, one might experience super-linear performance.

Although both the inside pass and outside pass have an upper bound of n^3 operations, the outside pass will have more operations than the inside pass for sentences of length > 1.

As a point of reference, our implementation computes the loss over the entire WSJ corpus in 5 minutes 30 seconds at a rate of 3,500 words per second using a single GPU.

Method	Serial	Parallel
Inside Pass	$O(n^3)$	$O(n)$
Outside Pass	$O(n^3)$	$O(n)$
Training Objective	$O(n \cdot N)$	$O(n)$
CKY	$O(n^3)$	$O(n)$

Table 8: Runtime complexity for methods associated with DIORA in terms of sentence length n and number of negative examples per token N. Each column represents the complexity when the values for each constituent are computed serially or in parallel.

A.5 Parse Trees

Examples of parse trees derived from the compatibility scores are shown in Figures 6 and 7. Some punctuation has been removed for readability.

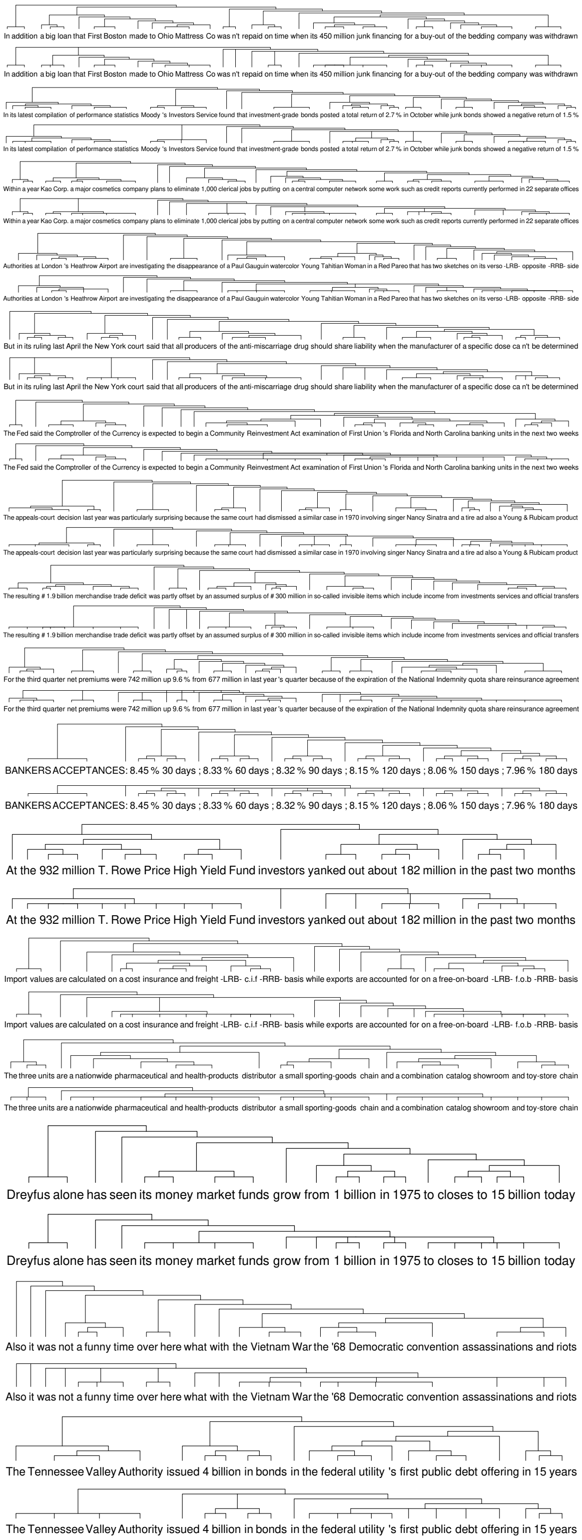

Figure 6: Examples where DIORA achieves 100% recall compared with the raw (n-ary) ground truth, but less than 100% accuracy on the binarized ground truth. DIORA's output is shown above the ground truth.

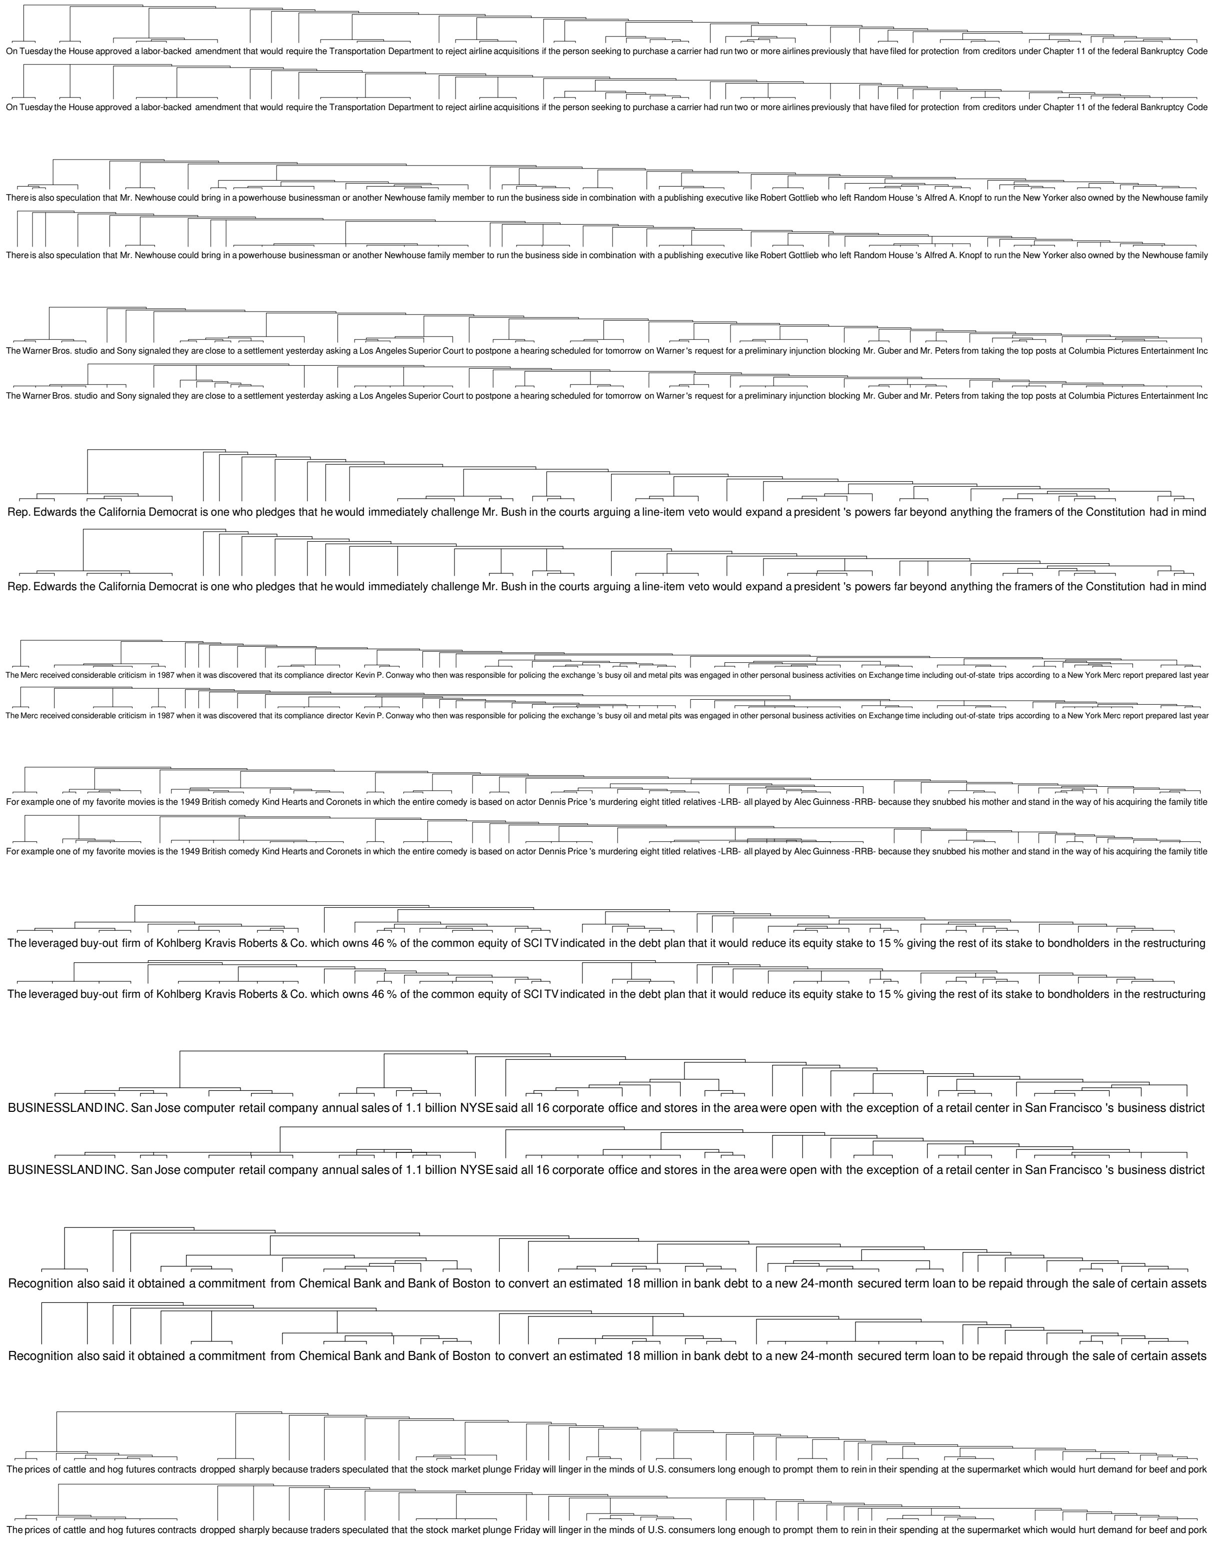

Figure 7: DIORA can perform close to the ground truth even on long sentences. In this figure, n-ary trees are shown for the ground truth. DIORA's output is shown above the ground truth.

Knowledge-Augmented Language Model and Its Application to Unsupervised Named-Entity Recognition

Abstract

Traditional language models are unable to efficiently model entity names observed in text. All but the most popular named entities appear infrequently in text providing insufficient context. Recent efforts have recognized that context can be generalized between entity names that share the same type (e.g., *person* or *location*) and have equipped language models with access to an external knowledge base (KB). Our Knowledge-Augmented Language Model (KALM) continues this line of work by augmenting a traditional model with a KB. Unlike previous methods, however, we train with an end-to-end predictive objective optimizing the perplexity of text. We do not require any additional information such as named entity tags. In addition to improving language modeling performance, KALM learns to recognize named entities in an entirely unsupervised way by using entity type information latent in the model. On a Named Entity Recognition (NER) task, KALM achieves performance comparable with state-of-the-art supervised models. Our work demonstrates that named entities (and possibly other types of world knowledge) can be modeled successfully using predictive learning and training on large corpora of text without any additional information.

1 Introduction

Language modeling is a form of unsupervised learning that allows language properties to be learned from large amounts of unlabeled text. As components, language models are useful for many Natural Language Processing (NLP) tasks such as generation (Parvez et al., 2018) and machine translation (Bahdanau et al., 2014). Additionally, the form of predictive learning that language modeling uses is useful to acquire text representations that can be used successfully to improve a number of downstream NLP tasks (Peters et al., 2018; Devlin et al., 2018). In fact, models pre-trained with a predictive objective have provided a new state-of-the-art by a large margin.

Current language models are unable to encode and decode factual knowledge such as the information about entities and their relations. Names of entities are an open class. While classes of named entities (e.g., *person* or *location*) occur frequently, each individual name (e.g, *Atherton* or *Zhouzhuang*) may be observed infrequently even in a very large corpus of text. As a result, language models learn to represent accurately only the most popular named entities. In the presence of external knowledge about named entities, language models should be able to learn to generalize across entity classes. For example, knowing that *Alice* is a name used to refer to a person should give ample information about the context in which the word may occur (e.g., *Bob visited Alice*).

In this work, we propose Knowledge Augmented Language Model (KALM), a language model with access to information available in a KB. Unlike previous work, we make no assumptions about the availability of additional components (such as Named Entity Taggers) or annotations. Instead, we enhance a traditional LM with a gating mechanism that controls whether a particular word is modeled as a general word or as a reference to an entity. We train the model end-to-end with only the traditional predictive language modeling perplexity objective. As a result, our system can model named entities in text more accurately as demonstrated by reduced perplexities compared to traditional LM baselines. In addition, KALM learns to recognize named entities completely unsupervised by interpreting the predictions of the gating mechanism at test time. In fact, KALM learns an unsupervised named entity tagger that rivals in accuracy supervised counterparts.

Proceedings of NAACL-HLT 2019, pages 1142–1150
Minneapolis, Minnesota, June 2 - June 7, 2019.

KALM works by providing a language model with the option to generate words from a set of entities from a database. An individual word can either come from a general word dictionary as in traditional language model or be generated as a name of an entity from a database. Entities in the database are partitioned by type. The decision of whether the word is a general term or a named entity from a given type is controlled by a gating mechanism conditioned on the context observed so far. Thus, KALM learns to predict whether the context observed is indicative of a named entity of a given type and what tokens are likely to be entities of a given type.

The gating mechanism at the core of KALM is similar to attention in Neural Machine Translation (Bahdanau et al., 2014). As in translation, the gating mechanism allows the LM to represent additional latent information that is useful for the end task of modeling language. The gating mechanism (in our case entity type prediction) is latent and learned in an end-to-end manner to maximize the probability of observed text. Experiments with named entity recognition show that the latent mechanism learns the information that we expect while LM experiments show that it is beneficial for the overall language modeling task.

This paper makes the following contributions:

- Our model, KALM, achieves a new state-of-the art for Language Modeling on several benchmarks as measured by perplexity.
- We learn a named entity recognizer without any explicit supervision by using only plain text. Our unsupervised named entity recognizer achieves a performance on par with the state-of-the supervised methods.
- We demonstrate that predictive learning combined with a gating mechanism can be utilized efficiently for generative training of deep learning systems beyond representation pre-training.

2 Related Work

Our work draws inspiration from Ahn et al. (2016), who propose to predict whether the word to generate has an underlying fact or not. Their model can generate knowledge-related words by copying from the description of the predicted fact. While theoretically interesting, their model functions only in a very constrained setting as it requires extra information: a shortlist of candidate entities that are mentioned in the text.

Several efforts successfully extend LMs with entities from a knowledge base and their types, but require that entity models are trained separately from supervised entity labels. Parvez et al. (2018) and Xin et al. (2018) explicitly model the type of the next word in addition to the word itself. In particular, Parvez et al. (2018) use two LSTM-based language models, an entity type model and an entity composite (entity type) model. Xin et al. (2018) use a similarly purposed entity typing module and a LM-enhancement module. Instead of entity type generation, Gu et al. (2018) propose to explicitly decompose word generation into sememe (a semantic language unit of meaning) generation and sense generation, but requires sememe labels.Yang et al. (2016) propose a pointer-network LM that can point to a 1-D or 2-D database record during inference. At each time step, the model decides whether to point to the database or the general vocabulary.

Unsupervised predictive learning has been proven effective in improving text understanding. ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) used different unsupervised objectives to pre-train text models which have advanced the state-of-the-art for many NLP tasks. Similar to these approaches KALM is trained end-to-end using a predictive objective on large corpus of text.

Most unsupervised NER models are rule-based (Collins and Singer, 1999; Etzioni et al., 2005; Nadeau et al., 2006) and require feature engineering or parallel corpora (Munro and Manning, 2012). Yang and Mitchell (2017) incorporate a KB to the CRF-biLSTM model (Lample et al., 2016) by embedding triples from a KB obtained using *TransE* (Bordes et al., 2013). Peters et al. (2017) add pre-trained language model embeddings as knowledge to the input of a CRF-biLSTM model, while still requiring labels in training.

To the best of our knowledge, KALM is the first unsupervised neural NER approach. As we discuss in Section 5.4, KALM achieves results comparable to supervised CRF-biLSTM models.

3 Knowledge-Augmented Language Model

KALM extends a traditional, RNN-based neural LM. As in traditional LM, KALM predicts probabilities of words from a vocabulary V_g, but it can also generate words that are names of entities of a specific type. Each entity type has a separate vocabulary $\{V_1, ..., V_K\}$ collected from a KB. KALM learns to predict from context whether to expect an entity from a given type and generalizes over entity types.

3.1 RNN language model

At its core, a language model predicts a distribution for a word y_{t+1} given previously observed words $c_t := [y_1, ..., y_{t-1}, y_t]$. Models are trained by maximizing the likelihood of the observed next word. In an LSTM LM, the probability of a word, $P(y_{t+1}|c_t)$, is modeled from the hidden state of an LSTM (Hochreiter and Schmidhuber, 1997):

$$P(y_{t+1} = i|c_t) = \frac{\exp(\boldsymbol{W}^p_{i,:} \cdot \boldsymbol{h}_t)}{\sum_{w=1}^{|V_g|} \exp(\boldsymbol{W}^p_{w,:} \cdot \boldsymbol{h}_t)} \tag{1}$$

$$\boldsymbol{h}_t, \boldsymbol{\gamma}_t = lstm(\boldsymbol{h}_{t-1}, \boldsymbol{\gamma}_{t-1}, \boldsymbol{y}_t) \tag{2}$$

where $lstm$ refers to the LSTM step function and h_i, $\boldsymbol{\gamma}_i$ and y_i are the hidden, memory and input vectors, respectively. $\boldsymbol{W}^p$ is a projection layer that converts LSTM hidden states into logits that have the size of the vocabulary $|V_g|$.

3.2 Knowledge-Augmented Language Model

KALM builds upon the LSTM LM by adding type-specific entity vocabularies $V_1, V_2, ..., V_K$ in addition to the general vocabulary V_g. Type vocabularies are extracted from the entities of specific type in a KB. For a given word, KALM computes a probability that the word represents an entity of that type by using a type-specific projection matrix $\{\boldsymbol{W}^{p,j}|j = 0, ..., K\}$. The model also computes the probability that the next word represents different entity types given the context observed so far. The overall probability of a word is given by the weighted sum of the type probabilities and the probability of the word under the give type.

More precisely, let τ_i be a latent variable denoting the type of word i. We decompose the probability in Equation 1 using the type τ_{t+1}:

$$\begin{aligned} P(y_{t+1}|c_t) &= \sum_{j=0}^{K} P(y_{t+1}, \tau_{t+1} = j|c_t) \\ &= \sum_{j=0}^{K} P(y_{t+1}|\tau_{t+1} = j, c_t) \\ &\quad \cdot P(\tau_{t+1} = j|c_t) \end{aligned} \tag{3}$$

Where $P(y_{t+1}|\tau_{t+1}, c_t)$ is a distribution of entity words of type τ_{t+1}. As in a general LM, it is computed by projecting the hidden state of the LSTM and normalizing through softmax (eq. 4). The type-specific projection matrix $\boldsymbol{W}^{p,j}$ is learned during training.

We maintain a type embedding matrix $\boldsymbol{W}^e$ and use it in a similar manner to compute the probability that the next word has a given type $P(\tau_{t+1}|c_t)$ (eq. 5). The only difference is that we use an extra projection matrix, $\boldsymbol{W}^h$ to project $\boldsymbol{h}_t$ into lower dimensions. Figure 1a illustrates visually the architecture of KALM.

$$P(y_{t+1} = i|\tau_{t+1} = j, c_t) = \frac{\exp(\boldsymbol{W}^{p,j}_{i,:} \cdot \boldsymbol{h}_t)}{\sum_{w=1}^{|V_j|} \exp(\boldsymbol{W}^{p,j}_{w,:} \cdot \boldsymbol{h}_t)} \tag{4}$$

$$P(\tau_{t+1} = j|c_t) = \frac{\exp(\boldsymbol{W}^e_{j,:} \cdot (\boldsymbol{W}^h \cdot \boldsymbol{h}_t))}{\sum_{k=0}^{K} \exp(\boldsymbol{W}^e_{k,:} \cdot (\boldsymbol{W}^h \cdot \boldsymbol{h}_t))} \tag{5}$$

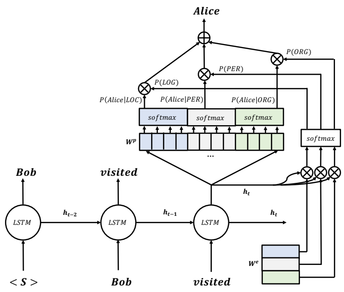
3.3 Type representation as input

In the base KALM model the input for word y_t consists of its embedding vector $\boldsymbol{y}_t$. We enhance the base model by adding as inputs the embedding of the type of the previous word. As type information is latent, we represent it as the weighted sum of the type embeddings weighted by the predicted probabilities:

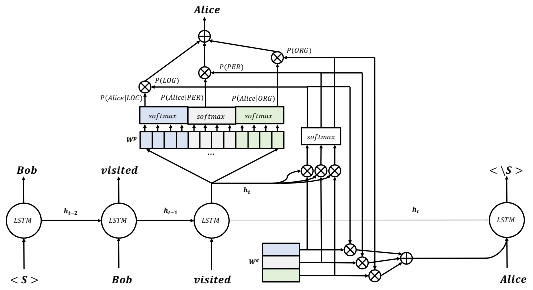
$$\boldsymbol{\nu}_{t+1} = \sum_{j=0}^{K} P(\tau_{t+1} = j|c_t) \cdot \boldsymbol{W}^e_{j,:} \tag{6}$$

$$\tilde{\boldsymbol{y}}_{t+1} = [\boldsymbol{y}_{t+1}; \boldsymbol{\nu}_{t+1}] \tag{7}$$

$P(\tau_{t+1} = j|c_t)$ is computed using Equation 5 and e_j is the type embedding vector.



(a) Basic model architecture of KALM.



(b) Adding type representation as input to KALM.

Figure 1: KALM's architectures

Adding type information as input serves two purposes: in the forward direction, it allows KALM to model context more precisely based on predicted entity types. During back propagation, it allows us to learn latent types more accurately based on subsequent context. The model enhanced with type input is illustrated in Figure 1b.

4 Unsupervised NER

The type distribution that KALM learns is latent, but we can output it at test time and use it to predict whether a given word refers to an entity or a general word. We compute $P(\tau_{t+1}|c_t)$ using eq. 5 and use the most likely entity type as the named entity tag for the corresponding word y_{t+1}.

This straightforward approach, however, predicts the type based solely on the left context of the tag being predicted. In the following two subsections, we discuss extensions to KALM that allow it to utilize the right context and the word being predicted itself.

4.1 Bidirectional LM

While we cannot use a bidirectional LSTM for generation, we can use one for NER, since the entire sentence is known.

For each word, KALM generates the hidden vectors $\boldsymbol{h}_{l,t}$ and $\boldsymbol{h}_{r,t}$ representing context coming from left and right directions, as shown in Equations 8 and 9.

$$\boldsymbol{h}_{l,t}, \boldsymbol{\gamma}_{l,t} = lstm_l(\boldsymbol{h}_{l,t-1}, \boldsymbol{\gamma}_{l,t-1}, [\boldsymbol{y}_{l,t}; \boldsymbol{\nu}_{l,t}]) \quad (8)$$

$$\boldsymbol{h}_{r,t}, \boldsymbol{\gamma}_{r,t} = lstm_r(\boldsymbol{h}_{r,t+1}, \boldsymbol{\gamma}_{r,t+1}, [\boldsymbol{y}_{r,t}; \boldsymbol{\nu}_{r,t}]) \quad (9)$$

We concatenate the hidden vectors from the two directions to form an overall context vector $\boldsymbol{h}_t$, and generate the final type distribution using Equation 5.

Training the bidirectional model requires that we initialize the hidden and cell states from both ends of a sentence. Suppose the length of a sentence is n. The the cross entropy loss is computed for only the $n-2$ symbols in the middle. Similarly, we compute only the types of the $n-2$ symbols in the middle during inference.

4.2 Current word information

Even bidirectional context is insufficient to predict the word type by itself. Consider the following example: *Our computer models indicate Edouard is going to ___*[1] The missing word can be either a location (e.g., *London*), or a general word (e.g., *quit*). In an NER task we observe the underlined words: *Our computer models indicate Edouard is going to London.* In order to learn predictively, we cannot base the type prediction on the current token. Instead, we can use a prior type information $P(\tau_t|y_t)$, pre-computed from entity popularity information available in many KBs. We incorporate the prior information $P(\tau_t|y_t)$ in two different ways described in the two following subsections.

4.2.1 Decoding with type prior

We incorporate the type prior $P(\tau_t|y_t)$ directly by combining it linearly with the predicted type:

$$\begin{aligned} P(\tau_t|c_l, c_r, y_t) =& \frac{P(y_t|\tau_t, c_l, c_r)}{2P(y_t|c_l, c_r)} \cdot P(\tau_t|c_l, c_r) \\ &+ \frac{P(c_l, c_r|\tau_t, y_t)}{2P(c_l, c_r|y_t)} \cdot P(\tau_t|y_t) \\ =& \alpha \cdot P(\tau_t|c_l, c_r) \\ &+ \beta \cdot P(\tau_t|y_t) \end{aligned} \quad (10)$$

The coefficients α and β are free parameters and are tuned on a small amount of withheld data.

---

[1] All the examples are selected from the CoNLL 2003 training set.

4.2.2 Training with type priors

An alternative for incorporating the pre-computed $P(\tau_t|y_t)$ is to use it during training to regularize the type distribution. We use the following optimization criterion to compute the loss for each word:

$$\begin{aligned} L = & H(P(y_i|c_l, c_r), P(\hat{y}_i|c_l, c_r)) \\ & + \lambda \cdot ||KL(P(\tau_i|c_l, c_r), P(\tau_i|y_i))||^2 \end{aligned} \quad (11)$$

where $\hat{y}_i$ is the actual word, $H(.)$ is the cross entropy function, and $KL(.)$ measures the KL divergence between two distributions. A hyperparameter λ (tuned on validation data) controls the relative contribution of the two loss terms. The new loss forces the learned type distribution, $P(\tau_i|c_l, c_r)$, to be close to the expected distribution $P(\tau_i|y_i)$ given the information in the database. This loss is specifically tailored to help with unsupervised NER.

5 Experiments

We evaluate KALM on two tasks: language modeling and NER. We use two datasets: *Recipe* used only for LM evaluation and *CoNLL 2003* used for both the LM and NER evaluations.

5.1 Data

Recipe The recipe dataset[2] is composed of 95,786 recipes, We follow the same preprocessing steps as in Parvez et al. (2018) and divide the crawled dataset into training, validation and testing. A typical sentence after preprocessing looks like the following: "in a large mixing bowl combine the butter sugar and the egg yolks". The entities in the recipe KB are recipe ingredients. The 8 supported entity types are *dairy*, *drinks*, *fruits*, *grains*, *proteins*, *seasonings*, *sides*, and *vegetables*. In the sample sentence above, the entity names are *butter*, *sugar*, *egg* and *yolks*, typed as *dairy*, *seasonings*, *proteins* and *proteins*, respectively.

CoNLL 2003 Introduced in Tjong Kim Sang and De Meulder (2003), the CoNLL 2003 dataset is composed of news articles. It contains text and named entity labels in English, Spanish, German and Dutch. We experiment only with the English version. We follow the CoNLL labels and separate the KB into four entity types: *LOC* (location), *MISC* (miscellaneous), *ORG* (organization), and *PER* (person).

Statistics about the recipe and the CoNLL 2003 dataset are presented in Table 1.

	train	valid	test
#sent	61302	15326	19158
#tok	7223474	1814810	2267797

	train	valid	test
#sent	14986	3465	3683
#tok	204566	51577	46665

Table 1: Statistics of recipe and CoNLL 2003 datasets

The information about the entities in each of the KBs is shown in Table 2. The recipe KB is provided along with the recipe dataset[3] as a conglomeration of typed ingredients. The KB used by CoNLL 2003 is extracted from WikiText-2. We filtered the entities which are not belonging to the 4 types of CoNLL 2003 task.

type	dairy	drinks	fruits	grains
#entities	80	84	110	158

type	proteins	seasonings	sides	vegetables
#entities	316	180	140	156

type	LOC	MISC	ORG	PER
#entity words	1503	1211	3005	5404

Table 2: Statistics of recipe and CoNLL 2003 KBs

5.2 Implementation details

We implement KALM by extending the AWD-LSTM[4] language model in the following ways:

Vocabulary We use the entity words in Table 2 to form $V_1, ..., V_K$ We extract 51,677 general words in the recipe dataset, and 17,907 general words in CoNLL 2003 to form V_0. Identical words that fall under different entity types, such as *Washington* in *George Washington* and *Washington D.C.*, share the same input embeddings.

Model The model has an embedding layer of 400 dimensions, LSTM cell and hidden states of 1,150 dimensions, and 3 stacked LSTM layers. We scale the final LSTM's hidden and cell states to 400 dimensions, and share weights between the projection layer $\boldsymbol{W}^p$ and the word embedding layer. Each entity type in the knowledge base is represented by a trainable 100-dimensional embedding vector. When concatenating the weighted

---

[3] The KB can be found in `https://github.com/uclanlp/NamedEntityLanguageModel`

[4] `https://github.com/salesforce/awd-lstm-lm`

average of the type embeddings to the input, we expand the input dimension of the first LSTM layer to 500. All trainable parameters are initialized uniformly randomly between -0.1 and 0.1, except for the bias terms in the decoder linear layer, which are initialized to 0.

For regularization, we adopt the techniques in AWD-LSTM, and use an LSTM weight dropout rate of 0, an LSTM first-layers locked dropout rate of 0.3, an LSTM last-layer locked dropout rate of 0.4, an embedding Bernoulli dropout rate of 0.1, and an embedding locked dropout rate of 0.65. Also, we impose L2 penalty on LSTM pre-dropout weights with coefficient 1, and L2 penalty on LSTM dropout weights with coefficient 2, both added to the cross entropy loss.

Optimization We use the same loss penalty, dropout schemes, and averaged SGD (ASGD) as in Merity et al. (2017). The initial ASGD learning rate is 10, weight decay rate is 1.2×10^{-6}, non-monotone trigger for ASGD is set to 5, and gradient clipping happens at 0.25. The models are trained until the validation set performance starts to decrease.

5.3 Language modeling

First, we test how good KALM is as a language model compared to two baselines.

5.3.1 Baselines

- **AWD-LSTM** (Merity et al., 2017) is the state-of-the-art word-level language model as measured on WikiText-2 and Penn Treebank. It uses ASGD optimization, a new dropout scheme and novel penalty terms in the loss function to improve over vanilla LSTM LMs.

- **Named-entity LM** (NE-LM) (Parvez et al., 2018) consists of a *type model* that outputs $P(\tau_{i+1}|\tau_i, \tau_{i-1}, ...)$ and an *entity composite model* that outputs $P(y_{i+1}|\{y_i, \tau_i\}, \{y_{i-1}, \tau_{i-1}\}, ...)$. The *type model* is trained on corpora with entity type labels, whereas the *entity composite model* has an input for words and another input for the corresponding types, and so needs to be trained on both the labeled corpus and the unlabeled version of the same corpus. At inference time, a joint inference heuristic aggregates type model and entity composite model predictions into a word prediction. Since both models require type labels as input, each generation step of NE-LM requires not only the previously generated words $[y_i, y_{i-1}, ...]$, but also the type labels for these words $[\tau_i, \tau_{i-1}, ...]$.

5.3.2 Results

For language modeling we report word prediction perplexity on the recipe dataset and CoNLL 2003. Perplexity is defined as the following.

$$PP = e^{-\sum\limits_{t=1}^{N} \frac{1}{N} \log P(y_t)} = \sqrt[N]{\prod_{t=1}^{N} \frac{1}{P(y_t)}} \quad (12)$$

We use publicly available implementations to produce the two baseline results. We also compare the language models in the bidirectional setting, which the reference implementations do not support. In that setting, we transform both models in NE-LM to be bidirectional.

Discussion Table 3 shows that KALM outperforms the two baselines in both unidirectional and bidirectional settings on both datasets. The improvement relative to NE-LM is larger in the unidirectional setting compared to the bidirectional setting. We conjecture that this is because in that setting NE-LM trains a bidirectional NER in a supervised way. The improvement relative to NE-LM is larger on CoNLL 2003 than on the recipe dataset. We believe that the inference heuristic used by NE-LM is tuned specifically to recipes and is less suitable to the CoNLL setting.

We also find that training KALM on more unlabeled data further reduces the perplexity (see Table 4), and study how the quality of the KB affects the perplexity. We discuss both these results in Section 5.4.

5.4 NER

In this section, we evaluate KALM in NER against two supervised baselines.

5.4.1 Baselines

We train two supervised models for NER on the CoNLL 2003 dataset: a **biLSTM** and a **CRF-biLSTM**. We replicate the hyperparameters used by Lample et al. (2016), who demonstrate the state-of-the-art performance on this dataset. We use a word-level model, and 100 dimensional pretrained GloVe embeddings (Pennington et al., 2014) for initialization. We train for 50 epochs, at which point the models converge.

	model	unidirectional		bidirectional	
		validation	test	validation	test
Recipe	AWD-LSTM	3.14	2.99	1.98	2
	NE-LM	2.96	2.24	1.85	1.73
	KALM	**2.75**	**2.20**	**1.85**	**1.71**
CoNLL 2003	AWD-LSTM	5.48	5.94	4.85	5.3
	NE-LM	5.67	5.77	4.68	4.94
	KALM	**5.36**	**5.43**	**4.64**	**4.74**

Table 3: Language modeling results on the recipe and CoNLL 2003 datasets

5.4.2 Results

We evaluate the unsupervised KALM model under the following configurations:

- Basic: bidirectional model with aggregated type embeddings fed to the input at the next time step;
- With type priors: using $P(\tau_t|y_t)$ in the two ways described in Section 4.2;
- Extra data: Since KALM is unsupervised, we can train it on extra data. We use the WikiText-2 corpus in addition to the original CoNLL training data.

WikiText-2 is a standard language modeling dataset released with Merity et al. (2016). It contains Wikipedia articles from a wide range of topics. In contrast, the CoNLL 2003 corpus consists of news articles. Table 4 show statistics about the raw / characer level WikiText-2 and the CoNLL 2003 corpora. Despite the domain mismatch between the WikiText and CoNLL corpora, the WikiText coverage of the entity words that exist in the CoNLL dataset is high. Specifically, most of the person, location and organization entity words that appear in CoNLL either have a Wikipedia section, or are mentioned in a Wiki article. Therefore, we expect that the addition of WikiText can guide the unsupervised NER model to learn better entity type regularities. Indeed, the result presented in the rightmost column of Table 4 shows that when adding WikiText-2 to CoNLL 2003, the perplexity for the KALM model for the news text of CoNLL 2003 is decreased: from 4.69 down to **2.29**.

We show NER results in Table 5. The table lists the F1 score for each entity types, as well as the overall F1 score.

Discussion Even the basic KALM model learns context well – it achieves an overall F1 score of 0.72 for NER. This illustrates that KALM has learned to model entity classes entirely from surrounding context. Adding prior information as to whether a word represents different entity types helps to bring the F1 score to 0.76.

The strength of an unsupervised model is that it can be trained on large corpora. Adding the Wikitext-2 corpus improves the NER score of KALM to 0.84.

To give a sense of how the unsupervised models compare with the supervised model with respect to training data size, we trained biLSTM and CRF-biLSTM on a randomly sampled subset of the training data of successively decreasing sizes. The resulting F1 scores are shown in Figure 2.

Our best model scores 0.86, same as a CRF-biLSTM trained on around 40% of the training data. It is less than 0.03 behind the best supervised CRF-biLSTM. The best KALM model almost always scores higher than biLSTM without the CRF loss.

Lastly, we perform an ablation experiment to gauge how sensitive KALM is to the quality of the knowledge base. Previous studies (Liu et al., 2016; Zhang et al., 2012) have shown that the amount of knowledge retrieved from KBs can impact the performance of NLP models such as relation extraction systems substantially. In this experiment, we deliberately corrupt the entity vocabularies $V_0, ..., V_{K-1}$ by moving a certain percentage of randomly selected entity words from V_i to the general vocabulary V_g. Figure 3 shows language modeling perplexities on the validation set, and NER F1 scores on the test set as a function of the corruption percentage. The language modeling performance stops reacting to KB corruption beyond a certain extent, whereas the NER performance keeps dropping as the number of entities removed from $V_1, V_2, ...$ increases. This result shows the importance of the quality of the KB

entity ratio	unique entity ratio	size ratio	LM perplexity
92.80%	82.56%	2.62	2.29 : 4.69

6 Conclusion

We propose Knowledge Augmented Language Model (KALM), which extends a traditional RNN LM with information from a Knowledge Base. We show that real-world knowledge can be used successfully for natural language understanding by using a probabilistic extension. The latent type information is trained end-to-end using a predictive objective without any supervision. We show that the latent type information that the model learns can be used for a high-accuracy NER system. We believe that this modeling paradigm opens the door for end-to-end deep learning systems that can be enhanced with latent modeling capabilities and trained in a predictive manner end-to-end. In ways this is similar to the attention mechanism in machine translation where an alignment mechanism is added and trained latently against the overall translation perplexity objective. As with our NER tags, machine translation alignments are empirically observed to be of high quality.

In future work, we look to model other types of world knowledge beyond named entities using predictive learning and training on large corpora of text without additional information, and to make KALM more robust against corrupted entities.

to KALM.

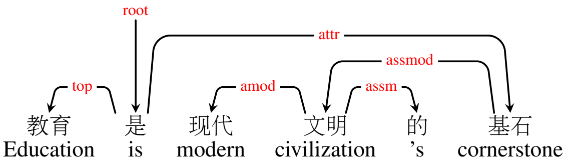
Abstract

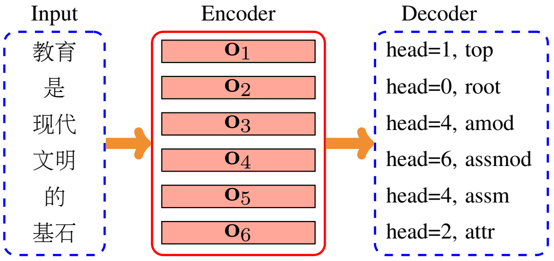
Syntax has been demonstrated highly effective in neural machine translation (NMT). Previous NMT models integrate syntax by representing 1-best tree outputs from a well-trained parsing system, e.g., the representative Tree-RNN and Tree-Linearization methods, which may suffer from error propagation. In this work, we propose a novel method to integrate source-side syntax implicitly for NMT. The basic idea is to use the intermediate hidden representations of a well-trained end-to-end dependency parser, which are referred to as syntax-aware word representations (SAWRs). Then, we simply concatenate such SAWRs with ordinary word embeddings to enhance basic NMT models. The method can be straightforwardly integrated into the widely-used sequence-to-sequence (Seq2Seq) NMT models. We start with a representative RNN-based Seq2Seq baseline system, and test the effectiveness of our proposed method on two benchmark datasets of the Chinese-English and English-Vietnamese translation tasks, respectively. Experimental results show that the proposed approach is able to bring significant BLEU score improvements on the two datasets compared with the baseline, 1.74 points for Chinese-English translation and 0.80 point for English-Vietnamese translation, respectively. In addition, the approach also outperforms the explicit Tree-RNN and Tree-Linearization methods.

1 Introduction

In the past few years, neural machine translation (NMT) has drawn increasing interests due to its simplicity and promising performance (Bahdanau et al., 2014; Jean et al., 2015; Luong and Manning, 2015; Luong et al., 2015; Shen et al., 2016; Vaswani et al., 2017). The widely used sequence-to-sequence (Seq2Seq) framework combined with attention mechanism achieves significant improvement over the traditional statistical machine translation (SMT) models on a variety of language pairs, such as Chinese-English (Shi et al., 2016; Mi et al., 2016; Vaswani et al., 2017; Cheng et al., 2018). Under an encoder-decoder architecture, the Seq2Seq framework first encodes the source sentence into a sequence of hidden vectors, and then incrementally predicts the target sentence (Cho et al., 2014a).



• An example of input dependency tree.



• SAWRs, where the encoder outputs are used as inputs for NMT similar to source-side word embeddings.

Figure 1: An example to illustrate our method of encoding source dependency syntax, where the English translation is “Education is the cornerstone of modern civilization” for the source Chinese input.

Recently, inspired by the success of syntax-based SMT (Williams et al., 2016), researchers propose a range of interesting approaches for exploiting syntax information in NMT models, as syntactic trees could offer long-distance relations in sentences (Shi et al., 2016; Wu et al., 2017b; Li

Minneapolis, Minnesota, June 2 - June 7, 2019.

et al., 2017; Bastings et al., 2017; Hashimoto and Tsuruoka, 2017).

As a straightforward method, tree-structured recurrent neural network (**Tree-RNN**) can elegantly model the source-side syntax and globally encode the whole trees. Eriguchi et al. (2016), Chen et al. (2017a) and Yang et al. (2017) show that Tree-RNN can effectively integrate syntax-oriented trees into Seq2Seq NMT models.

Regardless of the effectiveness of Tree-RNN, we find that it suffers from a severe low-efficiency problem because of the heterogeneity of different syntax trees, which leads to increasing difficulties for batch computation compared with sequential inputs. Even with deliberate batching method of Neubig et al. (2017), our preliminary experiments show that Tree-RNN with gated recurrent unit (GRU) can lead to nearly four times slower performance when it is integrated into a classical Seq2Seq system.

To solve the problem, **Tree-Linearization** is a good alternative for syntax encoding. The main idea is to linearize syntax trees into sequential symbols, and then exploit the resulting sequences as inputs for NMT. Li et al. (2017) propose a depth-first method to traverse a constituent tree, converting it into a sequence of symbols mixed with sentential words and syntax labels. Similarly, Wu et al. (2017b) combine several strategies of tree traversing for dependency syntax integration.

In this work, we present an implicit syntax encoding method for NMT, enhancing NMT models by syntax-aware word representations (**SAWRs**). Figure 1 illustrates the basic idea, where trees are modeled indirectly by sequential vectors extracted from an encoder-decoder dependency parser. On the one hand, the method avoids the structural heterogeneity and thus can be integrated efficiently, and on the other hand, it does not require discrete 1-best tree outputs, alleviating the error propagation problem induced from syntax parsers. Concretely, the vector outputs are extracted from the encoding outputs of the encoder-decoder dependency parser. As shown in Figure 1, the encoding outputs, denoted as $\boldsymbol{o} = \boldsymbol{o}_1 \cdots \boldsymbol{o}_6$, are then integrated into Seq2Seq NMT models by directly concatenated with the source input word embeddings after a linear projection.

We start with a Seq2Seq baseline with attention mechanism (Bahdanau et al., 2014) for study, following previous studies of the same research line, and then integrate source dependency syntax by SAWRs. We conduct experiments on Chinese-English and English-Vietnamese translation tasks, respectively. The results show that our method is very effective in source syntax integration. With source dependency syntax, the performances of Chinese-English and English-Vietnamese translation can be significantly boosted by 1.74 BLEU points and 0.80 BLEU points, respectively. We also compare the method with the representative Tree-RNN and Tree-Linearization approaches of syntax integration, finding that our method is able to achieve larger improvements than the two approaches for both tasks. All the codes are released publicly available at https://github.com/zhangmeishan/SYN4NMT under Apache License 2.0.

2 Baseline

We take the simple yet effective Seq2Seq model with attention mechanism proposed by Luong et al. (2015) as our baseline. Under the standard encoder-decoder architecture, an encoder first maps the source-language input sentence into a sequence of hidden vectors, and a decoder then incrementally predicts the target output sentence. In particular, we should notice that several recent models (Vaswani et al., 2017; Zheng et al., 2017; Cheng et al., 2018) which have been shown to be more powerful can also serve as our baseline, since these models focus on very different aspects of NMT, which could be potentially complementary with our focus of syntax integration. We will demonstrate it by experimental analysis as well.

2.1 Encoder

In the encoder part, a single-layer bi-directional recurrent neural network (Bi-RNN) is employed to encode the sentence in order to capture features from the current word and the unbounded left and right contextual words. Given a source-language input sentence $\boldsymbol{x} = x_1 \cdots x_n$ and its embedding sequence $\boldsymbol{e}^{x_1} \cdots \boldsymbol{e}^{x_n}$, the Bi-RNN produces an encoding sequence of dense vectors $\boldsymbol{h} = \boldsymbol{h}_1 \cdots \boldsymbol{h}_i \cdots \boldsymbol{h}_n$:

$$\begin{aligned} \boldsymbol{h}_i &= \overrightarrow{\boldsymbol{h}}_i \oplus \overleftarrow{\boldsymbol{h}}_i, \\ \overrightarrow{\boldsymbol{h}}_i &= \mathtt{rnn}^{\mathrm{L}}(\boldsymbol{e}^{x_i}, \overrightarrow{\boldsymbol{h}}_{i-1}) \\ \overleftarrow{\boldsymbol{h}}_i &= \mathtt{rnn}^{\mathrm{R}}(\boldsymbol{e}^{x_i}, \overleftarrow{\boldsymbol{h}}_{i+1}) \end{aligned} \tag{1}$$

where $\mathtt{rnn}^{\mathrm{L}/R}$ can be either GRU (Cho et al., 2014b) or LSTM. We use GRU all through this paper for efficiency following Chen et al. (2017a).

2.2 Decoder

The decoder part incrementally predicts the target word sequence $\boldsymbol{y} = y_1 \cdots y_m$, whose translation probability is defined as follows:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \prod_{j=1}^{m} p(y_j|y_1 \cdots y_{j-1}, \boldsymbol{h}). \tag{2}$$

The training objective is to maximize the probability of the reference translation. During evaluation, we aim to search for a target sentence with the highest probability for a given source sentence.

The probability of the j-th target word is computed by a two-layer feed-forward neural network:

$$p(y_j|y_1 \cdots y_{j-1}, \boldsymbol{h}) = g(\boldsymbol{s}_{j-1}, \boldsymbol{c}_j), \tag{3}$$

where $\boldsymbol{s}_{j-1} = \mathtt{rnn}^{\text{tgt}}(\boldsymbol{e}^{y_{j-1}} \oplus \boldsymbol{c}_{j-1}, \boldsymbol{s}_{j-2})$ is the output of a left-to-right RNN over the predicted words, and the $\boldsymbol{c}_j/\boldsymbol{c}_{j-1}$ is the weighted sum over the encoding sequence $\boldsymbol{h}$ of the source sentence via the attention mechanism, which is computed as follows:

$$\begin{aligned} \boldsymbol{c}_j &= \sum_{k=1}^{n} \alpha_{j,k} \boldsymbol{h}_k \\ \alpha_{j,k} &= \frac{\exp(\beta_{j,k})}{\sum_{l=1}^{n} \exp(\beta_{j,l})} \\ \beta_{j,l} &= \boldsymbol{s}_{j-1}^{\mathrm{T}} \boldsymbol{W}^a \boldsymbol{h}_l \end{aligned} \tag{4}$$

where $\boldsymbol{W}^a$ is the model parameter in attention.

3 Our Method

Syntax information has been demonstrated to be valuable for NMT. Previously, there were two representative approaches to encode syntax into an NMT model. The first approach directly represents an input syntax tree by **Tree-RNN**, and then uses the Tree-RNN outputs as additional encoder inputs for NMT. The second approach models source syntax trees indirectly by first converting a hierarchical tree into a sequence of symbols, and then use the symbols as inputs for NMT. The second method is referred to as **Tree-Linearization** here.

Tree-RNN is able to represent the syntax structures fully and comprehensively. However, because of the heterogeneity of different syntax trees, this approach suffers serious inefficiency problem as the increased difficulty of batch computation for GPU neural computation. The second approach exploits an alternative sequence to substitute the original trees, which solves the inefficiency problem. But it may bring loss of syntax information because the hierarchical tree structure is no longer maintained in the new representation, which could be potentially useful for NMT.

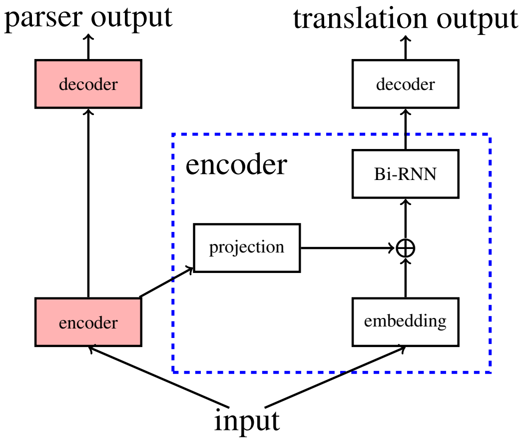

Figure 2: The framework of the SAWR approach, where the left part shows the encoder-decoder of a supervised dependency parsing model and the right part shows the NMT encoder-decoder.

Both the two syntax integration approaches are based on discrete 1-best outputs of a supervised dependency parser, which may suffer from the error propagation problem. Incorrect syntax trees as inputs for NMT may produce erroneous outputs, leading to inappropriate translation results. In order to alleviate the problem, we present a novel method not using the discrete parsing outputs.

We focus on supervised dependency parsing models which can be formalized as an encoder-decoder architecture, and exploit the encoder outputs as the inputs for our Seq2Seq NMT model. The encoder outputs are sequences of dense vectors aligning with the source sentential words, as shown in Figure 1, and thus they could be easily combined with the encoder part of our NMT model. We refer to this method as **SAWR** for brief. Our approach takes the implicit hidden outputs from a supervised parser as inputs for NMT, which greatly reduces the direct influence brought from discrete 1-best parser outputs.

Figure 2 shows the framework of SAWR. Concretely, we first project the encoder outputs of a dependency parsing model into a sequence of vectors by a feed-forward linear layer, as shown by the projection module in Figure 2:

$$\boldsymbol{s}_i = \boldsymbol{W}\boldsymbol{o}_i + \boldsymbol{b} \quad (5)$$

where $\boldsymbol{o}{=}\boldsymbol{o}_1 \cdots \boldsymbol{o}_n$ is the encoder output of a parsing model, $\boldsymbol{W}$ and $\boldsymbol{b}$ are model parameters. Then we concatenate the resulting vectors with the source embeddings as inputs for the baseline Bi-RNN Encoder. Thus the encoder process can be formalized as follows:

$$\boldsymbol{h} = \text{Bi-RNN}\big(\boldsymbol{e}^{x_1} \oplus \boldsymbol{s}_1, \cdots, \boldsymbol{e}^{x_n} \oplus \boldsymbol{s}_n\big). \quad (6)$$

Noticeably, the SAWR method can be regarded as an adaption of joint learning as well. We can train both dependency parsing and machine translation model parameters concurrently. In this work, we focus on the machine translation task and do not involve the training objective of dependency parsing. However, we can still finetune model parameters of the encoder part of dependency parsing by back-propagating the training losses of NMT into this part as well.

Actually, SAWRs are also similar to the ELMO embeddings (Peters et al., 2018). ELMO learns context word representations by using language model as objective, while SAWRs learn syntax-aware word representations by using dependency parsing as objective. On the other hand, compared with the Tree-RNN and Tree-Linearization methods which encode syntax trees by neural networks directly, SAWRs are less sensitive to the output syntax trees. Thus the SAWR method can alleviate the error propagation problem.

4 Experiments

4.1 Settings

Data. We conduct experiments on the Chinese-English and English-Vietnamese translation tasks, respectively. For Chinese-English, we use the parallel training data from the publicly available LDC corpora,[1] with 28.3M Chinese words and 34.5M English words, respectively, consisting of 1.25M sentence pairs, and test model performances on the NIST datasets, using NIST MT02 as the development data, and MT03-06 as test datasets. For English-Vietnamese, we use the standard IWSLT 2015 dataset,[2] which consists of about 133K sentence pairs, and evaluate our models by exploiting the TED tst2012 and tst2013 as the development and test datasets, respectively.

For the source side sentences, we construct vocabularies of the most frequent 50K words, while for the target side sentences, we apply byte-pair encodings (BPE) (Sennrich et al., 2016) with 32K merges to obtain subword units, and construct the target vocabularies by the most frequent 32K subwords. During training, we use only the sentence pairs whose source and target lengths both are no longer than 50 and 150 for Chinese-English and English-Vietnamese translations, respectively.

Evaluation. We use the case insensitive 4-gram BLEU score as the main evaluation metrics (Papineni et al., 2002), and adopt the script `multi-bleu.perl` in the Mose toolkit.[3] Significance tests are conducted based on the best-BLEU results for each approach by using bootstrap resampling (Koehn, 2004).

Alternatively, in order to compare the effectiveness of our model with other syntax integration methods, we implement a **Tree-RNN** approach and a **Tree-Linearization** approach, respectively:

- Tree-RNN: We build a one-layer bi-directional Tree-RNN with GRU over input word embeddings, producing syntax-enhanced word representations, which are then fed into the encoder of NMT as basic inputs. The method is similar to the model proposed by Chen et al. (2017a).
- Tree-Linearization: We first convert dependency trees into constituent trees (Sun and Wan, 2013), and then feed it into the NMT model proposed by Li et al. (2017).

Hyperparameters. We set the dimension sizes of all hidden neural layers to 1024, except the input layers for RNNs (i.e. input word embeddings and the projection layer of SAWR), which are set to 512. We initialize all model parameters by random uniform distribution between $[-0.1, 0.1]$. We apply dropout on the output layer of word translation with a ratio of 0.5.

We adopt the Adam algorithm (Kingma and Ba, 2014) for parameter optimization, with the initial learning rate of 5×10^{-4}, the gradient clipping threshold of 5, and the mini-batch size of 80. During translation, we employ beam search for decoding with the beam size of 5.

Table 1: Final results of Chinese-English translation. All syntax-integrated approaches are significantly better than the baseline system ($p < 0.05$).

Source-Side Parsing. We employ the state-of-the-art BiAffine dependency parser recently proposed by Dozat and Manning (2016) to obtain the source-side dependency syntax information. The BiAffine parser can also be understood as an encoder-decoder model, where the encoder part is a three-layer bi-directional LSTM over the input words, and the decoder uses BiAffine operations to score all candidate dependency arcs and finds the highest-scoring trees via dynamic programming.

For Chinese-English translation, we train the dependency parser on Chinese Treebank 7.0 with Stanford dependencies,[4] using 50K random sentences as the training data and the remaining as the test data. The parser achieves 81.02% parsing accuracy (labeled attached score, LAS) on the test dataset. For English-Vietnamese translation, we train the dependency parser on English WSJ corpus, following the same data split as Dozat and Manning (2016), and obtaining a LAS of 93.84% on the test dataset.[5]

4.2 Speed Comparison

All our experiments are run on a single GPU NVIDIA TITAN Xp. We report the averaged one-epoch training time on the Chinese-English translation dataset (consuming all 125M sentence pairs) as follows:

Baseline	105 min
SAWR	142 min
Tree-RNN	498 min
Tree-Linearization	137 min

The SAWR system spends averaged 142 minutes,[6] 37 minutes slower than the baseline model. The Tree-Linearization spends averaged 137 minutes per epoch, which is the fastest syntax integration method. Our SAWR approach spends 5 more minutes than Tree-Linearization, appropriate 3.5% of the total spend time per epoch, which could be negligible. The Tree-RNN model spends 498 minutes per epoch, nearly four times slower than the baseline model.[7] According to the results, we can conclude that the Tree-RNN model is highly inefficient for encoding dependency syntax, whereas the SAWR and Tree-Linearization are almost as efficient as the baseline Seq2Seq system.

4.3 Main Results

4.3.1 Chinese-English Translation

Table 1 shows the main results of all approaches on Chinese-English datasets. Considering the effect of random initialization, we train three individual models for each approach, and use the averaged BLEU scores for fair comparisons.

According to the results, we can see that all syntax-integrated approaches can bring significant improvements over the baseline system, which denotes that syntax is highly effective for Chinese-English machine translation. In addition, the proposed SAWR approach obtains the largest BLEU improvements, averaged $\Delta = 1.74$ BLEU points better than the baseline system. The Tree-RNN and Tree-Linearization approaches bring improve-

---

[4] https://nlp.stanford.edu/software/stanford-dependencies.shtml

[5] For simplicity, we use only words as inputs for both Chinese and English dependency parsing, avoiding the influences brought by other inputs, such as automatic POS tags.

[6] We exclude the time consumed by the encoder part of the dependency parsing model for fair comparisons, as other methods require to perform parsing in an offline way.

[7] The Tree-RNN model is implemented with deliberate batching motivated by Neubig et al. (2017), without which the model is intolerably slow, reaching about 1,900 minutes per epoch.

System	tst 2013 / Δ
Baseline	28.29
SAWR	**29.09/+0.80**
Tree-RNN	28.51/+0.22
Tree-Linearization	28.93/+0.64

Table 2: Final Results on the IWSLT 2015 English-Vietnamese translation task. Only SAWR is significantly better than the baseline system ($p < 0.05$).

ments of averaged $\Delta = 1.32$ and $\Delta = 1.23$ BLEU points, respectively. The results show that our implicit syntax-aware encoding method is better than Tree-RNN and Tree-Linearization.

We compare our NMT models with other state-of-the-art methods as well. The results are just for reference since experimental details could be very different. In particular, we list the relative improvements over the corresponding baseline models by integrating syntax structures, which are calculated according to their papers. All these studies exploit lower baselines compared with our models. The Tree-RNN and Tree-Linearization are essentially similar to Chen et al. (2017a) and Li et al. (2017), respectively. As shown, our approaches can still obtain large improvements based on a stronger baseline.

4.3.2 English-Vietnamese Translation

Table 2 shows the final results on the IWSLT 2015 English-Vietnamese translation task. The overall tendency is similar to that of Chinese-English translation. The syntax information can boost the translation performances by using any of the three approaches. The SAWR approach gives the best translation performance, significantly outperform the baseline system by $\Delta = 0.80$ BLEU points. While although the other two approaches bring better performances, the improvements are not significant. The results demonstrate the advantage of the proposed implicit SAWR approach. By not using the 1-best parser outputs, our approach can reduce the error propagation problem, thus bring larger improvements with syntax.

In particular, we find that the increases of BLEU scores are smaller than that of Chinese-English translation by integrating syntactic features. The averaged BLEU increases are 0.55 for English-Vietnamese and 1.43 for Chinese-English. The possible reason may be due to that the source English sentences are more grammatically rigorous than Chinese sentences. For example, the English functional words such as “of” and “‘s” which indicate the possessive relationship, should be always kept in sentences by standard, while their Chinese correspondence “的” may be omitted in sentences.

Parser	MT03	MT04	MT05	MT06	Average
no Tune	**38.42**	**40.60**	**38.27**	**38.04**	**38.83**
Tune	37.33	39.45	36.93	37.03	37.69

Table 3: The influence of fine-tuning parser parameters in the SAWR system.

4.4 Analysis

In this section, we conduct analysis on Chinese-English translation from different aspects to better understand the SAWR approach of integrating source-side dependency syntax for NMT.

4.4.1 Fine-Tuning Syntax-Oriented Inputs

The SAWR approach directly uses the encoder outputs of a dependency parser as extra inputs for NMT. In the above experiments, we keep the parser model parameters fixed, letting them uninfluenced from NMT optimization. Actually, this part can be further fine tuned along with the NMT learning, by treating them as one kind model parameters. Thus there arises a question that whether fine-tuning the parser model parameters can bring better performance.

As an interesting attempt, we can simultaneously fine tune the parameters of both the parser and the Seq2Seq NMT model during training. Figure 3 shows the results. We can see that fine-tuning decreases the average BLEU score by $38.83 - 37.69 = 1.14$ significantly. This may be because that fine-tuning disorders the representation ability of the parser and makes its function more overlapping with other network components. This further demonstrates that pretrained syntax-aware word representations are helpful for NMT.

4.4.2 Alignment Study

Alignment quality is an important metric to illustrate and evaluate machine translation outputs. Here we study how syntax features influence the alignment results for NMT. We approximate the alignment scores by the attention probabilities as shown in Equation 4.[8] For better understanding

---

[8] We aim to offer an intuitive interpretation by a carefully-selected example. In fact, the alignment computation method here may be problematic (Koehn and Knowles, 2017).

System	MT03	MT04	MT05	MT06	Average/Δ
Baseline×3	40.90	43.25	40.64	40.16	41.24
SAWR×3	41.94	44.59	41.91	41.97	42.60/+1.36
Tree-RNN×3	42.03	44.15	41.50	41.41	42.27/+1.03
Tree-Linearization×3	41.74	44.23	41.32	41.44	42.18/+0.94
Hybrid	**42.72**	**45.14**	**42.38**	**42.15**	**43.10/+1.86**

Table 4: Ensemble performances, where the Hybrid model denotes SAWR + Tree-RNN + Tree-Linearization.

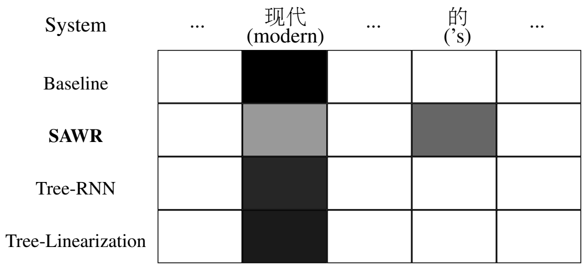

Figure 3: Alignments for the baseline and syntax-integrated systems, where the same example in Figure 1 is analyzed and the target English word is "of".

the effectiveness of syntax, we choose the target-side English word "of" for comparison, which is a grammatical functional word.

Figure 3 shows the alignment probability distributions returned by different approaches. Intuitively, this word should be aligned with the Chinese word "的(de)". But according to the results, we can see that only the SAWR model distributes a high attention score to it, which is consistent with our intuition. The other three models are all aligned to the source word "现代 (modern)" with high confidence over 85%. The possible reason for "of" being aligned to "现代 (modern)" could be due to that "of modern" is a high-frequency collocation in the training corpora.

4.4.3 Ensemble Study

Here we perform model ensembles to examine the divergences of the three syntax-integration approaches (Zhou et al., 2017b; Denkowski and Neubig, 2017). Intuitively, the hetero-approach ensemble which combines three NMT models of different methods should obtain better performances than homo-approach ensembles which combine three NMT models of the same method, since NMT models of different syntax-integrations approaches have larger divergences.

Table 4 shows the results. First, we can see that ensemble is one effective technique to improve the translation performances. More importantly, the results show that the heterogeneous ensemble achieves averaged BLEU improvements by $43.10 - 41.24 = 1.86$ points, better than the gains achieved by all three homo-approach ensembles, denoting that the three approaches could be mutually complementary in representing dependency syntax, and the resulting models of the three approaches are highly diverse.

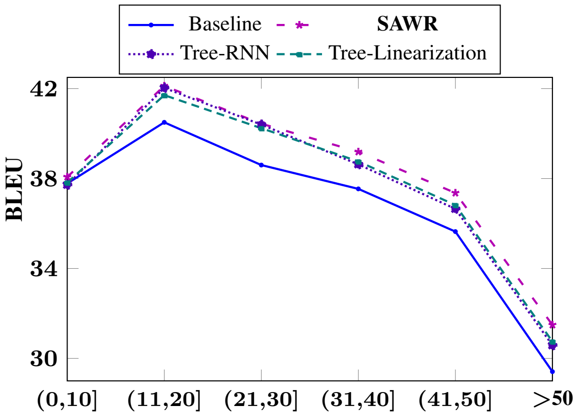

Figure 4: The effect of source input length.

4.4.4 Analysis by Source Sentence Length

Intuitively, by introducing the source syntax into the NMT model, relations between long-distance words are explicitly modeled by dependency trees, thus we can expect that models enhanced by source syntax are able to bring better translations for longer sentences. Figure 4 shows the performances of the baseline and all syntax-enriched models in terms of source sentence lengths, where we bin all the MT03-MT06 sentences by their lengths into six intervals. The results show that the BLEU scores are improved significantly when source sentential lengths are over 10, which confirms our intuition.

4.4.5 Effect of Parsing Performance

Finally, we examine how the performance of the dependency parser influences the final translation quality. While the full dependency parser is

System	MT03	MT04	MT05	MT06	Average/Δ
Transformer	40.45	42.76	40.09	39.67	40.74
SAWR	**41.63**	**43.60**	**41.68**	**40.21**	**41.78/+1.04**
Tree-RNN	41.24	43.38	41.04	40.02	41.42/+0.68
Tree-Linearization	41.12	43.02	41.04	39.86	41.26/+0.52

Table 5: Final results based on the transformer. Only the SAWR results are significantly better ($p < 0.05$).

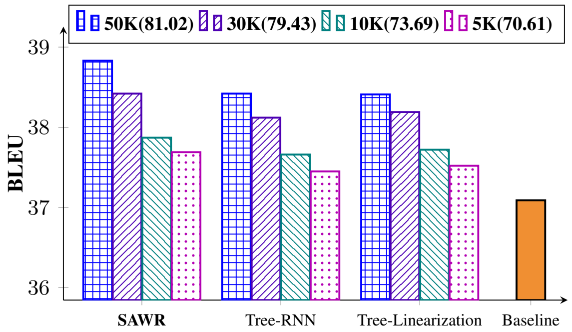

Figure 5: The effect of dependency parsing performances on our proposed approaches.

trained on 50K sentences, we retrain three weaker dependency parsers on 30K, 10K and 5K sentences, respectively. Figure 5 shows the NMT BLEU scores and the parsing accuracies. It is clear that the parsing accuracy directly influences the translation quality, indicating the effectiveness and importance of exploiting syntactic information.

4.4.6 Transformer as Baseline

Here we conduct experiments based on the transformer NMT model (Vaswani et al., 2017), which is a stronger baseline, to further verify the effectiveness of our proposed method. This also demonstrates that the proposed SAWR method does not limit to a certain NMT baseline. Concretely, we extend the bottom word representations by incorporating syntactic encodings $s{=}s_1 \cdots s_n$ (shown in Equation 5) into them, and then feed them into the transformer encoder by a linear projection layer to align with the input dimension. We implement Tree-RNN and Tree-Linearization for Transformer in a similar way, only adapting the source input word representing. We adopt a widely-used setting with 8 heads, 6 layers and the hidden dimension size of 512.

Table 5 shows the results. As shown, the transformer results are indeed much better than RNN-based baseline. The BLEU scores show an average increase of $40.74 - 37.09 = 3.65$. In addition, we can see that syntax information can still give positive influences based on the transformer. The SAWR approach can also outperform the baseline system significantly. Particularly, we find that our SAWR approach is much more effective than the Tree-RNN and Tree-Linearization approaches. The results further demonstrate the effectiveness of SAWRs in syntax integration for NMT.

5 Related Work

By explicitly expressing the structural connections between words and phrases, syntax trees been demonstrated helpful in SMT (Liu et al., 2006; Cowan et al., 2006; Marton and Resnik, 2008; Xie et al., 2011; Li et al., 2013; Williams et al., 2016). Although the representative Seq2Seq NMT models are able to capture latent long-distance relations by using neural network structures such GRU and LSTM (Sutskever et al., 2014; Wu et al., 2016), recent studies show that explicitly integrating syntax trees into NMT models can bring further gains (Sennrich and Haddow, 2016; Shi et al., 2016; Zhou et al., 2017a; Wu et al., 2017a; Aharoni and Goldberg, 2017). Under the NMT setting, the exploration of syntax trees could be more flexible, because of the strong capabilities of neural network in representing arbitrary structures.

Recursive neural networks based on LSTM or GRU have been one natural method to model syntax trees (Zhu et al., 2015; Tai et al., 2015; Li et al., 2015; Zhang et al., 2016; Teng and Zhang, 2016; Miwa and Bansal, 2016; Kokkinos and Potamianos, 2017), which are capable of representing the entire trees globally. Eriguchi et al. (2016) present the first work to apply a bottom-up Tree-LSTM for NMT. The major drawback is that its bottom-up composing strategy is insufficient for bottom nodes. Thus bi-directional extensions have been suggested (Chen et al., 2017a; Yang et al., 2017). Since Tree-RNN suffers serious inefficiency problem, Li et al. (2017) suggest a Tree-Linearization alternative, which converts constituent trees into a sequence of symbols mixed with words and syntactic tags. The method is as effective as Tree-RNN approaches yet more effective. Noticeably, all these studies focus on constituent trees.

There have been several studies for NMT using dependency syntax. Hashimoto and Tsuruoka (2017) propose to combine the head information with sequential words together as source encoder inputs, where their input trees are latent dependency graphs. Recently, there are several studies by using convolutional neural structures to represent source dependency trees, where tree nodes are modeled individually (Chen et al., 2017b; Bastings et al., 2017). Wu et al. (2017b) build a syntax enhanced encoder by multiple Bi-RNNs over several different word sequences based on different traversing orders over dependency trees, i.e., the original sequential order and several tree-based orders. All these methods require certain extra efforts to encode the source dependency syntax over a baseline Seq2Seq NMT.

6 Conclusion

We proposed a novel syntax integration method, SAWR, to incorporate source dependency-based syntax for NMT. It encodes dependency syntax implicitly, not requiring discrete syntax trees as inputs. Experiments showed that the method can bring significantly better performances for both Chinese-English and English-Vietnamese translation tasks. In addition, we compared the method with two approaches based on Tree-RNN and Tree-Linearization, which has been previously exploited for syntax integration, finding that our method is more effective and meanwhile very efficient. We conducted several experimental analyses to study our proposed methods deeper.

Abstract

Current state-of-the-art NMT systems use large neural networks that are not only slow to train, but also often require many heuristics and optimization tricks, such as specialized learning rate schedules and large batch sizes. This is undesirable as it requires extensive hyperparameter tuning. In this paper, we propose a *curriculum learning framework for NMT* that reduces training time, reduces the need for specialized heuristics or large batch sizes, and results in overall better performance. Our framework consists of a principled way of deciding which training samples are shown to the model at different times during training, based on the estimated *difficulty* of a sample and the current *competence* of the model. Filtering training samples in this manner prevents the model from getting stuck in bad local optima, making it converge faster and reach a better solution than the common approach of uniformly sampling training examples. Furthermore, the proposed method can be easily applied to existing NMT models by simply modifying their input data pipelines. We show that our framework can help improve the training time and the performance of both recurrent neural network models and Transformers, achieving up to a 70% decrease in training time, while at the same time obtaining accuracy improvements of up to 2.2 BLEU.

1 Introduction

Neural Machine Translation (NMT; Kalchbrenner and Blunsom (2013); Bahdanau et al. (2015)) now represents the state-of-the-art adapted in most machine translation systems (Wu et al., 2016; Crego et al., 2016; Bojar et al., 2017a), largely due to its ability to benefit from end-to-end training on massive amounts of data. In particular, recently-introduced self-attentional Transformer architectures (Vaswani et al., 2017) are rapidly becoming the de-facto standard in NMT, having demonstrated both superior performance and training speed compared to previous architectures using recurrent neural networks (RNNs; (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014)). However, large scale NMT systems are often hard to train, requiring complicated heuristics which can be both time-consuming and expensive to tune. This is especially true for Transformers which, when carefully tuned, have been shown to consistently outperform RNNs (Popel and Bojar, 2018), but on the other hand, also rely on a number of heuristics such as specialized learning rates and large-batch training.

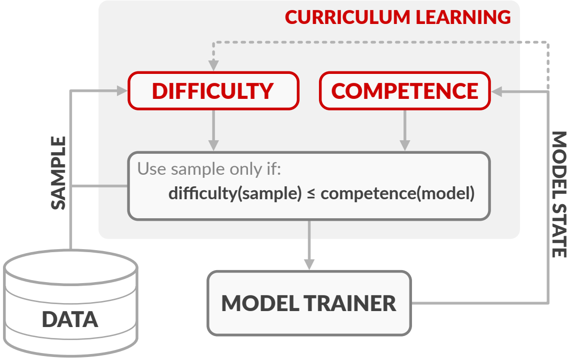

Figure 1: Overview of the proposed curriculum learning framework. During training, *difficulty* of each training sample is estimated and a decision whether to use it is made based on the current *competence* of the model.

In this paper, we attempt to tackle this problem by proposing a *curriculum learning framework* for training NMT systems that reduces training time, reduces the need for specialized heuristics or large batch sizes, and results in overall better performance. It allows us to train both RNNs and, perhaps more importantly, Transformers, with relative ease. Our proposed method is based on the idea of teaching algorithms in a similar manner as humans, from easy concepts to more difficult ones. This idea can be traced back to the work

Proceedings of NAACL-HLT 2019, pages 1162–1172
Minneapolis, Minnesota, June 2 - June 7, 2019.

of Elman (1993) and Krueger and Dayan (2009). The main motivation is that training algorithms can perform better if training data is presented in a specific order, starting from *easy* examples and moving on to more *difficult* ones, as the learner becomes more *competent*. In the case of machine learning, it can also be thought of as a means to avoid getting stuck in bad local optima early on in training. An overview of the proposed framework is shown in Figure 1.

Notably, we are not the first to examine curriculum learning for NMT, although other related works have met with mixed success. Kocmi and Bojar (2017) explore impact of several curriculum heuristics on training a translation system for a single epoch, presenting the training examples in an easy-to-hard order based on sentence length and vocabulary frequency. However, their strategy introduces all training samples during the first epoch, and how this affects learning in following epochs is not clear, with official evaluation results (Bojar et al., 2017b) indicating that final performance may indeed be hurt with this strategy. Contemporaneously to our work, Zhang et al. (2018) further propose to split the training samples into a predefined number of bins (5, in their case), based on various difficulty metrics. A manually designed curriculum schedule then specifies the bins from which the model samples training examples. Experiments demonstrate that benefits of curriculum learning are highly sensitive to several hyperparameters (e.g., learning rate, number of iterations spent in each phase, etc.), and largely provide benefits in convergence speed as opposed to final model accuracy.

In contrast to these previous approaches, we define a continuous curriculum learning method (instead of a discretized regime) with only one tunable hyperparameter (the duration of curriculum learning). Furthermore, as opposed to previous work which only focuses on RNNs, we also experiment with Transformers, which are notoriously hard to train (Popel and Bojar, 2018). Finally, unlike any of the work described above, we show that our curriculum approach helps not only in terms of convergence speed, but also in terms of the learned model performance. In summary, our method has the following desirable features:

1. **Abstract:** It is a novel, generic, and extensible formulation of curriculum learning. A number of previous heuristic-based approaches, such as that of Kocmi and Bojar (2017), can be formulated as special cases of our framework.
2. **Simple:** It can be applied to existing NMT systems with only a small modification to their training data pipelines.
3. **Automatic:** It does not require any tuning other than picking the value of a single parameter, which is the length of the curriculum (i.e., for how many steps to use curriculum learning, before easing into normal training).
4. **Efficient:** It reduces training time by up to 70%, whereas contemporaneous work of Zhang et al. (2018) reports reductions of up to 46%.
5. **Improved Performance:** It improves the performance of the learned models by up to 2.2 BLEU points, where the best setting reported by Zhang et al. (2018) achieves gains of up 1.55 BLEU after careful tuning.

In the next section, we introduce our proposed curriculum learning framework.

2 Proposed Method

We propose *competence-based curriculum learning*, a training framework based on the idea that training algorithms can perform better if training data is presented in a way that picks examples appropriate for the model's current *competence*. More specifically, we define the following two concepts that are central to our framework:

Difficulty: A value that represents the difficulty of a training sample and that may depend on the current state of the learner. For example, sentence length is an intuitive difficulty metric for natural language processing tasks. The only constraint is that difficulty scores are comparable across different training samples (i.e., the training samples can be ranked according to their difficulty).

Competence: A value between 0 and 1 that represents the progress of a learner during its training. It is defined as a function of the learner's state. More specifically, we define the competence, $c(t)$ at time t (measured in terms of training steps), of a learner as the proportion of training data it is allowed to use at that time. The training examples are ranked according to their difficulty and the learner is only allowed to use the top $c(t)$ portion of them at time t.

Using these two concepts, we propose Algorithm 1 (a high-level overview is shown in Figure 1, an example visualization of the first two steps is shown

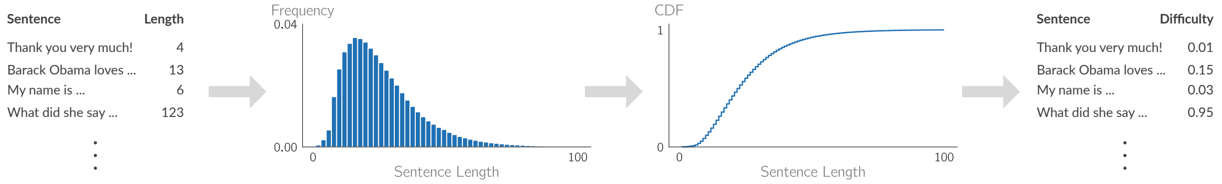

Figure 2: Example visualization of the preprocessing sequence used in the proposed algorithm. The histogram shown is that of sentence lengths from the WMT-16 `En→De` dataset used in our experiments. Here sentence lengths represent an example difficulty scoring function, d. "CDF" stands for the empirical "cumulative density function" obtained from the histogram on the left plot.

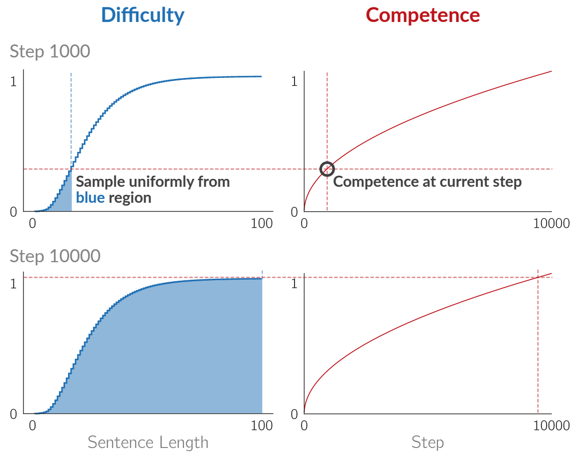

Figure 3: Example illustration of the training data "filtering" performed by our curriculum learning algorithm. At each training step: (i) the current competence of the model is computed, and (ii) a batch of training examples is sampled uniformly from all training examples whose difficulty is lower than that competence. In this example, we are using the sentence length difficulty heuristic shown in Equation 1, along with the square root competence model shown in Equation 7.

in Figure 2, and an example of the interaction between difficulty and competence is shown in Figure 3).

Note that, at each training step, we are not changing the relative probability of each training sample under the input data distribution, but we are rather constraining the domain of that distribution, based on the current competence of the learner. Eventually, once the competence becomes 1, the training process becomes equivalent to that without using a curriculum, with the main difference that the learner should now be more capable to learn from the more difficult examples. Given the dependence of this algorithm on the specific choices of the difficulty scoring function, d, and the competence function, c, we now describe our instantiations for training NMT models.

Algorithm 1: Competence-based curriculum learning algorithm.

```
Input: Dataset, $\mathcal{D} = \{s_i\}_{i=1}^{M}$, consisting of $M$
       samples, model trainer, $\mathcal{T}$, that takes as input
       batches of training data to use at each step,
       difficulty scoring function, $d$, and competence
       function, $c$.
Compute the difficulty, $d(s_i)$, for each $s_i \in \mathcal{D}$.
Compute the cumulative density function (CDF) of
  the difficulty scores. This results in one difficulty
  CDF score per sample, $\bar{d}(s_i) \in [0, 1]$. Illustrated in
  Figure 2.
for training step $t = 1, \ldots$ do
    Compute the model competence, $c(t)$.
    Sample a data batch, $B_t$, uniformly from all
      $s_i \in \mathcal{D}$, such that $\bar{d}(s_i) \leq c(t)$. Illustrated in
      Figure 3.
    Invoke the trainer, $\mathcal{T}$, using $B_t$ as input.
Output: Trained model.
```

2.1 Difficulty Metrics

There are many possible ways of defining the difficulty of translating a sentence. We consider two heuristics inspired by what we, as humans, may consider difficult when translating, and by factors which can negatively impact the optimization algorithms used when training NMT models. In the rest of this section we denote our training corpus as a collection of M sentences, $\{s_i\}_{i=1}^{M}$, where each sentence is a sequence of words. $s_i = \{w_0^i, \ldots, w_{N_i}^i\}$.

Sentence Length: We argue that it is harder to translate longer sentences, as longer sentences require being able to translate their component parts, which often consist of short sentences. Furthermore, longer sentences are intuitively harder to translate due to the propagation of errors made early on when generating the target language sentence. Therefore, a simple way to define the difficulty of a sentence $s_i = \{w_0^i, \ldots, w_{N_i}^i\}$ is as follows:

$$d_{\text{length}}(s_i) \triangleq N_i. \tag{1}$$

Note that we can compute this difficulty metric on either the source language sentence or the target language sentence. We only consider the source sentence in this paper [1].

Word Rarity: Another aspect of language that can affect the difficulty of translation is the frequency with which words appear. For example, humans may find rare words hard to translate because we rarely ever see them and it may be hard to recall their meaning. The same can be true for NMT models where: (i) the statistical strength of the training examples containing rare words is low and thus the model needs to keep revisiting such words in order to learn robust representations for them, and (ii) the gradients of the rare word embeddings tend to have high variance; they are overestimates of the true gradients in the few occasions where they are non-zero, and underestimates otherwise. This suggests that using word frequencies may be a helpful difficulty heuristic. Given a corpus of sentences, $\{s_i\}_{i=1}^M$, we define relative word frequencies as:

$$\hat{p}(w_j) \triangleq \frac{1}{N_{\text{total}}} \sum_{i=1}^{M} \sum_{k=1}^{N_i} \mathbb{1}_{w_k^i = w_j}, \qquad (2)$$

where $j = 1, \ldots, \#\{\text{unique words in corpus}\}$ and $\mathbb{1}_{\text{condition}}$ is the indicator function which is equal to 1 if its condition is satisfied and 0 otherwise. Next we need to decide how to aggregate the relative word frequencies of all words in a sentence to obtain a single difficulty score for that sentence. Previous research has proposed various pooling operations, such as minimum, maximum, and average (Zhang et al., 2018), but they show that they do not work well in practice. We propose a different approach. Ultimately, what might be most important is the overall likelihood of a sentence as that contains information about both word frequency and, implicitly, sentence length. An approximation to this likelihood is the product of the unigram probabilities, which is related to previous work in the area of active learning (Settles and Craven, 2008). This product can be thought of as an approximate language model (assuming words are sampled independently) and also implicitly incorporates information about the sentence length that was proposed earlier (longer sentence scores are products over more terms in $[0, 1]$ and are thus likely to be smaller). We thus propose the following difficulty heuristic:

$$d_{\text{rarity}}(s_i) \triangleq -\sum_{k=1}^{N_i} \log \hat{p}(w_k^i), \qquad (3)$$

where we use logarithms of word probabilities to prevent numerical errors. Note that negation is used because we define less likely (i.e., more rare) sentences as more difficult.

These are just two examples of difficulty metrics, and it is easy to conceive of other metrics such as the occurrence of homographs (Liu et al., 2018) or context-sensitive words (Bawden et al., 2018), the examination of which we leave for future work.

2.2 Competence Functions

For this paper, we propose two simple functional forms for $c(t)$ and justify them with some intuition. More sophisticated strategies that depend on the loss function, the loss gradient, or on the learner's performance on held-out data, are possible, but we do not consider them in this paper.

Linear: This is a simple way to define $c(t)$. Given an initial value $c_0 \triangleq c(0) \geq 0$ and a slope parameter r, we define:

$$c(t) \triangleq \min\left(1, tr + c_0\right). \qquad (4)$$

In this case, new training examples are constantly being introduced during the training process, with a constant rate r (as a proportion of the total number of available training examples). Note that we can also define $r = (1 - c_0)/T$, where T denotes the time after which the learner is fully competent, which results in:

$$c_{\text{linear}}(t) \triangleq \min\left(1, t\frac{1 - c_0}{T} + c_0\right). \qquad (5)$$

Root: In the case of the linear form, the same number of new and more difficult, examples are added to the training set, at all times t. However, as the training data grows in size, it gets less likely that any single data example will be sampled in a training batch. Thus, given that the newly added examples are less likely to be sampled, we propose to reduce the number of new training examples per unit time as training progresses to give the learner

---

[1] NMT models typically first pick up information about producing sentences of correct length. It can be argued that presenting only short sentences first may lead to learning a strong bias for the sentence lengths. In our experiments, we did not observe this to be an issue as the models kept improving and predicting sentences of correct length, throughout training.

sufficient time to assimilate their information content. More specifically, we define the rate in which new examples are added as inversely proportional to the current training data size:

$$\frac{dc(t)}{dt} = \frac{P}{c(t)}, \tag{6}$$

for some constant $P \geq 0$. Solving this simple differential equation, we obtain:

$$\int c(t)dc(t) = \int Pdt \Rightarrow c(t) = \sqrt{2Pt + D},$$

for some constants P and D. Then, we consider the following constraint: $c_0 \triangleq c(0) = \sqrt{D} \Rightarrow D = c_0^2$. Finally, we also have that $c(T) = 1 \Rightarrow P = (1 - c_0^2)/2T$, where T denotes the time after which the learner is fully competent. This, along with the constraint that $c(t) \in [0, 1]$ for all $t \geq 0$, results in the following definition:

$$c_{\text{sqrt}}(t) \triangleq \min\left(1, \sqrt{t\frac{1 - c_0^2}{T} + c_0^2}\right). \tag{7}$$

In our experiments, we refer to this specific formulation as the "square root" competence model. If we want to make the curve *sharper*, meaning that even more time is spent per sample added later on in training, then we can consider the following more general form, for $p \geq 1$:

$$c_{\text{root-}p}(t) \triangleq \min\left(1, \sqrt[p]{t\frac{1 - c_0^p}{T} + c_0^p}\right). \tag{8}$$

We observed that best performance is obtained when $p = 2$ and then, as we increase p, performance converges to that obtained when training without a curriculum. Plots of the competence functions we presented are shown in Figure 4.

2.3 Scalability

Our method can be easily used in large-scale NMT systems. This is because it mainly consists of a preprocessing step of the training data that computes the difficulty scores. The implementation we are releasing with this paper computes these scores in an efficient manner by building a graph describing their dependencies, as well as whether they are sentence-level scores (e.g., sentence length), or corpus-level (e.g., CDF), and using that graph to optimize their execution. Using only 8GB of memory, we can process up to 20k sentences per second when computing sentence rarity scores, and up to 150k sentences per second when computing sentence length scores.

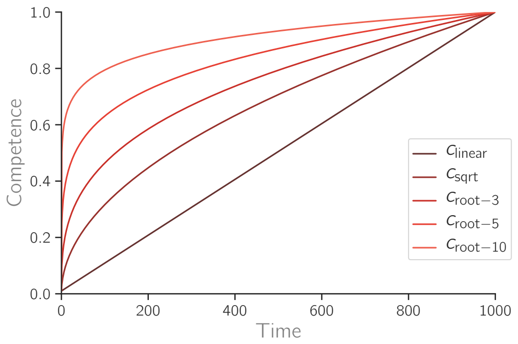

Figure 4: Plots of various competence functions with $c_0 = 0.01$ (initial competence value) and $T = 1,000$ (total duration of the curriculum learning phase).

3 Experiments

For our experiments, we use three of the most commonly used datasets in NMT, that range from a small benchmark dataset to a large-scale dataset with millions of sentences. Statistics about the datasets are shown in Table 1. We perform experiments using both RNNs and Transformers. For the RNN experiments we use a bidirectional LSTM for the encoder, and an LSTM with the attention model of Bahdanau et al. (2015) for the decoder. The number of layers of the encoder and the decoder are equal. We use a 2-layer encoder and a 2-layer decoder for all experiments on IWSLT datasets, and a 4-layer encoder and a 4-layer decoder for all experiments on the WMT dataset, due to the dataset's significantly larger size. For the Transformer experiments we use the BASE model proposed by Vaswani et al. (2017). It consists of a 6-layer encoder and decoder, using 8 attention heads, and 2,048 units for the feed-forward layers. The multi-head attention keys and values depth is set to the word embedding size. The word embedding size is 512 for all experiments. Furthermore, for the Transformer experiments on the two smaller datasets we do not use any learning rate schedule, and for the experiments on the largest dataset we use the default Transformer schedule. A detailed discussion on learning rate schedules for Transformers is provided near the end of this section. All of our experiments were conducted on a machine with a single Nvidia V100 GPU, and 24 GBs of system memory.

During training, we use a label smoothing factor of 0.1 (Wu et al., 2016) and the AMSGrad optimizer (Reddi et al., 2018) with its default parameters in TensorFlow, and a batch size of 5,120 tokens

Dataset	# Train	# Dev	# Test
IWSLT-15 `En→Vi`	133k	768	1268
IWSLT-16 `Fr→En`	224k	1080	1133
WMT-16 `En→De`	4.5m	3003	2999

Table 1: Number of parallel sentences in each dataset. “k” stands for “thousand” and “m” stands for “million”.

(due to GPU memory constraints). During inference, we employ beam search with a beam size of 10 and the length normalization scheme of Wu et al. (2016).[2]

Curriculum Hyperparameters. We set the initial competence c_0 to 0.01, in all experiments. This means that all models start training using the 1% easiest training examples. The curriculum length T is effectively the only hyperparameter that we need to set for our curriculum methods. In each experiment, we set T in the following manner: we train the baseline model without using any curriculum and we compute the number of training steps it takes to reach approximately 90% of its final BLEU score. We then set T to this value. This results in T being set to 5,000 for the RNN experiments on the IWSLT datasets, and 20,000 for the corresponding Transformer experiments. For WMT, we set T to 20,000 and 50,000 for RNNs and Transformers, respectively. Furthermore, we use the following notation and abbreviations when presenting our results:

- Plain: Trained without using any curriculum.
- SL: Curriculum with sentence length difficulty.
- SR: Curriculum with sentence rarity difficulty.
- Linear: Curriculum with the linear competence shown in Equation 5.
- Sqrt: Curriculum with the square root competence shown in Equation 7.

Data Preprocessing. Our experiments are performed using the machine translation library released by Platanios et al. (2018). We use the same data preprocessing approach the authors used in their experiments. While training, we consider sentences up to length 200. Similar to them, for the IWSLT-15 experiments we use a per-language vocabulary which contains the 20,000 most frequently occurring words, while ignoring words that appear less than 5 times in the whole corpus. For the IWSLT-16 and WMT-16 experiments we use a byte-pair encoding (BPE) vocabulary (Sennrich et al., 2016) trained using 32,000 merge operations, similar to the original Transformer paper by Vaswani et al. (2017).

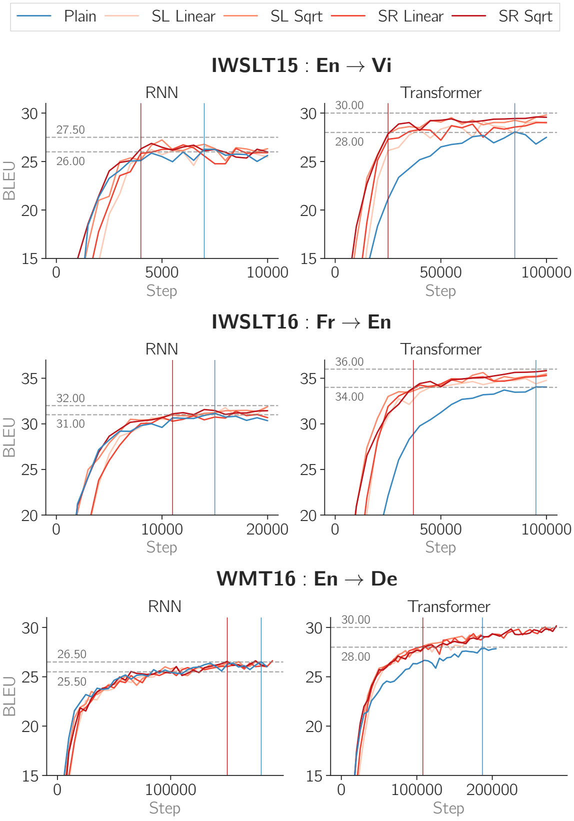

Figure 5: Plots illustrating the performance of various models on the test set, as training progresses. **Blue** lines represent the baseline methods when no curriculum is used, and **red** lines represent the same models when different versions of our curriculum learning framework are used to train them. The vertical lines represent the step in which the models attain the BLEU score that the baseline models attain at convergence.

Results. We present a summary of our results in Table 2 and we also show complete learning curves for all methods in Figure 5. The evaluation metrics we use are the test set BLEU score and the time it takes for the models using curriculum learning to obtain the BLEU score that the baseline models attain at convergence. We observe that Transformers consistently benefit from our curriculum learning approach, achieving gains of up to 2 BLEU, and reductions in training time of up to 70%. RNNs also benefit, but to a lesser extent. This is consistent with our motivation for this paper, which

---

[2] We emphasize that we did not run experiments with other architectures or configurations, and thus our baseline architectures were not chosen because they were favorable to our method, but rather because they were frequently mentioned in existing literature.

		RNN					TRANSFORMER					
		Plain	SL Curriculum		SR Curriculum		Plain	Plain*	SL Curriculum		SR Curriculum	
			c_{linear}	c_{sqrt}	c_{linear}	c_{sqrt}			c_{linear}	c_{sqrt}	c_{linear}	c_{sqrt}
BLEU	En→Vi	26.27	26.57	**27.23**	26.72	26.87	28.06	29.77	29.14	29.57	29.03	**29.81**
	Fr→En	31.15	31.88	**31.92**	31.39	31.57	34.05	34.88	34.98	35.47	35.30	**35.83**

Table 2: Summary of experimental results. For each method and dataset, we present the test set BLEU score of the best model based on validation set performance. We also show the relative time required to obtain the BLEU score of the best performing baseline model. For example, if an RNN gets to 26.27 BLEU in $10,000$ steps and the SL curriculum gets to the same BLEU in $3,000$ steps, then the plain model gets a score of 1.0 and the SL curriculum receives a score of $3,000/10,000 = 0.3$. "Plain" stands for the model trained without a curriculum and, for Transformers, "Plain*" stands for the model trained using the learning rate schedule shown in Equation 9.

stems from the observation that training RNNs is easier and more robust than training Transformers. Furthermore, the square root competence model consistently outperforms the linear model, which fits well with our intuition and motivation for introducing it. Regarding the difficulty heuristics, sentence length and sentence rarity both result in similar performance.

We also observe that, for the two small datasets, RNNs converge faster than Transformers in terms of both the number of training iterations and the overall training time. This is contrary to other results in the machine translation community (e.g., Vaswani et al., 2017), but could be explained by the fact that we are not using any learning rate schedule for training Transformers. However, they never manage to outperform Transformers in terms of test BLEU score of the final model. Furthermore, to the best of our knowledge, for IWSLT-15 we achieve state-of-the-art performance. The highest previously reported result was 29.03 BLEU (Platanios et al., 2018), in a multi-lingual setting. Using our curriculum learning approach we are able to achieve a BLEU score of 29.81 for this dataset.

Overall, we have shown that *our curriculum learning approach consistently outperforms models trained without any curriculum*, in both limited data settings and large-scale settings.

Learning Rate Schedule. In all of our IWSLT experiments so far, we use the default AMSGrad learning rate of 0.001 and intentionally avoid using any learning rate schedules. However, Transformers are not generally trained without a learning rate schedule, due to their instability. Such schedules typically use a warm-up phase, which means that the learning rate starts at a very low value and keeps increasing until the end of the warm-up period, after which a decay rate is typically used. In order to show that our curriculum learning approach can act as a principled alternative to such highly tuned learning rate schedules, we now present the results we obtain when training our Transformers using the following learning rate schedule:

$$\mathrm{lr}(t) \triangleq d_{\text{embedding}}^{-0.5} \min\left(t^{-0.5}, t \cdot T_{\text{warmup}}^{-1.5}\right), \qquad (9)$$

where t is the current training step, $d_{\text{embedding}}$ is the word embeddings size, and T_{warmup} is the number of warmup steps and is set to 10,000 in these experiments. This schedule was proposed in the original Transformer paper (Vaswani et al., 2017), and was tuned for the WMT dataset.

The results obtained when using this learning rate schedule are also shown in table 2, under the name "Plain*". *In both cases, our curriculum learning approach obtains a better model in about 70% less training time*. This is very important, especially when applying Transformers in new datasets, because such learning rate heuristics often require careful tuning. This tuning can be both very expensive and time consuming, often resulting in very complex mathematical expressions, with no clear motivation or intuitive explanation (Chen et al., 2018). Our curriculum learning approach achieves better results, in significantly less time, while only requiring one parameter (the length of the curriculum).

Note that even without using any learning rate schedule, our curriculum methods were able to achieve performance comparable to the "Plain*" in about twice as many training steps. "Plain" was not able to achieve a BLEU score above 2.00 even after fives times as many training steps, at which point we stopped these experiments.

Implementation and Reproducibility. We are releasing an implementation of our proposed method and experiments built on top of the machine translation library released by Platanios et al. (2018), using TensorFlow Scala (Platanios, 2018), and is available at `https://github.com/eaplatanios/symphony-mt`. Furthermore, all experiments can be run on a machine with a single Nvidia V100 GPU, and 24 GBs of system memory. Our most expensive experiments — the ones using Transformers on the WMT-16 dataset — take about 2 days to complete, which would cost about $125 on a cloud computing service such as Google Cloud or Amazon Web Services, thus making our results reproducible, even by independent researchers.

4 Related work

The idea of teaching algorithms in a similar manner as humans, from easy concepts to more difficult ones, has existed for a long time (Elman, 1993; Krueger and Dayan, 2009). Machine learning models are typically trained using stochastic gradient descent methods, by uniformly sampling mini-batches from the pool of training examples, and using them to compute updates for the model parameters. Deep neural networks, such as RNNs and Transformers, have highly non-convex loss functions. This makes them prone to getting stuck in saddle points or bad local minima during training, often resulting in long training times and bad generalization performance. Bengio et al. (2009) propose a curriculum learning approach that aims to address these issues by changing the mini-batch sampling strategy. They propose starting with a distribution that puts more weight on easy samples, and gradually increase the probability of more difficult samples as training progresses, eventually converging to a uniform distribution. They demonstrate empirically that such curriculum approaches indeed help decrease training times and sometimes even improve generalization.

Perhaps the earliest attempt to apply curriculum learning in MT was made by Zou et al. (2013). The authors employed a curriculum learning method to learn Chinese-English bilingual word embeddings, which were subsequently used in the context of phrase-based machine translation. They split the word vocabulary in 5 separate groups based on word frequency, and learned separate word embeddings for each of these groups in parallel. Then, they merged the 5 different learned embeddings and continued training using the full vocabulary. While this approach makes use of some of the ideas behind curriculum learning, it does not directly follow the original definition introduced by Bengio et al. (2009). Moreover, their model required 19 days to train. There have also been a couple of attempts to apply curriculum learning in NMT that were discussed in section 1.

There also exists some relevant work in areas other than curriculum learning. Zhang et al. (2016) propose training neural networks for NMT by focusing on hard examples, rather than easy ones. They report improvements in BLEU score, while only using the hardest 80% training examples in their corpus. This approach is more similar to boosting by Schapire (1999), rather than curriculum learning, and it does not help speed up the training process; it rather focuses on improving the performance of the trained model. The fact that hard examples are used instead of easy ones is interesting because it is somewhat contradictory to that of curriculum learning. Also, in contrast to curriculum learning, no ordering of the training examples is considered.

Perhaps another related area is that of active learning, where the goal is to develop methods that request for specific training examples. Haffari et al. (2009), Bloodgood and Callison-Burch (2010), and Ambati (2012) all propose methods to solicit training examples for MT systems, based on the occurrence frequency of n-grams in the training corpus. The main idea is that if an n-gram is very rare in the training corpus, then it is difficult to learn to translate sentences in which it appears. This is related to our sentence rarity difficulty metric and points out an interesting connection between curriculum learning and active learning.

Regarding training Transformer networks, Shazeer and Stern (2018) perform a thorough experimental evaluation of Transformers, when using different optimization configurations. They show that a significantly higher level of performance can be reached by not using momentum during optimization, as long as a carefully chosen learning rate schedule is used. Such learning rate schedules are often hard to tune because of the multiple seemingly arbitrary terms they often contain. Furthermore, Popel and Bojar (2018) show that, when using Transformers, increasing the batch size results in a better model at convergence. We believe this is indicative of very noisy gradients when starting to train Transformers and that higher batch sizes help increase the signal-to-noise ratio. We show that our proposed curriculum learning method offers a more principled and robust way to tackle this problem. Using our approach, we are able to train Transformers to state-of-the-art performance, using small batch sizes and without the need for peculiar learning rate schedules, which are typically necessary.

5 Conclusion and Future Work

We have presented a novel *competence-based* curriculum learning approach for training neural machine translation models. Our resulting framework is able to boost performance of existing NMT systems, while at the same time significantly reducing their training time. It differs from previous approaches in that it does not depend on multiple hyperparameters that can be hard to tune, and it does not depend on a manually designed discretized training regime. We define the notions of *competence*, for a learner, and *difficulty*, for the training examples, and propose a way to filter training data based on these two quantities. Perhaps most interestingly, we show that our method makes training Transformers faster and more reliable, but has a much smaller effect in training RNNs.

In the future, we are mainly interested in: (i) exploring more difficulty heuristics, such as measures of alignment between the source and target sentences (Kocmi and Bojar, 2017), sentence length discrepancies, or even using a pre-trained language model to score sentences, which would act as a more robust replacement of our sentence rarity heuristic, and (ii) exploring more sophisticated competence metrics that may depend on the loss function, the loss gradient, or on the learner's performance on held-out data. Furthermore, it would be interesting to explore applications of curriculum learning to multilingual machine translation (e.g., it may be easier to start with high-resource languages and move to low-resource ones later on). We would also like to explore the usefulness of our framework in more general machine learning tasks, outside of NMT.

Acknowledgments

We would like to thank Maruan Al-Shedivat and Dan Schwartz for the useful feedback they provided in early versions of this paper. This research was supported in part by AFOSR under grant FA95501710218.

Extract and Edit: An Alternative to Back-Translation for Unsupervised Neural Machine Translation

Jiawei Wu and **Xin Wang** and **William Yang Wang**
Department of Computer Science
University of California, Santa Barbara
Santa Barbara, CA 93106 USA
`{jiawei_wu,xwang,william}@cs.ucsb.edu`

Abstract

The overreliance on large parallel corpora significantly limits the applicability of machine translation systems to the majority of language pairs. Back-translation has been dominantly used in previous approaches for unsupervised neural machine translation, where pseudo sentence pairs are generated to train the models with a reconstruction loss. However, the pseudo sentences are usually of low quality as translation errors accumulate during training. To avoid this fundamental issue, we propose an alternative but more effective approach, **extract-edit**, to extract and then edit real sentences from the target monolingual corpora. Furthermore, we introduce a comparative translation loss to evaluate the translated target sentences and thus train the unsupervised translation systems. Experiments show that the proposed approach consistently outperforms the previous state-of-the-art unsupervised machine translation systems across two benchmarks (English-French and English-German) and two low-resource language pairs (English-Romanian and English-Russian) by more than 2 (up to 3.63) BLEU points.

1 Introduction

Promising results have been achieved in Neural Machine Translation (NMT) by representation learning (Cho et al., 2014b; Sutskever et al., 2014). But recent studies (Koehn and Knowles, 2017; Isabelle et al., 2017; Sennrich, 2017) highlight the overreliance of current NMT systems on large parallel corpora. In real-world cases, the majority of language pairs have very little parallel data, so the models need to leverage monolingual data to address this challenge (Gulcehre et al., 2015; Zhang and Zong, 2016; He et al., 2016; Yang et al., 2018).

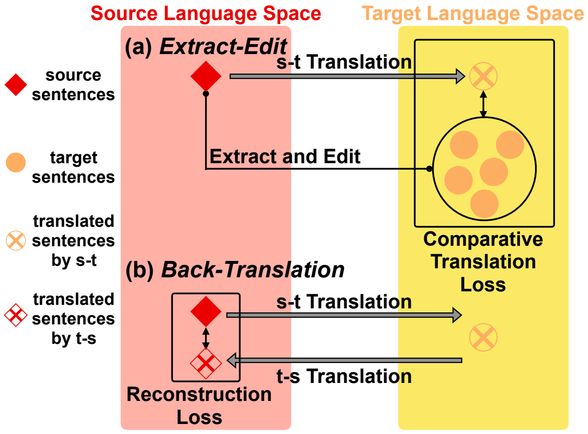

Figure 1: The comparison between two approaches of unsupervised NMT, extract-edit and back-translation. When training the source-to-target (s-t) translation model, instead of using the t-s back-translated sentences to train the model, we directly set the extracted-edited sentences as pivotal points to guide the training.

While many studies have explored how to use the monolingual data to improve translation performance with limited supervision, latest approaches (Lample et al., 2018a; Artetxe et al., 2018; Lample et al., 2018b) focus on the fully unsupervised scenario. Back-translation has been dominantly used in these approaches, where pseudo sentence pairs are generated to train the translation systems with a reconstruction loss. However, it is inefficient because the generated pseudo sentence pairs are usually of low quality. During the dual learning of back-translation, the errors could easily accumulate and thus the learned target language distribution would gradually deviate from the real target distribution. This critical drawback hinders the further development of the unsupervised NMT systems.

An alternative solution is to extract real parallel sentences from comparable monolingual corpora, and then use them to train the NMT systems. Recently, neural-based methods (Chu et al., 2016; Grover and Mitra, 2017; Grégoire and Langlais, 2018) aim to select potential parallel sentences

Proceedings of NAACL-HLT 2019, pages 1173–1183
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

from monolingual corpora in the same domain. However, these neural models need to be trained on a large parallel dataset first, which is not applicable to language pairs with limited supervision.

In this paper, we propose a radically different approach for unsupervised NMT—**extract-edit**, a powerful alternative to back-translation (see Figure 1). Specifically, to train the source-to-target translation model, we first extract potential parallel sentence candidates in the target language space given a source language sentence. Since it cannot be guaranteed that there always exist potential parallel sentence pairs in monolingual corpora, we further propose a simple but effective editing mechanism to revise the extracted sentences, making them aligned with the source language sentence. Then a comparative translation loss is introduced to evaluate the translated sentence based on the extracted-and-edited ones and train the translation model. Compared to back-translation, extract-edit avoids the distribution deviation issue by extracting and editing real sentences from the target language space. Those extracted-and-edited sentences serve as pivotal points in the target language space to guide the unsupervised learning. Thus, the learned target language distribution could be closer to the real one. The extract-edit model and the translation model, the two major parts of our method, can be jointly trained in a fully unsupervised way.

Empirical results on popular benchmarks show that exact-edit consistently outperforms the state-of-the-art unsupervised NMT system (Lample et al., 2018b) with back-translation across four different languages pairs. In summary, our main contributions are three-fold[1]:

- We propose a more effective alternative paradigm to back-translation, extract-edit, to train the unsupervised NMT systems with potentially real sentence pairs;
- We introduce a comparative translation loss for unsupervised learning, which optimizes the translated sentence by maximizing its relative similarity with the source sentence among the extracted-and-edited pairs;
- Our method advances the previous state-of-the-art NMT systems across four different language pairs under monolingual corpora only scenario.

2 Background

Without parallel sentence pairs as constraints on mapping language spaces, training NMT systems is an ill-posed problem because there are many potential mapping solutions. Nevertheless, some promising methods have been proposed in this field (Lample et al., 2018a; Artetxe et al., 2018; Lample et al., 2018b). The main technical protocol of these approaches can be summarized as three steps: *Initialization*, *Language Modeling*, and *Back-Translation*. In this section, we mainly introduce the three steps and the crucial settings that we have followed in our work.

In the remainder of the paper, we denote the space of source and target languages by $\mathcal{S}$ and $\mathcal{T}$, respectively. enc and dec refer to the encoder and decoder models in the sequence-to-sequence systems. $V_{s\to t}$ stands for the composition of enc in the source language and dec in the target language, which can be viewed as the source-to-target translation system.

Initialization Given the ill-posed nature of the unsupervised NMT task, a suitable initialization method can help model the natural priors over the mapping of two language spaces we expect to reach. There are mainly two initialization methods: (1) bilingual dictionary inference (Conneau et al., 2018; Artetxe et al., 2018; Lample et al., 2018a) and (2) byte-pair encoding (BPE) (Sennrich et al., 2016b; Lample et al., 2018b). As shown in Lample et al. (2018b), the inferred bilingual dictionary can provide a rough word-by-word alignment of semantics, and the BPE can reduce the vocabulary size and eliminate the presence of unknown words in the output results.

In our *extract-edit* approach, to extract potential parallel sentence pairs, we need to compare the semantic similarity of sentences between two languages first. A proper initialization can also help align the semantic spaces and extract potential parallel pairs within them. Thus, following the previous methods, we use the inferred bilingual dictionary as described in Conneau et al. (2018) for unrelated language pairs and the shared BPE in Lample et al. (2018b) as initialization for related ones.

Language Modeling After a proper initialization, given large amounts of monolingual data, we

Figure 2: The overview of our unsupervised NMT model based on the *extract-edit* approach. Given a source sentence, (a) the top-k potential parallel sentences of the target language are extracted via nearest neighbor search. (b) The extracted sentences are further edited with the source sentence. (c) The evaluation network evaluates the translated sentence and the extracted-and-edited sentences based on their similarities with the source sentence. Note that (1) all the encoders share the same parameters (same for decoders); (2) the decoding processes are non-differentiable, so the language modeling loss and the comparative translation loss are used to train the learning modules before and after the decoding processes, respectively.

can train language models on both source and target languages. These models express a data-driven prior about the composition of sentences in each language. In NMT, language modeling is accomplished via denosing autoencoding, by minimizing:

$$\begin{aligned}\mathcal{L}_{lm}(\theta_{enc},\theta_{dec}) =& \mathbb{E}_{x\sim\mathcal{S}}[-\log V_{s\to s}(x|C(x))]+\\ & \mathbb{E}_{y\sim\mathcal{T}}[-\log V_{t\to t}(y|C(y))]\end{aligned} \tag{1}$$

where C is a noise model with some words dropped and swapped, θ_{enc} and θ_{dec} are the learnable parameters of enc and dec. $V_{s\to s}$ and $V_{t\to t}$ are the encoder-decoder language models on the source and target sides, respectively.

In our *extract-edit* approach, we follow similar settings and adopt the noise model proposed by Lampe et al. (2018a). Note that the parameters of all enc are shared (same for dec) in our framework to ensure a strong alignment and mapping between two languages. This sharing operation is essential for both the translation model and the extract-edit model. Thus, we use enc to represent encoders in source language modeling $enc_{\mathcal{S}}$ and in target language modeling $enc_{\mathcal{T}}$ (same for dec).

Back-Translation Back-translation (Sennrich et al., 2016b) has been dominantly used in prior work to train the unsupervised NMT system. It couples the source-to-target translation model with a backward target-to-source model and trains the whole system with a reconstruction loss. This can be viewed as converting the unsupervised problem into a supervised scenario by generating pseudo language pairs (He et al., 2016).

Despite the popularity of back-translation in the previous methods (Lample et al., 2018a; Artetxe et al., 2018; Lample et al., 2018b), we argue that it suffers from the low-quality pseudo language pairs. Thus, in this work, we propose a new paradigm, extract-edit, to address this issue by extracting and editing potential real parallel sentences. Below we describe our approach in details.

3 Extract-Edit

The overview of our *extract-edit* approach is shown in Figure 2. We first extract and edit real sentences from the target language space according to their similarities with the source sentence. These extracted-and-edited sentences serve as pivotal points in the target language space, which locate a probable region where the real target sentence could be. Then we introduce a comparative translation loss to evaluate the translated sentence and train the system. Basically, the comparative translation loss encourages the translated sentence to approximate the real sentence by maximizing its relative similarity with the source sentence compared to the extracted-and-edited sentences. As a result, we manage to minimize the deviation of the learned target language distribution and the mapping noises between two language spaces.

3.1 Extract

Most existing methods in comparable corpora mining introduce two encoders to represent sentences of two languages separately, and then use another network to measure the similarity (Chu et al., 2016; Grover and Mitra, 2017; Grégoire and Langlais, 2018). However, owing to the shared encoders and decoders in language modeling, the semantic spaces of two languages are already strongly connected in our scenario.

Therefore, to avoid extra computation resources, we directly use the enc in language modeling to obtain sentence embeddings for two languages. As shown in Figure 2 (a), for a given source sentence s, we use the nearest neighbor search based on L_2 distance to find top-k real sentences from the target language space (k is a hyper-parameter decided empirically). The sentence embeddings used for searching are computed based on the shared encoder enc. The reason to choose top-k sentences rather than top-1 is to keep a high recall rate and obtain more related samples from the target language space. Finally, given the source sentence s, we denote M as a set of the k potential parallel target sentences:

$$M = \{t| \min_{1,\cdots,k}(||e_s - e_t||), t \in \mathcal{T}\}, \quad (2)$$

where e_s and e_t are sentence embeddings encoded by the shared encoder enc.

3.2 Edit

Even though the extracted sentences could serve as pivotal points to guide NMT, there is no guarantee that there always exists a parallel sentence in the target corpus. Thus, in order to make it closer to the real paired sentence in the target language space, we propose an editing mechanism to revise the extracted target sentence $t \in M$ based on the semantics of the source sentence s. As described in Figure 2 (b), we employ a maxpooling layer to reserve the more significant features between the source sentence embedding e_s and the extracted sentence embedding e_t ($t \in M$), and then decode it into a new sentence t':

$$M' = \{t'|t' = dec(\text{maxpooling}(e_s, e_t)), t \in M\}, \quad (3)$$

where M' is the set of the extracted-and-edited sentences. Based on the semantic information of the source sentence s, we can further improve the extracted results with this editing mechanism. Unlike other studies using the editing to generate more structural sentences (Guu et al., 2018; Hashimoto et al., 2018), here the revised sentences are designed to serve as better pivotal points in the target language space to guide the translation procedure. This can also be viewed as adding constraints when aligning the two language spaces.

3.3 Evaluate

Given a source sentence s, we can translate it as t^* using the source-to-target translation model $P_{s\to t}$. Meanwhile, a set M' of k sentences can also be generated by the extract-edit approach described above. Although the M' may contain potential parallel sentences t' for s, we cannot directly use (s, t') as ground-truth sentence pairs to train the translation model $V_{s\to t}$ because the NMT system is sensitive to noises (Cho et al., 2014a; Cheng et al., 2018). The rough operation like this will result in sub-optimal translation performance.

Therefore, in order to assess the quality of the translated sentence t^* and train the translation model $V_{s\to t}$, we introduce an evaluation network R for evaluating the relative similarities between the source and target sentences among all sentence pairs. The evaluation network R is a multilayer perceptron; it takes the target sentence embedding e_t and source sentence embedding e_s as inputs, and converts them into the joint embedding space as r_t and r_s. So the similarity

$$\alpha(t|s) = cosine(r_t, r_s) = \frac{r_t \cdot r_s}{||r_t||||r_s||}. \quad (4)$$

Then, a softmax-like formulation is used to compute the ranking score for the translated sentence t^* given the extracted-and-edited sentence set M':

$$P(t^*|s, M') = \frac{exp(\lambda\alpha(t^*|s))}{\sum_{t' \in M' \cup \{t^*\}} exp(\lambda\alpha(t'|s))}, \quad (5)$$

where the hyper-parameter λ is similar to the inverse temperature of the softmax function. Lower λ encourages the model to treat all extracted-edited sentences equally, while higher λ highlights the importance of sentences with higher-score.

3.4 Learning

Comparative Translation As introduced above, the ranking score calculates the relative similarity between the $< s, t^* >$ pair and all the extracted-and-edited pairs $< s, t' >$. Assuming we have a good evaluation network R with θ_R denoting its parameters, we further introduce the comparative translation loss $\mathcal{L}_{com}$ for unsupervised machine translation:

$$\mathcal{L}_{com}(\theta_{enc}|\theta_R) = -\mathbb{E}(\log P(t^* = V_{s\to t}(s)|s, M')), \tag{6}$$

where θ_{enc} is the parameters of the shared encoder enc. Basically, the translation model is trying to minimize the relative distance of the translated sentence t^* to the source sentence s compared to the top-k extracted-and-edited sentences in the target language space. Intuitively, we view the top-k extracted-and-edited sentences as the anchor points to locate a probable region in the target language space, and iteratively improve the source-to-target mapping via the comparative learning scheme.

Combined with the language modeling constraints as described in Equation 1, the final loss function for training the the translation model $V_{s\to t}$ is defined as:

$$\begin{aligned}\mathcal{L}_{s\to t}(\theta_{enc}, \theta_{dec}|\theta_R) =& \omega_{lm}\mathcal{L}_{lm}(\theta_{enc}, \theta_{dec}) + \\ & \omega_{com}\mathcal{L}_{com}(\theta_{enc}|\theta_R),\end{aligned} \tag{7}$$

where ω_{lm} and ω_{com} are hyper-parameters weighing the importance of the language modeling and the comparative learning.

Adversarial Objective Meanwhile, we need to learn a good evaluation network R to transform sentence embedding of the shared encoder into the comparable space. The evaluation network R is also shared by two languages to ensure a strong connection between two language spaces. Inspired by adversarial learning (Goodfellow et al., 2014), we can view our translation system as a "generator" that learns to generate a good translation with a higher similarity score than the extracted-and-edited sentences, and the evaluation network R as a "discriminator" that learns to rank the extracted-and-edited sentences (real sentences in the target language space) higher than the translated sentences. Thus, we have the following objective function for the evaluation network R:

$$\mathcal{L}_R(\theta_R) = -\mathbb{E}_{t' \in M'}(\log P(t^{'}|s, M')). \tag{8}$$

Algorithm 1: The algorithm of our unsupervised NMT system with *extract-edit* approach.

```
Given two monolingual corpora, source $\mathcal{S}$ and target $\mathcal{T}$;
Initialization as in Section 2;
Language Modeling as in Section 2 to obtain the
    initialized translation model $V^{(0)}_{s\to t} = enc^{(0)} \circ dec^{(0)}$;
for $n \leftarrow 1$ to $N$ do
    Given a source sentence $s$;
    Extract the top-$k$ target sentences as the set $M$;
    Edit the sentences in $M$ to obtain the set $M'$;
    Update the evaluation network
      $R : \theta_R \leftarrow \text{argmin}\mathcal{L}_R$;
    Update the shared encoder and decoder $R$:
      $\theta_{enc}, \theta_{dec} \leftarrow \text{argmin}\mathcal{L}_{s\to t}$;
    Update the translation model:
      $V^{(n+1)}_{s\to t} = enc^{(n)} \circ dec^{(n)}$;
return $V^{(N+1)}_{s\to t} = enc^{(N)} \circ dec^{(N)}$.
```

Based on Equation 7 and 8, the final adversarial objective is defined as

$$\begin{aligned}&\min_{\theta_{enc},\theta_{dec}} \max_{\theta_R} \mathcal{L}(\theta_{enc}, \theta_{dec}, \theta_R) \\ &= -\mathcal{L}_R(\theta_R) + \mathcal{L}_{s\to t}(\theta_{enc}, \theta_{dec}|\theta_R),\end{aligned} \tag{9}$$

where the translation model $V_{s\to t}$ and the evaluation network R play the two-player mini-max game. We evenly alternately update between the encoder-decoder translation model and the evaluation network. The detailed training procedure is described in Algorithm 1.

3.5 Model Selection

In the fully unsupervised setting, we do not have access to parallel sentence pairs. Thus, we need to find a criterion correlated with the translation quality to select hyper-parameters. For a neural translation model $V_{s\to t}$, we propose the following criterion $D_{s\to t}$ to tune the hyper-parameters:

$$D_{s\to t} = \mathbb{E}_{s\in\mathcal{S}}[\mathbb{E}(\log P(t^*|s, M'))], \tag{10}$$

where $t^* = V_{s\to t}(s)$. Basically, we choose the hyper-parameters with the maximum expectation of the ranking scores of all translated sentences.

4 Experiments

4.1 Datasets

We consider four language pairs: English-French (*en-fr*), English-German (*en-de*), English-Russian (*en-ru*) and English-Romanian (*en-ro*) for evaluation. For a fair comparison, we use the same corpora as in Lample et al. (2018b) for these languages for fair comparison. For English, French,

Table 1: The experimental results on all four language pairs and directions. The results are evaluated with BLEU metric on *newstest* 2014 for *en↔fr*and *newstest* 2016 for *en↔de*, *en↔ro* and *en↔ru*. The (+) and (−) stand for performance gains and loss separately compared with baseline models with the same NMT cells.

German and Russian, all the available sentences are used from the WMT monolingual News Crawl datasets from years 2007 through 2017. As for Romanian, we combine the News Crawl dataset and WMT'16 monolingual dataset. The translation results are evaluated on newstest 2014 for *en-fr*, and newstest 2016 for *en-de*, *en-ro* and *en-ru*.

4.2 Implementation Details

We follow previous methods (Koehn et al., 2007; Lample et al., 2018b) to initialize our models.

Initialization We use Moses scripts (Koehn et al., 2007) for tokenization. While the system requires cross-lingual BPE embeddings to initialize the shared lookup table for related languages, we set the number of BPE codes as $60,000$. Following the previous preprocessing protocol (Lample et al., 2018b), the embeddings are then generated using fastText (Bojanowski et al., 2017) with an embedding dimension of 512, a context window of size 5 and 10 negative samples.

Model Structure In this work, the NMT models can be built upon long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017) cells. For LSTM cells, both the encoder and decoder have 3 layers. As for Transformer, we use 4 layers both in the encoder and the decoder. As for both LSTM and Transformer, all encoder parameters are shared across two languages. Similarly, we share all decoder parameters across two languages. Both two model structure are optimized using Adam (Kingma and Ba, 2014) with a batch size of 32. The rate for LSTM cell is 0.0003 while Transformer's is set as 0.0001. The weights in Equation 7 are $\omega_{lm} = \omega_{ext} = 1$. The λ for calculating ranking scores is 0.5. As for the evaluation network R, we use a multilayer perceptron with two hidden layers of size 512. For efficient nearest neighbor search in the extracting step, we use the open-source Faiss library (Johnson et al., 2017)[2]. We calculate the similarity of sentences in

---

[2] `https://github.com/facebookresearch/faiss`

each episode instead of each batch for computational efficiency. At decoding time, sentences are generated using greedy decoding.

4.3 Results and Analysis

In this study, we aim to validate the effectiveness of extract-edit versus back-translation for unsupervised neural machine translation (NMT), so we set the unsupervised NMT method in Lample et al. (2018b) as the baseline because it currently achieves the state-of-the-art performance on all language pairs.[3] The overall translation results across four language pairs are shown in Table 1. In most of the cases, our proposed extract-edit approach can outperform the baseline models trained with back-translation. Our full models (LSTM/Transformer + Top-10 Extract + Edit) achieve more than 2 BLEU points improvement consistently across all the language pairs. Especially, on the *ru* → *en* translation with the Transformer cell, our full model surpasses the baseline score by 3.63 BLEU points. These results validate the effectiveness of our approach and indicate that the proposed extract-edit learning framework can learn a better mapping and alignment between language spaces than back-translation.

However, if extracting only top-1 target sentence in our approach, the performances are not always improved (e.g., *en* → *de*, *de* → *en*, and *en* → *ro*). Besides, *Top-10 Extract + Edit* models consistently outperforms *Top-1 Extract + Edit*. This is because more extracted-and-edited sentences lead to a higher recall, so more useful information will be used to guarantee the translation quality. The comparative translation loss can avoid the model suffering from the noise while taking advantage of more information. In other words, it is more likely to project the source sentence into the probable region in the target language space with more sentences serving as the anchor points, and the comparative learning scheme iteratively approximates towards more accurate target points. This highlights the importance of the extraction number k, which we further discuss next.

4.4 Ablation Study

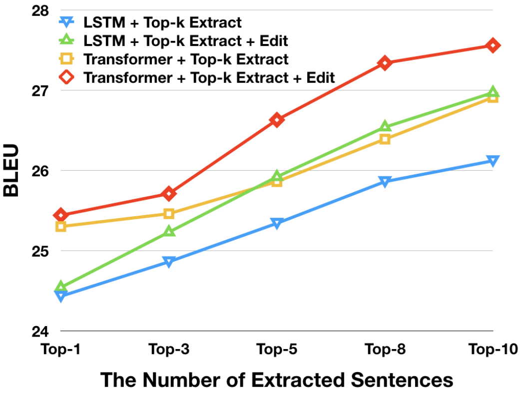

Figure 3: The effect of the number k of the extracted sentences in our approach on *en*→*fr* translation.

The Effect of Extraction Number k As shown in Table 1, the number k of the extracted-and-edited sentences plays a vital role in our approach. Thus for a more intuitive overview of its impact, we further train and evaluate multiple models with $k = 1, 3, 5, 8, 10$ on *en* → *fr* translation task. The detailed results are shown in Figure 3. This study shows that the translation performance of our approach is indeed improving as k increases. Because as we analyze above, larger k ensure a higher recall and thus more critical semantic information can be utilized to assist the translation. Besides, the diversity of extracted-and-edited sentences can potentially provide a more accurate localization of the probable region where the target sentence should be. Although we can infer that the models would perform even better with $k > 10$ from Figure 3, more computational resources will be required for that and we already observe a decelerated growth of BLEU scores from $k = 8$ to $k = 10$. Therefore, in this paper, we set $k = 10$ for the full models.

The Quality of Extraction Model In this section, we quantitatively evaluate the unsupervised extraction part of our model and compare it with the state-of-the-art supervised extraction model. Following Grégoire and Langlais (2018), we train a fully supervised parallel pair extraction model, where two Bi-LSTMs are implemented to encode sentences of two languages, and a feed-forward network is followed to culminate in a sigmoid output layer. The model is trained with around 500,000 English-French parallel sentence pairs sampled from Europarl corpus (Koehn, 2005). As for our unsupervised extraction model, we directly use the jointly trained extraction part in our frame-

---

[3] Note that for a fair comparison, we are not including the results of the unsupervised phrase-based statistical machine translation system (PBSMT). But theoretically, our extract-edit learning framework can be generalized to other types of machine translation systems such as PBSMT.

Noise	Model	Hits@1	Hits@3	Hits@5	Hits@8	Hits@10	Hits@15	Hits@20
0%	Supervised (Upperbound)	67.3	80.7	89.9	94.5	97.1	98.7	99.3
	Unsupervised (Ours)	52.2	54.6	68.8	80.2	89.1	91.8	93.3
50%	Supervised (Upperbound)	64.8	78.0	86.8	91.3	95.6	97.4	99.0
	Unsupervised (Ours)	46.9	49.7	62.1	73.4	83.2	87.6	89.2
90%	Supervised (Upperbound)	63.7	76.4	84.2	89.1	93.8	96.5	98.1

Table 2: The experimental results of parallel sentence mining on the *newstest* 2012 *en* → *fr* translation dataset with different levels of added sentence noises. Metric: The percentage of Hits@k.

Cell	Learning	BLEU
LSTM	MLE Loss	12.40
	Comparative Loss	24.54
Transformer	MLE Loss	14.15
	Comparative Loss	25.44

Table 3: The performance of the unsupervised NMT systems with different learning objectives on *en* → *fr newstest* 2014.

work to extract the potential parallel sentences based on the scores computed by Equation 4. For evaluation, we sample $1,000$ parallel sentences from the *newstest* 2014 corpus and create three test sets with a noise ratio 0%, 50%, and 90% to simulate noisy real-world data. We report Hits@k results, which shows the percentage of the golden parallel sentences appear within the top-k place.

The detailed results are shown in Table 2. Although our extraction model structure is different from the supervised extraction model, it can still give us a good insight into the upperbound and gap of performance. We can observe a noticeable gap between unsupervised and supervised methods, but the gap is narrowing as the rank increases. Meanwhile, in our unsupervised method, the performance grows quickly when $k \leq 10$. From Table 2 we also notice that $k = 10$ is a sweet point, where the accuracy is high and the computational cost is relatively acceptable.

The Effect of Comparative Translation Finally, we aim to roughly evaluate the effect of the proposed comparable translation loss in our model. Thus, we compare our model with a two-staged NMT system, where we extract and edit the parallel pairs and retrain the NMT system with the standard maximum likelihood estimation (MLE) loss in a supervised way (by taking the extracted-and-edited sentences as the ground-truth targets). We compare the performance on the *en* → *fr newstest* 2014 dataset, and the results are shown in Table 3. We can observe that with the MLE loss, the translation performance will drop nearly 50%. The results indirectly reflect that the NMT systems are sensitive to noises in the training datasets. Meanwhile, it demonstrates by treating extracted-edit sentences as pivotal points instead of ground truth, our proposed comparative translation loss can avoid the NMT model suffers from the noise.

4.5 Discussion

Although our extract-edit approach can achieve better performance than the back-translation mechanism, it is still worth mentioning that our approach has more strict constraints on the domains of the source and target corpus. The extract-edit approach will work well when there is information overlap in the two language spaces. When there is little overlap in terms of domains, it will be much harder to find a good cluster of initial candidates, which may also complicate the editing process. As for the back-translation mechanism, it requires less overlap in terms of the language spaces because the language priors can be learnt in any domains. However, the corpus with matching domains can be easily obtained nowadays (e.g., Wikipedia and the news articles), which makes our extract-edit approach still widely applicable.

5 Related Work

Unsupervised NMT The current NMT systems (Sutskever et al., 2014; Cho et al., 2014a; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) are known to easily overfit and result in an inferior performance when the training data is limited (Koehn and Knowles, 2017; Isabelle et al., 2017; Sennrich, 2017). Many research efforts have been spent on how to utilize the monolingual data to improve the NMT system when only limited supervision is available (Gulcehre et al., 2015; Sennrich et al., 2016a; He et al., 2016; Zhang and Zong, 2016; Yang et al., 2018). Recently, Lample et al. (2018a); Artetxe et al. (2018); Lample et al. (2018b) make encouraging progress on unsupervised NMT structure mainly based on initialization, denoising language modeling, and back-translation. However, all these unsupervised models are based on the back-translation learning framework to generate pseudo language pairs for training. Our work leverages the information from real target language sentences.

Comparable Corpora Mining Comparable corpora mining aims at extracting parallel sentences from comparable monolingual corpora such as news stories written on the same topic in different languages. Most of the previous methods align the documents based on metadata and then extract parallel sentences using human-defined features (Munteanu and Marcu, 2002, 2006; Hewavitharana and Vogel, 2011). Recent neural-based methods (Chu et al., 2016; Grover and Mitra, 2017; Grégoire and Langlais, 2018) learn to identify parallel sentences in the semantic spaces. However, these methods require large amounts of parallel sentence pairs to train the systems first and then test the performance on raw comparable corpora, which does not apply to languages with limited resources. Instead, we explore the corpora mining in an unsupervised fashion and propose a joint training framework with machine translation.

Retrieval-Augmented Text Generation Our work is also related to the recent work on applying retrieval mechanisms to augment text generation, such as image captioning (Kuznetsova et al., 2013; Mason and Charniak, 2014), dialogue generation (Song et al., 2016; Yan et al., 2016; Wu et al., 2018) and style transfer (Lin et al., 2017; Li et al., 2018). Some editing-based models (Guu et al., 2018; Hashimoto et al., 2018) are proposed to further enhance the retrieved text. Recent work in machine translation (Gu et al., 2018) augments an NMT model with sentence pairs retrieved by an off-the-shelf search engine. However, these methods are two-staged with supervised retrieval first. In our work, the extracted-edited sentences are not directly used as the ground truth to train the translation model. Instead, we view these sentences as pivotal points in the target language space and further we propose a comparative translation loss to train the system in a fully unsupervised way.

6 Conclusion

In this paper, we propose an *extract-edit* approach, an effective alternative to the widely-used back-translation in unsupervised NMT. Instead of generating pseudo language pairs to train the systems with the reconstruction loss, we design a comparative translation loss that leverages real sentences in the target language space. Empirically, our method advances the previous state-of-the-art NMT systems across four language pairs using the monolingual corpora only. Theoretically, we believe the extract-edit learning framework can be generalized to other types of unsupervised machine translation systems and even some other unsupervised learning tasks.

Abstract

Generalization and reliability of multilingual translation often highly depend on the amount of available parallel data for each language pair of interest. In this paper, we focus on zero-shot generalization—a challenging setup that tests models on translation directions they have not been optimized for at training time. To solve the problem, we (i) reformulate multilingual translation as probabilistic inference, (ii) define the notion of zero-shot consistency and show why standard training often results in models unsuitable for zero-shot tasks, and (iii) introduce a consistent agreement-based training method that encourages the model to produce equivalent translations of parallel sentences in auxiliary languages. We test our multilingual NMT models on multiple public zero-shot translation benchmarks (IWSLT17, UN corpus, Europarl) and show that agreement-based learning often results in 2-3 BLEU zero-shot improvement over strong baselines without any loss in performance on supervised translation directions.

1 Introduction

Machine translation (MT) has made remarkable advances with the advent of deep learning approaches (Bojar et al., 2016; Wu et al., 2016; Crego et al., 2016; Junczys-Dowmunt et al., 2016). The progress was largely driven by the encoder-decoder framework (Sutskever et al., 2014; Cho et al., 2014) and typically supplemented with an attention mechanism (Bahdanau et al., 2014; Luong et al., 2015b).

Compared to the traditional phrase-based systems (Koehn, 2009), neural machine translation (NMT) requires large amounts of data in order to reach high performance (Koehn and Knowles, 2017). Using NMT in a multilingual setting exacerbates the problem by the fact that given k languages translating between all pairs would require $O(k^2)$ parallel training corpora (and $O(k^2)$ models).

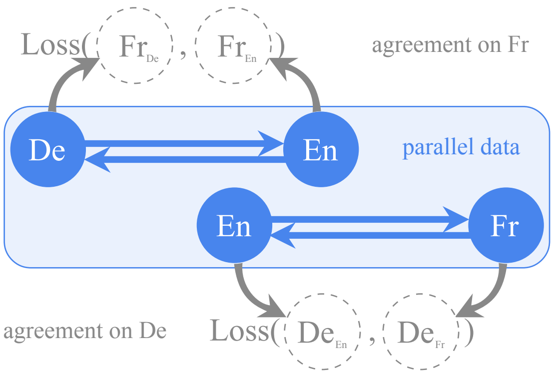

Figure 1: Agreement-based training of a multilingual NMT. At training time, given English-French (`En` ↔ `Fr`) and English-German (`En` ↔ `De`) parallel sentences, the model not only is trained to translate between the pair but also to agree on translations into a third language.

In an effort to address the problem, different multilingual NMT approaches have been proposed recently. Luong et al. (2015a); Firat et al. (2016a) proposed to use $O(k)$ encoders/decoders that are then intermixed to translate between language pairs. Johnson et al. (2016) proposed to use a single model and prepend special symbols to the source text to indicate the target language, which has later been extended to other text preprocessing approaches (Ha et al., 2017) as well as language-conditional parameter generation for encoders and decoders of a single model (Platanios et al., 2018).

Johnson et al. (2016) also show that a single multilingual system could potentially enable *zero-shot* translation, *i.e.*, it can translate between language pairs not seen in training. For example, given 3 languages—German (`De`), English (`En`), and French (`Fr`)—and training parallel data only for (`De`, `En`) and (`En`, `Fr`), at test time, the system could additionally translate between (`De`, `Fr`).

Zero-shot translation is an important problem. Solving the problem could significantly improve data efficiency—a single multilingual model would

Proceedings of NAACL-HLT 2019, pages 1184–1197
Minneapolis, Minnesota, June 2 - June 7, 2019.

be able to generalize and translate between any of the $O(k^2)$ language pairs after being trained only on $O(k)$ parallel corpora. However, performance on zero-shot tasks is often unstable and significantly lags behind the supervised directions. Moreover, attempts to improve zero-shot performance by fine-tuning (Firat et al., 2016b; Sestorain et al., 2018) may negatively impact other directions.

In this work, we take a different approach and aim to improve the training procedure of Johnson et al. (2016). First, we analyze multilingual translation problem from a probabilistic perspective and define the notion of *zero-shot consistency* that gives insights as to why the vanilla training method may not yield models with good zero-shot performance. Next, we propose a novel training objective and a modified learning algorithm that achieves consistency via agreement-based learning (Liang et al., 2006, 2008) and improves zero-shot translation. Our training procedure encourages the model to produce equivalent translations of parallel training sentences into an auxiliary language (Figure 1) and is provably zero-shot consistent. In addition, we make a simple change to the neural decoder to make the agreement losses fully differentiable.

We conduct experiments on IWSLT17 (Mauro et al., 2017), UN corpus (Ziemski et al., 2016), and Europarl (Koehn, 2017), carefully removing complete pivots from the training corpora. Agreement-based learning results in up to +3 BLEU zero-shot improvement over the baseline, compares favorably (up to +2.4 BLEU) to other approaches in the literature (Cheng et al., 2017; Sestorain et al., 2018), is competitive with pivoting, and does not lose in performance on supervised directions.

2 Related work

A simple (and yet effective) baseline for zero-shot translation is pivoting that chain-translates, first to a pivot language, then to a target (Cohn and Lapata, 2007; Wu and Wang, 2007; Utiyama and Isahara, 2007). Despite being a pipeline, pivoting gets better as the supervised models improve, which makes it a strong baseline in the zero-shot setting. Cheng et al. (2017) proposed a joint pivoting learning strategy that leads to further improvements.

Lu et al. (2018) and Arivazhagan et al. (2018) proposed different techniques to obtain "neural interlingual" representations that are passed to the decoder. Sestorain et al. (2018) proposed another fine-tuning technique that uses dual learning (He et al., 2016), where a language model is used to provide a signal for fine-tuning zero-shot directions.

Another family of approaches is based on distillation (Hinton et al., 2014; Kim and Rush, 2016). Along these lines, Firat et al. (2016b) proposed to fine tune a multilingual model to a specified zero-shot-direction with pseudo-parallel data and Chen et al. (2017) proposed a teacher-student framework. While this can yield solid performance improvements, it also adds multi-staging overhead and often does not preserve performance of a single model on the supervised directions. We note that our approach (and agreement-based learning in general) is somewhat similar to distillation at training time, which has been explored for large-scale single-task prediction problems (Anil et al., 2018).

A setting harder than zero-shot is that of fully unsupervised translation (Ravi and Knight, 2011; Artetxe et al., 2017; Lample et al., 2017, 2018) in which no parallel data is available for training. The ideas proposed in these works (*e.g.*, bilingual dictionaries (Conneau et al., 2017), backtranslation (Sennrich et al., 2015a) and language models (He et al., 2016)) are complementary to our approach, which encourages agreement among different translation directions in the zero-shot multilingual setting.

3 Background

We start by establishing more formal notation and briefly reviewing some background on encoder-decoder multilingual machine translation from a probabilistic perspective.

3.1 Notation

Languages. We assume that we are given a collection of k languages, $L_1, \dots, L_k$, that share a common vocabulary, V. A language, L_i, is defined by the marginal probability $\mathbb{P}(\mathbf{x}_i)$ it assigns to sentences (*i.e.*, sequences of tokens from the vocabulary), denoted $\mathbf{x}_i := (x^1, \dots, x^l)$, where l is the length of the sequence. All languages together define a joint probability distribution, $\mathbb{P}(\mathbf{x}_1, \dots, \mathbf{x}_k)$, over k-tuples of *equivalent sentences*.

Corpora. While each sentence may have an equivalent representation in all languages, we assume that we have access to only partial sets of equivalent sentences, which form *corpora*. In this work, we consider *bilingual* corpora, denoted $\mathcal{C}_{ij}$, that contain pairs of sentences sampled from $\mathbb{P}(\mathbf{x}_i, \mathbf{x}_j)$ and *monolingual* corpora, denoted $\mathcal{C}_i$, that contain sentences sampled from $\mathbb{P}(\mathbf{x}_i)$.

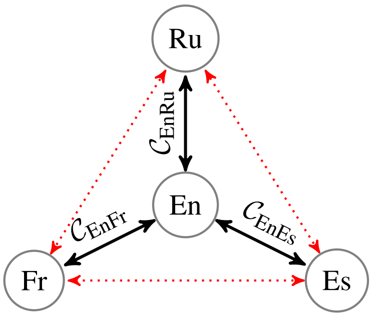

Figure 2: Translation graph: Languages (nodes), parallel corpora (solid edges), and zero-shot directions (dotted edges).

Translation. Finally, we define a *translation task* from language L_i to L_j as learning to model the conditional distribution $\mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i\right)$. The set of k languages along with translation tasks can be represented as a directed graph $\mathcal{G}(\mathcal{V}, \mathcal{E})$ with a set of k nodes, $\mathcal{V}$, that represent languages and edges, $\mathcal{E}$, that indicate translation directions. We further distinguish between two disjoint subsets of edges: (i) supervised edges, $\mathcal{E}_s$, for which we have parallel data, and (ii) zero-shot edges, $\mathcal{E}_0$, that correspond to zero-shot translation tasks. Figure 2 presents an example translation graph with supervised edges (`En` $\leftrightarrow$ `Es`, `En` $\leftrightarrow$ `Fr`, `En` $\leftrightarrow$ `Ru`) and zero-shot edges (`Es` $\leftrightarrow$ `Fr`, `Es` $\leftrightarrow$ `Ru`, `Fr` $\leftrightarrow$ `Ru`). We will use this graph as our running example.

3.2 Encoder-decoder framework

First, consider a purely bilingual setting, where we learn to translate from a source language, L_s, to a target language, L_t. We can train a translation model by optimizing the conditional log-likelihood of the bilingual data under the model:

$$\hat{\theta} := \arg\max_\theta \sum\nolimits_{\mathcal{C}_{st}} \log \mathbb{P}_\theta\left(\mathbf{x}_t \mid \mathbf{x}_s\right) \qquad (1)$$

where $\hat{\theta}$ are the estimated parameters of the model.

The encoder-decoder framework introduces a latent sequence, $\mathbf{u}$, and represents the model as:

$$\mathbb{P}_\theta\left(\mathbf{x}_t \mid \mathbf{x}_s\right) = \mathbb{P}_\theta^{\text{dec}}\left(\mathbf{x}_t \mid \mathbf{u} = f_\theta^{\text{enc}}(\mathbf{x}_s)\right) \qquad (2)$$

where $f_\theta^{\text{enc}}(\mathbf{x}_s)$ is the encoder that maps a source sequence to a sequence of latent representations, $\mathbf{u}$, and the decoder defines $\mathbb{P}_\theta^{\text{dec}}\left(\mathbf{x}_t \mid \mathbf{u}\right)$.[1] Note that $\mathbf{u}$ is usually deterministic with respect to $\mathbf{x}_s$ and accurate representation of the conditional distribution highly depends on the decoder. In neural machine translation, the exact forms of encoder and decoder are specified using RNNs (Sutskever et al., 2014), CNNs (Gehring et al., 2016), and attention (Bahdanau et al., 2014; Vaswani et al., 2017) as building blocks. The decoding distribution, $\mathbb{P}_\theta^{\text{dec}}\left(\mathbf{x}_t \mid \mathbf{u}\right)$, is typically modeled autoregressively.

3.3 Multilingual neural machine translation

In the multilingual setting, we would like to learn to translate in *all directions* having access to only few parallel bilingual corpora. In other words, we would like to learn a collection of models, $\{\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)\}_{i,j\in\mathcal{E}}$. We can assume that models are independent and choose to learn them by maximizing the following objective:

$$\mathcal{L}^{\text{ind}}(\theta) = \sum_{i,j\in\mathcal{E}_s} \sum_{(\mathbf{x}_i,\mathbf{x}_j)\in\mathcal{C}_{ij}} \log \mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right) \qquad (3)$$

In the statistics literature, this estimation approach is called *maximum composite likelihood* (Besag, 1975; Lindsay, 1988) as it composes the objective out of (sometimes weighted) terms that represent conditional sub-likelihoods (in our example, $\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)$). Composite likelihoods are easy to construct and tractable to optimize as they do not require representing the full likelihood, which would involve integrating out variables unobserved in the data (see Appendix A.1).

Johnson et al. (2016) proposed to train a multilingual NMT systems by optimizing a composite likelihood objective (3) while representing all conditional distributions, $\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)$, with a *shared* encoder and decoder and using language tags, l_t, to distinguish between translation directions:

$$\mathbb{P}\left(\mathbf{x}_t \mid \mathbf{x}_s\right) = \mathbb{P}_\theta^{\text{dec}}\left(\mathbf{x}_t \mid \mathbf{u}_{st} = f_\theta^{\text{enc}}(\mathbf{x}_s, l_t)\right) \qquad (4)$$

This approach has numerous advantages including: (a) simplicity of training and the architecture (by slightly changing the training data, we convert a bilingual NMT into a multilingual one), (b) sharing parameters of the model between different translation tasks that may lead to better and more robust representations. Johnson et al. (2016) also show that resulting models seem to exhibit some degree of zero-shot generalization enabled by parameter sharing. However, since we lack data for zero-shot directions, composite likelihood (3) misses the terms that correspond to the zero-shot models, and hence has no statistical guarantees for performance on zero-shot tasks.[2]

---

[1] Slightly abusing the notation, we use θ to denote all parameters of the model: embeddings, encoder, and decoder.

[2] In fact, since the objective (3) assumes that the models are independent, plausible zero-shot performance would be more indicative of the limited capacity of the model or artifacts in the data (*e.g.*, presence of multi-parallel sentences) rather than zero-shot generalization.

4 Zero-shot generalization & consistency

Multilingual MT systems can be evaluated in terms of *zero-shot performance*, or quality of translation along the directions they have not been optimized for (*e.g.*, due to lack of data). We formally define zero-shot generalization via consistency.

Definition 1 (Expected Zero-shot Consistency) *Let $\mathcal{E}_s$ and $\mathcal{E}_0$ be supervised and zero-shot tasks, respectively. Let $\ell(\cdot)$ be a non-negative loss function and $\mathcal{M}$ be a model with maximum expected supervised loss bounded by some $\varepsilon > 0$:*

$$\max_{(i,j)\in\mathcal{E}_s} \mathbb{E}_{\mathbf{x}_i,\mathbf{x}_j}\left[\ell(\mathcal{M})\right] < \varepsilon$$

We call $\mathcal{M}$ zero-shot consistent with respect to $\ell(\cdot)$ if for some $\kappa(\varepsilon) > 0$

$$\max_{(i,j)\in\mathcal{E}_0} \mathbb{E}_{\mathbf{x}_i,\mathbf{x}_j}\left[\ell(\mathcal{M})\right] < \kappa(\varepsilon),$$

where $\kappa(\varepsilon) \to 0$ as $\varepsilon \to 0$.

In other words, we say that a machine translation system is zero-shot consistent if low error on supervised tasks implies a low error on zero-shot tasks in expectation (*i.e.*, the system generalizes). We also note that our notion of consistency somewhat resembles error bounds in the domain adaptation literature (Ben-David et al., 2010).

In practice, it is attractive to have MT systems that are guaranteed to exhibit zero-shot generalization since the access to parallel data is always limited and training is computationally expensive. While the training method of Johnson et al. (2016) does not have guarantees, we show that our proposed approach is provably zero-shot consistent.

5 Approach

We propose a new training objective for multilingual NMT architectures with shared encoders and decoders that avoids the limitations of pure composite likelihoods. Our method is based on the idea of agreement-based learning initially proposed for learning consistent alignments in phrase-based statistical machine translation (SMT) systems (Liang et al., 2006, 2008). In terms of the final objective function, the method ends up being reminiscent of distillation (Kim and Rush, 2016), but suitable for joint multilingual training.

5.1 Agreement-based likelihood

To introduce agreement-based objective, we use the graph from Figure 2 that defines translation tasks between 4 languages ($\texttt{En}$, $\texttt{Es}$, $\texttt{Fr}$, $\texttt{Ru}$). In particular, consider the composite likelihood objective (3) for a pair of $\texttt{En} - \texttt{Fr}$ sentences, $(\mathbf{x}_{\texttt{En}}, \mathbf{x}_{\texttt{Fr}})$:

$$\begin{aligned}
&\mathcal{L}^{\text{ind}}_{\texttt{EnFr}}(\theta) \qquad (5)\\
&\quad = \log\left[\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}} \mid \mathbf{x}_{\texttt{En}}\right)\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{En}} \mid \mathbf{x}_{\texttt{Fr}}\right)\right]\\
&\quad = \log\Bigg[\sum_{\mathbf{z}'_{\texttt{Es}},\mathbf{z}'_{\texttt{Ru}}} \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}}, \mathbf{z}'_{\texttt{Es}}, \mathbf{z}'_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{En}}\right) \times\\
&\qquad\qquad \sum_{\mathbf{z}''_{\texttt{Es}},\mathbf{z}''_{\texttt{Ru}}} \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{En}}, \mathbf{z}''_{\texttt{Es}}, \mathbf{z}''_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{Fr}}\right)\Bigg]
\end{aligned}$$

where we introduced latent translations into Spanish ($\texttt{Es}$) and Russian ($\texttt{Ru}$) and marginalized them out (by virtually summing over all sequences in the corresponding languages). Again, note that this objective assumes independence of $\texttt{En} \to \texttt{Fr}$ and $\texttt{Fr} \to \texttt{En}$ models.

Following Liang et al. (2008), we propose to tie together the single prime and the double prime latent variables, $\mathbf{z}_{\texttt{Es}}$ and $\mathbf{z}_{\texttt{Ru}}$, to encourage agreement between $\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{En}}, \mathbf{z}_{\texttt{Es}}, \mathbf{z}_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{Fr}}\right)$ and $\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}}, \mathbf{z}_{\texttt{Es}}, \mathbf{z}_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{En}}\right)$ on the latent translations. We interchange the sum and the product operations inside the $\log$ in (5), denote $\mathbf{z} := (\mathbf{z}_{\texttt{Es}}, \mathbf{z}_{\texttt{Ru}})$ to simplify notation, and arrive at the following new objective function:

$$\begin{aligned}
&\mathcal{L}^{\text{agree}}_{\texttt{EnFr}}(\theta) := \qquad (6)\\
&\quad \log \sum_{\mathbf{z}} \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}}, \mathbf{z} \mid \mathbf{x}_{\texttt{En}}\right)\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{En}}, \mathbf{z} \mid \mathbf{x}_{\texttt{Fr}}\right)
\end{aligned}$$

Next, we factorize each term as:

$$\mathbb{P}\left(\mathbf{x}, \mathbf{z} \mid \mathbf{y}\right) = \mathbb{P}\left(\mathbf{x} \mid \mathbf{z}, \mathbf{y}\right)\mathbb{P}_\theta\left(\mathbf{z} \mid \mathbf{y}\right)$$

Assuming $\mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}} \mid \mathbf{z}, \mathbf{x}_{\texttt{En}}\right) \approx \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}} \mid \mathbf{x}_{\texttt{En}}\right)$,[3] the objective (6) decomposes into two terms:

$$\begin{aligned}
&\mathcal{L}^{\text{agree}}_{\texttt{EnFr}}(\theta) \qquad (7)\\
&\quad \approx \underbrace{\log \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{Fr}} \mid \mathbf{x}_{\texttt{En}}\right) + \log \mathbb{P}_\theta\left(\mathbf{x}_{\texttt{En}} \mid \mathbf{x}_{\texttt{Fr}}\right)}_{\text{composite likelihood terms}} +\\
&\qquad \underbrace{\log \sum_{\mathbf{z}} \mathbb{P}_\theta\left(\mathbf{z} \mid \mathbf{x}_{\texttt{En}}\right)\mathbb{P}_\theta\left(\mathbf{z} \mid \mathbf{x}_{\texttt{Fr}}\right)}_{\text{agreement term}}
\end{aligned}$$

---

[3] This means that it is sufficient to condition on a sentence in one of the languages to determine probability of a translation in any other language.

We call the expression given in (7) *agreement-based likelihood*. Intuitively, this objective is the likelihood of observing parallel sentences $(\mathbf{x}_{\texttt{En}}, \mathbf{x}_{\texttt{Fr}})$ *and* having sub-models $\mathbb{P}_\theta(\mathbf{z} \mid \mathbf{x}_{\texttt{En}})$ and $\mathbb{P}_\theta(\mathbf{z} \mid \mathbf{x}_{\texttt{Fr}})$ agree on all translations into `Es` and `Ru` at the same time.

Lower bound. Summation in the agreement term over $\mathbf{z}$ (*i.e.*, over possible translations into `Es` and `Ru` in our case) is intractable. Switching back from $\mathbf{z}$ to $(\mathbf{z}_{\texttt{Es}}, \mathbf{z}_{\texttt{Ru}})$ notation and using Jensen's inequality, we lower bound it with cross-entropy:[4]

$$\begin{aligned} \log \sum_{\mathbf{z}} \mathbb{P}_\theta(\mathbf{z} \mid \mathbf{x}_{\texttt{En}}) \, \mathbb{P}_\theta(\mathbf{z} \mid \mathbf{x}_{\texttt{Fr}}) & \\ \geq \mathbb{E}_{\mathbf{z}_{\texttt{Es}} \mid \mathbf{x}_{\texttt{En}}} \left[\log \mathbb{P}_\theta(\mathbf{z}_{\texttt{Es}} \mid \mathbf{x}_{\texttt{Fr}}) \right] + & \\ \mathbb{E}_{\mathbf{z}_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{En}}} \left[\log \mathbb{P}_\theta(\mathbf{z}_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{Fr}}) \right] & \end{aligned} \tag{8}$$

We can estimate the expectations in the lower bound on the agreement terms by sampling $\mathbf{z}_{\texttt{Es}} \sim \mathbb{P}_\theta(\mathbf{z}_{\texttt{Es}} \mid \mathbf{x}_{\texttt{En}})$ and $\mathbf{z}_{\texttt{Ru}} \sim \mathbb{P}_\theta(\mathbf{z}_{\texttt{Ru}} \mid \mathbf{x}_{\texttt{En}})$. In practice, instead of sampling we use greedy, continuous decoding (with a fixed maximum sequence length) that also makes $\mathbf{z}_{\texttt{Es}}$ and $\mathbf{z}_{\texttt{Ru}}$ differentiable with respect to parameters of the model.

5.2 Consistency by agreement

We argue that models produced by maximizing agreement-based likelihood (7) are zero-shot consistent. Informally, consider again our running example from Figure 2. Given a pair of parallel sentences in $(\texttt{En}, \texttt{Fr})$, agreement loss encourages translations from `En` to $\{\texttt{Es}, \texttt{Ru}\}$ and translations from `Fr` to $\{\texttt{Es}, \texttt{Ru}\}$ to coincide. Note that $\texttt{En} \to \{\texttt{Es}, \texttt{Fr}, \texttt{Ru}\}$ are supervised directions. Therefore, agreement ensures that translations along the zero-shot edges in the graph match supervised translations. Formally, we state it as:

Theorem 2 (Agreement Zero-shot Consistency) *Let L_1, L_2, and L_3 be a collection of languages with $L_1 \leftrightarrow L_2$ and $L_2 \leftrightarrow L_3$ be supervised while $L_1 \leftrightarrow L_3$ be a zero-shot direction. Let $\mathbb{P}_\theta(\mathbf{x}_j \mid \mathbf{x}_i)$ be sub-models represented by a multilingual MT system. If the expected agreement-based loss, $\mathbb{E}_{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3}[\mathcal{L}_{12}^{\text{agree}}(\theta) + \mathcal{L}_{23}^{\text{agree}}(\theta)]$, is bounded by some $\varepsilon > 0$, then, under some mild technical assumptions on the true distribution of the equivalent translations, the zero-shot cross-entropy loss is bounded as follows:*

$$\mathbb{E}_{\mathbf{x}_1, \mathbf{x}_3} \left[-\log \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_1) \right] \leq \kappa(\varepsilon)$$

where $\kappa(\varepsilon) \to 0$ as $\varepsilon \to 0$.

Algorithm 1 Agreement-based M-NMT training

```
input Architecture (GNMT), agreement coefficient ($\gamma$)
Initialize: $\theta \leftarrow \theta_0$
while not (converged or step limit reached) do
    Get a mini-batch of parallel src-tgt pairs, $(\mathbf{X}_s, \mathbf{X}_t)$
    Supervised loss: $\mathcal{L}^{\text{sup}}(\theta) \leftarrow \log \mathbb{P}_\theta(\mathbf{X}_t \mid \mathbf{X}_s)$
    Auxiliary languages: $L_a \sim \text{Unif}(\{1, \ldots, k\})$
    Auxiliary translations:
        $\mathbf{Z}_{a \leftarrow s} \leftarrow \text{Decode}(\mathbf{Z}_a \mid f_\theta^{\text{enc}}(\mathbf{X}_s, L_a))$
        $\mathbf{Z}_{a \leftarrow t} \leftarrow \text{Decode}(\mathbf{Z}_a \mid f_\theta^{\text{enc}}(\mathbf{X}_t, L_a))$
    Agreement log-probabilities:
        $\ell_{a \leftarrow s}^t \leftarrow \log \mathbb{P}_\theta(\mathbf{Z}_{a \leftarrow s} \mid \mathbf{X}_t)$
        $\ell_{a \leftarrow t}^s \leftarrow \log \mathbb{P}_\theta(\mathbf{Z}_{a \leftarrow t} \mid \mathbf{X}_s)$
    Apply stop-gradients to supervised $\ell_{a \leftarrow s}^t$ and $\ell_{a \leftarrow t}^s$
    Total loss: $\mathcal{L}^{\text{total}}(\theta) \leftarrow \mathcal{L}^{\text{sup}}(\theta) + \gamma(\ell_{a \leftarrow s}^t + \ell_{a \leftarrow t}^s)$
    Update: $\theta \leftarrow \text{optimizer\_update}(\mathcal{L}^{\text{total}}, \theta)$
end while
output $\theta$
```

For discussion of the assumptions and details on the proof of the bound, see Appendix A.2. Note that Theorem 2 is straightforward to extend from triplets of languages to arbitrary connected graphs, as given in the following corollary.

Corollary 3 *Agreement-based learning yields zero shot consistent MT models (with respect to the cross entropy loss) for arbitrary translation graphs as long as supervised directions span the graph.*

Alternative ways to ensure consistency. Note that there are other ways to ensure zero-shot consistency, *e.g.*, by fine-tuning or post-processing a trained multilingual model. For instance, pivoting through an intermediate language is also zero-shot consistent, but the proof requires stronger assumptions about the quality of the supervised source-pivot model.[5] Similarly, using model distillation (Kim and Rush, 2016; Chen et al., 2017) would be also provably consistent under the same assumptions as given in Theorem 2, but for a single, pre-selected zero-shot direction. Note that our proposed agreement-based learning framework is provably consistent for *all* zero-shot directions and does not require any post-processing. For discussion of the alternative approaches and consistency proof for pivoting, see Appendix A.3.

---

[4] Note that expectations in (8) are conditional on $\mathbf{x}_{\texttt{En}}$. Symmetrically, we can have a lower bound with expectations conditional on $\mathbf{x}_{\texttt{Fr}}$. In practice, we symmetrize the objective.

[5] Intuitively, we have to assume that source-pivot model does not assign high probabilities to unlikely translations as the pivot-target model may react to those unpredictably.

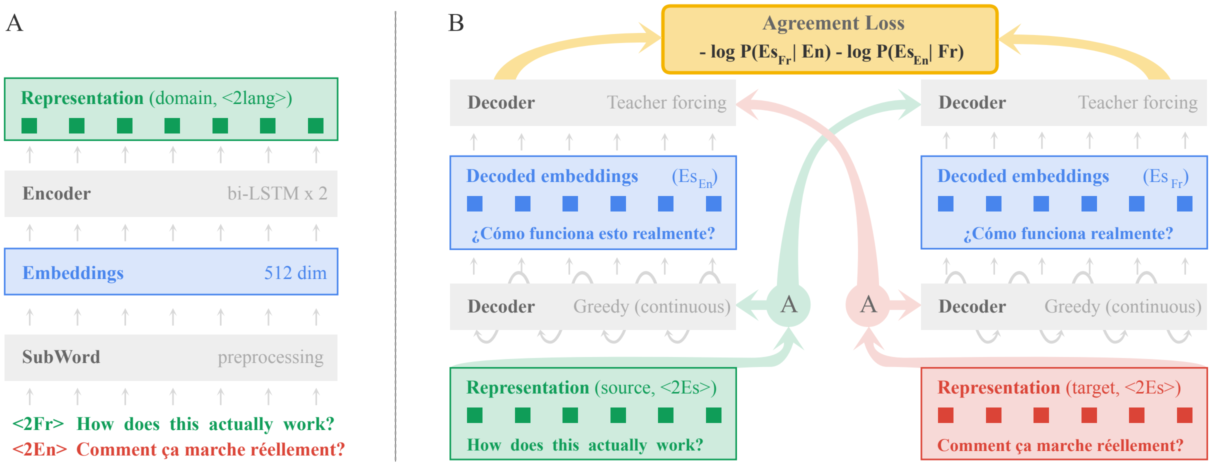

Figure 3: **A.** Computation graph for the encoder. The representations depend on the input sequence and the target language tag. **B.** Computation graph for the agreement loss. First, encode source and target sequences with the auxiliary language tags. Next, decode $\mathbf{z}_{\texttt{Es}}$ from both $\mathbf{x}_{\texttt{En}}$ and $\mathbf{x}_{\texttt{Fr}}$ using continuous greedy decoder. Finally, evaluate log probabilities, $\log \mathbb{P}_\theta\left(\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}}) \mid \mathbf{x}_{\texttt{Fr}}\right)$ and $\log \mathbb{P}_\theta\left(\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}}) \mid \mathbf{x}_{\texttt{En}}\right)$, and compute a sample estimate of the agreement loss.

5.3 Agreement-based learning algorithm

Having derived a new objective function (7), we can now learn consistent multilingual NMT models using stochastic gradient method with a couple of extra tricks (Algorithm 1). The computation graph for the agreement loss is given in Figure 3.

Subsampling auxiliary languages. Computing agreement over *all* languages for each pair of sentences at training time would be quite computationally expensive (to agree on k translations, we would need to encode-decode the source and target sequences k times each). However, since the agreement lower bound is a sum over expectations (8), we can approximate it by subsampling: at each training step (and for each sample in the mini-batch), we pick an auxiliary language uniformly at random and compute stochastic approximation of the agreement lower bound (8) for that language only. This stochastic approximation is simple, unbiased, and reduces per step computational overhead for the agreement term from $O(k)$ to $O(1)$.[6]

Overview of the agreement loss computation. Given a pair of parallel sentences, $\mathbf{x}_{\texttt{En}}$ and $\mathbf{x}_{\texttt{Fr}}$, and an auxiliary language, say $\texttt{Es}$, an estimate of the lower bound on the agreement term (8) is computed as follows. First, we concatenate $\texttt{Es}$ language tags to both $\mathbf{x}_{\texttt{En}}$ and $\mathbf{x}_{\texttt{Fr}}$ and encode the sequences so that both can be translated into $\texttt{Es}$ (the encoding process is depicted in Figure 3A). Next, we decode each of the encoded sentences and obtain auxiliary translations, $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}})$ and $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}})$, depicted as blue blocks in Figure 3B. Note that we now can treat pairs $(\mathbf{x}_{\texttt{Fr}}, \mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}}))$ and $(\mathbf{x}_{\texttt{En}}, \mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}}))$ as new parallel data for $\texttt{En} \to \texttt{Es}$ and $\texttt{Fr} \to \texttt{Es}$.

Finally, using these pairs, we can compute two log-probability terms (Figure 3B):

$$\begin{aligned} &\log \mathbb{P}_\theta\left(\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}}) \mid \mathbf{x}_{\texttt{En}}\right) \\ &\log \mathbb{P}_\theta\left(\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}}) \mid \mathbf{x}_{\texttt{Fr}}\right) \end{aligned} \tag{9}$$

using encoding-decoding with teacher forcing (same way as typically done for the supervised directions). Crucially, note that $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}})$ corresponds to a supervised direction, $\texttt{En} \to \texttt{Es}$, while $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}})$ corresponds to zero-shot, $\texttt{Fr} \to \texttt{Es}$. We want each of the components to (i) improve the zero-shot direction while (ii) minimally affecting the supervised direction. To achieve (i), we use continuous decoding, and for (ii) we use stop-gradient-based protection of the supervised directions. Both techniques are described below.

Greedy continuous decoding. In order to make $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}})$ and $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}})$ differentiable with respect to θ (hence, *continuous* decoding), at each decoding step t, we treat the output of the RNN, $\mathbf{h}^t$, as the key and use dot-product attention over the embedding vocabulary, $\mathbf{V}$, to construct $\mathbf{z}_{\texttt{Es}}^t$:

$$\mathbf{z}_{\texttt{Es}}^t := \operatorname{softmax}\left\{(\mathbf{h}^t)^\top \mathbf{V}\right\} \mathbf{V} \tag{10}$$

In other words, auxiliary translations, $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{En}})$ and $\mathbf{z}_{\texttt{Es}}(\mathbf{x}_{\texttt{Fr}})$, are fixed length sequences of differentiable embeddings computed in a greedy fashion.

---

[6] In practice, note that there is still a constant factor overhead due to extra encoding-decoding steps to/from auxiliary languages, which is about ×4 when training on a single GPU. Parallelizing the model across multiple GPUs would easily compensate this overhead.

Protecting supervised directions. Algorithm 1 scales agreement losses by a small coefficient γ. We found experimentally that training could be sensitive to this hyperparameter since the agreement loss also affects the supervised sub-models. For example, agreement of `En` $\to$ `Es` (supervised) and `Fr` $\to$ `Es` (zero-shot) may push the former towards a worse translation, especially at the beginning of training. To stabilize training, we apply the `stop_gradient` operator to the log probabilities and samples produced by the supervised sub-models before computing the agreement terms (9), to zero-out the corresponding gradient updates.

6 Experiments

We evaluate agreement-based training against baselines from the literature on three public datasets that have multi-parallel *evaluation data* that allows assessing zero-shot performance. We report results in terms of the BLEU score (Papineni et al., 2002) that was computed using `mteval-v13a.perl`.

6.1 Datasets

UN corpus. Following the setup introduced in Sestorain et al. (2018), we use two datasets, *UNcorpus-1* and *UNcorpus-2*, derived from the United Nations Parallel Corpus (Ziemski et al., 2016). *UNcorpus-1* consists of data in 3 languages, `En`, `Es`, `Fr`, where *UNcorpus-2* has `Ru` as the 4th language. For training, we use parallel corpora between `En` and the rest of the languages, each about 1M sentences, sub-sampled from the official training data in a way that ensures no multi-parallel training data. The *dev* and *test* sets contain 4,000 sentences and are all multi-parallel.

Europarl v7[7]**.** We consider the following languages: `De`, `En`, `Es`, `Fr`. For training, we use parallel data between `En` and the rest of the languages (about 1M sentences per corpus), preprocessed to avoid multi-parallel sentences, as was also done by Cheng et al. (2017) and Chen et al. (2017) and described below. The *dev* and *test* sets contain 2,000 multi-parallel sentences.

IWSLT17[8]**.** We use data from the official multilingual task: 5 languages (`De`, `En`, `It`, `Nl`, `Ro`), 20 translation tasks of which 4 zero-shot (`De` $\leftrightarrow$ `Nl` and `It` $\leftrightarrow$ `Ro`) and the rest 16 supervised. Note that this dataset has a significant overlap between parallel corpora in the supervised directions (up to 100K sentence pairs per direction). This implicitly makes the dataset multi-parallel and defeats the purpose of zero-shot evaluation (Dabre et al., 2017). To avoid spurious effects, we also derived **IWSLT17*** dataset from the original one by restricting supervised data to only `En` $\leftrightarrow \{$`De`, `Nl`, `It`, `Ro`$\}$ and removing overlapping pivoting sentences. We report results on both the official and preprocessed datasets.

Preprocessing. To properly evaluate systems in terms of zero-shot generalization, we preprocess Europarl and IWSLT* to avoid multi-lingual parallel sentences of the form *source-pivot-target*, where *source-target* is a zero-shot direction. To do so, we follow Cheng et al. (2017); Chen et al. (2017) and randomly split the overlapping pivot sentences of the original *source-pivot* and *pivot-target* corpora into two parts and merge them separately with the non-overlapping parts for each pair. Along with each parallel training sentence, we save information about source and target tags, after which all the data is combined and shuffled. Finally, we use a shared multilingual subword vocabulary (Sennrich et al., 2015b) on the training data (with 32K merge ops), separately for each dataset. Data statistics are provided in Appendix A.5.

6.2 Training and evaluation

Additional details on the hyperparameters can be found in Appendix A.4.

Models. We use a smaller version of the GNMT architecture (Wu et al., 2016) in all our experiments: 512-dimensional embeddings (separate for source and target sides), 2 bidirectional LSTM layers of 512 units each for encoding, and GNMT-style, 4-layer, 512-unit LSMT decoder with residual connections from the 2nd layer onward.

Training. We trained the above model using the *standard method* of Johnson et al. (2016) and using our proposed *agreement-based* training (Algorithm 1). In both cases, the model was optimized using Adafactor (Shazeer and Stern, 2018) on a machine with 4 P100 GPUs for up to 500K steps, with early stopping on the dev set.

Evaluation. We focus our evaluation mainly on zero-shot performance of the following methods:
(a) `Basic`, which stands for directly evaluating a multilingual GNMT model after standard training (Johnson et al., 2016).

Table 5: Results on our proposed IWSLT17*.

(b) `Pivot`, which performs pivoting-based inference using a multilingual GNMT model (after standard training); often regarded as gold-standard.
(c) `Agree`, which applies a multilingual GNMT model trained with agreement losses directly to zero-shot directions.

To ensure a fair comparison in terms of model capacity, all the techniques above use the same multilingual GNMT architecture described in the previous section. All other results provided in the tables are as reported in the literature.

Implementation. All our methods were implemented using TensorFlow (Abadi et al., 2016) on top of tensor2tensor library (Vaswani et al., 2018). Our code will be made publicly available.[9]

6.3 Results on UN Corpus and Europarl

UN Corpus. Tables 1 and 2 show results on the UNCorpus datasets. Our approach consistently outperforms `Basic` and `Dual-0`, despite the latter being trained with additional monolingual data (Sestorain et al., 2018). We see that models trained with agreement perform comparably to `Pivot`, outperforming it in some cases, *e.g.*, when the target is Russian, perhaps because it is quite different linguistically from the English pivot.

Furthermore, unlike `Dual-0`, `Agree` maintains high performance in the supervised directions (within 1 BLEU point compared to `Basic`), indicating that our agreement-based approach is effective as a part of a single multilingual system.

Europarl. Table 3 shows the results on the Europarl corpus. On this dataset, our approach consistently outperforms `Basic` by 2-3 BLEU points but lags a bit behind `Pivot` on average (except on `Es → De` where it is better). Cheng et al. (2017)[10] and Chen et al. (2017) have reported zero-resource results on a subset of these directions and our approach outperforms the former but not the latter on these pairs. Note that both Cheng et al. (2017) and Chen et al. (2017) train separate models for each language pair and the approach of Chen et al. (2017) would require training $O(k^2)$ models to encompass all the pairs. In contrast, we use a single multilingual architecture which has more limited model capacity (although in theory, our approach is also compatible with using separate models for each direction).

---

[9] www.cs.cmu.edu/~mshediva/code/

[10] We only show their best zero-resource result in the table since some of their methods require direct parallel data.

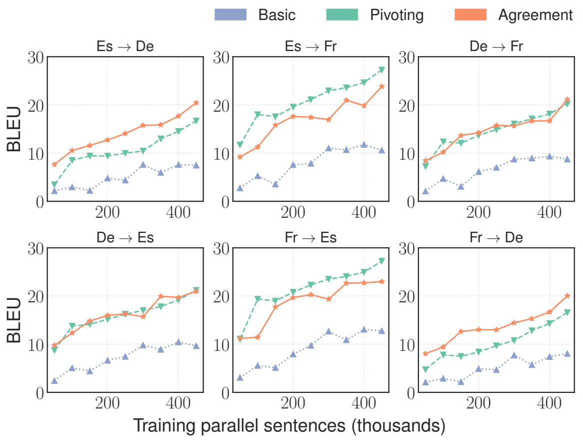

Figure 4: BLEU on the dev set for `Agree` and the baselines trained on smaller subsets of the Europarl corpus.

6.4 Analysis of IWSLT17 zero-shot tasks

Table 4 presents results on the original IWSLT17 task. We note that because of the large amount of data overlap and presence of many supervised translation pairs (16) the vanilla training method (Johnson et al., 2016) achieves very high zero shot performance, even outperforming `Pivot`. While our approach gives small gains over these baselines, we believe the dataset's pecularities make it not reliable for evaluating zero-shot generalization.

On the other hand, on our proposed preprocessed IWSLT17* that eliminates the overlap and reduces the number of supervised directions (8), there is a considerable gap between the supervised and zero-shot performance of `Basic`. `Agree` performs better than `Basic` and is slightly worse than `Pivot`.

6.5 Small data regime

To better understand the dynamics of different methods in the small data regime, we also trained all our methods on subsets of the Europarl for 200K steps and evaluated on the dev set. The training set size varied from 50 to 450K parallel sentences. From Figure 4, `Basic` tends to perform extremely poorly while `Agree` is the most robust (also in terms of variance across zero-shot directions). We see that `Agree` generally upper-bounds `Pivot`, except for the (`Es`, `Fr`) pair, perhaps due to fewer cascading errors along these directions.

7 Conclusion

In this work, we studied zero-shot generalization in the context of multilingual neural machine translation. First, we introduced the concept of zero-shot consistency that implies generalization. Next, we proposed a provably consistent agreement-based learning approach for zero-shot translation. Empirical results on three datasets showed that agreement-based learning results in up to +3 BLEU zero-shot improvement over the Johnson et al. (2016) baseline, compares favorably to other approaches in the literature (Cheng et al., 2017; Sestorain et al., 2018), is competitive with pivoting, and does not lose in performance on supervised directions.

We believe that the theory and methodology behind agreement-based learning could be useful beyond translation, especially in multi-modal settings. For instance, it could be applied to tasks such as cross-lingual natural language inference (Conneau et al., 2018), style-transfer (Shen et al., 2017; Fu et al., 2017; Prabhumoye et al., 2018), or multilingual image or video captioning. Another interesting future direction would be to explore different hand-engineered or learned data representations, which one could use to encourage models to agree on during training (*e.g.*, make translation models agree on latent semantic parses, summaries, or potentially other data representations available at training time).

Acknowledgments

We thank Ian Tenney and Anthony Platanios for many insightful discussions, Emily Pitler for the helpful comments on the early draft of the paper, and anonymous reviewers for careful reading and useful feedback.

A Appendices

A.1 Complete likelihood

Given a set of conditional models, $\{\mathbb{P}_\theta(\mathbf{x}_j \mid \mathbf{x}_i)\}$, we can write out the full likelihood over equivalent translations, $(\mathbf{x}_1, \dots, \mathbf{x}_k)$, as follows:

$$\mathbb{P}_\theta(\mathbf{x}_1, \dots, \mathbf{x}_k) := \frac{1}{Z} \prod_{i,j \in \mathcal{E}} \mathbb{P}_\theta(\mathbf{x}_j \mid \mathbf{x}_i) \tag{11}$$

where $Z := \sum_{\mathbf{x}_1,\dots,\mathbf{x}_k} \prod_{i,j\in\mathcal{E}} \mathbb{P}_\theta(\mathbf{x}_j \mid \mathbf{x}_i)$ is the normalizing constant and $\mathcal{E}$ denotes *all* edges in the graph (Figure 5). Given only bilingual parallel corpora, $\mathcal{C}_{ij}$ for $i, j \in \mathcal{E}_s$, we can observe only certain pairs of variables. Therefore, the log-likelihood of the data can be written as:

$$\mathcal{L}(\theta) := \sum_{i,j\in\mathcal{E}_s} \sum_{\mathbf{x}_i,\mathbf{x}_j\in\mathcal{C}_{ij}} \log \sum_{\mathbf{z}} \mathbb{P}_\theta(\mathbf{x}_1, \dots, \mathbf{x}_k) \tag{12}$$

Here, the outer sum iterates over available corpora. The middle sum iterates over parallel sentences in a corpus. The most inner sum marginalizes out unobservable sequences, denoted $\mathbf{z} := \{\mathbf{x}_l\}_{l\neq i,j}$, which are sentences equivalent under this model to $\mathbf{x}_i$ and $\mathbf{x}_j$ in languages other than L_i and L_j. Note that due to the inner-most summation, computing the log-likelihood is intractable.

We claim the following.

Claim 4 *Maximizing the full log-likelihood yields zero-shot consistent models (Definition 1).*

Proof. To better understand why this is the case, let us consider example in Figure 5 and compute the log-likelihood of $(\mathbf{x}_1, \mathbf{x}_2)$:

$$\begin{aligned}
&\log \mathbb{P}_\theta(\mathbf{x}_1, \mathbf{x}_2) \\
&\quad = \log \sum\nolimits_{\mathbf{x}_3,\mathbf{x}_4} \mathbb{P}_\theta(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4) \\
&\quad \propto \log \mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_2) + \log \mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_1) + \\
&\qquad \log \sum\nolimits_{\mathbf{x}_3,\mathbf{x}_4} \mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_3)\, \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_1) \times \\
&\qquad\qquad \mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_3)\, \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_2) \times \\
&\qquad\qquad \mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_4)\, \mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_1) \times \\
&\qquad\qquad \mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_4)\, \mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_2) \times \\
&\qquad\qquad \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_4)\, \mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_3)
\end{aligned}$$

Note that the terms that encourage agreement on the translation into L_3 are colored in green (similarly, terms that encourage agreement on the translation into L_4 are colored in blue). Since all other terms are probabilities and bounded by 1, we have:

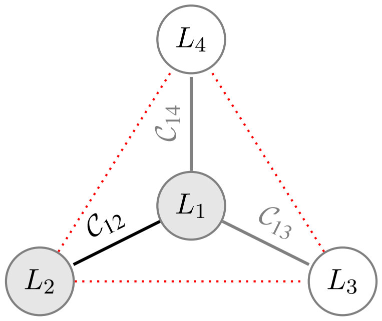

Figure 5: Probabilistic graphical model for a multilingual system with four languages (L_1, L_2, L_3, L_4). Variables can only be observed only in pairs (shaded in the graph).

$$\begin{aligned}
&\log \mathbb{P}_\theta(\mathbf{x}_1, \mathbf{x}_2) + \log Z \\
&\quad \leq \log \mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_2) + \log \mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_1) + \\
&\qquad \log \sum\nolimits_{\mathbf{x}_3,\mathbf{x}_4} \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_1) \mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_2) \times \\
&\qquad\qquad \mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_1) \mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_2) \\
&\quad \equiv \mathcal{L}^{\text{agree}}(\theta)
\end{aligned}$$

In other words, the full log likelihood lower-bounds the agreement objective (up to a constant $\log Z$). Since optimizing for agreement leads to consistency (Theorem 2), and maximizing the full likelihood would necessarily improve the agreement, the claim follows. ■

Remark 5 *Note that the other terms in the full likelihood also have a non-trivial purpose: (a) the terms* $\mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_3)$, $\mathbb{P}_\theta(\mathbf{x}_1 \mid \mathbf{x}_4)$, $\mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_3)$, $\mathbb{P}_\theta(\mathbf{x}_2 \mid \mathbf{x}_4)$*, encourage the model to correctly reconstruct* $\mathbf{x}_1$ *and* $\mathbf{x}_2$ *when back-translating from unobserved languages,* L_3 *and* L_4*, and (b) terms* $\mathbb{P}_\theta(\mathbf{x}_3 \mid \mathbf{x}_4)$, $\mathbb{P}_\theta(\mathbf{x}_4 \mid \mathbf{x}_3)$ *enforce consistency between the latent representations. In other words, full likelihood accounts for a combination of agreement, back-translation, and latent consistency.*

A.2 Proof of agreement consistency

The statement of Theorem 2 mentions an assumption on the true distribution of the equivalent translations. The assumption is as follows.

Assumption 6 *Let* $\mathbb{P}(\mathbf{x}_i \mid \mathbf{x}_j, \mathbf{x}_k)$ *be the ground truth conditional distribution that specifies the probability of* $\mathbf{x}_i$ *to be a translation of* $\mathbf{x}_j$ *and* $\mathbf{x}_k$ *into language* L_i*, given that* $(\mathbf{x}_j, \mathbf{x}_k)$ *are correct translations of each other in languages* L_j *and* L_k*, respectively. We assume:*

$$0 \leq \delta \leq \mathbb{E}_{\mathbf{x}_k \mid \mathbf{x}_i, \mathbf{x}_j} \left[\mathbb{P}(\mathbf{x}_i \mid \mathbf{x}_j, \mathbf{x}_k)\right] \leq \xi \leq 1$$

This assumption means that, even though there might be multiple equivalent translations, there must be not too many of them (implied by the δ lower bound) and none of them must be much more preferable than the rest (implied by the ξ upper bound). Given this assumption, we can prove the following simple lemma.

Lemma 7 *Let $L_i \to L_j$ be one of the supervised directions, $\mathbb{E}_{\mathbf{x}_i,\mathbf{x}_j}\left[-\log \mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)\right] \leq \varepsilon$. Then the following holds:*

$$\mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[\frac{\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)}{\mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k\right)}\right] \geq \log\frac{1}{\xi} - \varepsilon\delta$$

Proof. First, using Jensen's inequality, we have:

$$\log \mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[\frac{\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)}{\mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k\right)}\right] \geq$$
$$\mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[\log \mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right) - \log \mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k\right)\right]$$

The bound on the supervised direction implies that

$$\mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[-\log \mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)\right] \geq -\varepsilon\delta$$

To bound the second term, we use Assumption 6:

$$\mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[-\log \mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k\right)\right] \geq \log\frac{1}{\xi}$$

Putting these together yields the bound. ■

Now, using Lemma 7, we can prove Theorem 2.

Proof. By assumption, the agreement-based loss is bounded by ε. Therefore, expected cross-entropy on all supervised terms, $L_1 \leftrightarrow L_2$, is bounded by ε. Moreover, the agreement term (which is part of the objective) is also bounded:

$$-\mathbb{E}_{\mathbf{x}_i,\mathbf{x}_j}\left[\sum_{\mathbf{x}_k} \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right) \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)\right] \leq \varepsilon$$

Expanding this expectation, we have:

$$\sum_{\mathbf{x}_i,\mathbf{x}_j} \mathbb{P}\left(\mathbf{x}_i,\mathbf{x}_j\right) \sum_{\mathbf{x}_k} \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right) \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)]$$
$$= \sum_{\mathbf{x}_i,\mathbf{x}_j,\mathbf{x}_k} \mathbb{P}\left(\mathbf{x}_i,\mathbf{x}_j,\mathbf{x}_k\right) \times$$
$$\frac{\mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right)}{\mathbb{P}\left(\mathbf{x}_k \mid \mathbf{x}_i,\mathbf{x}_j\right)} \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)$$
$$= \sum_{\mathbf{x}_i,\mathbf{x}_k} \mathbb{E}_{\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k}\left[\frac{\mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right)}{\mathbb{P}\left(\mathbf{x}_k \mid \mathbf{x}_i,\mathbf{x}_j\right)}\right] \times$$
$$\mathbb{P}\left(\mathbf{x}_i,\mathbf{x}_k\right) \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)$$

Combining that with Lemma 7, we have:

$$\mathbb{E}_{\mathbf{x}_i,\mathbf{x}_k}\left[-\log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)\right] \leq \frac{\varepsilon}{\log\frac{1}{\xi} - \delta\varepsilon} \equiv \kappa(\varepsilon)$$

Since by Assumption 6, δ and ξ are some constants, $\kappa(\varepsilon) \to 0$ as $\varepsilon \to 0$. ■

A.3 Consistency of distillation and pivoting

As we mentioned in the main text of the paper, distillation (Chen et al., 2017) and pivoting yield zero-shot consistent models. Let us understand why this is the case.

In our notation, given $L_1 \to L_2$ and $L_2 \to L_3$ as supervised directions, distillation optimizes a KL-divergence between $\mathbb{P}_\theta\left(\mathbf{x}_3 \mid \mathbf{x}_2\right)$ and $\mathbb{P}_\theta\left(\mathbf{x}_3 \mid \mathbf{x}_1\right)$, where the latter is a zero-shot model and the former is supervised. Noting that KL-divergence lower-bounds cross-entropy, it is a loser bound on the agreeement loss. Hence, by ensuring that KL is low, we also ensure that the models agree, which implies consistency (a more formal proof would exactly follow the same steps as the proof of Theorem 2).

To prove consistency of pivoting, we need an additional assumption on the quality of the source-pivot model.

Assumption 8 *Let $\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)$ be the source-pivot model. We assume the following bound holds for each pair of equivalent translations, $\left(\mathbf{x}_j,\mathbf{x}_k\right)$:*

$$\mathbb{E}_{\mathbf{x}_i \mid \mathbf{x}_j,\mathbf{x}_k}\left[\frac{\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right)}{\mathbb{P}\left(\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k\right)}\right] \leq C$$

where $C > 0$ is some constant.

Theorem 9 (Pivoting consistency) *Given the conditions of Theorem 2 and Assumption 8, pivoting is zero-shot consistent.*

Proof. We can bound the expected error on pivoting as follows (using Jensen's inequality and the conditions from our assumptions):

$$\mathbb{E}_{\mathbf{x}_i,\mathbf{x}_k}\left[-\log \sum_{\mathbf{x}_j} \mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right) \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right)\right]$$
$$\leq \mathbb{E}_{\mathbf{x}_i,\mathbf{x}_j,\mathbf{x}_k}\left[-\mathbb{P}_\theta\left(\mathbf{x}_j \mid \mathbf{x}_i\right) \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right)\right]$$
$$\leq \sum_{\mathbf{x}_i,\mathbf{x}_k} \mathbb{E}_{\mathbf{x}_j \mid \mathbf{x}_i,\mathbf{x}_k}\left[\frac{\mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_j\right)}{\mathbb{P}\left(\mathbf{x}_k \mid \mathbf{x}_i,\mathbf{x}_j\right)}\right] \times$$
$$\mathbb{P}\left(\mathbf{x}_i,\mathbf{x}_k\right) \log \mathbb{P}_\theta\left(\mathbf{x}_k \mid \mathbf{x}_i\right)$$
$$\leq C\varepsilon$$

■

A.4 Details on the models and training

Architecture. All our NMT models used the GNMT (Wu et al., 2016) architecture with Luong attention (Luong et al., 2015b), 2 bidirectional encoder, and 4-layer decoder with residual connections. All hidden layers (including embeddings) had 512 units. Additionally, we used separate embeddings on the encoder and decoder sides as well as tied weights of the softmax that produced logits with the decoder-side (*i.e.*, target) embeddings. Standard dropout of 0.2 was used on all hidden layers. Most of the other hyperparameters we set to default in the T2T (Vaswani et al., 2018) library for the text2text type of problems.

Training and hyperparameters. We scaled agreement terms in the loss by $\gamma = 0.01$. The training was done using Adafactor (Shazeer and Stern, 2018) optimizer with 10,000 burn-in steps at 0.01 learning rate and further standard square root decay (with the default settings for the decay from the T2T library). Additionally, implemented agreement loss as a subgraph as a loss was not computed if γ was set to 0. This allowed us to start training multilingual NMT models in the burn-in mode using the composite likelihood objective and then switch on agreement starting some point during optimization (typically, after the first 100K iterations; we also experimented with 0, 50K, 200K, but did not notice any difference in terms of final performance). Since the agreement subgraph was not computed during the initial training phase, it tended to accelerate training of agreement models.

A.5 Details on the datasets

Statistics of the IWSLT17 and IWSLT17* datasets are summarized in Table 6. UNCorpus and and Europarl datasets were exactly as described by Sestorain et al. (2018) and Chen et al. (2017); Cheng et al. (2017), respectively.

Corpus	**Directions**	**Train**	**Dev** (dev2010)	**Test** (tst2010)
IWSLT17	`De` → `En`	206k	888	1568
	`De` → `It`	205k	923	1567
	`De` → `Nl`	0	1001	1567
	`De` → `Ro`	201k	912	1677
	`En` → `De`	206k	888	1568
	`En` → `It`	231K	929	1566
	`En` → `Nl`	237k	1003	1777
	`En` → `Ro`	220k	914	1678
	`It` → `De`	205k	923	1567
	`It` → `En`	231k	929	1566
	`It` → `Nl`	205k	1001	1669
	`It` → `Ro`	0	914	1643
	`Nl` → `De`	0	1001	1779
	`Nl` → `En`	237k	1003	1777
	`Nl` → `It`	233k	1001	1669
	`Nl` → `Ro`	206k	913	1680
	`Ro` → `De`	201k	912	1677
	`Ro` → `En`	220k	914	1678
	`Ro` → `It`	0	914	1643
	`Ro` → `Nl`	206k	913	1680
IWSLT17*	`De` → `En`	124k	888	1568
	`De` → `It`	0	923	1567
	`De` → `Nl`	0	1001	1567
	`De` → `Ro`	0	912	1677
	`En` → `De`	124k	888	1568
	`En` → `It`	139k	929	1566
	`En` → `Nl`	155k	1003	1777
	`En` → `Ro`	128k	914	1678
	`It` → `De`	0	923	1567
	`It` → `En`	139k	929	1566
	`It` → `Nl`	0	1001	1669
	`It` → `Ro`	0	914	1643
	`Nl` → `De`	0	1001	1779
	`Nl` → `En`	155k	1003	1777
	`Nl` → `It`	0	1001	1669
	`Nl` → `Ro`	0	913	1680
	`Ro` → `De`	0	912	1677
	`Ro` → `En`	128k	914	1678
	`Ro` → `It`	0	914	1643
	`Ro` → `Nl`	0	913	1680

Table 6: Data statistics for IWSLT17 and IWSLT17*. Note that training data in IWSLT17* was restricted to only `En` ↔ {`De`, `It`, `Nl`, `Ro`} directions and cleaned from complete pivots through `En`, which also reduced the number of parallel sentences in each supervised direction.

Abstract

Recently, the Transformer model (Vaswani et al., 2017) that is based solely on attention mechanisms, has advanced the state-of-the-art on various machine translation tasks. However, recent studies reveal that the lack of recurrence hinders its further improvement of translation capacity (Chen et al., 2018; Dehghani et al., 2019). In response to this problem, we propose to directly model recurrence for Transformer with an additional recurrence encoder. In addition to the standard recurrent neural network, we introduce a novel *attentive recurrent network* to leverage the strengths of both attention and recurrent networks. Experimental results on the widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation tasks demonstrate the effectiveness of the proposed approach. Our studies also reveal that the proposed model benefits from a *short-cut* that bridges the source and target sequences with a single recurrent layer, which outperforms its deep counterpart.

1 Introduction

Recently, Transformer (Vaswani et al., 2017) – a new network architecture based solely on attention mechanisms, has advanced the state-of-the-art on various translation tasks across language pairs. Compared with the conventional recurrent neural network (RNN) (Schuster and Paliwal, 1997) based model that leverages recurrence as the basic building module (Sutskever et al., 2014; Bahdanau et al., 2015; Chen et al., 2018), Transformer replaces RNN with self-attention network (SAN) to model the dependencies among input elements. One appealing strength of SAN is that it breaks down the sequential assumption to obtain the ability of highly parallel computation: input elements interact with each other simultaneously without regard to their distance.

However, prior studies empirically show that the lack of recurrence modeling hinders Transformer from further improvement of translation quality (Dehghani et al., 2019). Modeling recurrence is crucial for capturing several essential properties of input sequence, such as structural representations (Tran et al., 2016) and positional encoding (Shaw et al., 2018), which are exactly the weaknesses of SAN (Tran et al., 2018). Recently, Chen et al. (2018) show that the representations learned by SAN-based and RNN-based encoders are complementary to each other, and merging them can improve translation performance for RNN-based NMT models.

Starting from these findings, we propose to directly model recurrence for Transformer with an additional recurrence encoder. The recurrence encoder recurrently reads word embeddings of input sequence and outputs a sequence of hidden states, which serves as an additional information source to the Transformer decoder. In addition to the standard RNN, we propose to implement recurrence modeling with a novel *attentive recurrent network* (ARN), which combines advantages of both SAN and RNN. Instead of recurring over the individual symbols of sequences like RNN, the ARN recurrently revises its representations over a set of feature vectors, which are extracted by an attention model from the input sequence. Accordingly, ARN combines the strong global modeling capacity of SAN with the recurrent bias of RNN.

We evaluate the proposed approach on widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation tasks. Experimental results show that the additional recurrence encoder, implemented with either RNN or ARN,

Minneapolis, Minnesota, June 2 - June 7, 2019.

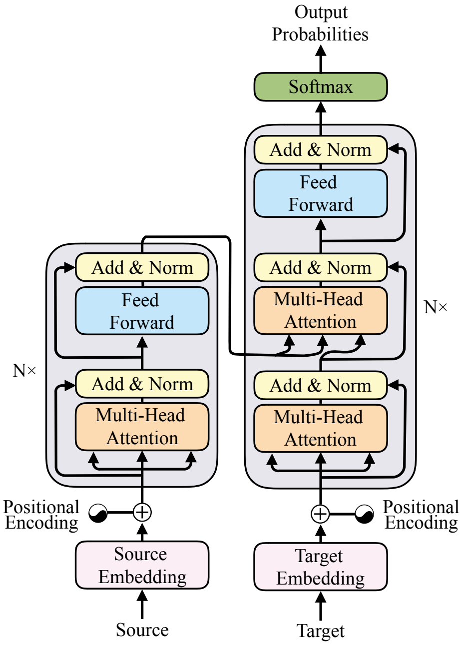

Figure 1: The architecture of Transformer.

consistently improves translation performance, demonstrating the necessity of modeling recurrence for Transformer. Specifically, the ARN implementation outperforms its RNN counterpart, which confirms the strength of ARN.

Further analyses reveal that our approach benefits from a *short-cut* that bridges the source and target sequences with shorter path. Among all the model variants, the implementation with shortest path performs best, in which the recurrence encoder is single layer and its output is only fed to the top decoder layer. It consistently outperforms its multiple deep counterparts, such as multiple-layer recurrence encoder and feeding the output of recurrence encoder to all the decoder layers. In addition, our approach indeed generates more informative encoder representations, especially representative on syntactic structure features, through conducting linguistic analyses on probing tasks (Conneau et al., 2018).

2 Background

Figure 1 shows the model architecture of Transformer. The encoder is composed of a stack of N identical layers, each of which has two sub-layers. The first sub-layer is a self-attention network, and the second one is a position-wise fully connected feed-forward network. A residual connection (He et al., 2016) is employed around each of two sub-layers, followed by layer normalization (Ba et al., 2016). Formally, the output of the first sub-layer $\mathbf{C}_e^n$ and the second sub-layer $\mathbf{H}_e^n$ are sequentially calculated as:

$$\mathbf{C}_e^n = \textsc{Ln}\big(\textsc{Self-Att}(\mathbf{H}_e^{n-1}) + \mathbf{H}_e^{n-1}\big), \quad (1)$$

$$\mathbf{H}_e^n = \textsc{Ln}\big(\textsc{Ffn}(\mathbf{C}_e^n) + \mathbf{C}_e^n\big), \quad (2)$$

where $\textsc{Self-Att}(\cdot)$, $\textsc{Ln}(\cdot)$, and $\textsc{Ffn}(\cdot)$ are respectively self-attention mechanism, layer normalization, and feed-forward network with ReLU activation in between.

In transformer, $\textsc{Self-Att}(\cdot)$ computes attention over the input $\mathbf{H}_e^{n-1}$ as follows:

$$\textsc{Self-Att}(\mathbf{H}_e^{n-1}) = softmax(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d_k}})\mathbf{V} \quad (3)$$

where $\{\mathbf{Q}, \mathbf{K}, \mathbf{V}\}$ are query, key and value vectors that are transformed from the input representations $\mathbf{H}_e^{n-1}$. $\sqrt{d_k}$ is the scaling factor where the d_k is the dimension size of the query and key vectors.

The decoder is also composed of a stack of N identical layers. In addition to two sub-layers in each decoder layer, the decoder inserts a third sub-layer $\mathbf{D}_d^n$ to perform attention over the output of the encoder $\mathbf{H}_e^N$:

$$\mathbf{C}_d^n = \textsc{Ln}\big(\textsc{Self-Att}(\mathbf{H}_d^{n-1}) + \mathbf{H}_d^{n-1}\big), \quad (4)$$

$$\mathbf{D}_d^n = \textsc{Ln}\big(\textsc{Att}(\mathbf{C}_d^n, \mathbf{H}_e^N) + \mathbf{C}_d^n\big), \quad (5)$$

$$\mathbf{H}_d^n = \textsc{Ln}\big(\textsc{Ffn}(\mathbf{D}_d^n) + \mathbf{D}_d^n\big), \quad (6)$$

where $\textsc{Att}(\mathbf{C}_d^n, \mathbf{H}_e^N)$ denotes attending the top encoder layer $\mathbf{H}_e^N$ with $\mathbf{C}_d^n$ as query. The top layer of the decoder $\mathbf{H}_d^N$ is used to generate the final output sequence.

3 Approach

In this section, we first describe the architecture of the introduced recurrence encoder and elaborate two types of neural network that are used as recurrence encoder in this work. Then we introduce the integration of recurrence encoder into the Transformer. Specifically, two strategies are presented to fuse the representations produced by the recurrence encoder and the conventional encoder. Finally we present the *short-cut* connection between the recurrence encoder and the decoder that we found very effective to use the learned representation to improve the translation performance under the proposed architecture.

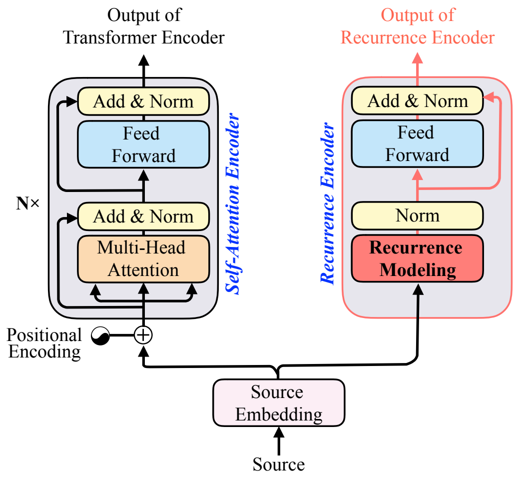

Figure 2: The architecture of Transformer augmented with an additional *recurrence encoder*, the output of which is directly fed to the top decoder layer.

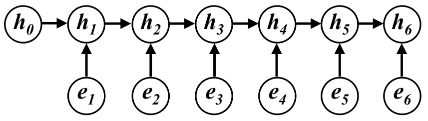
3.1 Recurrence Modeling

Figure 2 shows the architecture of the introduced *recurrence encoder* which reads word embeddings of source words and outputs a sequence of hidden states that embeds recurrent information. Similar to the Transformer encoder, it has a stack of N identical layers, each of which has two sub-layers. The first one is a recurrence modeling network and the second is a fully connected feed-forward network:

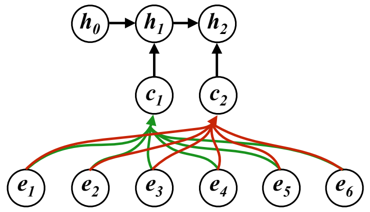
$$
\begin{aligned}
\mathbf{C}_r^n &= \textsc{Ln}(\textsc{Rec}(\mathbf{H}_r^{n-1}) + \mathbf{H}_r^{n-1}), &(7)\\
\mathbf{H}_r^n &= \textsc{Ln}(\textsc{Ffn}(\mathbf{C}_r^n) + \mathbf{C}_r^n), &(8)
\end{aligned}
$$

where $\textsc{Rec}(\cdot)$ is the function of recurrence modeling. Note that at the bottom layer of the recurrence encoder (N=1), we do not employ a residual connection on the recurrence sub-layer (i.e. Equation 7), which releases the constraint that $\mathbf{C}_r^1$ should share the same length with input embeddings sequence $\mathbf{E}_{in}$[1]. This offers a more flexible choice of the recurrence functions.

There are many possible ways to implement the general idea of recurrence modeling $\textsc{Rec}(\cdot)$. The aim of this paper is not to explore this whole space but simply to show that some fairly straightforward implementations work well. In this work, we investigate two representative implementations, namely RNN and its variation *attentive current network* that combines advantages of both RNN and attention models, as shown in Figure 3.



(a) Recurrent Neural Network



(b) Attentive Recurrent Network

Figure 3: Two implementations of recurrence modeling: (a) standard RNN, and (b) the proposed ARN.

Recurrent Neural Network (RNN) An intuitive choice of recurrence modeling is RNN, which is a standard network to model sequence orders. In this work, we use a bidirectional RNN (BiRNN), which is widely applied in RNN-based NMT models (Bahdanau et al., 2015; Chen et al., 2018). Each hidden state in the output representations $\mathbf{H}_{\text{RNN}}^n = \{\mathbf{h}_1^n, \ldots, \mathbf{h}_J^n\}$ is calculated as

$$
\begin{aligned}
\mathbf{h}_j^n &= [\overrightarrow{\mathbf{h}}_j; \overleftarrow{\mathbf{h}}_j], &(9)\\
\overrightarrow{\mathbf{h}}_j &= \overrightarrow{f}(\overrightarrow{\mathbf{h}}_{j-1}, \mathbf{h}_j^{n-1}), &(10)\\
\overleftarrow{\mathbf{h}}_j &= \overleftarrow{f}(\overleftarrow{\mathbf{h}}_{j+1}, \mathbf{h}_j^{n-1}), &(11)
\end{aligned}
$$

where $\overrightarrow{f}(\cdot)$ and $\overleftarrow{f}(\cdot)$ are the activation functions of forward and backward RNN respectively, which can be implemented as LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014). $\mathbf{h}_0^n$ is the initial state of RNN, which is the mean of $\mathbf{H}_{\text{RNN}}^{n-1}$. $\mathbf{H}_{\text{RNN}}^0$ represents the word embeddings of the input sequence.

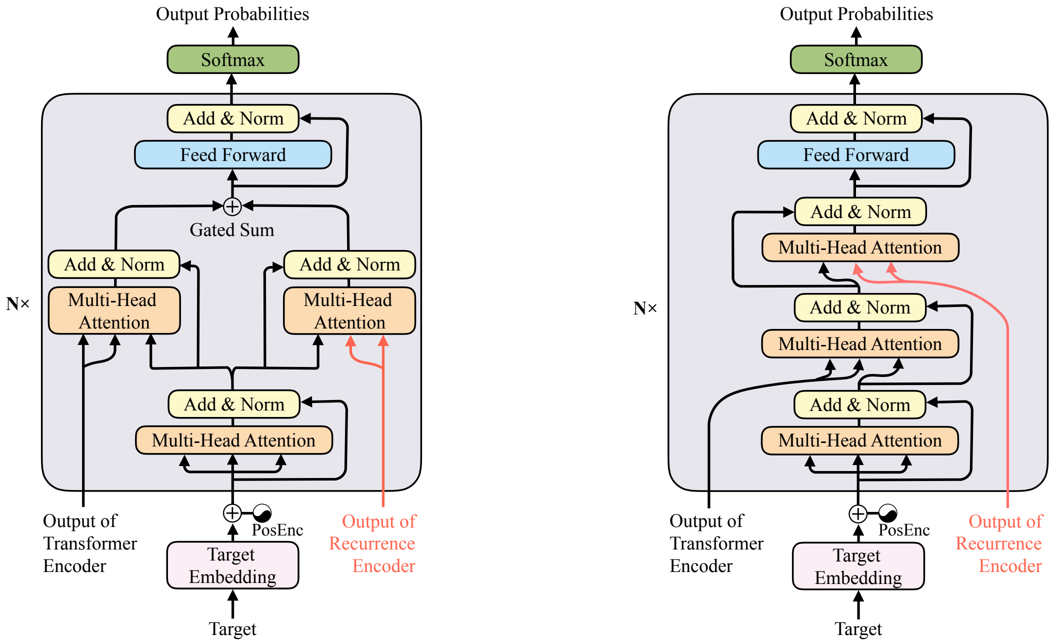
Attentive Recurrent Network (ARN) We can also extend RNN by recurring over a set of feature vectors extracted with an attention model, which allows the model to learn a compact, abstractive feature vectors over the input sequence. Specifically, the ARN performs T recurrent steps on the attentive output of the input representation $\mathbf{H}_r^{n-1}$:

$$
\begin{aligned}
\mathbf{h}_t^n &= f(\mathbf{h}_{t-1}^n, \mathbf{c}_t^n), &(12)\\
\mathbf{c}_t^n &= \textsc{Att}(\mathbf{h}_{t-1}^n, \mathbf{H}_r^{n-1}). &(13)
\end{aligned}
$$

The output representations $\mathbf{H}_{\text{ARN}}^n = \{\mathbf{h}_1^n, \ldots, \mathbf{h}_T^n\}$ are fed to the subsequent modules. Analogous to Equations 9-11, ARN can be extended to the bidirectional variant, i.e. BiARN,

---

[1] The input of the lowest layer in the recurrence encoder is the word embeddings of input sequence $\mathbf{E}_{in}$.



(a) Gated Sum (b) Stack

Figure 4: Different strategies to integrate the output of the additional *recurrence encoder* into the decoder.

except that the input is the attentive context vector $\mathbf{c}_t^n$ rather than the individual representation vector of the input sequence.

Note that, the number of recurrence step T is allowed to be unequal to the length of input sequence J. In contrast to RNN which recurs over the individual symbols of the input sequences, ARN recurrently revises its representations of all symbols in the sequence with an attention model.

3.2 Integrating into Transformer

Since the output of recurrence encoder unnecessarily shares the same length with that of Transformer encoder (e.g. when ARN is used as recurrence function), combination strategy on the encoder side, such as concatenating the outputs of both encoders (Chen et al., 2018), is not an universal solution in this scenario. Accordingly, we feed the information of the additional recurrence encoder into the decoder of Transformer. Specifically, we serve an additional attention layer $\mathbf{R}_d^n$ as the fourth sub-layer in each decoder block to perform attention over the output of the recurrence encoder $\mathbf{H}_r^N$. As shown in Figure 4, we present two strategies to integrate $\mathbf{R}_d^n$, namely *gated sum* and *stack*, which differ at how $\mathbf{R}_d^n$ interacts with the output of attention over the Transformer encoder, i.e., $\mathbf{D}_d^n$ in Equation 5.

Gated Sum The first strategy combines the outputs of the two attention sub-layers in a gating fusion (Figure 4(a)), in which the outputs of both encoders are attended simultaneously:

$$\begin{aligned}
\mathbf{R}_d^n &= \textsc{Ln}\big(\textsc{Att}(\mathbf{C}_d^n, \mathbf{H}_r^N) + \mathbf{C}_d^n\big), && (14)\\
\widehat{\mathbf{D}}_d^n &= \lambda_n \mathbf{D}_d^n + (1-\lambda_n)\mathbf{R}_d^n, && (15)\\
\mathbf{H}_d^n &= \textsc{Ln}\big(\textsc{Ffn}(\widehat{\mathbf{D}}_d^n) + \widehat{\mathbf{D}}_d^n\big), && (16)
\end{aligned}$$

where λ_n is an interpolation weight calculated by a logistic sigmoid function:

$$\lambda_n = sigmoid(\mathbf{D}_d^n, \mathbf{R}_d^n) \quad (17)$$

As seen, the output of self-attention layer $\mathbf{C}_d^n$ serves as a query to attend the outputs of both encoders (Equations 5 and 14), and the outputs of both attention models $\{\mathbf{D}_d^n, \mathbf{R}_d^n\}$ are combined via a gated sum (Equation 15), which is subsequently fed to the feed-forward layer (Equation 16).

Stack We can also arrange the sub-layers in a *stack* (Figure 4(b)), in which the outputs of both encoders are attended sequentially:

$$\begin{aligned}
\mathbf{R}_d^n &= \textsc{Ln}\big(\textsc{Att}(\mathbf{D}_d^n, \mathbf{H}_r^N) + \mathbf{D}_d^n\big), && (18)\\
\mathbf{H}_d^n &= \textsc{Ln}\big(\textsc{Ffn}(\mathbf{R}_d^n) + \mathbf{R}_d^n\big), && (19)
\end{aligned}$$

The decoder first attends the output of Transformer encoder, and the attention output $\mathbf{D}_d^n$ serves as the query to attend the output of recurrence encoder (Equation 18).

3.3 Short-Cut Effect

The introduced recurrence encoder provides an additional computation path ranging from the input sequence to the output sequence. Chung et al. (2017) and Shen et al. (2019) have shown that a shortcut for gradient back-propagation benefits language modeling. Inspired from them, we use a shorter path to transform the learned recurrence. We call this the "*short-cut effect*".

Among all the model variants, we implement shortest path as: the recurrence encoder is single layer and its output is only fed to the top decoder layer while the first $N-1$ decoder layers perform the same as the standard Transformer (e.g. Equations 4-6). Accordingly, the computation path is $\mathbf{E}_{in} \rightarrow \mathbf{H}_r \rightarrow \mathbf{R}_d^N \rightarrow \mathbf{H}_d^N$, then the decoder uses $\mathbf{H}_d^N$ to make a target word prediction. It is much simpler than that of the conventional Transformer, which transfers information learned from input sequences across multiple stacking encoder and decoder layers. We expect it outperforms its multiple deep counterparts, such as multiple-layer recurrence encoder and feeding the output of recurrence encoder to all the decoder layers.

4 Related Work

Improving Transformer Encoder From the perspective of representation learning, there has been an increasing amount of work on improving the representation power of SAN encoder. Bawden et al. (2018) and Voita et al. (2018) exploit external context for SAN encoder, while Yang et al. (2019) leverage the intermediate representations to contextualize the transformations in SAN. A number of recent efforts have explored ways to improve multi-head SAN by encouraging individual attention heads to extract distinct information (Strubell et al., 2018; Li et al., 2018). Concerning multi-layer SAN encoder, Dou et al. (2018, 2019) and Wang et al. (2018) propose to aggregate the multi-layer representations, and Dehghani et al. (2019) recurrently refine these representations. Our approach is complementary to theirs, since they focus on improving the representation power of SAN encoder, while we aim to complement SAN encoder with an additional recurrence encoder.

Along the direction of modeling recurrence for SAN, Vaswani et al. (2017) and Shaw et al. (2018) inject absolute position encoding and relative positional encoding to consider the position information respectively. Shen et al. (2018) introduce a directional self-attention network (DiSAN), which allows each token to attend to previous (or following) tokens only. Both studies verify the necessity of modeling recurrence for SAN. We re-implemented these approaches on top of Transformer, and experimental results show that our approach outperforms them by explicitly augmenting Transformer with an additional recurrence encoder. It should be emphasized that our approach is complementary to theirs, and combining them together is expected to further improve performance, which we leave for future work.

Closely related to our work, Chen et al. (2018) propose to combine SAN encoder with an additional RNN encoder. The main differences between our work and theirs are: 1) we enhance the state-of-the-art Transformer with recurrence information, while Chen et al. (2018) augment RNN-based models with SAN encoder. To this end, we propose a novel attentive recurrent network to implement the additional recurrence encoder in Transformer. We re-implemented the approach proposed by Chen et al. (2018) on top of Transformer. Experimental results indicate the superiority of our approach, which confirms our claim. In addition, we elaborately design the integration strategy to effectively feed the recurrence information to the decoder, and empirically show that the proposed model benefits from the *short-cut* effect.

Comparison to Reviewer Network Attentive recurrent network are inspired by the reviewer network, which is proposed by Yang et al. (2016) for the image caption generation task. There are two key differences which reflect how we have generalized from the original model. First, we perform attention steps over the source embeddings instead of the encoder representations. The main reason is that the Transformer encoder is implemented as multiple layers, and higher layers generally encode global information, as indicated by Peters et al. (2018). Second, we feed the feature vectors together with the original encoder representations to the decoder. In image caption generation, the source side (i.e. image) contains much more information than the target side (i.e. caption) (Tu et al., 2017). Therefore, they aim at learning a compact and abstractive representation from the source information, which serves as the only input to the decoder. In this work, we focus on leveraging the attention model to better learn the recurrence, which we expect to complement the Transformer model. In our preliminary experiments, attending over the encoder representations does not improve performance, while feeding the feature vectors only to the decoder seriously harms performance.

5 Experiment

5.1 Setup

We conducted experiments on the widely-used WMT14 English-to-German (4.6M sentence pairs, En⇒De) and WMT17 Chinese-to-English (20.6M sentence pairs, Zh⇒En) translation tasks. All the data had been tokenized and segmented into subword symbols using byte-pair encoding (Sennrich et al., 2016) with 32K merge operations[2]. We used case-sensitive NIST BLEU score (Papineni et al., 2002) as the evaluation metric, and *bootstrap resampling* (Koehn et al., 2003) for statistical significance test.

We implemented the proposed approaches on top of the Transformer model (Vaswani et al., 2017). Both in our model and related model of Subsection 5.3, the RNN is implemented with GRU (Cho et al., 2014) for fair comparison. We followed the configurations in Vaswani et al. (2017), and reproduced their reported results on the En⇒De task.

We initialized parameters of the proposed models by the pre-trained baseline model. We have tested both *Base* and *Big* models, which differ at hidden size (512 vs. 1024), filter size (2048 vs. 4096), and number of attention heads (8 vs. 16). In consideration of computation cost, we studied model variations with *Base* model on En⇒De task, and evaluated overall performances with both *Base* and *Big* models on both En⇒De and Zh⇒En translation tasks.

5.2 Impact of Components

In this subsection, we conducted ablation studies to evaluate the different implementations of the proposed model, e.g., recurrence encoder and integration strategy, under the proposed architecture.

Effect of Recurrence Modeling We first investigated the effect of recurrence encoder implementations, as listed in Table 1. We observed that introducing an additional recurrence encoder improves translation performance in all cases. Among all model variations, BiARN outperforms its BiRNN counterpart.

Model	Rec. Encoder	Speed	BLEU
Base	n/a	1.28	27.31
Ours	6-Layer BiRNN	1.10	27.54
	6-Layer BiARN	1.09	27.72
	3-Layer BiARN	1.15	28.10
	1-Layer BiARN	1.24	**28.21**

Table 1: Evaluation of recurrence encoder implementations. The output of recurrence encoder is fed to the top decoder layer in a stack fusion. "Speed" denotes the training speed (steps/second).

Model	Integration	to Dec.	BLEU
Base	n/a	n/a	27.31
Ours	Gated Sum	Top	28.12
	Gated Sum	All	28.02
	Stack	Top	**28.21**
	Stack	All	27.93

Table 2: Evaluation of decoder integration strategies.

Concerning BiARN models, reducing the layers consistently improves performance. Specifically, the 1-Layer BiARN achieves the best performances in both translation quality and training speed. This confirms the claim that the proposed approach benefits from a *short-cut* on gradient back-propagation. Accordingly, we adopted 1-Layer BiARN as the default setting in the following experiments.

Effect of Integration Strategies We then tested the effect of different integration strategies, as showed in Table 2. We have two observations. First, feeding only to the top decoder layer consistently outperforms feeding to all decoder layers with different integration strategies. This empirically reconfirms the short-cut effect. Second, the stack strategy marginally outperforms its gated sum counterpart. Therefore, in the following experiments, we adopted the "Stack + Top" model in Table 2 as defaulting setting.

5.3 Results

Performances across Languages Finally, we evaluated the proposed approach on the widely used WMT17 Zh⇒En and WMT14 En⇒De data, as listed in Table 3.

To make the evaluation convincing, we reviewed the prior reported systems, and built strong

baselines which outperform the reported results on the same data. As seen in Table 3, modeling recurrence consistently improves translation performance across model variations (BASE and BIG models) and language pairs (Zh⇒En and En⇒De), demonstrating the effectiveness and universality of our approach.

Comparison with Previous Work In order to directly compare our approach with the previous work on modeling recurrence, we re-implemented their approaches on top of the TRANSFORMER-BASE in WMT14 En⇒De translation task. For relative position encoding, we used unique edge representations per layer and head with clipping distance $k = 16$. For the DiSAN strategy, we applied a mask to the TRANSFORMER encoder, which constrains the SAN to focus on forward or backward elements. For the multi-column encoder, we re-implemented the additional encoder with six RNN layers.

Table 4 lists the results. As seen, all the recurrence enhanced approaches achieve improvements over the baseline model TRANSFORMER-BASE, which demonstrates the necessity of modeling recurrence for TRANSFORMER. Among these approaches, our approach (*i.e.,* 1-Layer BIARN Encoder) achieves the best performance.

5.4 Analysis

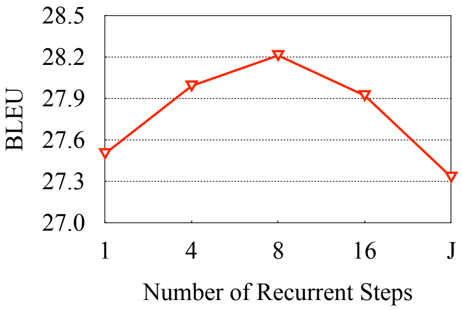

Figure 5: Effect of recurrent steps. The recurrence encoder is implemented as a single-layer BIARN. J denotes the length of the input sequence.

Effect of Recurrent Steps To verify the recurrence effect on the proposed model, we conducted experiments with different recurrent steps on single-layer BIARN model. As shown in Figure 5, the BLEU score typically goes up with the increase of the recurrent steps, while the trend does not hold when $T > 8$. This finding is consistent with Yang et al. (2016), which indicates that conducting too many recurrent steps fails to generate a compact representation. This is exactly one of the ARN's strengths.

Table 5: Classification accuracies on 10 probing tasks of evaluating linguistics embedded in the encoder outputs.

Linguistic Analyses In this section, we conducted 10 probing tasks[3] to study what linguistic properties are captured by the encoders (Conneau et al., 2018). A probing task is a classification problem that focuses on simple linguistic properties of sentences. 'SeLen' predicts the length of sentences in terms of number of words. 'WC' tests whether it is possible to recover information about the original words given its sentence embedding. 'TrDep' checks whether an encoder infers the hierarchical structure of sentences. In 'ToCo' task, sentences should be classified in terms of the sequence of top constituents immediately below the sentence node. 'BShif' tests whether two consecutive tokens within the sentence have been inverted. 'Tense' asks for the tense of the main-clause verb. 'SubN' focuses on the number of the main clause's subject. 'ObjN' tests for the number of the direct object of the main clause. In 'SoMo', some sentences are modified by replacing a random noun or verb with another one and the classifier should tell whether a sentence has been modified. 'CoIn' contains sentences made of two coordinate clauses. Half of sentences are inverted the order of the clauses and the task is to tell whether a sentence is intact or modified.

We used the pre-trained encoders of model variations in Table 1 to generate the sentence representations of input, which are used to carry out probing tasks. For the TRANSFORMER-BASE model, the mean of the encoder top layer representations is used as the sentence representation. For the proposed models, which have two encoders, two sentence representations are generated from the same way in base model. To make full use of the learned representations, we combined these two sentence representations via a gate as the final sentence representation to conduct the experiments.

Table 5 lists the results. Clearly, the proposed models significantly improve the classification accuracies, although there is still considerable difference among different variants. More specifically,

- Concerning surface properties, among the ARN variants, multi-layer ARN inversely decreases the accuracies, while 1-layer ARN consistently improves the accuracies. Considering the related results presented in Table 1 (Row 3-5), we believe that ARN benefits from the shallow structure.
- ARN tends to capture deeper linguistic properties, both syntactic and semantic. Especially, among these probing tasks, 'TrDep' and 'Toco' tasks are related to syntactic structure modeling. As expected, TRANSFORMER augmented with an additional encoders outperforms the baseline model, which demonstrates that the proposed models successfully model the syntactic structure.

6 Conclusion

In this work, we propose to directly model recurrence for Transformer with an additional recurrence encoder. We implement the recurrence encoder with a novel attentive recurrent network as well as RNN. The recurrence encoder is used to generate recurrence representations for the input sequence. To effectively feed the recurrence representations to the decoder to guide the output sequence generation, we study two strategies to integrate the recurrence encoder into the Transformer. To evaluate the effectiveness of the proposed model, we conduct experiments on large-scale WMT14 EN⇒DE and WMT17 ZH⇒EN datasets. Experimental results on two language pairs show that the proposed model achieves significant improvements over the baseline TRANSFORMER. Linguistic analyses on probing tasks

further show that our model indeed generates more informative representations, especially representative on syntactic structure features.

Future work includes validating the proposed model in other tasks, such as reading comprehension, language inference, and sentence classification. Another promising direction is to directly augment Transformer encoder on recurrence modeling without the additional encoder.

Abstract

Defining action spaces for conversational agents and optimizing their decision-making process with reinforcement learning is an enduring challenge. Common practice has been to use handcrafted dialog acts, or the output vocabulary, e.g. in neural encoder decoders, as the action spaces. Both have their own limitations. This paper proposes a novel latent action framework that treats the action spaces of an end-to-end dialog agent as latent variables and develops unsupervised methods in order to induce its own action space from the data. Comprehensive experiments are conducted examining both continuous and discrete action types and two different optimization methods based on stochastic variational inference. Results show that the proposed latent actions achieve superior empirical performance improvement over previous word-level policy gradient methods on both DealOrNoDeal and MultiWoz dialogs. Our detailed analysis also provides insights about various latent variable approaches for policy learning and can serve as a foundation for developing better latent actions in future research. [1]

1 Introduction

Optimizing dialog strategies in multi-turn dialog models is the cornerstone of building dialog systems that more efficiently solve real-world challenges, e.g. providing information (Young, 2006), winning negotiations (Lewis et al., 2017), improving engagement (Li et al., 2016) etc. A classic solution employs reinforcement learning (RL) to learn a dialog policy that models the optimal action distribution conditioned on the dialog state (Williams and Young, 2007). However, since there are infinite human language possibilities, an enduring challenge has been to define what the action space is. For traditional modular systems, the action space is defined by hand-crafted semantic representations such as dialog acts and slot-values (Raux et al., 2005; Chen et al., 2013) and the goal is to obtain a dialog policy that chooses the best hand-crafted action at each dialog turn. But it is limited because it can only handle simple domains whose entire action space can be captured by hand-crafted representations (Walker, 2000; Su et al., 2017). This cripples a system's ability to handle conversations in complex domains.

Conversely, end-to-end (E2E) dialog systems have removed this limit by directly learning a response generation model conditioned on the dialog context using neural networks (Vinyals and Le, 2015; Sordoni et al., 2015). To apply RL to E2E systems, the action space is typically defined as the entire vocabulary; every response output word is considered to be an action selection step (Li et al., 2016), which we denote as the word-level RL. Word-level RL, however, has been shown to have several major limitations in learning dialog strategies. The foremost one is that direct application of word-level RL leads to degenerate behavior: the response decoder deviates from human language and generates utterances that are incomprehensible (Lewis et al., 2017; Das et al., 2017; Kottur et al., 2017). A second issue is that since a multi-turn dialog can easily span hundreds of words, word-level RL suffers from credit assignment over a long horizon, leading to slow and suboptimal convergence (Kaelbling et al., 1996; He et al., 2018).

This paper proposes Latent Action Reinforcement Learning (LaRL), a novel framework that overcomes the limitations of word-level RL for E2E dialog models, marrying the benefits of a traditional modular approach in an unsupervised manner. The key idea is to develop E2E models that can invent their own discourse-level ac-

Proceedings of NAACL-HLT 2019, pages 1208–1218
Minneapolis, Minnesota, June 2 - June 7, 2019.

tions. These actions must be expressive enough to capture response semantics in complex domains (i.e. have the capacity to represent a large number of actions), thus decoupling the discourse-level decision-making process from natural language generation. Then any RL technique can be applied to this induced action space in the place of word-level output. We propose a flexible latent variable dialog framework and investigate several approaches to inducing latent action space from natural conversational data. We further propose (1) a novel training objective that outperforms the typical evidence lower bound used in dialog generation and (2) an attention mechanism for integrating discrete latent variables in the decoder to better model long responses.

We test this on two datasets, DealOrNoDeal (Lewis et al., 2017) and MultiWoz (Budzianowski et al., 2018), to answer two key questions: (1) what are the advantages of LaRL over Word-level RL and (2) what effective methods can induce this latent action space. Results show that LaRL is significantly more effective than word-level RL for learning dialog policies and it does not lead to incomprehensible language generation. Our models achieve 18.2% absolute improvement over the previous state-of-the-art on MultiWoz and discover novel and diverse negotiation strategies on DealOrNoDeal. Besides strong empirical improvement, our model analysis reveals novel insights, e.g. it is crucial to reduce the exposure bias in the latent action space and discrete latent actions are more suitable than continuous ones to serve as action spaces for RL dialog agents.

2 Related Work

Prior RL research in modular dialog management has focused on policy optimization over hand-crafted action spaces in task-oriented domains (Walker, 2000; Young et al., 2007). A dialog manager is formulated as a Partially Observable Markov Decision Process (POMDP) (Young et al., 2013), where the dialog state is estimated via dialog state tracking models from the raw dialog context (Lee, 2013; Henderson et al., 2014; Ren et al., 2018). RL techniques are then used to find the optimal dialog policy (Gasic and Young, 2014; Su et al., 2017; Williams et al., 2017). Recent deep-learning modular dialog models have also explored joint optimization over dialog policy and state tracking to achieve stronger performance (Wen et al., 2016; Zhao and Eskenazi, 2016; Liu and Lane, 2017).

A related line of work is reinforcement learning for E2E dialog systems. Due to the flexibility of encoder-decoder dialog models, prior work has applied reinforcement learning to more complex domains and achieved higher dialog-level rewards, such as open-domain chatting (Li et al., 2016; Serban et al., 2017a), negotiation (Lewis et al., 2017), visual dialogs (Das et al., 2017), grounded dialog (Mordatch and Abbeel, 2017) etc. As discussed in Section 1, these methods consider the output vocabulary at every decoding step to be the action space; they suffer from limitations such as deviation from natural language and sub-optimal convergence.

Finally, research in latent variable dialog models is closely related to our work, which strives to learn meaningful latent variables for E2E dialog systems. Prior work has shown that learning with latent variables leads to benefits like diverse response decoding (Serban et al., 2017b; Zhao et al., 2017; Cao and Clark, 2017), interpretable decision-making (Wen et al., 2017; Zhao et al., 2018) and zero-shot domain transfer (Zhao and Eskenazi, 2018). Also, driven by similar motivations of this work, prior studies have explored to utilize a coarse discrete node, either handcrafted or learned, to decouple the word generation process from dialog policy in E2E systems for better dialog policy (He et al., 2018; Yarats and Lewis, 2017). Our work differs from prior work for two reasons: (1) latent action in previous work is only auxiliary, small-scale and mostly learned in a supervised or semi-supervised setting. This paper focuses on unsupervised learning of latent variables and learns variables that are expressive enough to capture the entire action space by itself. (2) to our best knowledge, our work is the first comprehensive study of the use of latent variables for RL policy optimization in dialog systems.

3 Baseline Approach

E2E response generation can be treated as a conditional language generation task, which uses neural encoder-decoders (Cho et al., 2014) to model the conditional distribution $p(\mathbf{x}|\mathbf{c})$ where $\mathbf{c}$ is the observed dialog context and $\mathbf{x}$ is the system's response to the context. The format of the dialog context is domain dependent. It can vary from tex-

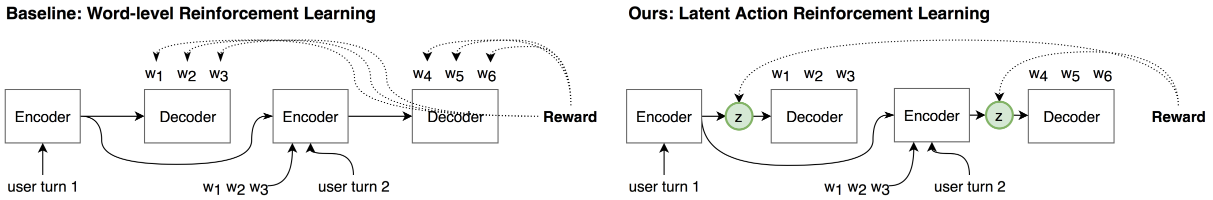

Figure 1: High-level comparison between word-level and latent-action reinforcement learning in a sample multi-turn dialog. The decoder network generates the response given the latent code $\mathbf{z}$. Dashed line denotes places where policy gradients from task rewards are applied to the model.

tual raw dialog history (Vinyals and Le, 2015) to visual and textual context (Das et al., 2017). Training with RL usually has 2 steps: supervised pretraining and policy gradient reinforcement learning (Williams and Zweig, 2016; Dhingra et al., 2017; Li et al., 2016). Specifically, the supervised learning step maximizes the log likelihood on the training dialogs, where θ is the model parameter:

$$\mathcal{L}_{SL}(\theta) = \mathbb{E}_{\mathbf{x},\mathbf{c}}[\log p_\theta(\mathbf{x}|\mathbf{c})] \tag{1}$$

Then the following RL step uses policy gradients, e.g. the REINFORCE algorithm (Williams, 1992) to update the model parameters with respect to task-dependent goals. We assume that we have an environment that the dialog agent can interact with and that there is a turn-level reward r_t at every turn t of the dialog. We can then write the expected discounted return under a dialog model θ as $J(\theta) = \mathbb{E}[\sum_0^T \gamma^t r_t]$, where $\gamma \in [0, 1]$ is the discounting factor and T is the length of the dialog. Often a baseline function b is used to reduce the variance of the policy gradient (Greensmith et al., 2004), leading to $R_t = \sum_{k=0}^{T-t} \gamma^k (r_{t+k} - b)$.

Word-level Reinforcement Learning: as shown in Figure 1, the baseline approach treats every output word as an action step and its policy gradient is:

$$\nabla_\theta J(\theta) = \mathbb{E}_\theta[\sum_{t=0}^{T}\sum_{j=0}^{U_t} R_{tj} \nabla_\theta \log p_\theta(w_{tj}|w_{<tj}, \mathbf{c}_t)] \tag{2}$$

where U_t is the number of tokens in the response at turn t and j is the word index in the response. It is evident that Eq 2 has a very large action space, i.e. $|V|$ and a long learning horizon, i.e. TU. Prior work has found that the direct application of Eq 2 leads to divergence of the decoder. The common solution is to alternate with supervised learning with Eq 2 at a certain ratio (Lewis et al., 2017). We denote this ratio as RL:SL=A:B, which means for every A policy gradient updates, we run B supervised learning updates. We use RL:SL=off for the case where only policy gradients are used and no supervised learning is involved.

4 Latent Action Reinforcement Learning

We now describe the proposed LaRL framework. As shown in Figure 1, a latent variable $\mathbf{z}$ is introduced in the response generation process. The conditional distribution is factorized into $p(\mathbf{x}|\mathbf{c}) = p(\mathbf{x}|\mathbf{z})p(\mathbf{z}|\mathbf{c})$ and the generative story is: (1) given a dialog context $\mathbf{c}$ we first sample a latent action $\mathbf{z}$ from $p_{\theta_e}(\mathbf{z}|\mathbf{c})$ and (2) generate the response by sampling $\mathbf{x}$ based on $\mathbf{z}$ via $p_{\theta_d}(\mathbf{x}|\mathbf{z})$, where p_{θ_e} is the dialog encoder network and p_{θ_d} is the response decoder network. Given the above setup, LaRL treats the latent variable $\mathbf{z}$ as its action space instead of outputting words in response $\mathbf{x}$. We can now apply REINFORCE in the latent action space:

$$\nabla_\theta J(\theta) = \mathbb{E}_\theta[\sum_{t=0}^{T} R_t \log p_\theta(\mathbf{z}|\mathbf{c}_t)] \tag{3}$$

Compared to Eq 2, LaRL differs by:

- Shortens the horizon from TU to T.
- Latent action space is designed to be low-dimensional, much smaller than V.
- The policy gradient only updates the encoder θ_e and the decoder θ_d stays intact.

These properties reduce the difficulties for dialog policy optimization and decouple high-level decision-making from natural language generation. The p_{θ_e} are responsible for choosing the best latent action given a context $\mathbf{c}$ while p_{θ_d} is only responsible for transforming $\mathbf{z}$ into the surface-form words. Our formulation also provides a flexible framework for experimenting with various types of model learning methods. In this paper, we focus on two key aspects: the type of latent variable

$\mathbf{z}$ and optimization methods for learning $\mathbf{z}$ in the supervised pre-training step.

4.1 Types of Latent Actions

Two types of latent variables have been used in previous research: continuous isotropic Gaussian distribution (Serban et al., 2017b) and multivariate categorical distribution (Zhao et al., 2018). These two types are both compatible with our LaRL framework and can be defined as follows:

Gaussian Latent Actions follow M dimensional multivariate Gaussian distribution with a diagonal covariance matrix, i.e. $\mathbf{z} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma}^2\mathbf{I})$. Let the encoder p_{θ_e} consist of two parts: a context encoder $\mathcal{F}$, a neural network that encodes the dialog context $\mathbf{c}$ into a vector representation $\mathbf{h}$, and a feed forward network π that projects $\mathbf{h}$ into $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$. The process is defined as follows:

$$\mathbf{h} = \mathcal{F}(\mathbf{c}) \tag{4}$$

$$\begin{bmatrix}\boldsymbol{\mu} \\ \log(\boldsymbol{\sigma}^2)\end{bmatrix} = \pi(\mathbf{h}) \tag{5}$$

$$p(\mathbf{x}|\mathbf{z}) = p_{\theta_d}(\mathbf{z}) \quad \mathbf{z} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma}^2\mathbf{I}) \tag{6}$$

where the sampled $\mathbf{z}$ is used as the initial state of the decoder for response generation. Also we use $p_\theta(\mathbf{z}|\mathbf{c}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \boldsymbol{\sigma}^2\mathbf{I})$ to compute the policy gradient update in Eq 3.

Categorical Latent Actions are M independent K-way categorical random variables. Each $\mathbf{z}_m$ has its own token embeddings to map latent symbols into vector space $\mathbf{E}_m \in \mathbb{R}^{K \times D}$ where $m \in [1, M]$ and D is the embedding size. Thus M latent actions can represent exponentially, K^M, unique combinations, making it expressive enough to model dialog acts in complex domains. Similar to Gaussian Latent Actions, we have

$$\mathbf{h} = \mathcal{F}(\mathbf{c}) \tag{7}$$

$$p(Z_m|\mathbf{c}) = \text{softmax}(\pi_m(\mathbf{h})) \tag{8}$$

$$p(\mathbf{x}|\mathbf{z}) = p_{\theta_d}(\mathbf{E}_{1:M}(\mathbf{z}_{1:M})) \quad \mathbf{z}_m \sim p(Z_m|\mathbf{c}) \tag{9}$$

For the computing policy gradient in Eq 3, we have $p_\theta(\mathbf{z}|\mathbf{c}) = \prod_{m=1}^{M} p(Z_m = \mathbf{z}_m|\mathbf{c})$

Unlike Gaussian latent actions, a matrix $\mathbb{R}^{M \times D}$ comes after the embedding layers $\mathbf{E}_{1:M}(\mathbf{z}_{1:M})$, whereas the decoder's initial state is a vector of size $\mathbb{R}^D$. Previous work integrated this matrix with the decoder by summing over the latent embeddings, i.e. $\mathbf{x} = p_{\theta_d}(\sum_1^M \mathbf{E}_m(\mathbf{z}_m))$, denoted as **Summation Fusion** for later discussion (Zhao et al., 2018). A limitation of this method is that it could lose fine-grained order information in each latent dimension and have issues with long responses that involve multiple dialog acts. Therefore, we propose a novel method, **Attention Fusion**, to combine categorical latent actions with the decoder. We apply the attention mechanism (Luong et al., 2015) over latent actions as the following. Let i be the step index during decoding. Then we have:

$$\alpha_{mi} = \text{softmax}(\mathbf{h}_i^T \mathbf{W}_a \mathbf{E}_m(\mathbf{z}_m)) \tag{10}$$

$$\mathbf{c}_i = \sum_{m=1}^{M} \alpha_{mi} \mathbf{E}_m(\mathbf{z}_m) \tag{11}$$

$$\widetilde{\mathbf{h}}_i = \tanh(\mathbf{W}_s \begin{bmatrix}\mathbf{h}_i \\ \mathbf{c}_i\end{bmatrix}) \tag{12}$$

$$p(w_i|\mathbf{h}_i, \mathbf{c}_i) = \text{softmax}(W_o \widetilde{\mathbf{h}}_i) \tag{13}$$

The decoder's next state is updated by $\mathbf{h}_{i+1} = \text{RNN}(\mathbf{h}_i, w_{i+1}), \widetilde{\mathbf{h}}_i)$ and $\mathbf{h}_0$ is computed via summation-fusion. Thus attention fusion lets the decoder focus on different latent dimensions at each generation step.

4.2 Optimization Approaches

Full ELBO: Now given a training dataset $\{\mathbf{x}, \mathbf{c}\}$, our base optimization method is via stochastic variational inference by maximizing the evidence lowerbound (ELBO), a lowerbound on the data log likelihood:

$$\mathcal{L}_{full}(\theta) = p_{q(\mathbf{z}|\mathbf{x},\mathbf{c})}(\mathbf{x}|\mathbf{z}) - \text{D}_{\text{KL}}[q(\mathbf{z}|\mathbf{x}, \mathbf{c})\|p(\mathbf{z}|\mathbf{c})] \tag{14}$$

where $q_\gamma(\mathbf{z}|\mathbf{x}, \mathbf{c})$ is a neural network that is trained to approximate the posterior distribution $q(\mathbf{z}|\mathbf{x}, \mathbf{c})$ and $p(\mathbf{z}|\mathbf{c})$ and $p(\mathbf{x}|\mathbf{z})$ are achieved by $\mathcal{F}$, π and p_{θ_d}. For Gaussian latent actions, we use the reparametrization trick (Kingma and Welling, 2013) to backpropagate through Gaussian latent actions and the Gumbel-Softmax (Jang et al., 2016) to backpropagate through categorical latent actions.

Lite ELBO: a major limitation is that Full ELBO can suffer from exposure bias at latent space, i.e. the decoder only sees $\mathbf{z}$ sampled from $q(\mathbf{z}|\mathbf{x}, \mathbf{c})$ and never experiences $\mathbf{z}$ sampled from $p_\theta(\mathbf{z}|\mathbf{c})$, which is always used at testing time. Therefore, in this paper, we propose a simplified ELBO for encoder-decoder models with stochastic latent variables:

$$\mathcal{L}_{lite}(\theta) = p_{p(\mathbf{z}|\mathbf{c})}(\mathbf{x}|\mathbf{z}) - \beta \text{D}_{\text{KL}}[p(\mathbf{z}|\mathbf{c}))\|p(\mathbf{z})] \tag{15}$$

Essentially this simplified objective sets the posterior network the same as our encoder, i.e. $q_\gamma(\mathbf{z}|\mathbf{x},\mathbf{c}) = p_{\theta_e}(\mathbf{z}|\mathbf{c})$, which makes the KL term in Eq 14 zero and removes the issue of exposure bias. But this leaves the latent spaces unregularized and our experiments show that if we only maximize $p_{p(\mathbf{z}|\mathbf{c})}(\mathbf{x}|\mathbf{z})$ there is overfitting. For this, we add the additional regularization term $\beta \mathrm{D}_{\mathrm{KL}}[p(\mathbf{z}|\mathbf{c}))\|p(\mathbf{z})]$ that encourages the posterior be similar to certain prior distributions and β is a hyper-parameter between 0 and 1. We set the $p(\mathbf{z})$ for categorical latent actions to be uniform, i.e. $p(\mathbf{z}) = 1/K$, and set the prior for Gaussian latent actions to be $\mathcal{N}(\mathbf{0},\mathbf{I})$, which we will show that are effective.

5 Experiment Settings

5.1 DealOrNoDeal Corpus and RL Setup

DealOrNoDeal is a negotiation dataset that contains 5805 dialogs based on 2236 unique scenarios (Lewis et al., 2017). We hold out 252 scenarios for testing environment and randomly sample 400 scenarios from the training set for validation. The results are evaluated from 4 perspectives: Perplexity (PPL), Reward, Agree and Diversity. PPL helps us to identify which model produces the most human-like responses, while Reward and Agree evaluate the model's negotiation strength. Diversity indicates whether the model discovers a novel discourse-level strategy or just repeats dull responses to compromise with the opponent. We closely follow the original paper and use the same reward function and baseline calculation. At last, to have a fair comparison, all the compared models shared the identical judge model and user simulator, which are a standard hierarchical encoder-decoder model trained with Maximum Likelihood Estimation (MLE).

5.2 Multi-Woz Corpus and Novel RL Setup

Multi-Woz is a slot-filling dataset that contains 10438 dialogs on 6 different domains. 8438 dialogs are for training and 1000 each are for validation and testing. Since no prior user simulator exists for this dataset, for a fair comparison with the previous state-of-the-art we focus on the Dialog-Context-to-Text Generation task proposed in (Budzianowski et al., 2018). This task assumes that the model has access to the ground-truth dialog belief state and is asked to generate the next response at every system turn in a dialog. The results are evaluated from 3 perspectives: BLEU, Inform Rate and Success Rate. The BLEU score checks the response-level lexical similarity, while Inform and Success Rate measure whether the model gives recommendations and provides all the requested information at dialog-level. Current state-of-the-art results struggle in this task and MLE models only achieve 60% success (Budzianowski et al., 2018). To transform this task into an RL task, we propose a novel extension to the original task as follows:

1. For each RL episode, randomly sample a dialog from the training set
2. Run the model on every system turn, and do not alter the original dialog context at every turn given the generated responses.
3. Compute Success Rate based on the generated responses in this dialog.
4. Compute policy gradient using Eq 3 and update the parameters.

This setup creates a variant RL problem that is similar to the Contextual Bandits (Langford and Zhang, 2008), where the goal is to adjust its parameters to generate responses that yield better Success Rate. Our results show that this problem is challenging and that word-level RL falls short.

5.3 Language Constrained Reward (LCR) curve for Evaluation

It is challenging to quantify the performance of RL-based neural generation systems because it is possible for a model to achieve high task reward and yet not generate human language (Das et al., 2017). Therefore, we propose a novel measure, the Language Constrained Reward (LCR) curve as an additional robust measure. The basic idea is to use an ROC-style curve to visualize the tradeoff between achieving higher reward and being faithful to human language. Specifically, at each checkpoint i over the course of RL training, we record two measures: (1) the PPL of a given model on the test data $p_i = \mathrm{PPL}(\theta_i)$ and (2) this model's average cumulative task reward in the test environment R_i^t. After RL training is complete, we create a 2D plot where the x-axis is the maximum PPL allowed, and the y-axis is the best achievable reward within the PPL budget in the testing environments:

$$y = \max_i R_i^t \quad \text{subject to} \quad p_i < x \tag{16}$$

As a result, a perfect model should lie in the upper left corner whereas a model that sacrifices language quality for higher reward will lie in the lower right corner. Our results will show that the LCR curve is an informative and robust measure for model comparison.

6 Results: Latent Actions or Words?

We have created 6 different variations of latent action dialog models under our LaRL framework. To demonstrate the advantages of LaRL, during the RL training step, we set RL:SL=off for all latent action models, while the baseline word-level RL models are free to tune RL:SL for best performance. For latent variable models, their perplexity is estimated via Monte Carlo $p(\mathbf{x}|\mathbf{c}) \approx \mathbb{E}_{p(\mathbf{z}|\mathbf{c})}[p(\mathbf{x}|\mathbf{z})p(\mathbf{z}|\mathbf{c})]$. For the sake of clarity, this section only compares the best performing latent action models to the best performing word-level models and focuses on the differences between them. A detailed comparison of the 6 latent space configurations is addressed in Section 7.

6.1 DealOrNoDeal

The baseline system is a hierarchical recurrent encoder-decoder (HRED) model (Serban et al., 2016) that is tuned to reproduce results from (Lewis et al., 2017). Word-level RL is then used to fine-tune the pre-trained model with RL:SL=4:1. On the other hand, the best performing latent action model is LiteCat. Best models are chosen based on performance on the validation environment.

The results are summarized in Table 2 and Figure 2 shows the LCR curves for the baseline with the two best models plus LiteAttnCat and baseline without RL:SL. From Table 2, it appears that the word-level RL baseline performs better than LiteCat in terms of rewards. However, Figure 2 shows that the two LaRL models achieve strong task rewards with a much smaller performance drop in language quality (PPL), whereas the word-level model can only increase its task rewards by deviating significantly from natural language.

	PPL	Reward	Agree%	Diversity
Baseline	5.23	3.75	59	109
LiteCat	5.35	2.65	41	58
Baseline +RL	8.23	**7.61**	86	5
LiteCat +RL	**6.14**	7.27	**87**	**202**

Table 2: Results on DealOrNoDeal. Diversity is measured by the number of unique responses the model used in all scenarios from the test data.

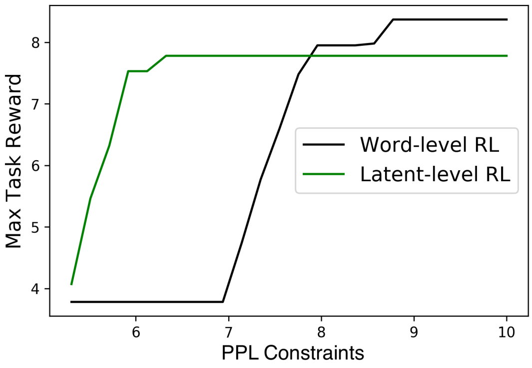

Figure 2: LCR curves on DealOrNoDeal dataset.

Closer analysis shows the word-level baseline severely overfits to the user simulator. The caveat is that the word-level models have in fact discovered a loophole in the simulator by insisting on 'hat' and 'ball' several times and the user model eventually yields to agree to the deal. This is reflected in the diversity measure, which is the number of unique responses that a model uses in all 200 testing scenarios. As shown in Figure 3, after RL training, the diversity of the baseline model drops to only 5. It is surprising that the agent can achieve high reward with a well-trained HRED user simulator using only 5 unique utterances. On the contrary, LiteCat increases its response diversity after RL training from 58 to 202, suggesting that LiteCat discovers novel discourse-level strategies in order to win the negotiation instead of exploiting local loopholes in the same user simulator. Our qualitative analysis confirms this when we observe that our LiteCat model is able to use multiple strategies in negotiation, e.g. elicit preference question, request different offers, insist on key objects etc. See supplementary material for example conversations.

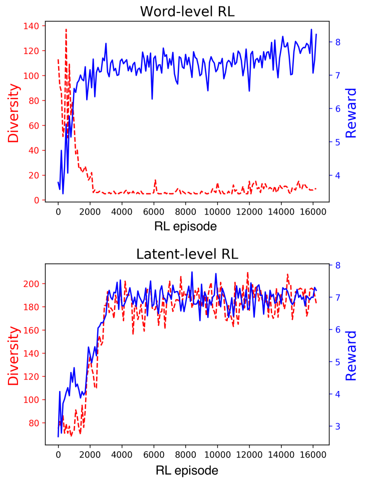

Figure 3: Response diversity and task reward learning curve over the course of RL training for both word RL:SL=4:1 (left) and LiteCat (right).

6.2 MultiWoz

For MultiWoz, we reproduce results from (Budzianowski et al., 2018) as the baseline. After RL training, the best LaRL model is LiteAttnCat and the best word-level model is word RL:SL=off. Table 3 shows that LiteAttnCat is on par with the baseline in the supervised learning step, showing that multivariate categorical latent variables alone are powerful enough to match with continuous hidden representations for modeling dialog actions. For performance after RL training, LiteAttnCat achieves near-human performance in terms of success rate and inform rate, obtaining 18.24% absolute improvement over the MLE-based state-of-the-art (Budzianowski et al., 2018). More importantly, perplexity only slightly increases from 4.05 to 5.22. On the other hand, the word-level RL's success rate also improves to 79%, but the generated responses completely deviate from natural language, increasing perplexity from 3.98 to 17.11 and dropping BLEU from 18.9 to 1.4.

	PPL	BLEU	Inform	Success
Human	/	/	90%	82.3%
Baseline	3.98	18.9	71.33%	60.96%
LiteAttnCat	4.05	19.1	67.98%	57.36%
Baseline +RL	17.11	1.4	80.5%	79.07%
LiteAttnCat +RL	**5.22**	**12.8**	**82.78%**	**79.2%**

Table 3: Main results on MultiWoz test set. RL models are chosen based on performance on the validation set.

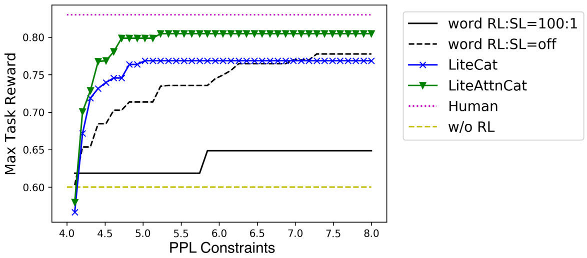

Figure 4: LCR curves on the MultiWoz dataset.

Figure 4 shows the LCR curves for MultiWoz, with a trend similar to the previous section: the word-level models can only achieve task reward improvement by sacrificing their response decoder PPL. Figure 4 also shows the LCR curve for the baseline trained with RL:SL=100:1, hoping that supervised learning can force the model to conform to natural language. While PPL and BLEU are indeed improved, it also limits final reward performance. The latent-level models, on the contrary, do not suffer from this tradeoff. We also observe that LiteAttnCat consistently outperforms LiteCat on MultiWoz, confirming the effectiveness of Attention Fusion for handling long dialog responses with multiple entities and dialog acts. Lastly, Table 4 qualitatively exhibits the generation differences between the two approaches. The RL:SL=off model learns to continuously output entities to fool the evaluation script for high success rate, whereas LiteCatAttn learns to give more information while maintaining the language quality.

Context	**Sys** I have [value_count] trains matching your request . Is there a specific day and time you would like to travel? **Usr** I would like to leave on [value_day] and arrive by [value_time].
Model	**Generated Response**
word RL:SL=off	[train_id] is leaving [value_place] on [value_day] on [value_day] on [train_id] [train_id] [value_count] [train_id] leaving ...
word RL:SL=100	[train_id] leaves at [value_time] . would you like me to book you a ticket ?
LiteAttnCat	[train_id] leaves [value_place] at [value_time] and arrives in [value_place] at [value_time]. Would you like me to book that for you ?

Table 4: Example responses from baselines and LiteCatAttn on MultiWoz.

7 Model Analysis

We compare the 6 variants of latent action models on DealOrNoDeal and MultiWoz. Table 5 shows performance of the models that are pre-trained only with supervised learning. Figure 5 shows LCR curves for the 3 models pre-trained with $\mathcal{L}_{lite}$ and fine-tuned with policy gradient reinforcement learning. The following are the main findings based on these results.

Deal	PPL	Reward	Agree%	Diversity
Baseline	3.23	3.75	59	109
Gauss	110K	2.71	43	176
LiteGauss	5.35	4.48	65	91
Cat	80.41	3.9	62	115
AttnCat	118.3	3.23	51	145
LiteCat	5.35	2.67	41	58
LiteAttnCat	5.25	3.69	52	75
MultiWoz	PPL	BLEU	Inform%	Succ%
Baseline	3.98	18.9	71.33	60.96
Gauss	712.3	7.54	60.5	23.0
LiteGauss	4.06	19.3	56.46	48.06
Cat	7.07	13.7	54.15	42.04
AttnCat	12.01	12.6	63.9	45.8
LiteCat	4.10	19.1	61.56	49.15
LiteAttnCat	4.05	19.1	67.97	57.36

Table 5: Comparison of 6 model variants with only supervised learning training.

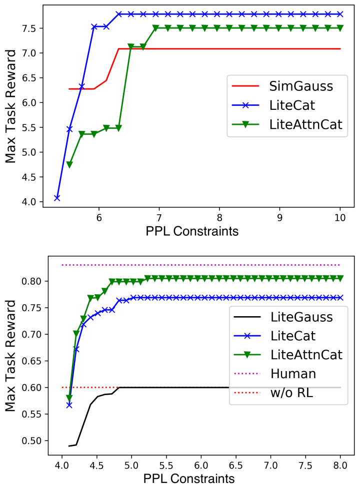

Figure 5: LCR curves on DealOrNoDeal and MultiWoz. Models with $\mathcal{L}_{full}$ are not included because their PPLs are too poor to compare to the Lite models.

$\mathcal{L}_{lite}$ outperforms $\mathcal{L}_{full}$ as a pre-train objective. Table 5 shows that models with $\mathcal{L}_{full}$ fall behind their Lite counterparts on PPL and BLEU. We attribute this to the exposure bias in the latent space, i.e. the decoder is not trained to consider the discrepancy between the posterior network and actual dialog policy network. Meanwhile, the full models tend to enjoy higher diversity at pre-training, which agrees with the diversity-promoting effect observed in prior research (Zhao et al., 2017). However, our previous discussion on Figure 3 shows that Lite models are able to increase their response diversity in order to win more in negotiation through RL training. This is fundamentally different from diversity in pre-training, since diversity in LaRL is optimized to improve task reward, rather than to better model the original data distribution. Table 6 shows the importance of latent space regularization. When β is 0, both LiteCat and LiteGauss reach suboptimal policies with final reward that are much smaller than the regularized versions ($\beta = 0.01$). The reason behind this is that the unregularized pre-trained policy has very low entropy, which prohibits sufficient exploration in the RL stage.

β	0.0	0.01	β	0.0	0.01
LiteCat	4.23	7.27	LiteGauss	4.83	6.67

Table 6: Best rewards in test environments on DealOrNoDeal with various β.

Categorical latent actions outperform Gaussian latent actions. Models with discrete actions consistently outperform models with Gaussian ones. This is surprising since continuously distributed representations are a key reason for the success of deep learning in natural language processing. Our finding suggests that (1) multivariate categorical distributions are powerful enough to model complex natural dialog responses semantics, and can achieve on par results with Gaussian or non-stochastic continuous representations. (2) categorical variables are a better choice to serve as action spaces for reinforcement learning. Figure 5 shows that Lite(Attn)Cat easily achieves strong rewards while LiteGauss struggles to improve its reward. Also, applying REINFORCE on Gaussian latent actions is unstable and often leads to model divergence. We suspect the reason for this is the unbounded nature of continuous latent space: RL exploration in the continuous space may lead to areas in the manifold that are not covered in supervised training, which causes undefined decoder behavior given $\mathbf{z}$ in these unknown areas.

8 Conclusion and Future Work

In conclusion, this paper proposes a latent variable action space for RL in E2E dialog agents. We present a general framework with a regularized ELBO objective and attention fusion for discrete variables. The methods are assessed on two dialog tasks and analyzed using the proposed LCR curve. Results show our models achieve superior performance and create a new state-of-the-art success rate on MultiWoz. Extensive analyses enable us to gain insight on how to properly train latent variables that can serve as the action spaces for dialog agents. This work is situated in the approach concerning practical latent variables in dialog agents, being able to create action abstraction in an unsupervised manner. We believe that our findings are a basic first step in this promising research direction.

A.2 DealOrNoDeal Example Conversations

The followings are examples dialogs generated from word-level models (Table 9) and latent-level models (Table 10).

Scenario 1
1 book, 1 hat and 3 balls available.
Value Function
Agent: book=1, hat=6, ball=1.
User: book=1, hat=6, ball=1.
Dialog
Agent: I'd like the hat and 2 balls.
User: Deal.
Agent: SELECTION
Outcome: Agreement
Agent: 1 hat and 2 balls; User: 1 book and 1 ball
Agent reward = 8; User reward = 2
Scenario 2
4 books, 1 hat and 1 ball available.
Value Function
Agent: book=0, hat=7, ball=3;
User: book=1, hat=6, ball=0.
Dialog
User: I can offer you 1 hat and 2 books.
Agent: I need the hat and ball.
User: That won't work for me. I can offer you one book and the hat.
Agent: I need the hat and ball.
User: I have to have the hat.
Agent: I need the hat and ball.
User: Okay.
Agent: SELECTION
Outcome: Agreement
Agent: 1 hat and 1 ball; User: 4 books
Agent reward = 10; User reward = 4

Table 9: Example dialogs between baseline with the user model. Agent is trained with word-level policy gradient and the user is a supervised pre-trained model.

Scenario 1
2 books, 2 hats and 1 ball available.
Value Function
Agent: book=3, hat=0, ball=4;
User: book=2, hat=3, ball=0.
Dialog
Agent: Can i have the books and one ball?
User: I would like the books and the hats then.
Agent: I would like the ball and books.
User: Deal.
Agent: SELECTION
Outcome: Agreement
Agent: 2 books and 1 ball
User: 2 hats
Agent reward = 10, User reward = 6
Scenario 2
2 books, 1 hat and 3 ball available.
Value Function
Agent: book=0, hat=4, ball=2;
User: book=3, hat=1, ball=1.
Dialog
Agent: I would like the hat and balls.
User: I cannot accept that. I need the hat and books.
Agent: Can I have the hat and balls, you get the rest?
User: Okay, deal.
Agent: SELECTION.
Outcome: Agreement
Agent: 1 hat and 3 ball
User: 2 books
Agent reward = 10, Simulator reward = 6

Table 10: Example dialogs between LiteCat and the user model. Agent is trained with latent-level policy gradient and the user is a supervised pre-trained model.

Skeleton-to-Response: Dialogue Generation Guided by Retrieval Memory

Abstract

Traditional generative dialogue models generate responses solely from input queries. Such information is insufficient for generating a specific response since a certain query could be answered in multiple ways. Recently, researchers have attempted to fill the information gap by exploiting information retrieval techniques. For a given query, similar dialogues are retrieved from the entire training data and considered as an additional knowledge source. While the use of retrieval may harvest extensive information, the generative models could be overwhelmed, leading to unsatisfactory performance. In this paper, we propose a new framework which exploits retrieval results via a skeleton-to-response paradigm. At first, a skeleton is extracted from the retrieved dialogues. Then, both the generated skeleton and the original query are used for response generation via a novel response generator. Experimental results show that our approach significantly improves the informativeness of the generated responses.

1 Introduction

This paper focuses on tackling the challenges to develop a chit-chat style dialogue system (also known as chatbot). Chit-chat style dialogue system aims at giving meaningful and coherent responses given a dialogue query in the open domain. Most modern chit-chat systems can be categorized into two categories, namely, information retrieval-based (IR) models and generative models.

The IR-based models (Ji et al., 2014; Hu et al., 2014) directly copy an existing response from a training corpus when receiving a response request. Since the training corpus is usually collected from real-world conversations and possibly post-edited by a human, the retrieved responses are informative and grammatical. However, the performance of such systems drops when a given dialogue history is substantially different from those in the training corpus.

The generative models (Shang et al., 2015; Vinyals and Le, 2015; Li et al., 2016a), on the other hand, generate a new utterance from scratch. While those generative models have better generalization capacity in rare dialogue contexts, the generated responses tend to be universal and non-informative (e.g., “I don’t know”, “I think so” etc.) (Li et al., 2016a). It is partly due to the diversity of possible responses to a single query (i.e., the *one-to-many* problem). The dialogue query alone cannot decide a meaningful and specific response. Thus a well-trained model tends to generate the most frequent (safe but boring) responses instead.

To summarize, IR-based models may give informative but inappropriate responses while generative models often do the opposite. It is desirable to combine both merits. Song et al. (2016) used an extra encoder for the retrieved response. The resulted dense representation, together with the original query, is used to feed the decoder in a standard SEQ2SEQ model (Bahdanau et al., 2014). Weston et al. (2018) used a single encoder that takes the concatenation of the original query and the retrieved as input. Wu et al. (2019) noted that the retrieved information should be used in awareness of the context difference, and further proposed to construct an edit vector by explicitly encoding the lexical differences between the input query and the retrieved query.

However, in our preliminary experiments, we found that the IR-guided models are inclined to degenerate into a copy mechanism, in which the generative models simply repeat the retrieved response without necessary modifications. Sharp performance drop is caused when the retrieved re-

Minneapolis, Minnesota, June 2 - June 7, 2019.

sponse is irrelevant to the input query. A possible reason is that both useful and useless information is mixed in the dense vector space, which is uninterpretable and uncontrollable.

To address the above issue, we propose a new framework, skeleton-to-response, for response generation. Our motivations are two folds: (1) The guidance from IR results should only specify a response aspect or pattern, but leave the query-specific details to be elaborated by the generative model itself; (2) The retrieval results typically contain excessive information, such as inappropriate words or entities. It is necessary to filter out irrelevant words and derive a useful skeleton before use.

Our approach consists of two components: a skeleton generator and a response generator. The skeleton generator extracts a response skeleton by detecting and removing unwanted words in a retrieved response. The response generator is responsible for adding query-specific details to the generated skeleton for query-to-response generation. A dialogue example illustrating our idea is shown in Fig. 1. Due to the discrete choice of skeleton words, the gradient in the training process is no longer differentiable from the response to the skeleton generator. Two techniques are proposed to solve this issue. The first technique is to employ the policy gradient method for rewarding the output of the skeleton generator based on the feedback from a pre-trained critic. An alternative technique is to solve both the skeleton generation and the response generation in a multi-task learning fashion.

Our contributions are summarized as below: (1) We develop a novel framework to inject the power of IR results into generative response models by introducing the idea of skeleton generation; (2) Our approach generates response skeletons by detecting and removing unnecessary words, which facilitates the generation of specific responses while not spoiling the generalization ability of the underlying generative models; (3) Experimental results show that our approach significantly outperforms other compared methods, resulting in more informative and specific responses.

2 Models

In this work, we propose to construct a response skeleton based on the results of IR systems for guiding the response generation. The skeleton-to-response paradigm helps reduce the search space of possible responses and provides useful elements missing in the given query.

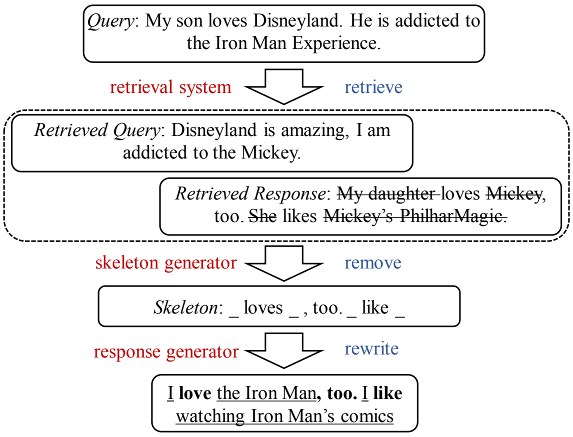

Figure 1: Our idea of leveraging the retrieved query-response pair. It first constructs a response skeleton by removing some words in the retrieved response, then a response is generated via rewriting based on the skeleton.

Our model consists of two components, namely, the skeleton generator and the response generator. These components are parameterized by the above two probabilistic models, denoted by θ_{ske} and θ_{res} respectively. Fig. 2 depicts the overall architecture of our proposed framework.

2.1 Skeleton Generator

The skeleton generator transforms a retrieved response into a skeleton by explicitly removing inappropriate or useless information regarding the input query q. We consider this procedure as a series of word-level masking actions. Following Wu et al. (2019), we first construct an edit vector by comparing the difference between the original query q and the retrieved query q'. In (Wu et al., 2019) the edit vector is used to guide the response generation directly. In our model, the edit vector is used to estimate the probability of being reserved or being masked for every word in a sentence. We define two word sets, namely *insertion words* I and *deletion words* D. The insertion words include words that are in the original query q, but not in the retrieved query q', while the deletion words do the opposite.

The two bags of words highlight the changes in the dialogue context, corresponding to the changes in the response. The edit vector z is thus defined as the concatenation of the representations of the two bags of words. We use the weighted sum of the

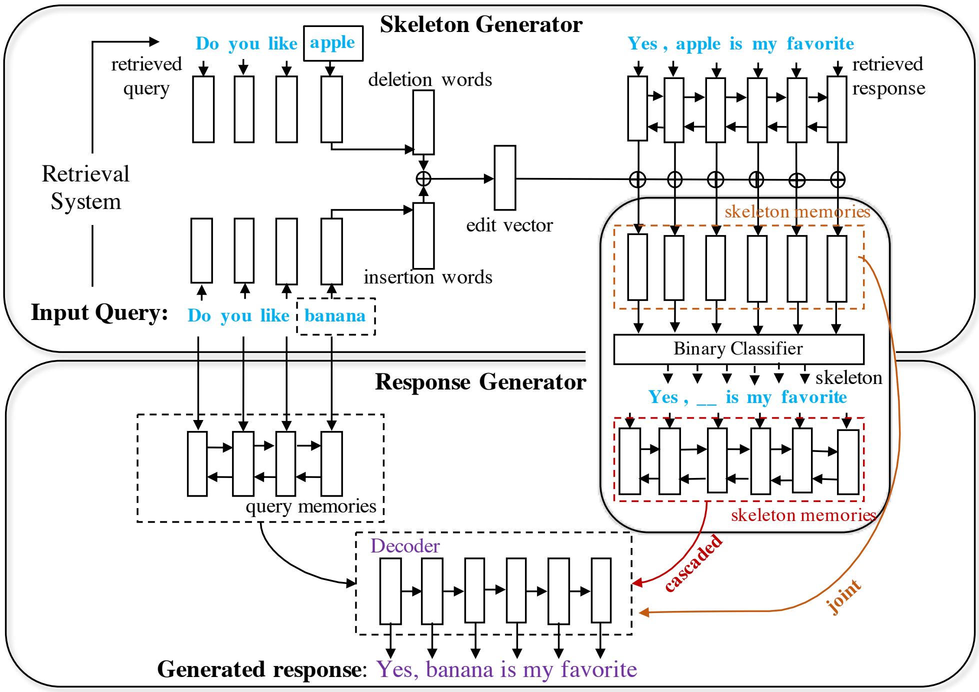

Figure 2: The architecture of our framework. Given a query "Do you like banana", a similar historical query "Do you like apple" is retrieved along with its response, i.e., "Yes, apple is my favorite". Upper: The skeleton generator removes inappropriate words and extracts a response skeleton. Lower: The response generator generates a response based on both the skeleton and the query.

word embeddings to get the dense representations of I and D. The edit vector is computed as:

$$z = \sum_{w_1 \in I} \alpha_{w_1} \Phi(w_1) \oplus \sum_{w_2 \in D} \beta_{w_2} \Phi(w_2), \quad (1)$$

where $\oplus$ is the concatenation operation. Φ maps a word to its corresponding embedding vector, α_{w_1} and β_{w_2} are the weights of an insertion word w_1 and a deletion word w_2 respectively. The weights of different words are derived by an attention mechanism (Luong et al., 2015). Formally, the retrieved response $r' = (r'_1, r'_2 \ldots, r'_{|r'|})$ is processed by a bidirectional GRU network (biGRU). We denote the states of the biGRU (i.e. concatenation of forward and backward GRU states) as $(h_1, h_2, \ldots, h_{|r'|})$. The weight α_{w_1} is calculated by:

$$\alpha_{w_1} = \frac{\exp(s_{w_1})}{\sum_{w \in I} \exp(s_w)},$$

$$s_{w_1} = v_I^\top \tanh(W_I[\Phi(w_1) \oplus h_{|r'|}]), \quad (2)$$

where v_I and W_I are learnable parameters. The weight β_{w_2} is obtained in a similar way with another set of parameters v_D and W_D.

After acquiring the edit vector, we transform the prototype response r' to a skeleton t by the following equations:

$$t = (\phi(r'_1, h_1, z), \phi(r'_2, h_2, z), \cdots, \phi(r'_{|r'|}, h_{|r'|}, z)),$$

$$\phi(r'_i, h_i, z) = \begin{cases} < \text{blank} > & \text{if } \hat{m}_i = 0, \\ r'_i & \text{else} \end{cases}, \quad (3)$$

where $\hat{m}_i$ is the indicator and equals 0 if r'_i is replaced with a placeholder "<blank>" and 1 otherwise. The probability of $\hat{m}_i = 1$ is computed by

$$P(\hat{m}_i = 1) = \text{sigmoid}(W_m[h_i \oplus z] + b_m). \quad (4)$$

2.2 Response Generator

The response generator can be implemented using most existing IR-augmented models (Song et al., 2016; Weston et al., 2018; Pandey et al., 2018), just by replacing the retrieved response input with the corresponding skeleton. We discuss our choices below.

Encoders Two separate bidirectional LSTM (biLSTM) networks are used to obtain the distributed representations of the query memories and the skeleton memories, respectively. For biLSTM, the concatenation of the forward and the backward hidden states at each token position is considered a memory slot, producing two memory pools: $\mathcal{M}_q = \{h_1, h_2, \dots, h_{|q|}\}$ for the input query, and $\mathcal{M}_t = \{h'_1, h'_2, \dots, h'_{|t|}\}$ for the skeleton.[1]

Decoder During the generation process, our decoder reads information from both the query and the skeleton using attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). To query the memory pools, the decoder uses the hidden state s_t of itself as the searching key. The matching score function is implemented by bilinear functions:

$$\alpha(h_k, s_t) = {h_k}^T W_q s_t; \beta(h'_k, s_t) = {h'_k}^T W_t s_t, \tag{5}$$

where W_q and W_t are trainable parameters. A query context vector c_t is then computed as a weighted sum of all memory slots in $\mathcal{M}_q$, where the weight for a memory slot h_k is $\exp(\alpha(h_k, s_t))/(\sum_{i=1}^{|q|} \exp(\alpha(h_i, s_t)))$. A skeleton context vector c'_t is computed in a similar spirit by using $\beta(h'_k, s_t)$'s.

The probability of generating the next word r_t is then jointly determined by the decoder's state s_t, the query context c_t and the skeleton context c'_t. We first fuse the information of s_t and c_t by a linear transformation. For c'_t, a gating mechanism is additionally introduced to control the information flow from skeleton memories. Formally, the probability of the next token r_t is estimated by y_t followed by a softmax function over the vocabulary:

$$y_t = (W_c[s_t \oplus c_t]) \cdot g_t + c'_t \cdot (1 - g_t), \tag{6}$$

where $g_t = f_g(s_t, c_t, c'_t)$ is implemented by a single layer neural network with sigmoid output layer.

3 Learning

Given that our skeleton generator performs non-differentiable hard masking, the overall model cannot be trained end-to-end using the standard maximum likelihood estimate (MLE). A possible solution that circumvents this problem is to treat the skeleton generation and the response generation as two parallel tasks and solve them jointly in a multi-task learning fashion. An alternative is to bridge the skeleton generator and the final response output using reinforcement learning (RL) methods, which can exclusively inform the skeleton generator with the ultimate goal. The latter option is referred as *cascaded integration* while the former is called *joint integration*.

Recall that we have formulated the skeleton generation as a series of binary classifications. Nevertheless, most of the dialogue datasets are end-to-end query-response pairs without explicit skeletons. Hence, we propose to construct *proxy skeletons* to facilitate the training.

Definition 1 Proxy Skeleton: *Given a training quadruplet (q, q', r, r') and a stop word list S, the proxy skeleton for r is generated by replacing some tokens in r' with a placeholder "<blank>". A token r'_i is kept if and only if it meets the following conditions*

1. $r'_i \notin S$

2. r'_i is a part of the longest common subsequence (LCS) (Wagner and Fischer, 1974) of r and r'.

The proxy skeletons are used in different manners according to the integration method, which we will introduce below.

3.1 Joint Integration

To avoid breaking the differentiable computation, we connect the skeleton generator and the response generator via a shared network architecture rather than by passing the discrete skeletons. Concretely, the last hidden states in our skeleton generator (i.e, the hidden states that are utilized to make the masking decisions) are used as the skeleton memories in response generation. The training objective is the sum of the proxy skeleton labels likelihood $L(\theta_{ske})$ and the response likelihood $L(\theta_{res})$:

$$L(\theta_{res} \cup \theta_{ske}) = L(\theta_{res}) + \eta L(\theta_{ske}), \tag{7}$$

where η is a harmonic weight, and it is set as 1.0 in our experiments.

3.2 Cascaded Integration

Policy gradient methods (Williams, 1992) can be applied to optimize the full model while keeping it running as cascaded process. We regard the skeleton generator as the first RL agent, and the response generator as the second one. The final output generated by the pipeline process and the

---

[1] Note the skeleton memory pool $\mathcal{M}_t$ could contain multiple response skeletons, further discussed in the experiment section.

intermediate skeleton are denoted by $\hat{r}$ and $\hat{t}$ respectively. Given the original query q and the generated response $\hat{r}$, a reward $R(q, \hat{r})$ for generating $\hat{r}$ is calculated. All network parameters are then optimized to maximize the expected reward by the policy gradient.

The reward function R should convey both the naturalness of the generated response and its relevance to the given query q. A pre-trained critic is utilized to make the judgment. Inspired by comparative adversarial learning in (Li et al., 2018), we design the critic as a classifier that receives four inputs every time: the query q, a human-written response r, a machine-generated response $\hat{r}$ and a random response $\overline{r}$ (yet written by human). The critic is trained to pick the human-written response r among others correctly. Formally, the following objective is maximized:

$$\log D(r|q, \hat{r}, \overline{r}, r) = \log \frac{\exp({h_r}^{\mathrm{T}} M_D h_q)}{\sum\limits_{x \in \{\hat{r}, \overline{r}, r\}} \exp({h_x}^{\mathrm{T}} M_D h_q)}, \tag{8}$$

where h_x is a vector representation of x, produced by a bidirectional LSTM (the last hidden state), and M_D is a trainable matrix.[2]

4 Related Work

Multi-source Dialogue Generation Chit-chat style dialogue system dates back to ELIZA (Weizenbaum, 1966). Early work uses hand-crafted rules, while modern systems usually use data-driven approaches, e.g., information retrieval techniques. Recently, end-to-end neural approaches (Vinyals and Le, 2015; Serban et al., 2016; Li et al., 2016a; Sordoni et al., 2015) have attracted increasing interest. For those generative models, a notorious problem is the “safe response” problem: the generated responses are dull and generic, which may attribute to the lack of sufficient input information. The query alone cannot specify an informative response. To mitigate the issue, many research efforts have been paid to introducing other information source, such as unsupervised latent variable (Serban et al., 2017; Zhao et al., 2018; Cao and Clark, 2017; Shen et al., 2017), discourse-level variations (Zhao et al., 2017), topic information (Xing et al., 2017), speaker personality (Li et al., 2016b) and knowledge base (Ghazvininejad et al., 2018; Zhou et al., 2018). Our work follows the similar motivation and uses the output of IR systems as the additional knowledge source.

Combination of IR and Generative models To combine IR and generative models, early work (Qiu et al., 2017) tried to re-rank the output from both models. However, the performance of such models is limited by the capacity of individual methods. Most related to our work, Song et al. (2016); Weston et al. (2018) and Wu et al. (2019) encoded the retrieved result into distributed representation and used it as the additional conditionals along with the standard query representation. While the former two only used the target side of the retrieved pairs, the latter took advantages of both sides. In a closed domain conversation setting, Pandey et al. (2018) further proposed to weight different training instances by context similarity. Our model differs from them in that we take an extra intermediate step for skeleton generation to filter the retrieval information before use, which shows the effectiveness in avoiding the erroneous copy in our experiments.

Multi-step Language Generation Our work is also inspired by the recent success of decomposing an end-to-end language generation task into several sequential sub-tasks. For document summarization, Chen and Bansal (2018) first select salient sentences and then rewrite them in parallel. For sentiment-to-sentiment translation, Xu et al. (2018) first use a neutralization module to remove emotional words and then add sentiment to the neutralized content. Not only does their decomposition improve the overall performance, but also makes the whole generation process more interpretable. Our skeleton-to-response framework also sheds some light on the use of retrieval memories.

5 Experiments

5.1 Data

We use the preprocessed data in (Wu et al., 2019) as our test bed. The total dataset consists of about 20 million single-turn query-response pairs collected from Douban Group[3]. Since similar contexts may correspond to totally different responses, the training quadruples (q, r, q', r') for

---

[2] Note the classifier could be fine-tuned with the training of our generators, which falls into the adversarial learning setting (Goodfellow et al., 2014).

[3] https://www.douban.com/group

IR-augmented models are constructed based on response similarity. All response are indexed by Lucene.[4] For each (q, r) pair, top 30 similar responses with their corresponding contexts are retrieved $\{(q'_i, r'_i)\}_{i=1}^{30}$. However, only those satisfying $0.3 \leq Jaccard(r, r'_i) \leq 0.7$ are leveraged for training, where $Jaccard$ measures the Jaccard distance. The reason for the data filter is that nearly identical responses drive the model to do simple copy while distantly different responses make the model ignore the retrieval input. About 42 million quadruples are obtained afterward.

For computational efficiency, we randomly sample 5 million quadruples as training data for all experiments. The test set consists of 1,000 randomly selected queries that are not in our training data.[5] For a fair comparison, when training a generative model without the help of IR, the quadruples are split into pairs.

5.2 Model Details

We implement the skeleton generator based on a bidirectional recurrent neural network with 500 LSTM units. We concatenate the hidden states from both directions. The word embedding size is set to 300. For the response generator, the encoder for queries, the encoder for skeletons and the decoder are three two-layer recurrent neural networks with 500 LSTM units, where both encoders are bidirectional. We use dropout (Srivastava et al., 2014) to alleviate overfitting. The dropout rate is set to 0.3 across different layers. The same architecture for the encoders and the decoder is shared across the following baseline models, if applicable.

5.3 Compared Methods

- **Seq2Seq** the standard attention-based RNN encoder-decoder model (Bahdanau et al., 2014).
- **MMI** SEQ2SEQ with Maximum Mutual Information (MMI) objective in decoding (Li et al., 2016a). In practice, an inverse (response-to-query) SEQ2SEQ model is used to rerank the N-best hypothesizes from the standard SEQ2SEQ model (N equals 100 in our experiments).

model	human score	dist-1	dist-2
IR	2.093	**0.238**	**0.723**
IR+rerank	2.520	0.208	0.586
Seq2Seq	2.433	0.156	0.336
MMI	2.554	0.170	0.464
EditVec	2.588†	0.154	0.394
SKP	2.581	0.152	0.406
JNT	2.612†	0.147	0.377
CAS	**2.747**	0.156	0.411

Table 1: Response performance of different models. Sign tests on human score show that the CAS is significantly better than all other methods with p-value $<$ 0.05, and the p-value $<$ 0.01 except for those marked by $\dagger$.

model	P	R	F_1	Acc.
JNT	0.32	0.61	0.42	0.60
CAS	0.50	0.86	0.63	0.76

Table 2: Performance of skeleton generator.

- **EditVec** the model proposed by Wu et al. (2019), where the edit vector z is used directly at each decoding step by concatenating it to the word embeddings.
- **IR** the Lucene system is also used a benchmark.[6]
- **IR+rerank** rerank the results of **IR** by **MMI**.

Besides, We use **JNT** to denote our model with joint integration, and **CAS** for our model with cascaded integration. To validate the usefulness of the proposed skeletons. We design a response generator that takes an intact retrieval response as its skeleton input (i.e., to completely skip the skeleton generation step), denoted by **SKP**.[7]

5.4 Evaluation Metrics

Our method is designed to improve the informativeness of the generative model and alleviate the inappropriateness problem of the retrieval model. To measure the performance effectively, we use

---

[4] https://lucene.apache.org/core/

[5] Note the retrieval results for test data are based on query similarity, and no data filter is adopted.

[6] Note IR selects response candidates from the entire data collection, not restricted to the filtered one.

[7] There are some other IR-augmented models using standard SEQ2SEQ models as SKP. Weston et al. (2018) used a rule to select either the generated response or the retrieved response as output, while we would like to focus on improving the quality of generated responses. Pandey et al. (2018) concentrated on closed domain conversations, their hierarchical encoder is not suitable for our open domain setting. We thus omit the empirical comparison with them.

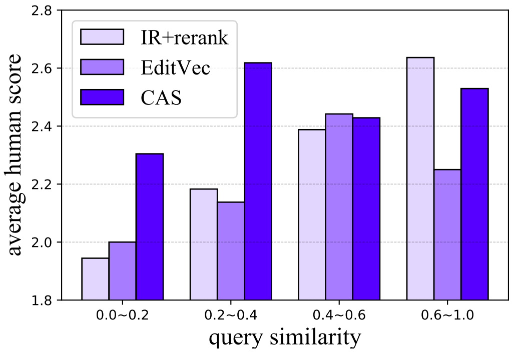

Figure 3: Response quality v.s. query similarity.[8]

human evaluation along with two automatic evaluation metrics.

- **Human evaluation** We asked three experienced annotators to score the group of responses (the best output of each model) for 300 test queries. The responses are rated on a five-point scale. A response should be scored 1 if it can hardly be considered a valid response, 3 if it is a valid but not informative response, 5 if it is an informative response, which can deepen the discussion of the current topic or lead to a new topic. 2 and 4 are for decision dilemmas.

- **dist-1 & dist-2** It is defined as the number of unique uni-grams (**dist-1**) or bi-grams (**dist-2**) dividing by the total number of tokens, measuring the diversity of the generated responses (Li et al., 2016a). Note the two metrics do not necessarily reflect the response quality as the target queries are not taken into consideration.

5.5 Response Generation Results

The results are depicted in Table 1. Overall, both of our models surpass all other methods, and our cascaded model (CAS) gives the best performance according to human evaluation. The contrast with the SKP model illustrates that the use of skeletons brings a significant performance gain.

According to the dist-1&2 metrics, the generative models achieve significantly better diversity by the use of retrieval results. The retrieval method yields the highest diversity, which is consistent with our intuition that the retrieval responses typically contain a large amount of information though they are not necessarily appropriate. The model of MMI also gives strong diversity, yet we find that it tends to merely repeat the words in queries. By removing the words in queries, the dist-2 of MMI and CAS become 0.710 and 0.751 respectively. It indicates our models are better at generating new words.

To further reveal the source of performance gain, we study the relation between response quality and query similarity (measured by the Jaccard similarity between the input query and the retrieved query). Our best model (CAS) is compared with the strong IR system (IR-rerank) and the previous state-of-the-art (EditVec) in Fig. 3. The CAS model significantly boosts the performance when query similarity is relatively low, which indicates that introducing skeletons can alleviate erroneous copy and keep a strong generalization ability of the underlying generative model.

5.6 More Analysis of Our Framework

Here, we present further discussions and empirical analysis of our framework.

Generated Skeletons Although generating skeletons is not our primary goal, it is interesting to assess the skeleton generation. The word-level precision (P), recall (R), F_1 score (F_1) and accuracy (Acc.) of the well-trained skeleton generators are reported in Table 2, taking the proxy skeletons as golden references.

Table 3 shows some skeleton-to-response examples of the CAS model and a case study among different models. In the leftmost example in Table 3, the MMI and the EditVec simply repeat the query while the retrieved response is weakly related to the query. Our CAS model extracts a useful word 'boy' from the retrieved response and generates a more interesting response. In the middle example, the MMI response makes less sense, and some private information is included in the retrieved response. Our CAS model removes the privacy without the loss of informativeness, while the outputs by other models are less informative. The rightmost case shows that our response generator is able to recover the possible mistakes made by the skeleton generator.

Retrieved Response v.s. Generated Response To measure the extent that the generative models are copying the retrieval, we compute the edit distances between generated responses and retrieved

---

[8] We merge the ranges $[0.6, 0.8]$ and $[0.8, 1.0]$ due to the sparsity of highly similar pairs.

Query	善良的妹子会幸福一生的 May you kind girls have a happy life	好的到时候有时间骑车出来玩嘛， 我觉得在大理最适合骑车玩了 OK, Let’s ride when free. It is Dali.	把你联系方式给我 Tell me your contact

JNT	我不是善良的妹子 I am not a kind girl	我也在大理 I am in Dali, too	我不是联系的 I am not the contact person

Table 3: Upper: Skeleton-to-response examples of the CAS model. Lower: Responses from different models are for comparison.

responses. As shown in Fig. 4, in the comparison between the SKP and other models, the use of skeletons makes the generated response deviate more from its prototype response. Ideally, when the retrieved context is very similar to the input query, the changes between the generated response and the prototype response should be minor. Conversely, the changes should be drastic. Fig. 4 also shows that our models can learn this intuition.

Single v.s. Multiple Retrieval Pair(s) For a given query q, the retrieval pair set R_q could contain multiple query-response pairs. We investigate two ways of using it under the CAS setting.

- **Single** For each query-response pair $(q'_i, r'_i) \in R_q$, a response $\hat{r}_i$ is generated solely based on q, and (q'_i, r'_i). The resulted responses are re-ranked by generation probability.

- **Multiple** The whole retrieval set R_q is used in a single run. Multiple skeletons are generated and concatenated in the response generation stage.

The results are shown in Table 4. We attribute the failure of **Multiple** to the huge variety of the retrieved responses. The response generator receives many heterogeneous skeletons, yet it has no idea which to use. It remains an open question on how to effectively use multiple retrieval pairs for generating one single response, and we leave it for future work.

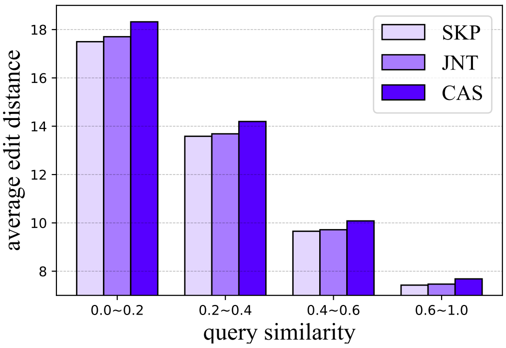

Figure 4: Changes between retrieved and generated responses v.s. query similarity.

setting	human score	dist-1	dist-2
Single	2.747	0.156	0.411
Multiple	1.976	0.178	0.414

6 Conclusion

In this paper, we proposed a new methodology to enhance generative models with information retrieval technologies for dialogue response generation. Given a dialogue context, our methods generate a skeleton based on historical responses that respond to a similar context. The skeleton serves as an additional knowledge source that helps specify the response direction and complement the response content. Experiments on real world data validated the effectiveness of our method for more informative and appropriate responses.

Abstract

Although recent neural conversation models have shown great potential, they often generate bland and generic responses. While various approaches have been explored to diversify the output of the conversation model, the improvement often comes at the cost of decreased relevance (Zhang et al., 2018). In this paper, we propose a SpaceFusion model to jointly optimize diversity and relevance that essentially fuses the latent space of a sequence-to-sequence model and that of an autoencoder model by leveraging novel regularization terms. As a result, our approach induces a latent space in which the distance and direction from the predicted response vector roughly match the relevance and diversity, respectively. This property also lends itself well to an intuitive visualization of the latent space. Both automatic and human evaluation results demonstrate that the proposed approach brings significant improvement compared to strong baselines in both diversity and relevance. [1]

1 Introduction

The field of neural response generation is advancing rapidly both in terms of research and commercial applications (Gao et al., 2019; Zhou et al., 2018; Yoshino et al., 2019; Zhang et al., 2019). Nevertheless, vanilla sequence-to-sequence (S2S) models often generate bland and generic responses (Li et al., 2016a). Li et al. (2016a) encourage diversity by re-ranking the beam search results according to their mutual information with the conversation context. However, as beam search itself often produces lists of nearly identical sequences, this method can require a large beam width (e.g. 200). As a result, re-ranking can be extremely time-consuming, raising difficulties for real-time applications. This highlights the need to improve the diversity of candidates before re-ranking, and the need to optimize for diversity during training rather than just at the decoding stage.

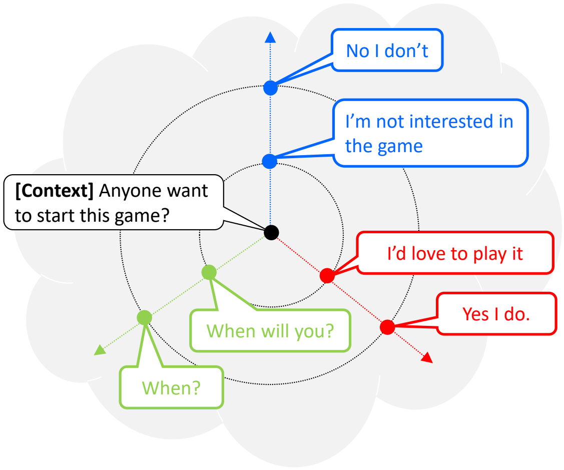

Figure 1: Illustration of one **context** and its multiple **responses** in the latent space induced by our model. Distance and direction from the predicted response vector given the context roughly match the relevance and diversity, respectively. Based on the example in Table 2.[2]

While various approaches have been explored to diversify the output of conversation models, the improvement often comes at the cost of decreased response relevance along other dimensions. For instance, Zhao et al. (2017) present an approach to enhancing diversity by mapping diverse responses to a probability distribution using a conditional variational autoencoder (CVAE). Despite the improved response diversity, this approach reduces response relevance as measured against the baseline. One possible reason for this diversity-relevance trade-off is that such probabilistic approaches are not explicitly encouraged to induce a disentangled representation in latent space for

---

[2] For simplicity, we omitted the response at the center: "I would love to play this game". See Table 2 for more details.

Proceedings of NAACL-HLT 2019, pages 1229–1238
Minneapolis, Minnesota, June 2 - June 7, 2019.

controlling diversity and relevance independently. Consider a Gaussian distribution, which is widely used for CVAE. A Gaussian distribution naturally brings frequent responses near its mean, and the resulting responses are often generic and boring. To generate diverse and interesting responses, one needs to sample a little distance from the mean. But doing so naturally leads to infrequent and thus even irrelevant responses.

In this paper, we propose a novel geometrical approach that explicitly encourages a structured latent space in which the distance and direction from a predicted response vector roughly match the relevance and diversity, respectively, as illustrated in Figure 1. To induce such a latent space, we leverage two different models: 1) a S2S model, producing the predicted response vector (the black dot at the center in Figure 1), and 2) an autoencoder (AE) model, yielding the vectors for potential responses (the colored dots). In order to make the S2S and AE share the same latent space (the cloud), we use the same decoder for both and train them jointly end-to-end with novel regularization terms. As this fuses the two latent spaces, we refer to our model as SPACEFUSION.

Regularization is necessary because only sharing the decoder, as in (Luan et al., 2017), does not necessarily align the latent spaces obtained by S2S and AE respectively or impose a disentangled structure onto the space. We introduce two regularization terms to tackle this issue. 1) interpolation term: we encourage a smooth semantic transition along the path between the predicted response vector and each target response vector (arrowed lines in Figure 1). This term effectively prevents semantically different responses from aligning in the same direction, essentially scattering them over different directions. 2) fusion term: we want the vectors from the two models to be distributed in a homogeneous manner, rather than forming two separate clusters (Figure 5) that can potentially make sampling non-trivial. With the resulting latent space, we can control relevance and diversity by respectively adjusting distance and direction from a predicted response vector, without sacrificing each other greatly.

Our approach also lends itself well to the intuitive visualization of latent space. Since our model allows us to geometrically find not only the predicted response vector but also the target response vector as in Figure 5, we can visually interpret the structure of latent space and identify major issues thereof. We devote Section 5.1 to show comprehensive examples for visualization-based analysis.

Automatic and human evaluations demonstrate that the proposed approach improves both the diversity and relevance of the responses, compared to strong baselines on two datasets with one-to-many context-response mapping.

2 Related Work

Grounded conversation models utilize extra context inputs besides conversation history, such as persona (Li et al., 2016b), textual knowledge (Ghazvininejad et al., 2017; Galley et al., 2019), dialog act (Zhao et al., 2017) and emotion (Huber et al., 2018). Our approach does not depend on such extra input and thus is complementary to this line of studies.

Variational autoencoder (VAE) models explicitly model the uncertainty of responses in latent space. Bowman et al. (2016) used VAE with Long-Short Term Memory (LSTM) cells to generate sentences. The basic idea of VAE is to encode the input x into a probability distribution (e.g. Gaussian) z instead of a point encoding. However, it suffers from the *vanishing latent variable problem* (Bowman et al., 2016; Zhao et al., 2017) when applied to text generation tasks. Bowman et al. (2016); Fu et al. (2019) proposed to tackle this problem with word dropping and specific KL annealing methods. Zhao et al. (2017) proposed to add a *bag-of-word* loss, complementary to KL annealing. Applying this to a CVAE conversation model, they showed that even greedy decoding can generate diverse responses. However, as VAE/CVAE conversation models can be limited to a simple latent representations such as standard Gaussian distribution, Gu et al. (2018) proposed to enrich the latent space by leveraging a Gaussian mixture prior. Our work takes a geometrical approach that is fundamentally different from probabilistic approaches to tackle the limitations of parameteric distributions in representation and difficulties in training.

Decoding and ranking encourage diversity during the decoding stage. As "vanilla" beam search often produces lists of nearly identical sequences, Vijayakumar et al. (2016) propose to include a dissimilarity term in the objective of beam search decoding. Li et al. (2016a) re-ranked the results obtained by beam search based on mutual information with the context using a separately trained response-to-context S2S model.

Multi-task learning is another line of studies related to the present work (see Section 3.2). Sennrich et al. (2016) use multi-task learning to improve neural machine translation by utilizing monolingual data, which usually far exceeds the amount of parallel data. A similar idea is applied by Luan et al. (2017) to conversational modeling, involving two tasks: 1) a S2S model that learns a context-to-response mapping using conversation data, and 2) an AE model that utilizes speaker-specific non-conversational data. The decoders of S2S and AE were shared, and the two tasks were trained alternately.

3 The SPACEFUSION Model

3.1 Problem statement

Let $\mathcal{D} = [(x_0, y_0), (x_1, y_1), \cdots, (x_n, y_n)]$ denote a conversational dataset, where x_i and y_i are a context and its response, respectively. x_i consists of one or more utterances. Our aim is to train a model on $\mathcal{D}$ to generate relevant and diverse responses given a context.

3.2 Fusing latent spaces

We design our model to induce a latent space where different responses for a given context are in different directions around the predicted response vector, as illustrated in Figure 1. Then we can obtain diverse responses by varying the direction and keep their relevance by sampling near the predicted response vector.

To fulfill this goal, we first produce the predicted response representation z_{S2S} and target response representations z_{AE} using an S2S model and an AE model, respectively, as illustrated in Figure 2. Both encoders are implemented using stacked Gated Recurrent Unit (GRU) (Cho et al., 2014) cells followed by a noise layer that adds multivariate Gaussian noise $\epsilon \sim N(0, \sigma^2\mathbf{I})$. We then explicitly encourage smooth semantic transition along the path from z_{S2S} to z_{AE} by imposing any interpolation between them to generate the same response via the following loss term:

$$\mathcal{L}_{\text{interp}} = -\frac{1}{|y|} \log p(y|z_{\text{interp}}) \tag{1}$$

where $z_{\text{interp}} = u z_{\text{S2S}} + (1-u) z_{\text{AE}}$ and $u \sim U(0,1)$ is a uniformly distributed random variable. $|y|$ is the number of words in y. Note that it is this regularization term that effectively prevents significantly different responses from aligning in the same direction, essentially scattering them over different directions. In order for this interpolation loss to work, we share the same decoder for both AE and S2S models as in (Luan et al., 2017). The decoder consists of stacked GRU cells followed by a softmax layer. It is worth mentioning that z_{interp} is not just randomly drawn from a single line but from a richer probabilistic region as both z_{interp} and z_{S2S} are stochastic due to the random component ϵ.

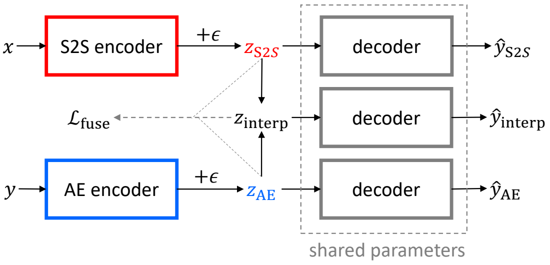

Figure 2: SPACEFUSION model architecture.

Now, we want vectors from both the AE and S2S models to be distributed in a homogeneous manner scattered over the entire space while keeping the distance between z_{S2S} and z_{AE} as small as possible for any (context-response) pair in the training data. This objective is represented in the following regularization term:

$$\begin{aligned}\mathcal{L}_{\text{fuse}} = &\sum_{i \in \text{batch}} \frac{d(z_{\text{S2S}}(x_i), z_{\text{AE}}(y_i))}{n} \\ &- \sum_{i,j \in \text{batch}, i \neq j} \frac{d(z_{\text{S2S}}(x_i), z_{\text{S2S}}(x_j))}{n^2 - n} \\ &- \sum_{i,j \in \text{batch}, i \neq j} \frac{d(z_{\text{AE}}(y_i), z_{\text{AE}}(y_j))}{n^2 - n}\end{aligned} \tag{2}$$

where n is the batch size and $d(a, b)$ is the root mean square of the difference between a and b. For each batch, we basically disperse vectors obtained by the same model and pull the predicted response vectors to the corresponding target response vectors. In practice, we found that the performance is better if the Euclidean distance is clipped to a prescribed maximum value.[3]

Finally, with weight parameters α and β, the

---

[3] This value is set as 0.3 for the present experiments

loss function is defined as:

$$\begin{aligned}\mathcal{L} = &- \frac{1}{|y|}\log p(y|z_{\text{S2S}}) \\ &- \frac{1}{|y|}\log p(y|z_{\text{AE}}) \\ &+ \alpha\mathcal{L}_{\text{interp}} + \beta\mathcal{L}_{\text{fuse}}\end{aligned} \tag{3}$$

As $\mathcal{L}_{\text{interp}}$ and $\mathcal{L}_{\text{fuse}}$ encourage the path between z_{S2S} and z_{AE} to be smooth and short while scattering vectors over the entire space, they effectively fuse the z_{S2S} latent space and the z_{AE} latent space. Accordingly we refer this approach as SPACEFUSION with path regularization.

3.3 Training

In contrast to previous multi-task conversation model (Luan et al., 2017), where S2S and AE are trained alternately, our approach trains S2S and AE at the same time by minimizing the loss function of Equation 3.

3.4 Inference

Like Zhao et al. (2017); Bowman et al. (2016), for a given context, we sample different latent vectors to obtain multiple hypotheses. This is done by adding a random vector r that is uniformly sampled from a hypersphere of radius $|r|$ to the prediction $z_{\text{S2S}}(x)$.

$$z(x, r) = z_{\text{S2S}}(x) + r \tag{4}$$

where $|r|$ is tuned on the validation set to optimize the trade-off between relevance and diversity. $z(x, r)$ is then fed to the decoder as the initial state of GRU cells. We then generate responses using greedy decoding.[4]

4 Experiment Setup

4.1 Datasets

We used the following datasets. Some of their key features are presented in Table 1.

Switchboard: We use the version offered by Zhao et al. (2017), which is an extension of the original version by Godfrey and Holliman (1997). Zhao et al. (2017) collected multiple references for the test set using information retrieval (IR) techniques followed by human filtering, and randomly split the data into 2316/60/62 conversations for train/validate/test, respectively. Each conversation has multiple turns and thus multiple (x, y) pairs, as listed in Table 1. As our approach does not utilize extra information except conversation history, we removed the meta data (e.g. gender, age, prompt) from this dataset.

	Switchboard	Reddit
train (x, y) samples	0.2M	7.3M
test (x, y) samples	5418	5000
ref. source	IR+filtering	natural
ref. availability	test only	train/vali/test
ref. per context	7.7	24.1

Table 1: Key features of the datasets.

Reddit: As the Switchboard dataset is relatively small and multiple references are synthetically constructed, we have developed another multi-reference dataset by extracting posts and comments on Reddit.com during 2011 collected by a third party.[5] As each Reddit post and comment may have multiple comments, it is a natural source of multi-reference responses. We further filtered the data based on the number of replies to obtain the final conversation dataset in which each context has at least 10 different responses, and on average the number of responses is 24.1 for a given context. The size is significantly larger than Switchboard, as listed in Table 1. The conversations are randomly shuffled before being split into train/valid/test subsets.

4.2 Model setup

Both encoders and the shared decoder consist of two GRU cells, each with 128 hidden units. The variance of the noise layer in each decoder is $\sigma^2 = 0.1^2$. The word embedding dimension is 128. The weight parameters (see Equation 3) are set as $\alpha = 1$ and $\beta = 30$. For both datasets, the inference radius $|r|$ (see Equation 4) is set to 1.5 which optimizes F1 score on the validation set. All models are trained using the Adam method (Kingma and Ba, 2014) with a learning rate of 0.001 on both datasets until convergence (around 4 epochs for Reddit and 10 epochs for Switchboard).

4.3 Automatic evaluation

For a given context x, we have N_r reference responses and generate the same number of hypothe-

---

[4] Although we use greedy decoding in this work, other decoding techniques, such as beam search, can be applied.

[5] `http://files.pushshift.io/reddit/comments/`

ses.[6] We define the following metrics based on 4-gram BLEU (Papineni et al., 2002), as suggested by Zhao et al. (2017).

$$\text{Precision} = \frac{1}{N_r}\sum_{i=1}^{N_r}\max_{j\in[1,N_r]}\text{BLEU}(r_j, h_i)$$

$$\text{Recall} = \frac{1}{N_r}\sum_{j=1}^{N_r}\max_{i\in[1,N_r]}\text{BLEU}(r_j, h_i)$$

$$\text{F1} = 2\,\frac{\text{precision}\cdot\text{recall}}{\text{precision}+\text{recall}}$$

We use Precision as an approximate surrogate metric for relevance and Recall for diversity. It should be noted that recall is not equivalent to other diversity metrics, e.g., distinct (Li et al., 2016a) and entropy (Zhang et al., 2018), which only depend on hypotheses. One potential issue of these metrics is that even randomly generated responses may yield a high diversity score. F1 is the harmonic average of these two and is used to measure the overall response quality.

4.4 Human evaluation

We conduct a human evaluation using crowdworkers. For each hypothesis, given its context, we ask three annotators to individually measure the quality, on a scale of 1 to 5, in terms of two aspects: relevance and interest. Interestingness is treated as an estimation of the diversity, as these two are often correlated. The hypotheses from all systems are shuffled before being provided to annotators. System names are invisible to the annotators.

4.5 Baselines

We compare the proposed model with the following baseline models:

S2S+Sampling: We consider a vanilla version of S2S model. The dimensions are similar to our model: both encoder and decoder consist of two stacked GRU cells with 128 hidden units, and the word embedding size is 128. As in the baseline in Zhao et al. (2017), we applied softmax sampling at inference time to generate multiple hypotheses.

CVAE+BOW: For the CVAE conversation model, we use the original implementation and hyperparameters of Zhao et al. (2017) with the bag-of-words (BOW) loss. The number of trainable model parameters is 15.4M, which is much larger than our model (3.2M).

MTask: Since our approach utilizes a multi-task learning scheme, we also compare it against a vanilla multi-task learning model, MTask, similar to (Luan et al., 2017), to illustrate the effect of space fusion. The model architecture and hyperparameters are identical to the proposed model except that the loss function is $\mathcal{L} = -\log p(y|z_{\text{S2S}}) - \log p(y|z_{\text{AE}})$.

5 Results and Analysis

5.1 In-depth analysis of latent space

In this section, we undertake an in-depth analysis to verify whether the latent space induced by our method manifests desirable properties, namely: 1) disentangled space structure between relevance and diversity, 2) homogeneous space distribution in which semantics changes smoothly without holes. We first provide a qualitative investigation based on real examples. Then, we present a set of corpus-level quantitative analyses focused on geometric properties.

5.1.1 Qualitative examples

In Table 2, we investigate three different directions from the context "`Anyone want to start this game?`" , which is a real example taken from Reddit. The three different directions correspond to clearly different semantics: "`No I don't`", "`when?`" and "`Yes I do.`" If we generate a response with the vector predicted by the S2S model ($u = 0$), our model outputs "`I would love to play this game`" which is highly relevant to the context. Now as we move along each direction, we can see our model gradually transforms the response toward the corresponding responses of each direction. For instance, towards "`No I don't`", our model gradually transforms the response to "`I am not interested in the game`" ($u = 0.18$) and then "`I am not interested.`" ($u = 0.21$). In contrary, towards "`Yes I do`", the response transforms to "`I would love to play it.`" ($u = 0.15$). Besides the positive or negative directions, the same transition applies to other directions such as "`When?`". This example clearly shows that there is a rough correspondence

---

[6] We set the number of hypotheses equal to the number of references to encourage precision and recall have comparable impact on F1

between geometric properties and semantic properties in the latent space induced by our method as shown in Figure 1– the relevance of the response decreases as we move away from the predicted response vector and different directions are associated with semantically different responses.

5.1.2 Direction vs. diversity

In order to quantitatively verify the correspondence between *direction* and *diversity*, we visualize the distribution of cosine similarities among multiple references for each context for a set of 1000 random samples drawn from the test dataset. Specifically, for a context x_k and its associated reference responses $[y_{k,0}, y_{k,1}, \cdots]$, we compute the cosine similarity between $z_{\text{AE}}(y_{k,i}) - z_{\text{S2S}}(x_k)$ and $z_{\text{AE}}(y_{k,j}) - z_{\text{S2S}}(x_k)$. In Figure 3, we compare the distribution of our model with that of MTask, which does not employ our regularization terms. While our method yields a bell shaped curve with average cosine similarity being close to zero (0.38), the distribution of MTask is extremely skewed with average cosine similarity being close to 1 (0.95). This indicates that the directions of the reference responses are more evenly distributed in our latent space whereas everything is packed in a narrow band in the MTask’s space. This essentially makes the inference process simple and robust in that one can choose arbitrary directions to generate diverse responses.

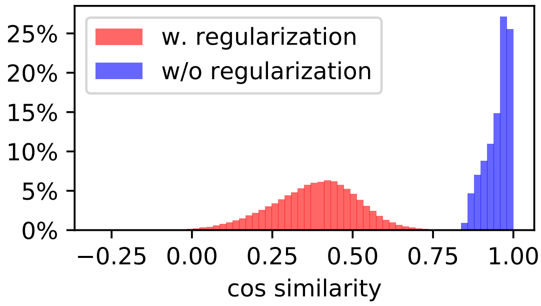

Figure 3: Distribution of the directions from a given context to its multiple responses, measured by the cosine similarity between $z_{\text{AE}}(y_{k,i}) - z_{\text{S2S}}(x_k)$ and $z_{\text{AE}}(y_{k,j}) - z_{\text{S2S}}(x_k)$. Histogram calculated based on 1000 x_k from Reddit test data and visualized with bin width of 0.02.

5.1.3 Distance vs. relevance

In order to quantitatively verify the correspondence between *distance* and *relevance*, we visualize the perplexity of reference responses along the path from the associated z_{S2S} ($u = 0$) to the z_{AE} ($u = 1$) corresponding to the predicted response. In Figure 4, we compare our model with MTask, which as already noted, does not employ our regularization terms. While our model shows a gradual increase in perplexity, there is a huge bump for MTask’s line. This clearly indicates that there is a rough correspondence between distance and relevance in our latent space whereas even a slight change can lead to an irrelevant response in the MTask’s space.

We further illustrate the smooth change in relevance according to distance for a specific example in Table 3. Given the context “`Anyone want to start this game?`”, our model

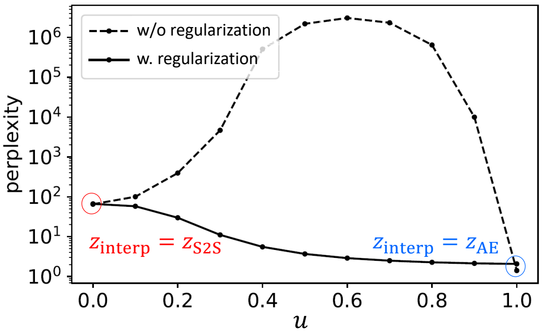

Figure 4: Perplexity of z_{interp} on the Reddit test dataset as a function of u for simple multi-task model (without regularization, dashed line) and SPACEFUSION (with regularization, solid line).

is able to transition from the predicted response “`I would love to play this game`” to a one of reference responses “`Yes I do`”. The relevance smoothly descreases, generating intermediate responses such as “`I would love to play it.`” In contrary, the MTask model tends to produce irrelevant or ungrammatical responses as it moves away from the predicted response.

5.1.4 Homogeneity and Convexity

Other desirable properties, with which we want to equip our latent space are *homogeneity* and *convexity*. If the space is not homogeneous, we have to sample differently depending on the regional traits. If the space is not convex, we have to worry about running into the holes that are not properly associated with valid semantic meanings. In order to verify homogeneity and convexity, we visualize our latent space in a 2D space produced by the multidimensional scaling (MDS) algorithm (Borg and Groenen, 2003), which approximately preserves pairwise distance. For comparison, we also provide a visualization for MTask. As shown in Figure 5, our latent space offers great homogeneity and convexity regardless of which model is used to produce a dot (i.e. z_{S2S} or z_{AE}). In contrary, MTask’s latent space forms two separate clusters for z_{S2S} and z_{AE} with a large gap in-between where no training samples were mapped to.

5.2 Automatic evaluation

We let each system generate 100 hypotheses $\{h_j\}$ for each context x_i in the test dataset. Assuming x_i has $N_{r,i}$ references, we pick the top $N_{r,i}$ distinct hypotheses ranked by $\log p(h_j|x_i) + \lambda|h_j|$. Similar to (Li et al., 2016a; Wu et al., 2016), we takes $|h_j|$ into consideration, as BLEU is sensitive to length.

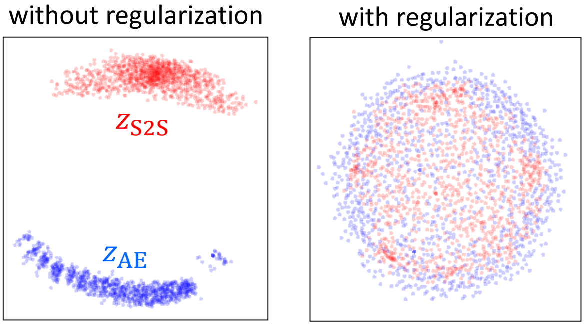

Figure 5: MDS visualization of the two latent spaces: z_{s2s} (red dots) and z_{AE} (blue dots) of 1000 randomly picked (x, y) pairs from the Reddit test dataset. Left: multi-task model (without regularization); right: SPACEFUSION (with regularization).

For fair comparison, λ is tuned such that the average hypothesis length becomes roughly the same for all systems and approaches the average length of the references.[7]

The automatic evaluation results are reported in Table 4. On both datasets, the proposed system consistently outperforms the baselines by a large margin in Precision, Recall, and F1.

Examples of system outputs and human references can be found in Table 5 and Table 6 for Reddit and Switchboard, respectively. As shown in the examples, CVAE+BOW and other baseline models may generate diverse but not-so-relevant responses.

dataset	model	Precision	Recall	F1
Switchboard	SPACEFUSION	**1.22**	**0.66**	**0.86**
	CVAE+BOW	0.76	0.57	0.65
	MTask	0.75	0.43	0.54
	S2S+Sampling	0.57	0.48	0.52
Reddit	SPACEFUSION	**0.40**	**0.26**	**0.31**
	CVAE+BOW	0.16	0.18	0.17
	MTask	0.31	0.18	0.23
	S2S+Sampling	0.10	0.11	0.11

6 Conclusion

We propose a SpaceFusion model to jointly optimize diversity and relevance that leverages novel regularization terms to essentially fuse the latent space of a S2S model with that of an autoencoder model. This fused latent space exhibits desirable properties such as smooth semantic interpolation between two points. The distance and direction from the predicted response vector roughly match relevance and diversity, respectively. These properties also enable intuitive visualization of the latent space. Both automatic and human evaluation results demonstrate that the proposed approach brings significant improvement compared to strong baselines in terms of both diversity and relevance. In future work, we will provide theoretical justification of the effectiveness of the proposed regularization terms. We expect that this technique will find application as an efficient ”mixing board” for conversation that draws on multiple sources of information.

context	**A**: Are they doing a lot of recycling out in ***? **B**: Well at my workplace they are. We have places for aluminum cans and we have everybody been issued a separate trash can for recyclable paper. Let's see them get that word straight. **A**: Uh-huh **B**: As far as the community goes, it's pretty much voluntary. Nothing's been done. ***. We have just private garbage services.
SpaceFusion	○ They're not recycling as a matter of fact. ○ And it's a waste of time ○ You know the paper is a big recycling program. ○ But they just put it in the trash ○ Or if you have a recycling bag or anything like that.
CVAE +BOW	○ Um - hum. ○ Oh that would be nice. ○ Is that right? ○ It's a it's a luxury ○ Well that's interesting.
MTask	○ Um - hum. ○ That's right. ○ I don't know how much money you're going to do it. ○ That's right. ○ Yeah

Disentangling Language and Knowledge in Task-Oriented Dialogs

Abstract

The Knowledge Base (KB) used for real-world applications, such as booking a movie or restaurant reservation, keeps changing over time. End-to-end neural networks trained for these task-oriented dialogs are expected to be immune to any changes in the KB. However, existing approaches breakdown when asked to handle such changes. We propose an encoder-decoder architecture (BoSsNet) with a novel Bag-of-Sequences (BoSs) memory, which facilitates the disentangled learning of the response's language model and its knowledge incorporation. Consequently, the KB can be modified with new knowledge without a drop in interpretability. We find that BoSsNet outperforms state-of-the-art models, with considerable improvements (>10%) on bAbI OOV test sets and other human-human datasets. We also systematically modify existing datasets to measure disentanglement and show BoSsNet to be robust to KB modifications.

1 Introduction

Task-oriented dialog agents converse with a user with the goal of accomplishing a specific task and often interact with a knowledge-base (KB). For example, a restaurant reservation agent (Henderson et al., 2014) will be grounded to a KB that contains the names of restaurants, and their details.

In real-world applications, the KB information could change over time. For example, (1) a KB associated with a movie ticket booking system gets updated every week based on new film releases, and (2) a restaurant reservation agent, trained with the knowledge of eateries in one city, may be deployed in other cities with an entirely different range of establishments. In such situations, the system should have the ability to conform to new-found knowledge unseen during its training. Ideally, the training algorithm must learn to disentangle the language model from the knowledge interface model. This separation will enable the system to generalize to KB modifications, without a loss in performance.

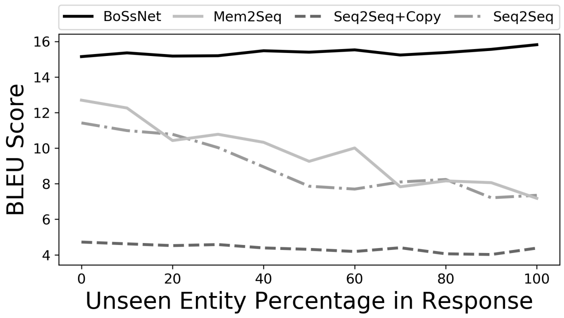

Figure 1: Performance of various task-oriented dialog systems on the CamRest dataset as the percentage of unseen information in the KB changes.

Moreover, for achieving good progress towards the user's task, the agent must also retain the ability to draw inferences based on past utterances and the KB. Notably, we find that existing approaches either achieve this disentanglement or effective progress towards the task, but not both.

For instance, Mem2Seq (Madotto et al., 2018) exhibits satisfactory performance when tested on the training KB. It represents the dialog history and the KB knowledge as a *bag of words* in a flat memory arrangement. This enables Mem2Seq to revisit each word several times, as needed, obtaining good performance. But at the same time, flat memory prevents it from capturing any surrounding context – this deteriorates its performance rapidly when the amount of new unseen information in the KB increases, as shown in Figure 1. On the other hand, the performance of copy augmented sequence-to-sequence network (Seq2Seq+Copy) (Eric and Manning, 2017), is robust to changes in the KB, but fails to achieve acceptable task-oriented performance. It captures context by representing the entire dialog history as one continuous *sequence*. However, it can be difficult for a sequence encoder to reason

over long dialogs found in real-world datasets and its ability to learn the task gets hampered.

We propose BoSsNet, a novel network that effectively disentangles the language and knowledge models, and also achieves state-of-the-art performance on three existing datasets.

To achieve this, BoSsNet makes two design choices. First, it encodes the conversational input as a *bag of sequences* (BoSs) memory, in which the input representation is built at two levels of abstraction. The *higher level* flat memory encodes the KB tuples and utterances to facilitate effective inferencing over them. The *lower level* encoding of each individual utterance and tuple is constructed via a sequence encoder (Bi-GRU). This enables the model to maintain the sequential context surrounding each token, aiding in better interpretation of unseen tokens at test time. Second, we augment the standard cross-entropy loss used in dialog systems with an additional loss term to encourage the model to only copy KB tokens in a response, instead of generating them via the language model. This combination of sequence encoding and additional loss (along with dropout) helps in effective disentangling between language and knowledge.

We perform evaluations over three datasets – bAbI (Bordes and Weston, 2017), CamRest (Wen et al., 2016), and Stanford Multi-Domain Dataset (Eric et al., 2017). Of these, the last two are real-world datasets. We find that BoSsNet is competitive or significantly better on standard metrics in all datasets as compared to state-of-the-art baselines. We also introduce a *knowledge adaptability* (KA) evaluation, in which we systematically increase the percentage of previously unseen entities in the KB. We find that BoSsNet is highly robust across all percentage levels. Finally, we also report a human-based evaluation and find that BoSsNet responses are frequently rated higher than other baselines.

Overall, our contributions are:

1. We propose BoSsNet, a novel architecture to disentangle the language model from knowledge incorporation in task-oriented dialogs.

2. We introduce a *knowledge adaptability* evaluation to measure the ability of dialog systems to scale performance to unseen KB entities.

3. Our experiments show that BoSsNet is competitive or significantly better, measured via standard metrics, than the existing baselines on three datasets.

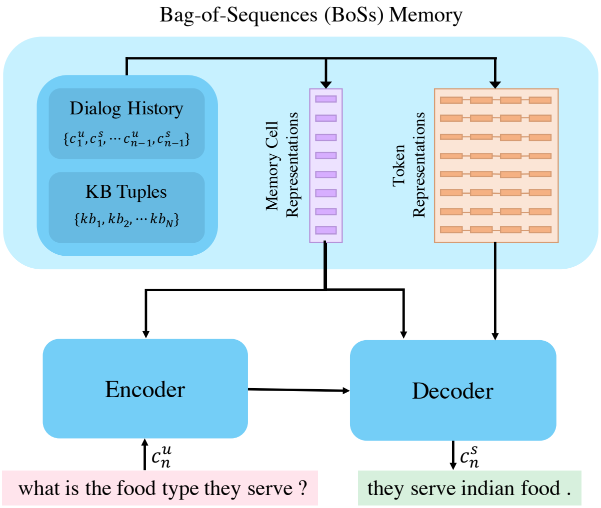

Figure 2: The dialog history and KB tuples stored in the memory have memory cell representations and token representations. The encoder understands the last user utterance using only the memory cell representations. The decoder generates the next response using both representations.

We release our code and *knowledge adaptability* (KA) test sets for further use by the research community.[1]

2 The BoSsNet Architecture

The proposed Bag-of-Sequences Memory Network has an encoder-decoder architecture that takes as input (1) dialog history, which includes a sequence of previous user utterances $\{c_1^u, \ldots, c_n^u\}$ and system responses $\{c_1^s, \ldots, c_{n-1}^s\}$, and (2) KB tuples $\{kb_1, \ldots, kb_N\}$. The network then generates the next system response $c_n^s = \langle y_1 y_2 \ldots y_T \rangle$ word-by-word. The simplified architecture of BoSsNet is shown in Figure 2.

In this section, we first describe the BoSs memory which contains the dialog history and KB tuples, followed by how the memory is consumed by the encoder and the decoder. We finally define the loss function, which, along with dropout, enables disentangled learning of language and knowledge.

2.1 Bag-of-Sequences Memory

The memory M contains the dialog history $\{c_1^u, c_1^s, \ldots, c_{n-1}^u, c_{n-1}^s\}$ and the KB tuples $\{kb_1, \ldots, kb_N\}$. Each utterance in the dialog history and each KB tuple is placed in a memory cell. As utterances and tuples are inherently a sequence, we represent each memory cell m_i as

---

[1] https://github.com/dair-iitd/BossNet

an ordered sequence of tokens $\langle w_i^1 w_i^2 \dots w_i^{|m_i|} \rangle$. For an utterance, the word tokens are followed by a temporal indicator and a speaker indicator {\$u, \$s}. For example, {`good, morning, #1, $s`} indicates this was the first utterance by the system. For a KB tuple, the tokens are sequenced as {*subject, predicate, object*} followed by temporal indicator and a kb indicator (`$db`).

Token representation is generated using a bidirectional GRU. Let the outputs of the forward and backward GRUs for the token w_i^j be denoted as $\overrightarrow{h_i^j}$ and $\overleftarrow{h_i^j}$ respectively. Then the token representation $\phi(w_i^j)$ is given by Eq. 1. Memory cell representation $\psi(m_i)$ is computed by concatenating the forward GRU output of its last token and the backward GRU output of its first token as in Eq. 2.

$$\phi(w_i^j) = [\overrightarrow{h_i^j}; \overleftarrow{h_i^j}] \tag{1}$$

$$\psi(m_i) = [\overrightarrow{h_i^{|m_i|}}; \overleftarrow{h_i^1}] \tag{2}$$

2.2 The BoSsNet Encoder

The encoder used in BoSsNet is similar to the multi-hop attention encoder with layer-wise weights proposed by Sukhbaatar et al. (2015). The encoder in Sukhbaatar et al. (2015) uses two different embedding matrices, whereas we use just one to reduce the number of parameters. The encoder considers the last user utterance as the query $q = \psi(c_n^u)$ and computes the reduced representation q_r using the memory M as follows:

$$\begin{aligned} p_i &= \text{softmax}(q^T \psi(m_i)) && (3)\\ o &= W_r \sum\nolimits_i p_i \psi(m_i) && (4)\\ q_r &= o + W_o q && (5) \end{aligned}$$

where $W_r, W_o \in \mathbb{R}^{d \times d}$ are learnable parameters. The hop step can be re-iterated, by assigning the output of the previous hop as the new input query, i.e., setting $q = q_r$. The output of the encoder after K hops, q_r^k, is assigned as the initial state of the BoSsNet decoder.

2.3 The BoSsNet Decoder

BoSsNet models a copy-augmented sequence decoder, which generates the response one word at a time. At any decode time step t, the decoder can either *generate* a word from the decode vocabulary or *copy* a word from the memory. Consequently, the decoder computes: (1) generate distribution $P_g(y_t)$ over the decode vocabulary, and (2) copy distribution $P_c(y_t)$ over words in the memory.

The generate distribution is computed using a standard sequence decoder (Sutskever et al., 2014) by attending (Luong et al., 2015) over the memory cell representations ψ. The copy distribution is generated by using a *two-level attention*. Given the decoder state s_t, it first computes attention α_t over the memory cells. Then it computes attention over the tokens in each memory cell m_i. Finally it multiplies both these attentions to compute $P_c(y_t)$ as follows:

$$\alpha_i^t = \text{softmax}(s_t \psi(m_i)) \tag{6}$$

$$e_{ij}^t = s_t \phi(w_i^j) \tag{7}$$

$$\beta_{ij}^t = \alpha_i^t * \frac{\exp(e_{ij}^t)}{\sum_k \exp(e_{ik}^t)} \tag{8}$$

$$P_c(y_t = w) = \sum_{ij: w_i^j = w} \beta_{ij}^t \tag{9}$$

The copy and generate distributions are combined using a soft gate $g_s^t \in [0, 1]$ as in See et al. (2017). g_s^t is a function of the decoder state at time t and the word decoded in the previous time step.

2.4 Loss

The decoder is trained using cross-entropy loss. The loss per response is defined as:

$$\mathcal{L}_{ce} = -\sum_{t=1}^{T} \log\Big(g_s^t P_g(y_t) + (1 - g_s^t) P_c(y_t)\Big) \tag{10}$$

where T is the number of words in the sequence to be generated and y_t is the word to be generated at time step t. The decision to generate or copy is learnt implicitly by the network. However, to attain perfect disentanglement, the KB words should be copied, while the language should be generated. In other words, any word in the response that is present in the BoSs KB memory should have a low g_s. To obtain this behavior, we define a disentangle label D_l for each word in the response. This label is set to 1 if the word is present in the BoSs KB memory and 0 otherwise. We define a disentangle loss as follows:

$$\mathcal{L}_d = -\sum_{t=1}^{T} g_s^t \log D_l^t + (1 - g_s^t) \log(1 - D_l^t) \tag{11}$$

We randomly drop some words with disentangle label set to 1. This *Disentangle Label Dropout (DLD)* works in tandem with the disentangle loss and BoSs memory – it encourages the model to copy KB words whenever possible, based on their surrounding words. The overall loss is given as:

$$\mathcal{L} = \mathcal{L}_{ce} + \gamma \mathcal{L}_d \tag{12}$$

The relative weight of $\mathcal{L}_d$ in the overall loss is controlled using a hyper-parameter (γ). The dropout rate is also a hyper-parameter.

3 Experimental Setup

We perform experiments on three task-oriented dialog datasets: bAbI Dialog (Bordes and Weston, 2017), CamRest (Wen et al., 2016), and Stanford Multi-Domain Dataset (Eric et al., 2017).

bAbI Dialog consists of synthetically generated dialogs with the goal of restaurant reservation. The dataset consists of five different tasks, all grounded to a KB. This KB is split into two mutually exclusive halves. One half is used to generate the train, validation, and test sets, while the other half is used to create a second test set called the OOV test set.

CamRest is a human-human dialog dataset, collected using the Wiz-of-Oz framework, also aimed at restaurant reservation. It is typically used to evaluate traditional slot filling systems. In order to make it suitable for end-to-end learning, we stripped the handcrafted state representations and annotations in each dialog, and divided the 676 available dialogs into train, validation, and test sets (406, 135, and 135 dialogs, respectively).

Stanford Multi-Domain Dataset (SMD) is another human-human dialog dataset collected using the Wiz-of-Oz framework. Each conversation is between a driver and an in-car assistant. The other datasets consist of dialogs from just one domain (restaurant reservation), whereas SMD consists of dialogs from multiple domains (calendar scheduling, weather information retrieval, and navigation).

3.1 Knowledge Adaptability (KA) Test Sets

Each bAbI dialog task has an additional OOV test set, which helps to evaluate a model's robustness to change in information in the KB. A model that perfectly disentangles language and knowledge should have no drop in accuracy on the OOV test set when compared to the non-OOV test set. To measure the degree of disentanglement in a model, we generated 10 additional test sets for each real-world corpus by varying the percentage (in multiples of 10) of unseen entities in the KB. We systematically picked random KB entities and replaced all their occurrences in the dialog with new entity names. We will refer to these generated dialogs as the *Knowledge Adaptability* (KA) test sets.

3.2 Baselines

We compare BoSsNet against several existing end-to-end task-oriented dialog systems. These include retrieval models, such as the query reduction network (QRN) (Seo et al., 2017), memory network (MN) (Bordes and Weston, 2017), and gated memory network (GMN) (Liu and Perez, 2017). We also compare against generative models such as a sequence-to-sequence model (Seq2Seq), a copy augmented Seq2Seq (Seq2Seq+Copy) (Gulcehre et al., 2016), and Mem2Seq (Madotto et al., 2018).[2] For fairness across models, we do not compare against key-value retrieval networks (Eric et al., 2017) as they simplify the dataset by canonicalizing all KB words in dialogs.

We noticed that the reported results in the Mem2Seq paper are not directly comparable, as they pre-processed[3] training data in SMD and bAbI datasets. For fair comparisons, we re-run Mem2Seq on the original training datasets. For completeness we mention their reported results (with pre-processing) as Mem2Seq*.

3.3 Evaluation Metrics

We evaluate BoSsNet and other models based on their ability to generate valid responses. The per-response accuracy (Bordes and Weston, 2017) is the percentage of generated responses that exactly match their respective gold response. The per-dialog accuracy is the percentage of dialogs with all correctly generated responses. These accuracy metrics are a good measure for evaluating datasets with boilerplate responses such as bAbI.

To quantify performance on other datasets, we use BLEU (Papineni et al., 2002) and Entity F1 (Eric and Manning, 2017) scores. BLEU measures the overlap of n-grams between the generated response and its gold response and has become a popular measure to compare task-oriented dialog systems. Entity F1 is computed by micro-F1 over KB entities in the entire set of gold responses.

---

[2] We thank the authors for releasing a working code at `https://github.com/HLTCHKUST/Mem2Seq`

[3] Mem2Seq used the following pre-processing on the data: 1) The subject (restaurant name) and object (rating) positions of the rating KB tuples in bAbI dialogs are flipped 2) An extra fact was added to the navigation tasks in SMD which included all the properties (distance, address, etc.) combined together as the subject and *poi* as the object. See Appendix.

3.4 Human Evaluation

We use two human evaluation experiments to compare (1) the *usefulness* of a generated response with respect to solving the given task, and (2) the *grammatical correctness* and *fluency* of the responses on a 0–3 scale. We obtain human annotations by creating Human Intelligence Tasks (HITs) on Amazon Mechanical Turk (AMT). For each test condition (percentage of unseen entities), we sampled 50 dialogs from Camrest and SMD each, and two AMT workers labeled each system response for both experiments, resulting in 200 labels per condition per dataset per system. We evaluate four systems in this study, leading to a total of 1600 labels per condition. The detailed setup is given in the Appendix.

3.5 Training

We train BoSsNet using an Adam optimizer (Kingma and Ba, 2014) and apply gradient clipping with a clip-value of 40. We identify hyper-parameters based on the evaluation of the held-out validation sets. We sample word embedding, hidden layer, and cell sizes from $\{64, 128, 256\}$ and learning rates from $\{10^{-3}, 5\times10^{-4}, 10^{-4}\}$. The hyper-parameter γ in the loss function is chosen between [0-1.5]. The Disentangle Label Dropout rate is sampled from $\{0.1, 0.2\}$. The number of hops for multi-hop attention in the encoder is sampled from $\{1, 3, 6\}$. The best hyper-parameter setting for each dataset is reported in the Appendix.

4 Experimental Results

Our experiments evaluate three research questions.

1. *Performance Study*: How well is BoSsNet able to perform the tasks of our three datasets as compared to the baseline models?
2. *Disentanglement Study*: How robust are the models in generalizing on the KA test sets?
3. *Ablation Study*: What is the performance gain from each novel feature in BoSsNet?

4.1 Performance Study

Table 1 reports the per-response and per-dialog (in parentheses) accuracies on the bAbI dialog tasks. The multi-hop retrieval-based models such as QRN, MN and GMN perform well on the non-OOV test sets for tasks 1, 2, and 5, but fail to exhibit similar performance on the corresponding OOV test sets. This result is expected as these models are trained to retrieve from a pre-defined set of responses. Their poor non-OOV performance on tasks 3 and 4 is attributed to an error in the bAbI dataset construction, due to which, the non-OOV and OOV test conditions are the same for these tasks (see Appendix).

A simple generative model (Seq2Seq) achieves accuracies comparable to the multi-hop retrieval models. Enabling it with the ability to copy from the context (Seq2Seq+Copy) shows a considerable increase in performance, especially on the OOV test sets (and non-OOV tests for tasks 3 and 4).

The strong performance of simple sequence encoders when compared with multi-hop encoders (in retrieval models) raises a question about the value of multi-hop inference. Mem2Seq answers this question, by obtaining improvements in several tasks, specifically on their OOV test sets. This clearly shows that multi-hop inference and the copy mechanism are essentials for task-oriented dialogs.

Despite gains from the Mem2Seq model, the performance difference between the non-OOV and OOV test sets remains large. BoSsNet succeeds to bridge this gap with its ability to better interpret unseen words, using their surrounding context. It obtains significant improvements on average of about 34% per-dialog accuracy and 10% per-response accuracy for the bAbI OOV test sets.

In Table 2, we report results on the real-world datasets. BoSsNet greatly outperforms other models in both Entity F1 metric and BLEU scores on CamRest. On SMD, BoSsNet achieves the best only in Entity F1. On further analysis of the generated responses we observe that BoSsNet responses often convey the necessary entity information from the KB. However, they consist of meaningful phrases with little lexical overlap with the gold response, reducing the BLEU scores. We investigate this further in our human evaluation.

Human Evaluation: We summarize the human evaluation results for real-world datasets in Table 3. BoSsNet shows the best performance on Camrest, and is judged useful 77 times out of 100. Also, it has the highest average grammatical correctness score of 2.28 (very close to Seq2Seq and Mem2Seq). BoSsNet performs on par with Mem2Seq and Seq2Seq in its ability to relay appropriate information to solve SMD dialog tasks, and has a slightly higher grammaticality score.

4.2 Disentanglement Study

We use our generated knowledge adaptability (KA) test sets to measure the robustness of BoSsNet

Table 4: Example from bAbI Task 5 KA test set with 100% OOV entities. Identifying the address of an unseen restaurant is challenging for all models.

and the other baselines to changes in the KB. We perform this experiment on 4 different tasks, namely bAbI tasks 1 and 5, CamRest, and SMD.

Figures 3 and 4 show the per-response accuracies of the two bAbI dialog tasks plotted against the percentage of unseen entities in KA sets. From Figure 3 we observe that BoSsNet remains immune to any variablity in the KB content, whereas the performance of Mem2Seq and Seq2Seq models drops drastically due to their inability to capture semantic representations of the injected KB entities. We see a similar trend in Figure 4, but here all the models show a drop in performance, with BoSsNet appearing the most steady. We explain this trend using the example dialog in Table 4. In the current dialog context, the system is required to provide the address of the selected restaurant, but since more than one restaurant in the KB is unseen, it becomes ambiguous for the network to identify the correct restaurant and infer its address. In the end, the system is forced to pick a random address – the probability of which being correct decreases as more restaurants become unseen.

The performance on the CamRest KA test sets is illustrated in Figures 1 and 5. BoSsNet has the best performance with even a slight increase in both BLEU and Entity F1 metrics as more OOV content is injected in the dialog, probably because it is clear that it needs to copy when processing unseen entities. Seq2Seq+Copy is unable to perform well in CamRest as the length of the input (dialog history + KB tuples) is long and the size of the training set is also small. We believe that Seq2Seq+Copy works best in an environment with an abundance of short dialog training data (e.g., bAbI task 1 in Figure 3).

SMD consists of dialogs with a large KB and a highly varying response pattern. This makes it very difficult to learn the language model – reflected in the low BLEU scores for all the systems. BoSsNet still provides the best F1 entity score due to

	CamRest		SMD	
	Info	**Grammar**	**Info**	**Grammar**
Seq2Seq	26	2.28	22	**2.44**
Seq2Seq+Copy	22	1.22	16	1.04
Mem2Seq	35	2.06	26	1.9
BoSsNet	**80**	**2.44**	**51**	2.28

Table 5: AMT Evaluations on CamRest and SMD (50% unseen) KA datasets

its ability to inference efficiently on the large KB (Figure 6). Mem2Seq shows the best BLEU score performance on the original test set, but its performance drop of 42.5%, from 10.3 at 0% unseen to 5.93 at 100% unseen, is a lot heavier than that of BoSsNet which only drops 7.6% – 8.27 at 0% unseen to 7.64 at 100% unseen.

Human Evaluation: We summarize the human evaluation results for real-world datasets on the 50% unseen KA test set in Table 5. BoSsNet again outperforms the baselines and is labeled *successful* twice more often than the next best model on both Camrest and SMD. Seq2Seq appears to produce better sentence structures on the SMD dataset, primarily because it does not attempt to learn inference on the KB, allowing it to solely focus on learning the language model better.

4.3 Ablation Study

We assess the value of each model element, by removing it from BoSsNet. Table 6 reports the per-response accuracy scores for various configurations of BoSsNet on bAbI dialog tasks. It also reports the BLEU and entity F1 metric of various configurations on CamRest.

Without BoSs Memory: This configuration uses the Bag-of-Bags (BoB) Memory rather than BoSs memory. The BoB memory is a simplified representation, similar to the one in the original Memory Networks. Here the token representation is the vector embedding of the token with no influence from the surrounding words and the memory cell representation is the sum of all its token embeddings. As a result, each word w representation is influenced equally by all words in a memory cell, irrespective of its distance from w. This makes capturing context in the immediate neighbourhood harder. Inability to capture the correct context prevents the configuartion from generalizing to OOV test sets.

Without Disentangled Loss: Disentangled Loss ($\mathcal{L}_d$) plays an important role in enforcing that KB words be copied and other language be generated. By removing this loss component, it achieves better BLEU score in CamRest, but with a drop in Entity F1. Without the disentangled loss, the model sometimes learns to generate KB words. This severely affects OOV performance. As described earlier, an error in bAbI dataset construction tasks 3 and 4 effectively injects the validation set with a lot of OOVs. This anomaly in conjunction with the dropout (DLD), helps the configuration in achieving an acceptable performance for those tasks.

Without Disentangled Label Dropout: BoSsNet learns to generate language and copy KB words. Without DLD, the model learns to memorize words to be copied rather than learning the context under which a word should be copied. Hence, the performance on OOV test sets is much inferior compared to the non-OOV setting.

Overall, we notice that combining all three model elements is necessary in obtaining the best performance across all tasks.

4.4 Qualitative Evaluation

We qualitatively compare the performance of BoSsNet with other baselines using examples.

Table 7, demonstrates the ability of BoSsNet to copy entities (restaurant name and address) in its response. The other baselines either generate unwanted or irrelevant entities in their response, or fail to copy altogether. BoSsNet also best captures the language model effectively with a slight paraphrasing of the gold response.

Table 8 contains only unseen entities. This example highlights the shortcomings of the Seq2Seq model as it ends up predicting a restaurant encountered during training. Mem2Seq copies a restaurant name without learning to sort the restaurants based on rating. BoSsNet, with its efficient memory addressing, is seen to be able to solve both issues.

5 Related Work

Compared to the traditional slot-filling based dialog (Williams and Young, 2007; Wen et al., 2017; Williams et al., 2017), end-to-end training methods (e.g., (Bordes and Weston, 2017), this work) do not require handcrafted state representations and their corresponding annotations in each dialog. Thus, they can easily be adapted to a new domain. We discuss end-to-end approaches along two verticals: 1) decoder: whether the response is retrieved or generated and 2) encoder: how the dialog history and KB tuples are encoded.

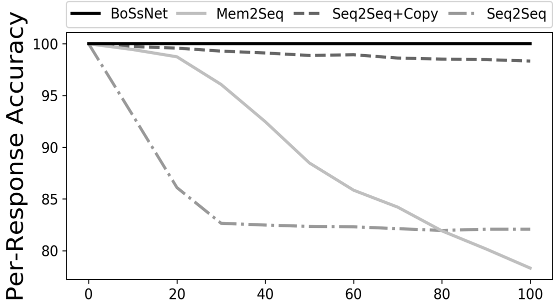

Figure 3: bAbI Task 1: Per-response accuracy comparison on KA sets

Table 6: Ablation study: impact of each model element on BoSsNet

Most of the existing end-to-end approaches *retrieve* a response from a pre-defined set (Bordes and Weston, 2017; Liu and Perez, 2017; Seo et al., 2017). These methods are generally successful when they have to provide boilerplate responses – they cannot construct responses by using words in KB not seen during training. Alternatively, generative approaches are used where the response is *generated* one word at a time (Eric and Manning, 2017; Madotto et al., 2018). These approaches mitigate the unseen entity problem by incorporating the ability to copy words from the input (Vinyals et al., 2015; Gu et al., 2016). The copy mechanism has also found success in summarization (Nallapati et al., 2016; See et al., 2017) and machine translation (Gulcehre et al., 2016). BoSsNet is also a copy incorporated generative approach.

For encoding, some approaches represent the dialog history as a sequence (Eric and Manning, 2017; Gulcehre et al., 2016). Unfortunately, using a single long sequence for encoding also enforces an order over the set of KB tuples making it harder to perform inferencing over them. Other approaches represent the dialog context as a bag. Original Memory Networks (Bordes and Weston, 2017) and its extensions encode each memory element (utterance) as an average of all constituent words – this cannot point to individual words, and hence cannot be used with a copy mechanism. Mem2Seq encodes each word individually in a flat memory. Unfortunately, this loses the contextual information around a word, which is needed to decipher an unseen word. In contrast, BoSsNet uses a bag of sequences encoding, where KB tuples are a set for easier inference, and also each utterance is a sequence for effectively learning when to copy.

6 Conclusions

We propose BOSSNET for training task-oriented dialog systems in an end-to-end fashion. BOSSNET combines a novel bag of sequences memory for storing a dialog history and KB tuples, with a copy-augmented generative decoder to construct dialog responses. It augments standard cross entropy loss of a sequence decoder with an additional term to encourage the model to copy KB words. BOSS memory and new loss term, in conjunction with a disentangle label dropout, enables the decoder to disentangle its language and knowledge models.

BOSSNET achieves the state of the art results on bAbI dialog dataset, outperforming existing models by 10 points or more in its OOV conditions. In the knowledge adaptability test, we find that BOSSNET is highly robust to increasing the percentage of unseen entities at test time, suggesting a good language-knowledge disentanglement. Human evaluations show that BOSSNET responses are highly informative and slightly more grammatical compared to baselines. We will release our code and all curated datasets for further research.

A Two-Level attention on BoSs Memory

To visualize the benefit of two-level attention used on BOSS memory by the decoder, we compare attention weights for two models: our proposed *two-level attention* and a variant with just *one-level attention* (over all the words in the memory). In the example of a sample dialog from bAbI Task 3, shown in Figure 7, the decoder is aimed at predicting the second best restaurant *3 stars*, given that the restaurant with rating *8 stars* has already been suggested and rejected. We show attention only on the KB entries for brevity.

The models share some similarities in their distribution of attention. First, the attention weights are localized over the restaurant names, indicating the preference of the system to point to a specific restaurant. This is supported by the g_s values, 3.14 x 10^{-5} and 1.15 x 10^{-4} for two-level attention and one-level attention respectively, i.e., both models prefer to copy rather than generate. Moreover, entries with the same restaurant name have similar attention weights, reflecting the robustness of the distribution.

We also observe that two-level attention is able to perform the difficult task of *sorting* the restaurant entries based on decreasing order of rating (number of stars). It gives more weight to entries with a high rating (*3 stars* $>$ *2 stars* $>$ *1 star*) and suppresses the weights of any previously suggested restaurant.

The attention over memory cells provides BOSSNET with the ability to infer over multiple sets of tuples. The ability to sort the restaurants and reject a previously seen restaurant can be observed by the attention heat map of Memory cells. Attention over tokens on the other hand can push the attention weights towards either the subject or object in the KB tuple, based on the query's request. Thus using both in conjunction helps BOSSNET perform significantly better than the baselines and illustrates the importance of the BOSS memory in comparison to a flat memory layout.

B Reproducibility

We list out the complete set of hyperparameters used to train BOSSNET for the various datasets in Table 9. Our code will be made publicably accessible for future research purposes. Our trained models and evaluation scripts will also be provided. We will also make our end-to-end reconstruced Camrest dataset along with our whole batch of knowledge adaptability test sets available.

C Example Predictions of BOSSNET and Baselines

Examples from SMD is shown in Table 12 respectively. Examples from KA test set with percentage of unseen entites set to 50 from CamRest and SMD are shown in Table 11 and Table 13 respectively. Examples from KA test set with percentage of unseen entites set to 100 from bAbI dialog Task 1 is shown in Table 10.

D Dataset Preprocessing and Faults

D.1 Mem2Seq Preprocessing

Mem2Seq paper used the following pre-processing on the data:

1. The subject (restaurant name) and object (rating) positions of the rating KB tuples in bAbI dialogs are flipped, while the order remains the same for other tuples remains the same. This pre-processing is illustrated in Figure 8

2. an extra fact was added to the navigation tasks in In-Car Assistant with all the properties (such as distance, address) combined together as the subject and *poi* as the object. This pre-processing is illustrated in Figure 9

The pre-processing has major impact on the performance of Mem2Seq, as it can only copy objects of a KB tuple, while the subject and relation can never be copied.

D.2 bAbI Dataset Faults

The KB entities present in validation and non-OOV test sets for task 3 and 4 do not overlap with those in the train set. This effectively means that non-OOV and OOV test conditions are the same for tasks 3 and 4. This explains the low performance of baseline models on task 3 and 4 non-OOV test sets.

E AMT Setup

Response Relevance Test We show a sample of an Human Intelligence Task (HIT) on Amazon Mechanical Turk in Figure 10a. We randomize the responses generated by the three baseline models and BOSSNET on the same dialog and ask the user to tick all those response options that seem to capture the relevant information of the given sample response. A total of 200 such annotations were collected for Camrest and SMD each.

Response Grammar Test We show a sample of an Human Intelligence Task (HIT) on Amazon Mechanical Turk in Figure 10b. We randomize the responses generated by the three baseline models and BOSSNET on the same dialog and ask the user to rate each response based on the grammatical correctness and natural flow of the sentence. The rating ranges from 0-3 where 0 being the worst and 3 being the best. Note) the sentences were not asked to be rated with respect to each other, but instead as individual occurrences. A total of 200 such annotations were collected for Camrest and SMD each.

F Multi-Hop vs 1-Hop Encoders

Table 14 shows the performance of bAbI tasks and CamRest on two BOSSNET encoder settings. Multi-hops in encoder helps in bAbI task 3 and 5, as they require inferencing over the KB tuples (sorting restaurants by rating) to recommend a restaurant. We also see substantial improvements on CamRest in both BLEU and entity F1 metric.

Chatbot Response Validation (Click to expand)

Each HIT contains an incomplete conversation between a human and a bot that assists in reserving a table in restaurants. The list of restaurants the bot has access to is listed below.

Please select all the options that could be a relevant response to the incomplete conversation. A sample relevant response is posted below.

If none of the responses are appropriate, then please select the best one of the four

If an option conveys the relevant information, ignoring the grammatical mistakes, then please select the option.

Restaurant List

Restaurant	Address	Area	Cuisine	Phone	Pricerange	Postcode
da_vinci_pizzeria	20_milton_road_chesterton	north	italian	01223_351707	cheap	cb41jy

Conversation So Far:

USER	i am interested in a restaurant located in the north part of town that specializes in indonesian food , please
BOT	there are no restaurants serving indonesian food in the north part of town . would you like me to look in another part of town
USER	what about italian food
BOT	da_vinci_pizzeria is a restaurant serving italian food in the north part of town . would you like any additional information
USER	yes , may i have the address and phone number please

Sample Valid Respose: the address is 20_milton_road_chesterton and the phone number is 01223_351707

Option_1	the address is 20_milton_road_chesterton at 20_milton_road_chesterton the phone number is 01223_351707 is there anything else i can help you with
Option_2	da_vinci_pizzeria and the phone number
Option_3	the address is 20_milton_road_chesterton , and phone number is 01223_351707
Option_4	sure is at 30_bridge_street_city_centre and their phone number is is UNK there anything i i i help you you

Instructions

We present 4 different responses that have been created by different chatbots:

- Please rate each response based on grammatical correctness and fluency.
- Rating will be done on a scale of 0-3, where 0 is a completely incorrect sentence and 3 is a fully/nearly grammatically correct and natural sounding sentence.
- Note) The sentences are responses to specific tasks, so don't penalize for proper nouns like "flying_duck" which could be a possible restaurant suggested to the user.
- If a certain response is empty, give it a 0 rating.
- Give a low rating if the sentence is incomplete, e.g., "the weather"

Example

- the the the is restaurant in in in . . . **Rating 1**
- the flying_duck is is a restaurant in the south part of town. **Rating 3**
- the flying_duck is a . part of town **Rating 2**
- . . . restaurant is in . of town **Rating 1**

Option_1	frankie_and_bennys is a italian restaurant in the south . would you like their phone number
Option_2	there is an expensive restaurant in the the the the the the the the the the
Option_3	chiquito_restaurant_bar is an expensive restaurant in the the part part of of town would you like their their
Option_4	is expensive expensive the south south

Select all the options that are possible valid responses to the above conversation:

Abstract

Neural networks equipped with self-attention have parallelizable computation, light-weight structure, and the ability to capture both long-range and local dependencies. Further, their expressive power and performance can be boosted by using a vector to measure pairwise dependency, but this requires to expand the alignment matrix to a tensor, which results in memory and computation bottlenecks. In this paper, we propose a novel attention mechanism called "Multi-mask Tensorized Self-Attention" (MTSA), which is as fast and as memory-efficient as a CNN, but significantly outperforms previous CNN-/RNN-/attention-based models. MTSA 1) captures both pairwise (token2token) and global (source2token) dependencies by a novel compatibility function composed of dot-product and additive attentions, 2) uses a tensor to represent the feature-wise alignment scores for better expressive power but only requires parallelizable matrix multiplications, and 3) combines multi-head with multi-dimensional attentions, and applies a distinct positional mask to each head (subspace), so the memory and computation can be distributed to multiple heads, each with sequential information encoded independently. The experiments show that a CNN/RNN-free model based on MTSA achieves state-of-the-art or competitive performance on nine NLP benchmarks with compelling memory- and time-efficiency.

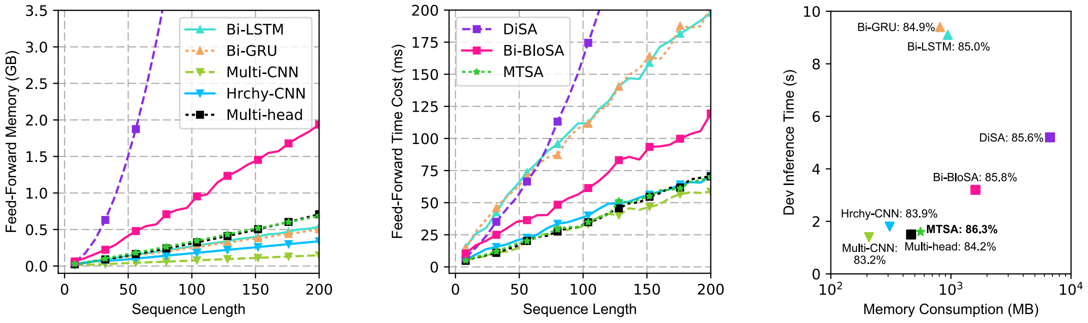
1 Introduction

Recurrent neural network (RNN) and convolutional neural network (CNN) have been broadly used as context fusion modules for natural language processing (NLP) tasks. Recently, RNN/CNN in conjunction with an attention mechanism has been proven to be effective for contextual feature modeling in a wide range of NLP tasks, including sentiment classification (Li et al., 2018), machine translation (Bahdanau et al., 2015), reading comprehension (Seo et al., 2017; Yu et al., 2018), etc. More recently, self-attention mechanisms have been developed for context fusion and syntactic dependency modeling with the advantage of fewer parameters, more parallelizable computation, and better empirical performance (Hu et al., 2017; Vaswani et al., 2017; Shen et al., 2018a). In addition, neural networks based solely on self-attention mechanisms have achieved state-of-the-art quality on many NLP tasks, e.g., machine translation (Vaswani et al., 2017), sentence embedding (Shen et al., 2018a) and semantic role labeling (Tan et al., 2017).

Self-attention mechanisms can be categorized into two classes according to the type of dependency each aims to model. The first category is *token2token* self-attention (Hu et al., 2017; Vaswani et al., 2017; Shen et al., 2018a) that captures syntactic dependency between every two tokens in a sequence. An efficient dot-product compatibility function is usually deployed to measure this pairwise dependency (Vaswani et al., 2017). In contrast, additive compatibility function captures the dependency by multi-layer perceptron (MLP), and can usually achieve better performance (Britz et al., 2017). Its expressive power can be further improved if expanded to multiple dimensions (Shen et al., 2018a). This multi-dim self-attention empirically surpasses dot-product one, but suffers from expensive computation and memory, which grow linearly with the number of features and quadratically with the sequence length. Hence, it is not scalable to long sequences in practice.

The second category is *source2token* self-attention (Liu et al., 2016; Lin et al., 2017; Shen et al., 2018a) aiming to capture global dependency, i.e., the importance of each token to the entire sequence for a specific task. Its time and space complexities grow linearly, rather than quadratically,

Proceedings of NAACL-HLT 2019, pages 1256–1266
Minneapolis, Minnesota, June 2 - June 7, 2019.



(a) (b) (c)

Figure 1: (a) Memory consumption and (b) time cost *vs.* sequence length on synthetic data; (c) memory load (x-axis), inference time on dev set (y-axis) and test accuracy on the SNLI dataset.

with the sequence length. Hence, it is empirically efficient in terms of memory and computation even if expanded to multiple dimensions, i.e., using a vector of feature-wise scores instead of a scalar for the global dependency. But, it is hard to reach state-of-the-art performance on NLP tasks due to the lack of pairwise and local dependencies.

In this paper, we propose a novel attention mechanism called multi-mask tensorized self-attention (MTSA), for context fusion. In MTSA, 1) the pairwise dependency is captured by an efficient dot-product based token2token self-attention, while the global dependency is modeled by a feature-wise multi-dim source2token self-attention, so they can work jointly to encode rich contextual features; 2) self-attention alignment scores are tensorized for more expressive power in that each pair of tokens has one score for each feature, but no tensor computation is required other than simple and efficient matrix multiplications when implemented; 3) the tensors above are computed in multiple subspaces (i.e., in a multi-head fashion) rather than in the original input space, so the required memory and computation can be distributed to multiple subspaces; and 4) a distinct positional mask is applied to each head in order to encode rich structural information such as the sequential order and relative position of tokens.

In the experiments, we build CNN/RNN-free neural networks based on MTSA for sentence embedding and sequence tagging tasks, including natural language inference, semantic role labeling, sentiment analysis, question-type classification, machine translation, etc. The results demonstrate that MTSA achieves state-of-the-art or competitive performance on nine benchmark datasets. To summarize the comparison of MTSA with recently popular models, we show the memory consumption and time cost *vs.* sequence length respectively in Figure 1(a) and 1(b) on synthetic data (batch size of 64 and feature channels of 300). On the SNLI (Bowman et al., 2015), a public dataset for language inference, as shown in Figure 1(c), MTSA achieves the best result but is as fast and as memory-efficient as the CNNs (all baselines and the benchmark are detailed in Section 4).

Notations: 1) lowercase denotes a vector; 2) bold lowercase denotes a sequence of vectors (stored as a matrix); and 3) uppercase denotes a matrix or tensor.

2 Background

2.1 Attention Mechanism

Given an input sequence of token embeddings or memory slots $\boldsymbol{x} = [x_1, \dots, x_n] \in \mathbb{R}^{d_e \times n}$, and a vector representation of a query $q \in \mathbb{R}^{d_q}$, attention mechanism (Bahdanau et al., 2015; Luong et al., 2015) computes an alignment score between each token x_i and q by a compatibility function $f(x_i, q)$, which aims to measure the dependency/relevance between x_i and q, or the attention of q to x_i, w.r.t. a given task. The scores are transformed into probabilities through a $\mathrm{softmax}$ function. These probabilities are then used as weights to sum all the tokens and generate a contextual embedding for q, i.e.,

$$p(z|\boldsymbol{x}, q) = \mathrm{softmax}(a), \quad a = [f(x_i, q)]_{i=1}^{n},$$
$$s = \sum_{i=1}^{n} p(z = i|\boldsymbol{x}, q) \cdot x_i = \mathbb{E}_{i \sim p(z|\boldsymbol{x}, q)}[x_i], \quad (1)$$

where $a \in \mathbb{R}^n$ denotes the vector of n alignment scores, $p(z|\boldsymbol{x}, q)$ is the categorical distribution for attention probabilities, which is derived from applying softmax function to a. And, $s \in \mathbb{R}^{d_e}$ is the output vector for the query q.

There are two major types of compatibility functions, leading to the two most frequently used attention mechanisms. The first one is dot-product or multiplicative compatibility function (Eq.(2)), which composes **dot-product attention** mechanism (Luong et al., 2015) using cosine similarity to model the dependencies. The other one is additive or multi-layer perceptron (MLP) compatibility function (Eq.(3)) that results in **additive attention** mechanism (Bahdanau et al., 2015) using MLP to model the dependencies.

$$f(x_i, q) = \langle W^{(d1)} x_i, W^{(d2)} q \rangle, \qquad (2)$$

$$f(x_i, q) = w^T \sigma_a(W^{(a)}[x_i; q] + b^{(a)}) + b, \qquad (3)$$

where $W^{(d1)} \in \mathbb{R}^{d_i \times d_e}$, $W^{(d2)} \in \mathbb{R}^{d_i \times d_q}$, $W^{(a)} \in \mathbb{R}^{d_a \times (d_e + d_q)}$, $w \in \mathbb{R}^{d_a}$ are learnable parameters, $\langle \cdot, \cdot \rangle$ denotes inner-product. Empirically, networks with additive attention usually outperform those with dot-product attention, but require more computation time and memory (Britz et al., 2017).

Multi-dim attention mechanism (Shen et al., 2018a) expands the alignment score in previous attention mechanisms to a vector for feature-wise scores, each computed on a feature dimension. It has greater capacity to model complex dependencies, and can handle context variation and polysemy problems harassing many NLP tasks. **In particular, it replaces vector $w^T \in \mathbb{R}^{1 \times d_a}$ in additive compatibility function (Eq.(3)) with a matrix $W \in \mathbb{R}^{d_e \times d_a}$, and thus produces d_e scores to describe the attention of q to x_i.**

2.2 Self-Attention Mechanism

Self-attention mechanism is a special case of attention mechanisms, where the query q stems from the input sequence itself. Self-attention mechanisms can be classified into token2token or source2token self-attention mechanism according to the type of dependency each aims to model.

A) Token2token self-attention mechanism (Vaswani et al., 2017; Shen et al., 2018a) aims at producing a context-aware representation for each token in light of its syntactic dependencies on other tokens from the same sequence. Two examples of token2token self-attention are 1) scaled dot-product self-attention which composes the multi-head self-attention (Vaswani et al., 2017), and 2) masked self-attention used in directional self-attention (Shen et al., 2018a).

A.1) Scaled dot-product attention mechanism (Vaswani et al., 2017) in general form has three arguments: query tokens $\boldsymbol{q} \in \mathbb{R}^{d_i \times m}$, key tokens $\boldsymbol{k} \in \mathbb{R}^{d_i \times n}$ and value tokens $\boldsymbol{v} \in \mathbb{R}^{d_h \times n}$ associated with the key tokens. It uses a scaled dot-product function to model the relationship between each query and key, and finally outputs a sequence $\boldsymbol{s} = [s_1, \dots, s_m] \in \mathbb{R}^{d_h \times m}$ such that

$$\boldsymbol{s} = \mathrm{sdpAttn}(\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}) \triangleq \boldsymbol{v}\, \mathrm{softmax}(\frac{\boldsymbol{q}^T \boldsymbol{k}}{\sqrt{d_q}})^T \qquad (4)$$

A special case of this mechanism is that the three input arguments are derived from the same source, i.e., ***q*/*k*/*v*** $= f^{q/k/v}(\boldsymbol{x})$, which can be referred to as a token2token self-attention, namely scaled dot-product self-attention. As for **multi-head attention** mechanism, the input is projected into multiple subspaces, then parameter-untied scaled dot-product attention is applied to the embeddings in each subspace. The results for multiple subspaces are concatenated to form the final output $\boldsymbol{s}$, i.e.,

$$\boldsymbol{s} = W^{(o)}[H_1; \dots; H_h], \qquad (5)$$
$$\text{where } H_c = \mathrm{sdpAttn}(W_c^q \boldsymbol{q}, W_c^k \boldsymbol{k}, W_c^v \boldsymbol{v}).$$

A.2) Masked self-attention mechanism (Shen et al., 2018a) uses multi-dim compatibility function to model the dependency between every two tokens in a sequence, and uses positional mask to encode sequential information. It overcomes inherent problem appearing in self-attention compared to RNNs on the lack of sequential information. Its compatibility function is defined as

$$f(x_i, x_j) = c \cdot \tanh\{(W^{(m)}[x_i; x_j] + b^{(m)})/c\} + M_{i,j} \qquad (6)$$

where c is a constant scalar, $W^{(m)} \in \mathbb{R}^{d_e \times 2d_e}$ is learnable weight matrix, and M is a positional mask with each entry $M_{i,j} \in \{-\infty, 0\}$. When $M_{i,j} = -\infty$, applying softmax function to the alignment scores results in a zero attention probability, which cuts off the attention of x_j to x_i. Hence, masked self-attention with an asymmetric mask, where $M_{ij} \neq M_{ji}$, can encode sequential or other structural information (Shen et al., 2018a; Im and Cho, 2017). To this end, two positional masks have been proposed to encode the forward and backward order information respectively, i.e.,

$$M_{i,j}^{fw} = \begin{cases} 0, & i < j \\ -\infty, & \text{otherwise} \end{cases} \quad M_{i,j}^{bw} = \begin{cases} 0, & i > j \\ -\infty, & \text{otherwise} \end{cases}$$

Furthermore, **directional self-attention** (DiSA) (Shen et al., 2018a) concatenates the features produced by masked self-attention mechanisms with the forward and backward positional masks (i.e., M^{fw}, M^{bw}), leading to context-ware representations with bi-directional information encoded.

B) Source2token self-attention mechanism (Liu et al., 2016; Lin et al., 2017; Shen et al., 2018a) is designed for sentence embedding or sequence compression, which is based on the importance of each token x_i to the entire source sequence $\boldsymbol{x}$ for a specific task. Specifically, it removes the query q from the compatibility function $f(x_i, q)$ when computing the alignment score. For example, the compatibility function of additive source2token self-attention mechanism is to simply remove q from Eq.(3).

3 Proposed Models

In this section, we firstly elaborate on tensorized self-attention (TSA) in Section 3.1, which captures both pairwise and global dependencies by combining the two types of self-attention mechanisms introduced in Section 2.2. Then, we extend TSA to multi-mask tensorized self-attention (MTSA) in Section 3.2 by applying different positional masks to TSA in multiple subspaces (multi-head fashion). Lastly, in Section 3.3, we present an efficient computation scheme for MTSA without any high-rank tensor computation involved even if tensorized alignment scores are used.

3.1 Tensorized Self-Attention (TSA)

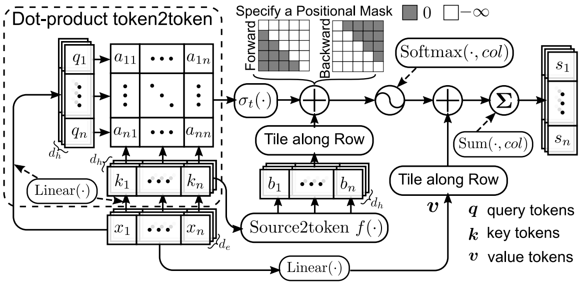


Figure 2: Tensorized self-attention (TSA) Mechanism.

Tensorized self-attention (TSA), whose structure is illustrated in Figure 2, is a neural mechanism that can be trained to model both pairwise and global dependencies, while any previous self-attention mechanism only focuses on one type of dependencies. TSA models both types by combining the aforementioned token2token and source2token self-attention mechanisms. This generates an $n \times n \times d_h$ tensor containing the alignment scores between every two tokens on each feature dimension. These scores are then normalized and transformed into probability weights, which are used to sum all dependent tokens and then generate the contextual embedding for each input token. We will demonstrate later in Section 3.3 that only matrix rather than tensor operation is required when executing the procedures above.

To facilitate the elaboration of proposed models and keep the consistent notation with prior attention mechanisms, TSA first projects the input embeddings $\boldsymbol{x}$ into three spaces to represent the query, key and value tokens, respectively.

$$\boldsymbol{q} = W^{(t1)}\boldsymbol{x}, \ \boldsymbol{k} = W^{(t2)}\boldsymbol{x}, \text{ and } \boldsymbol{v} = W^{(t3)}\boldsymbol{x}, \quad (7)$$

where $W^{(t1)}, W^{(t2)} \in \mathbb{R}^{d_i \times d_e}$ and $W^{(t3)} \in \mathbb{R}^{d_h \times d_e}$ are learnable weights for projections.

TSA then integrates two kinds of compatibility functions from two self-attention mechanisms respectively. Firstly, the scaled dot-product self-attention is used to capture dependency between every two tokens. Dot-product operations are fast, and sufficient to model the **pairwise dependency** in most tasks. Its compatibility function is

$$f^t(k_i, q_j) = \langle k_i, \ q_j \rangle / \sqrt{d_i}, \ \ \forall i, j \in [n], \quad (8)$$

where $\langle \cdot, \cdot \rangle$ is inner-product operation. Then, a multi-dim source2token self-attention mechanism is used to estimate the contribution of each token to the given task on each feature dimension. It aims at capturing the importance of each token to the entire input sequence w.r.t. the task, i.e., the **global dependency**. The multi-dim extension only linearly increases the memory and computation of source2token self-attention by a multiplicative factor d_h, but is essentially helpful to improve expressive capability in line with prior works (Shen et al., 2018a). Its compatibility function is

$$f^s(k_i) = W^{(s2)}\sigma_m(W^{(s1)}k_i + b^{(s1)}) + b^{(s2)}, \quad (9)$$

where $\forall i \in [n]$, $W^{(s1)} \in \mathbb{R}^{d_a \times d_i}, W^{(s2)} \in \mathbb{R}^{d_h \times d_a}$ are the learnable weights, and $\sigma_m(\cdot)$ is an activation function. The compatibility function used in TSA broadcasts the scalar alignment score $f^t(k_i, q_j) \in \mathbb{R}$ computed by the token2token self-attention to all d_h feature dimensions, and then adds them to the feature-wise score vector

$f^s(k_i) \in \mathbb{R}^{d_h}$ computed by the source2token self-attention. In addition, the positional masks from masked self-attention (in Section 2.2) are also integrated to encode sequential and structural information. These yield following compatibility function of TSA.

$$\left[f^{tsa}(k_i, q_j)\right]_l = \sigma_t\left(f^t(k_i, q_j)\right) + \sigma_s([f^s(k_i)]_l) + M_{i,j}, \tag{10}$$

where $\forall i, j \in [n]$, $\forall l \in [d_h]$. $\sigma_t(\cdot)$ and $\sigma_t(\cdot)$ are two scale functions. They control the way to combine two kinds of scores and their weights.

For each query token q_j, a $\mathrm{softmax}$ function is applied to the alignment scores $[f^{tsa}(k_i, q_j)]_{i=1}^n$ on each feature dimension, resulting in a categorical distribution over all value tokens $[v_i]_{i=1}^n$ based on corresponding key tokens $[k_i]_{i=1}^n$. The probability of token q_j attending to v_i on the l^{th} feature dimension (i.e., $z_l = i$) is

$$p(z_l = i|\boldsymbol{k}, q_j) \triangleq [p_i^j]_l \triangleq \frac{e^{\left[f^{tsa}(k_i, q_j)\right]_l}}{\sum_{g=1}^n e^{\left[f^{tsa}(k_g, q_j)\right]_l}}, \tag{11}$$

where, $\forall i, j \in [n]$, $\forall l \in [d_h]$. TSA outputs a contextual embedding for each input token on every feature dimension as the weighted sum of all the value token embeddings on that dimension, where the weights are provided by the probabilities in Eq.(11). It is the expectation of sampling a value token embeddings on each feature dimension according to the feature-wise probability distribution, i.e.,

$$\boldsymbol{s} \triangleq [s_j]_{j=1}^n, \quad \text{where} \tag{12}$$

$$s_j \triangleq \left[\mathbb{E}_{i \sim p(z_l|\boldsymbol{k}, q_j)}([v_i]_l)\right]_{l=1}^{d_h} = \sum\nolimits_{i=1}^n p_i^j \cdot v_i$$

3.2 Multi-Mask Tensorized Self-Attention (MTSA) Mechanism

Rather than computing attention in the original input space, multi-head attention (Vaswani et al., 2017) projects the input sequence to multiple subspaces, applies attention to the projected embedding in each subspace, and concatenates their outputs at last. The computations associated with multiple heads can be completed in parallel. By using adequate heads, each with a low-dimensional subspace (i.e., the representation dimension for each head is updated by $d_h \leftarrow d_h/h$ where h is the number of head), it reduces parameters and memory/computation cost and increases diversity of the attention. In addition, to encode different kinds of sequential or structural information, multiple different positional masks (e.g., forward, backward and multi-length window) can be further applied to the multiple heads.

The memory-/time-efficiency and expressive power of TSA can be improved by using the combination of the multi-head and multi-mask techniques introduced above. By writing TSA mechanism as a function $\mathrm{TSA}(\boldsymbol{x}, M)$ with input sequence $\boldsymbol{x} \in \mathbb{R}^{d_e \times n}$ and a positional mask $M \in \mathbb{R}^{n \times n}$, and the output given by Eq.(12), multi-mask tensorized self-attention (MTSA) produces

$$\boldsymbol{s} = W^{(o)}[H_1; \ldots; H_h], \quad \text{where } H_c = \mathrm{TSA}^c(\boldsymbol{x}, M^c), \tag{13}$$

where $W^{(o)} \in \mathbb{R}^{h \cdot d_h \times h \cdot d_h}$, h is the number of heads, TSA^c denotes the c^{th} parameter-independent TSA block that produces a d_h-dim representation in the c^{th} subspace, M^c represents the positional mask applied to attention in the c^{th} subspace, $[\cdot; \ldots; \cdot]$ denotes a vertical concatenation operation, and $\boldsymbol{s} \in \mathbb{R}^{h \cdot d_h \times n}$ is the output of MTSA. In our experiments, we apply forward mask to half of the heads and apply backward mask to the other half to encode bi-directional order information of the input sequence.

3.3 Computation-Optimized MTSA

Algorithm 1 Multi-Mask Tensorized Self-Attention

```
Input: input sequence $\boldsymbol{x} \in \mathbb{R}^{d_e \times n}$, head number $h$, subspace dimension $d_h$, positional masks $\{M^c\}_{c=1}^h$, and weights/biases: $\{W_c^{(t1)}, W_c^{(t2)} \in \mathbb{R}^{d_i \times d_e}, W_c^{(t3)} \in \mathbb{R}^{d_h \times d_e}, W_c^{(s1)} \in \mathbb{R}^{d_a \times d_i}, W_c^{(s2)} \in \mathbb{R}^{d_h \times d_a}$, and $b_c^{(s1)}, b_c^{(s2)}\}_{c=1}^h$, and $W^{(o)}$
Output: contextual embeddings $\boldsymbol{s} = [s_1, \ldots, s_n] \in \mathbb{R}^{h \cdot d_h \times n}$
for all $c = 1, \ldots, h$ do    ▷ Computing $h$-head in parallel
    $\boldsymbol{q^c}, \boldsymbol{k^c}, \boldsymbol{v^c} \leftarrow W_c^{(t1)}\boldsymbol{x}, W_c^{(t2)}\boldsymbol{x}, W_c^{(t3)}\boldsymbol{x}$
    $R_c \leftarrow \frac{(\boldsymbol{k^c})^T \boldsymbol{q^c}}{\sqrt{d_h}}$    ▷ $n \times n$ token2token attention scores
    $S_c \leftarrow W_c^{(s2)}\sigma_m(W_c^{(s1)}\boldsymbol{k^c} + b_c^{(s1)}) + b_c^{(s2)}$    ▷ $d_h \times n$ scores of source2token attention
    $E_c^R \leftarrow \exp(\sigma_t(R_c)) \cdot \exp(M^c)$    ▷ Applying mask $M^c$ to token2token weights
    $E_c^S \leftarrow \exp(\sigma_s(S_c))$; $E_c^X \leftarrow \boldsymbol{v^c} \cdot E_c^S$    ▷ Applying source2token weights $E_c^S$ to $\boldsymbol{v^c}$
    $H_c \leftarrow E_c^X E_c^R / E_c^S E_c^R$    ▷ Applying masked token2token weights $E_c^R$ and normalizing
end for
Return $\boldsymbol{s} \leftarrow W^{(o)}[H_1; \ldots; H_h]$    ▷ Vertical concatenation of the outputs from all $h$ heads
```

As shown in Eq.(10) and Eq.(11), TSA or each head of MTSA needs to compute the attention scores and probabilities as $n \times n \times d_h$ tensors. In accordance with multi-dim self-attention (Shen et al., 2018a), this makes TSA more expressively powerful and improves the final performance for sequence modeling, but terribly leads to memory explosion and computational bottleneck on long sequences with large n and d_h. Fortunately, in MTSA, it is possible to significantly reduce the demand on computations to matrix-only operations by exploring the computational structure.

A memory-optimized and highly-parallelizable computation scheme for MTSA is given in Algorithm 1. For each head, the score matrices of token2token and source2token are computed in steps 3 and 4 respectively. Then, we combine token2token scores with the positional mask to form a new mask in step 5, and compute the $d_h \times n$ output embedding with the weighs from the multi-dim source2token self-attention in step 6. Finally, in step 7, we apply the new mask from step 5 to the weighted embedding from step 6 and complete the normalization. This procedure generates the exactly same output as Eq.(13)but no any tensor operation is incurred.

4 Experiments

We compare MTSA with commonly-used context fusion baselines on several NLP tasks[1]. When addressing a sentence embedding problem, a multi-dim source2token self-attention is applied on the top of context fusion module to produce the sequence embedding. Codes are implemented in Python with Tensorflow and executed on a single NVIDIA GTX 1080Ti graphics card. In addition, data for both time cost and memory consumption are collected under Tensorflow-1.7 with CUDA9 and cuDNN7.

The context fusion baselines include **1) Bi-LSTM** (Graves et al., 2013): 600D bi-directional LSTM consisting of 300D forward plus 300D backward LSTMs, **2) Bi-GRU** (Chung et al., 2014): 600D bi-directional GRU, **3) Multi-CNN** (Kim, 2014): three CNNs with 200D kernels to model 3/4/5-grams respectively, **4) Hrchy-CNN** (Gehring et al., 2017): 3-layer 300D stacked CNN with kernel size 5, gated linear units (Dauphin et al., 2016) and residual connections (He et al., 2016), **5) Multi-head** (Vaswani et al., 2017): 600D multi-head self-attention with 8 heads (75-dim subspace per head) and positional embedding used by Vaswani et al. (2017), **6) DiSA** (Shen et al., 2018a): 600D directional self-attention mechanism consisting of 300D forward and 300D backward masked self-attentions, and **7) Bi-BloSA** (Shen et al., 2018c): 600D bi-directional block self-attention with intra-/inter-block self-attention, aiming to reduce the time and space complexities of multi-dim self-attention by using hierarchical structure.

4.1 Natural Language Inference

Natural language inference (NLI) aims at speculating on the relationship between a premise and a corresponding hypothesis, where the relationship could be *entailment*, *neutral* or *contradiction*. In experiments, we first compare MTSA with other baselines on the Stanford Natural Language Inference (Bowman et al., 2015) (SNLI) dataset.

Following the method of applying *sentence-encoding* model to NLI given by Bowman et al. (2016), two parameter-tied sentence-encoding models are used to generate embeddings for premise and hypothesis, resulting in s^p and s^h respectively. The concatenation of s^p, s^h, $s^p - s^h$ and $s^p \odot s^h$ representing the relationship is passed into a 3-way neural classifier for final prediction.

The experimental results of the models from the official leaderboard, baselines, and MTSA are shown in Table 1. MTSA achieves state-of-the-art performance with less time and memory cost. Compared to the methods from the leaderboard, MTSA outperforms RNN-based encoders (e.g., Residual stacked enc.), RNN+attention encoders (e.g., Deep Gated Attn.) and even parsing trees based encoders (e.g., Gumbel TreeLSTM enc.) by a large margin. Compared to the two competitive self-attention networks with complicated and expensive training computations, MTSA trained in end-to-end manner achieves the same state-of-the-art performance by using much fewer parameters and less computational time.

Compared to baselines, MTSA is $4 \sim 5\times$ faster than RNN-based models and outperforms CNN-based models given a similar number of parameters and computation time. Moreover, compared to the dot-product self-attention (Multi-head), MTSA costs similar time and memory but performs more expressively powerful self-attention, and thus achieves better performance. Furthermore, compared to the multi-dim self-

MTSA w/o proposed modules	1.8m	1.1	84.3 (-2.0)

Table 3: An ablation study of MTSA on SNLI.

attention (DiSA and Bi-BloSA), MTSA uses much less memory and time but even produces much better prediction quality.

In addition, to further improve the state-of-the-art performance, in contrast to training from scratch, a language model built on the Transformer (Vaswani et al., 2017) unsupervisedly pretrained on large English corpus (detailed by Radford et al. (2018)) is transfered for the baseline and proposed models for *sentence-encoding* based NLI tasks. As shown in Table 2, MTSA integrated with pretrained language model can achieve new state-of-the-art accuracy on both SNLI and Multi-Genre Natural Language Inference (MultiNLI) (Williams et al., 2017)[2] among all *sentence-encoding* models.

An ablation study of MTSA is shown in Table 3 to verify the capability of its each part in context fusion. The results show that token2token (modeling pairwise dependency), source2token (modeling global dependency), and positional masks (encoding sequential information) all contribute important information to sequence modeling, and the contributions are complementary.

4.2 Semantic Role Labeling

To verify the capability of MTSA in generating context-aware representation of each token, we compare it with baselines on semantic role labeling (SRL) task, which aims to tag each token from an input sequence with a label for its semantic role. Particularly, given a sentence, the goal of SRL is to identify the arguments of each target verb into semantic roles, which can benefit many downstream NLP tasks. SRL has two steps:

Table 5: Experimental results on five sentence classification benchmarks. References: [a](Mikolov et al., 2013), [b](Kiros et al., 2015), [c](Kalchbrenner et al., 2014), [d](Lei and Zhang, 2017).

1) assigning either a semantic argument or non-argument to a given predicate and 2) labeling a specific semantic role for the identified argument.

We follow the experimental setup in Tan et al. (2017), where the SRL task is treated as a BIO tagging problem. Tan et al. (2017) designed a deep attentive neural net by stacking multi-head self-attention, named as deepatt, to perform context fusion, whose output is then passed to a neural classifier to make the final decision. The results achieved by previous methods, baselines, and MTSA are shown in Table 4, which demonstrates that MTSA achieves new state-of-the-art performance on the CoNLL-05 dataset by costing similar training time as CNN and multi-head self-attention baselines.

4.3 Sentence Classifications

The goal of sentence classification is to predict the correct label for a sentence in various scenarios. We evaluate the models on five sentence classification benchmarks for different NLP tasks, which include **1) CR** (Hu and Liu, 2004): customer reviews of various products to predict whether the review is positive or negative, **2) MPQA** (Wiebe et al., 2005): an opinion polarity detection subtask of the MPQA dataset, **3) SUBJ** (Pang and Lee, 2004): subjectivity dataset where a label indicates whether a sentence is subjective or objective, **4) TREC** (Li and Roth, 2002): question-type classification dataset which classifies the question sentences into six classes, **5) SST-5** (Socher et al., 2013): the Stanford Sentiment Treebank dataset with five sentiment labels. The reported accuracies for CR, MPQA, and SUBJ are the mean of 10-fold cross validation. The accuracies for TREC are the mean of five runs on the dev set, and the accuracies for SST-5 are the mean of five runs on the test set. All standard deviations are shown in parentheses.

The prediction accuracies achieved on these five benchmarks are shown in Table 5. MTSA achieves the best prediction accuracy on CR, MPQA, TREC and SST-5 benchmarks with better time efficiency and a lower memory load.

4.4 Machine Translation

We also evaluate proposed model on WMT 2014 English-German translation task for exhaustive comparisons with multi-head attention. We replace multi-head self-attention modules in the encoder of official Transformer implementation with MTSA module and do not tune the hyperparameters. Although our computation resources is limited, we use two training setups and also introduce t-test to ensure that MTSA consistently outperforms multi-head self-attention in Transformer.

Model	Multi-head (Transformer)	MTSA
Param#	61.38M	61.58M
Setup1	23.64	24.09
	p-value: 0.001 (6 runs)	
Setup2	26.98	27.21
	p-value: 0.080 (3 runs)	

Table 6: Results for the Transformer with either multi-head self-attention or proposed MTSA. The reported BLEU values for Setup 1 and 2 are the mean of 5 and 3 runs respectively.

For **Setup1**, we use default hyperparameter set of *transformer_base_single_gpu* provided by official implementation with 1 × P100 , batch size of 2048 and training step of 250K, and report BLEU value for the last checkpoint. For **Setup2**, we use the hyperparameter set of *transformer_base* with the modification of 1) using 4× instead of 8 × P100, 2) increasing batch size from 4096 to 6144 per GPU, and 3) using training step of 133K.

As shown in Table 6, with small p-value for both training setup 1 and 2, the encoder with MTSA significantly outperforms that with multi-head self-attention, which demonstrates that multi-dim based MTSA modeling both pairwise and global dependencies is more expressive than dot-product based multi-head self-attention. Although the results do not improve state-of-the-art BLEU value of machine translation task, the purpose of this experiment to verify the effectiveness of MTSA in contrast to dot-product based multi-head self-attention is accomplished.

5 Conclusion

In conclusion, MTSA is highly parallelizable with more expressive power since it efficiently captures the pairwise dependency at token level, but delicately models the global dependency at feature level, and distributes computations to multiple heads, each equipped with a distinct positional mask. These lead to a sweet spot of the trade-off between performance and efficiency, and make MTSA as memory-efficient as CNN and scalable to long sequences but outperform previous (and even multi-dim) self-attention mechanisms in terms of prediction quality. The experiments conducted on nine NLP tasks verify that the MTSA can reach state-of-the-art performance with appealing efficiency.

WiC: the Word-in-Context Dataset
for Evaluating Context-Sensitive Meaning Representations

Abstract

By design, word embeddings are unable to model the dynamic nature of words' semantics, i.e., the property of words to correspond to potentially different meanings. To address this limitation, dozens of specialized meaning representation techniques such as sense or contextualized embeddings have been proposed. However, despite the popularity of research on this topic, very few evaluation benchmarks exist that specifically focus on the dynamic semantics of words. In this paper we show that existing models have surpassed the performance ceiling of the standard evaluation dataset for the purpose, i.e., Stanford Contextual Word Similarity, and highlight its shortcomings. To address the lack of a suitable benchmark, we put forward a large-scale Word in Context dataset, called WiC, based on annotations curated by experts, for generic evaluation of context-sensitive representations. WiC is released in https://pilehvar.github.io/wic/.

1 Introduction

One of the main limitations of mainstream word embeddings lies in their static nature, i.e., a word is associated with the same embedding, independently from the context in which it appears. Therefore, these embeddings are unable to reflect the dynamic nature of ambiguous words[1], in that they can correspond to different (potentially unrelated) meanings depending on their usage in context (Camacho-Collados and Pilehvar, 2018). To get around this limitation dozens of proposals have been put forward, mainly in two categories: multi-prototype embeddings (Reisinger and Mooney, 2010; Neelakantan et al., 2014; Pelevina et al., 2016), which usually leverage context clustering in order to learn distinct representations for individual meanings of words, and contextualized word embeddings (Melamud et al., 2016; Peters et al., 2018), which instead compute a single dynamic embedding for a given word which can adapt itself to arbitrary contexts for the word.

Despite the popularity of research on these specialised embeddings, very few benchmarks exist for their evaluation. Most works in this domain either perform evaluations on word similarity datasets (in which words are presented in isolation; hence, they are not suitable for verifying the dynamic nature of word semantics) or carry out impact analysis in downstream NLP applications (usually, by taking word embeddings as baseline). Despite providing a suitable means of verifying the effectiveness of the embeddings, the downstream evaluation cannot replace generic evaluations as it is difficult to isolate the impact of embeddings from many other factors involved, including the algorithmic configuration and parameter setting of the system. To our knowledge, the Stanford Contextual Word Similarity (SCWS) dataset (Huang et al., 2012) is the only existing benchmark that specifically focuses on the dynamic nature of word semantics.[2] In Section 4 we will explain the limitations of this dataset for the evaluation of recent work in the literature.

In this paper we propose WiC, a novel dataset that provides a high-quality benchmark for the evaluation of context-sensitive word embeddings. WiC provides multiple interesting characteristics: (1) it is suitable for evaluating a wide range of techniques, including contextualized word and sense representation and word sense disambiguation; (2) it is framed as a binary classification dataset, in which, unlike SCWS, identical words are paired with each other (in different con-

---

[1] Ambiguous words are important as they constitute the most frequent words in a natural language (Zipf, 1949).

[2] With a similar goal in mind but focused on hypernymy, Vyas and Carpuat (2017) developed a benchmark to assess the capability of automatic systems to detect hypernymy relations in context.

texts); hence, a context-insensitive word embedding model would perform similarly to a random baseline; and (3) it is constructed using high quality annotations curated by experts.

2 WiC: the Word-in-Context dataset

We frame the task as binary classification. Each *instance* in WiC has a target word w, either a verb or a noun, for which two contexts, c_1 and c_2, are provided. Each of these contexts triggers a specific meaning of w. The task is to identify if the occurrences of w in c_1 and c_2 correspond to the same meaning or not. Table 1 lists some examples from the dataset. In what follows in this section, we describe the construction procedure of the dataset.

2.1 Construction

Contextual sentences in WiC were extracted from example usages provided for words in three lexical resources: (1) WordNet (Fellbaum, 1998), the standard English lexicographic resource; (2) VerbNet (Kipper-Schuler, 2005), the largest domain-independent verb-based resource; and (3) Wiktionary[3], a large collaborative-constructed online dictionary. We used WordNet as our core resource, exploiting BabelNet's mappings (Navigli and Ponzetto, 2012) as a bridge between Wiktionary and VerbNet to WordNet. Lexicographer examples constitute a reliable base for the construction of the dataset, as they are curated in a way to be clearly distinguishable across different senses of a word.

2.1.1 Compilation

As explained above, the dataset is composed of instances, each of which contain a target word and two examples containing the target word. An instance can be either positive or negative, depending on whether the corresponding c_1 and c_2 are listed for the same sense of w in the target resource. In order to compile the dataset, we first obtained all the possible positive and negative instances from all resources, with the only condition of the surface word form occurring in both c_1 and c_2.[4] The total number of initial examples extracted from all resources at this stage were 23,949, 10,564 and 636 for WordNet, Wiktionary and VerbNet, respectively. We first compiled the test and development sets with two constraints: (1) not having more than three instances for the same target word, and (2) not having repeated contextual sentences across instances. These constraints were enforced to have a diverse and balanced set which covers as many unique words as possible. With all these constraints in mind, we set apart 1,600 and 800 instances for the test and development sets, respectively. We ensured that all the splits were balanced for their positive and negative examples. The remaining instances whose examples did not overlap with test and development formed our initial training dataset.

Semi-automatic check. Even though very few in number, all resources (even exprt-based ones) contain errors such as incorrect part-of-speech tags or ill-formed examples. Moreover, the extraction of examples and the mappings across resources were not always accurate. In order to have as few resource-specific and mapping errors as possible, all training, development and test sets were semi-automatically post-processed, either with small fixes whenever possible or by removing problematic instances otherwise.

2.1.2 Pruning

WordNet is known to be a fine-grained resource (Navigli, 2006). Often, different senses of the same word are hardly distinguishable from one another even for humans. For example, more than 40 senses are listed for the verb *run*, with many of them corresponding to similar concepts, e.g., "move fast", "travel rapidly", and "run with the ball". In order to avoid this high-granularity, we performed an automatic pruning of the resource, removing instances with subtle sense distinctions. Sense clustering is not a very well-defined problem (McCarthy et al., 2016) and there are different strategies to perform this sense distinction (Snow et al., 2007; Pilehvar et al., 2013; Mancini et al., 2017). We adopted a simple strategy and

---

[3] https://www.wiktionary.org/

[4] Given that WordNet provides examples for synsets (rather than word senses), a target word (sense) might not occur in all the examples of its corresponding synset.

removed all pairs whose senses were first degree connections in the WordNet semantic graph, including sister senses, and those which belonged to the same supersense, i.e. sense clusters from the Wordnet lexicographer files[5]. There are a total of 44 supersenses in WordNet, comprising semantic categories such as *shape*, *substance* or *event*. This coarsening of the WordNet sense inventory has been shown particularly useful in downstream applications (Rüd et al., 2011; Severyn et al., 2013; Flekova and Gurevych, 2016; Pilehvar et al., 2017). In the next section we show that the pruning resulted in a significant boost in the clarity of the dataset.

2.2 Quality check

To verify the quality and the difficulty of the dataset and to estimate the human-level performance upperbound, we randomly sampled four sets of 100 instances from the test set, with an overlap of 50 instances between two of the annotators. Each set was assigned to an annotator who was asked to label each instance based on whether they thought the two occurrences of the word referred to the same meaning or not.[6] The annotators were not provided with knowledge from any external lexical resource (such as WordNet). Specifically, the number of senses and the sense distinctions of the word (in the target sense inventory) were unknown to the annotators.

We found the average human accuracy on the dataset to be 80.0% (individual scores of 79%, 79%, 80% and 82%). We take this as an estimation of the human-level performance upperbound of the dataset. For the overlapping section, we computed the agreement between the two annotators to be 80%. Note that the annotators were not provided with sense distinctions to resemble the more difficult scenario for unsupervised models (which do not benefit from sense-based knowledge resources). Having access to sense definitions/distinctions would have substantially raised the performance bar.

Impact of pruning. To check the effectiveness of our pruning strategy, we also sampled a set of 100 instances from the batch of instances that were pruned from the dataset. Similarly, the annotators were asked to independently label instances in the set. We computed the average accuracy on this set to be 57% (56% and 58%), which is substantially lower than that for the final pruned set (i.e. 80%). This indicates the success of our pruning strategy in improving the semantic clarity of the dataset.

Split	Instances	Nouns	Verbs	Unique words
Training	5,428	49%	51%	1,256
Dev	638	62%	38%	599
Test	1,400	59%	41%	1,184

Table 2: Statistics of different splits of WiC.

2.3 Statistics

Table 2 shows the statistics of the different splits of WiC. The test set contains a large number of unique target words (1,256), reflecting the variety of the dataset. The large training split of 5,428 instances makes the dataset suitable for various supervised algorithms, including deep learning models. Only 36% of the target words in the test split overlap with those in the training, with no overlap of contextual sentences across the splits. This makes WiC extremely challenging for systems that heavily rely on pattern matching.

3 Experiments

We experimented with recent multi-prototype and contextualized word embedding techniques. Evaluation of other embedding models as well as word sense disambiguation systems is left for future work.

Contextualized word embeddings. One of the pioneering contextualized word embedding models is **Context2Vec** (Melamud et al., 2016), which computes the embedding for a word in context using a multi-layer perceptron which is built on top of a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) language model. We used the 600-d UkWac pre-trained models[7]. **ELMo** (Peters et al., 2018) is a character-based model which learns dynamic word embeddings that can change depending on the context. ELMo embeddings are essentially the internal states of a deep LSTM-based language model, pre-trained on a large text corpus. We used the 1024-d pre-trained models[8] for two configurations: ELMo$_1$, the first LSTM hidden state, and ELMo$_3$, the weighted sum of the

---

[5] wordnet.princeton.edu/documentation/lexnames5wn

[6] Annotators were not lexicographers. To make the task more understandable, they were asked if in their opinion the two words would belong to the same dictionary entry or not.

[7] https://github.com/orenmel/context2vec

[8] https://www.tensorflow.org/hub/modules/google/elmo/1

3 layers of LSTM. A more recent contextualized model is **BERT** (Devlin et al., 2019). The technique is built upon earlier contextual representations, including ELMo, but differs in the fact that, unlike those models which are mainly unidirectional, BERT is bidirectional, i.e., it considers contexts on both sides of the target word during representation. We experimented with two pre-trained BERT models: *base* (768 dimensions, 12 layer, 110M parameters) and *large* (1024 dimensions, 24 layer, 340M parameters).[9] Around 22% of the pairs in the test set had at least one of their target words not covered by these models. For such out-of-vocabulary cases, we used BERT's default tokenizer to split the unknown word to subwords and computed its embedding as the centroid of the corresponding subwords' embeddings.

Multi-prototype embeddings. We experiment with three recent techniques that release 300-d pre-trained multi-prototype embeddings[10]. **JBT**[11] (Pelevina et al., 2016) induces different senses by clustering graphs constructed using word embeddings and computes embedding for each cluster (sense). **DeConf**[12] (Pilehvar and Collier, 2016) exploits the knowledge encoded in WordNet. For each sense, it extracts from the resource the set of semantically related words, called sense biasing words, which are in turn used to compute the sense embedding. **SW2V**[13] (Mancini et al., 2017) is an extension of Word2Vec (Mikolov et al., 2013a) for jointly learning word and sense embeddings, producing a shared vector space of words and senses as a result. For these three methods we follow the disambiguation strategy suggested by Pelevina et al. (2016): for each example we retrieve the closest sense embedding to the context vector, which is computed by averaging its contained words' embeddings.

Sentence-level baselines. We also report results for two baseline models which view the task as context (sentence) similarity. The **BoW** system views the sentence as a bag of words and computes a simple embedding as average of its words. The system makes use of Word2vec (Mikolov et al., 2013b) 300-d embeddings pre-trained on the Google News corpus. **Sentence LSTM** is another baseline, which differently from the other models, does not obtain explicit encoded representations of the target word or sentence. The system has two LSTM layers with 50 units, one for each context side, which concatenates the outputs and passes that to a feedforward layer with 64 neurons, followed by a dropout layer at rate 0.5, and a final one-neuron output layer of sigmoid activation.

	MLP	**Threshold**
Contextualized word-based models		
Context2vec	57.9 ± 0.9	59.7
ElMo$_1$	56.4 ± 0.6	57.1
ElMo$_3$	57.2 ± 0.8	56.3
BERT$_{large}$	57.4 ± 1.0	**63.8**
BERT$_{base}$	**60.2** ± 0.4	63.6
Multi-prototype models		
DeConf*	52.4 ± 0.8	62.1
SW2V*	54.1 ± 0.5	59.1
JBT	54.1 ± 0.6	54.5
Sentence-level baselines		
BoW	54.2 ± 1.3	61.0
Sentence LSTM	53.1 ± 0.9	

Table 3: Accuracy % performance of different models on the WiC dataset. The estimated (human-level) performance is 80.0 (cf. Section 2.2) and a random baseline would perform at 50.0. Systems marked with * make use of external lexical resources.

We used two simple binary classifiers in our experiments on top of all comparison systems (except for the LSTM baseline). **MLP**: a simple dense network with 100 hidden neurons (ReLU activation), and one output neuron (sigmoid activation), tuned on the development set (batch size: 32; optimizer: Adam; loss: binary crossentropy). Given the stochasticity of the network optimizer, we report average results for five runs (± standard deviation). **Threshold**: a simple threshold-based classifier based on the cosine distance of the two input vectors, tuned with step size 0.02 on the development set.

3.1 Results

Table 3 shows the results on WiC. In general, the dataset proves to be very difficult for all the techniques, with the best model, i.e., BERT$_{large}$, providing around 14% absolute improvement over a random baseline. Among the two classifiers, the simple threshold-based strategy, which computes

---

[9] https://github.com/google-research/bert/blob/master/

[10] *Multi-prototype* embeddings are also referred to as *sense* embeddings in the literature.

[11] https://github.com/uhh-lt/sensegram

[12] https://pilehvar.github.io/deconf/

[13] http://lcl.uniroma1.it/sw2v

the cosine distance between the two encodings, proves to be more efficient than the MLP network which might not be suitable for this setting with small amount of training data. The 16.2% absolute accuracy difference between human-level upperbound and state-of-the-art performance suggests, however, a challenging dataset and encourages future research in context-sensitive word embeddings to leverage WiC in their evaluations.

Among the contextualized word-based models, after BERT, Context2vec provides more competitive results on the dataset. However, surprisingly, neither ELMo nor Context2vec are able to improve over the simple sentence BoW baseline (which also outperforms the sentence LSTM baseline) using the threshold strategy. This raises a question about the ability of these models in capturing fine-grained semantics of words in various contexts. Finally, as far as multi-prototype techniques are concerned, DeConf is the best performer. We note that DeConf indirectly benefits from sense-level information from WordNet encoded in its embeddings. The same applies to SW2V, which leverages knowledge from a significantly larger lexical resource, i.e., BabelNet (Navigli and Ponzetto, 2012).

4 Related work

The Stanford Contextual Word Similarity (SCWS) dataset (Huang et al., 2012) comprises 2003 word pairs and is analogous to standard word similarity datasets, such as RG-65 (Rubenstein and Goodenough, 1965) and SimLex (Hill et al., 2015), in which the task is to automatically estimate the semantic similarity of word pairs. Ideally, the estimated similarity scores should have high correlation with those given by human annotators. However, there is a fundamental difference between SCWS and other word similarity datasets: each word in SCWS is associated with a context which triggers a specific meaning of the word. The unique property of the dataset makes it a suitable benchmark for multi-prototype and contextualized word embeddings. However, in the following, we highlight some of the limitations of the dataset which hinder its suitability for evaluating existing techniques.

Inter-rater agreement (IRA) is widely accepted as a metric to assess the annotation quality of a dataset. The metric reflects the homogeneity of ratings which is expected to be high for a well-defined task and a qualified set of annotators. For each word pair in SCWS ten scores were obtained through crowdsourcing. We computed the pairwise IRA to be 0.35 (in terms of Spearman ρ correlation) which is a very low figure. The mean IRA (between each annotator and the average of others), which can be taken as a human-level performance upperbound, is 0.52. Moreover, most of the instances in SCWS have context pairs with different target words.[14] This makes it possible to test context-independent models, which only considers word pairs in isolation, on the dataset. Importantly, such a context-independent model can easily surpass the human-level performance upperbound. For instance, we computed the performance of the Google News Word2vec pre-trained word embeddings (Mikolov et al., 2013b) on the dataset to be 0.65 (ρ), which is significantly higher than the optimistic IRA for the dataset. In fact, Dubossarsky et al. (2018) showed how the reported high performance of multi-prototype techniques in this dataset was not due to an accurate sense representation, but rather to a subsampling effect, which had not been controlled for in similarity datasets. In contrast, a context-insensitive word embedding model would perform no better than a random baseline on our dataset.

5 Conclusions

In this paper we have presented a benchmark for evaluating context-sensitive word representations. The proposed dataset, WiC, is based on lexicographic examples, which constitute a reliable basis to validate different models in their ability to perceive and discern different meanings of words. We tested some of the recent state-of-the-art contextualized and multi-prototype embedding models on our dataset. The considerable gap between the performance of these models and the human-level upperbound suggests ample room for future work on modeling the semantics of words in context.

Acknowledgments

We would like to thank Luis Espinosa-Anke and Carla Pérez-Almendros for their help with the manual evaluation and Kiamehr Rezaee for running the BERT experiments.

---

[14] Only 8% (12% if ignoring PoS) of SCWS pairs are identical but their assigned scores (by average 6.8) are substantially higher than the dataset average of 3.6 on a [0,10] scale.

Abstract

Peer review is a core element of the scientific process, particularly in conference-centered fields such as ML and NLP. However, only few studies have evaluated its properties empirically. Aiming to fill this gap, we present a corpus that contains over 4k reviews and 1.2k author responses from ACL-2018. We quantitatively and qualitatively assess the corpus. This includes a pilot study on paper weaknesses given by reviewers and on quality of author responses. We then focus on the role of the rebuttal phase, and propose a novel task to predict after-rebuttal (i.e., final) scores from initial reviews and author responses. Although author responses do have a marginal (and statistically significant) influence on the final scores, especially for borderline papers, our results suggest that a reviewer's final score is largely determined by her initial score and the distance to the other reviewers' initial scores. In this context, we discuss the *conformity bias* inherent to peer reviewing, a bias that has largely been overlooked in previous research. We hope our analyses will help better assess the usefulness of the rebuttal phase in NLP conferences.

1 Introduction

Peer review is a widely adopted quality control mechanism in which the value of scientific work is assessed by several reviewers with a similar level of competence. Although peer review has been at the core of the scientific process for at least 200 years (Birukou et al., 2011), it is also a subject of debate: for instance, it has been found that peer reviewing can hardly recognize prospectively well-cited papers or major flaws (Ragone et al., 2013). Further, Langford and Guzdial (2015) observed substantial disagreement between two sets of reviews on the same set of submissions for the prestigious Conference on Neural Information Processing Systems (NeurIPS) 2014.

The *rebuttal* phase plays an important role in peer reviewing especially in top-tier conferences in Natural Language Processing (NLP). It allows authors to provide *responses* to address the criticisms and questions raised in the reviews and to defend their work. Although there is evidence that reviewers do update their evaluations after the rebuttal phase[1], it remains unclear what causes them to do so, and especially, whether they react to the author responses per se, or rather adjust to the opinions of their co-reviewers ("*peer pressure*").

In order to obtain further insights into the reviewing process, especially regarding the role of the rebuttal phase in peer reviewing, in this work we present and analyze a review corpus of *the 56th Annual Meeting of the Association for Computational Linguistics (ACL-2018)*. Every reviewer/author was asked whether she consented to freely using her review/author-response for research purposes and publishing the data under an appropriate open-source license within at earliest 2 years from the acceptance deadline (see supplementary material for the original consent agreement). 85% reviewers and 31% authors have consented to sharing their data. The corpus comprises over 4k reviews (including review texts and scores) and 1.2k author responses. Uniquely, the corpus includes both before- and after-rebuttal reviews for both accepted and rejected papers, making it a highly valuable resource for the community to study the role of the rebuttal phase. The corpus as well as our source code and annotations are publicly avail-

able at `https://github.com/UKPLab/naacl2019-does-my-rebuttal-matter`.

Our contributions are threefold. First, in §3, we assess the corpus both *quantitatively* (e.g., correlating Overall Score with aspect scores such as Originality and Readability) and *qualitatively* (e.g., identifying key terms that differentiate "good" from "bad" author responses, annotating paper weaknesses given by reviewers, and rating the quality of individual author responses). Second, in §4, we develop a model to predict whether a reviewer will increase/decrease/keep her initial scores after the rebuttal. We do so in order to analyze and disentangle the sources of review updates during the rebuttal stage. We find that factoring in the author responses only marginally (but statistically significantly) improves the classification performance, and the score update decision is largely determined by the scores of peer reviewers. Third, in §5, we discuss multiple types of biases in the score update process, some of which potentially undermine the 'crowd-wisdom' of peer reviewing.

2 Related Work

Several sources provide review and author response data. Since 2013, the NeurIPS main conference publishes the reviews of accepted papers and their author responses. However, these reviews only include the review texts for after-rebuttal reviews. Also, reviews of rejected papers and author responses are not published. Some Machine Learning and NLP conferences, for instance ICLR (International Conference on Learning Representations) and ESWC (Extended Semantic Web Conference), adopt the *open review* model, which allows anyone to access the reviews and author responses. However, most major NLP conferences have not yet adopted the open-review model, and the reviews and author responses in open- and non-open-review venues are likely to be different because people behave differently when their actions are observable (Andreoni and Petrie, 2004).

Kang et al. (2018) provide a corpus of computer science papers from ACL, NeurIPS, CoNLL (The SIGNLL Conference on Computational Natural Language Learning) and ICLR, together with the accept/reject decisions and reviews for a subset of the papers. They suggest several tasks with respective baselines, such as predicting review aspect scores from paper- and review-based features. However, their corpus contains neither before-rebuttal reviews nor author responses, and the size of their review set from NLP conferences (only 275 reviews from ACL-2017 and 39 reviews from CoNLL-2016) is much smaller than ours.

Hua et al. (2019) compile a corpus consisting of 14.2k reviews from major NLP and machine learning conferences. In addition, they annotate 10k argumentative propositions in 400 reviews, and train state-of-the-art proposition segmentation and classification models on the data. But similar to Kang et al. (2018), their corpus does not include before-rebuttal reviews or author responses.

Several publications specifically address the peer reviewing process. Falkenberg and Soranno (2018) investigate what makes a paper review helpful to a journal editor within a specific scientific field. Birukou et al. (2011) and Kovanis et al. (2017) discuss the shortcomings of the review process in general, such as its inability to detect major flaws in papers (Godlee et al., 1998) and its ineffectiveness in selecting papers that will have high citation counts in the future (Ragone et al., 2013). They discuss alternatives to the standard review process such as crowd-based reviewing and review-sharing, i.e., resubmitting a rejected work to another venue along with its past reviews. Ragone et al. (2013) analyze peer reviews across nine anonymized computer science conferences and, among others, identify reviewer biases of multiple types (affiliation, gender, geographical, as well as rating bias: consistently giving higher or lower scores than other reviewers) and propose means for debiasing reviews. However, none of these works quantitatively measures the influence of the rebuttal phase on the final review scores, nor do they provide any corpora facilitating such studies.

Our work is also related to *meta science*, which studies the scientific process in general, i.e., how scientific information is created, verified and distributed (cf. Fortunato et al. (2018)). In this context, our work can be seen as a study on how scientific information is verified.

3 Review Corpus

ACL-2018 adopts a reviewing workflow similar to that of other major NLP conferences: after paper assignment, typically three reviewers evaluate a paper independently. After the rebuttal, reviewers can access the author responses and other peer reviews, and discuss their viewpoints. Reviews

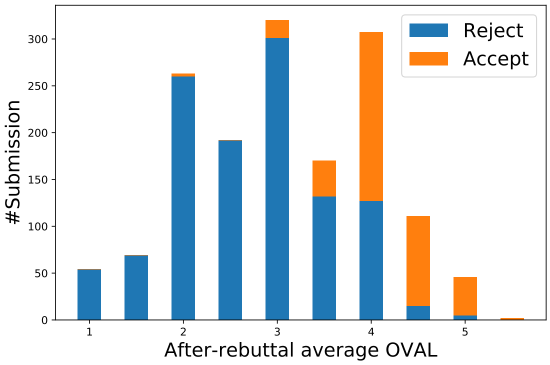

Figure 1: Distribution of accept/reject decisions.

Category	Size
Before-rebuttal reviews	3875 (1213 reviewers, 1538 submissions)
After-rebuttal reviews	4054 (1275 reviewers, 1542 submissions)
Author responses	1227 (499 submissions)

Table 1: Statistics of the ACL-2018 corpus. Some reviewers submitted their reviews after the rebuttal started, hence the size of the after-rebuttal reviews is larger than that of the before-rebuttal reviews.

	CMP	ORG	RDB	RPB	SND	SBS	OVAL	CONF
CMP	1.00	0.40	0.37	0.38	0.53	0.54	0.59	-0.10

CONF	-0.10	-0.09	0.11	0.04	-0.06	-0.11	-0.12	1.00

Figure 2: Score correlation matrix.

include both *scores* (Overall Score `OVAL`, Reviewer Confidence `CONF`, Soundness `SND`, Substance `SBS`, Originality `ORG`, Meaningful Comparison `CMP` and Readability `RDB`) and free-text comments. `OVAL` are integers in $[1, 6]$, while all other scores are integers in $[1, 5]$.

We first provide an overview of our corpus in §3.1, and then present analyses for the reviews and author responses in §3.2 and §3.3, respectively.

3.1 Overview of the Corpus

The corpus has three parts: the before-rebuttal reviews (including review texts and scores), the after-rebuttal reviews, and the author responses. The corpus does not contain the submissions, nor the information of the reviewers, e.g., their gender, country, affiliation or seniority level; nevertheless, we perform some analyses on the submissions and the reviewers' information and present the statistics in the supplementary material.

Basic statistics of our corpus are summarized in Table 1. 1542 submissions (1016 long, 526 short) have at least one review opted in. 1538 submissions have at least one before- and one after-rebuttal review opted in. Among the 1542 submissions, 380 submissions (24.6%) were accepted: 255 long, 125 short, and the remaining 1162 were rejected: 761 long, 401 short. The distribution of their accept/reject decisions is illustrated in Fig. 1.

3.2 Reviews

Score Correlation. In line with Kang et al. (2018), we first assess the impact of individual aspect scores on the overall score by measuring their Pearson correlation, illustrated in Fig. 2. We find that `OVAL` is most strongly correlated with `SND` and `SBS`, followed by `ORG` and `CMP`. `CONF` shows weak positive correlation to `RDB`: the less readable a paper is, the less confident the reviewers will be. Note that our correlation results are different from those reported by Kang et al. (2018), who report that the `OVAL` has low Pearson correlation with `SND` (0.01) and `ORG` (0.08). While the differences might be caused by a variation in aspect definitions, we believe that our estimate is more reliable as the dataset analyzed in Kang et al. (2018) is substantially smaller than ours.

Review Texts. ACL-2018 adopts the novel *argument-based* review template, which asks reviewers to provide *positive* and *negative* arguments for and against the submission, respectively. In addition, reviewers can also list their questions to the authors in the *questions* section of the review template. Most reviewers made good use of the argument-based template: among the 4054 after-rebuttal reviews, 3258 (80.4%) provide positive arguments, 3344 (82.5%) provide negative arguments, and 1627 (40.1%) provide questions. The number and length of arguments/questions are summarized in Table 2.

Score Changes. Table 3 shows how many reviews increase (INC), decrease (DEC) or keep (KEEP) their overall scores after rebuttal. For

Component	Number	Length (token)
Pos. Arg.	1.92±1.31	22±17
Neg. Arg.	2.38±1.56	56±53
Questions	0.87±1.36	35±31

Table 2: Numbers and lengths of different components in each review (mean±standard deviation).

Type	Num.	#Paper	Acpt.%	$\Delta_{\texttt{OVAL}}$
INC	245	227	49.8	2.65 → 3.76
DEC	248	221	7.2	4.17 → 3.04
KEEP	3377	1119	22.8	3.13 → 3.13
Total	3870	1538	24.7	3.17 → 3.17

Table 3: Statistics of different types of reviews.

the 227 papers that receive at least one INC review (first row in Table 3), their acceptance rate is 49.8%, much higher than those 221 papers with at least one DEC (7.2%) and those 1119 papers with no score update (22.8%). Hence, the score update has a large impact on the final accept/reject decision. Note that 29 papers receive both INC and DEC reviews, of which five were accepted finally.

Fig. 3 summarizes the `OVAL` updates. Most reviewers stick to their initial scores after rebuttal. For those who update, the score change usually amounts to just one point in absolute value. However, most updates happen in the borderline area (overall score 3-4) where the score update might influence the overall acceptance decision. We find that the changes in aspect scores occur much less often than the changes in overall scores: only 5% of the reviews have any of the aspect scores updated after rebuttal, and only 1% of the reviews change the confidence value. In these rare cases, aspect score changes are consistent with their `OVAL` changes, e.g., if the `OVAL` increases, no aspect score decreases.

Submission Time. Fig. 4 illustrates the distribution of the first submission time of reviews. 51.6% reviews were submitted within the last 3 days before the deadline. We also find that the mean submission time of the INC reviews is around 20 hours earlier than that of the DEC reviews, and the difference is statistically significant (p-value 0.009, double-tailed t-test). Moreover, we find that submission time is weakly positively correlated with initial score, which means that reviewers who submit early have slightly lower scores on average, which may explain their tendency to increase their scores later on, given our results in §4.

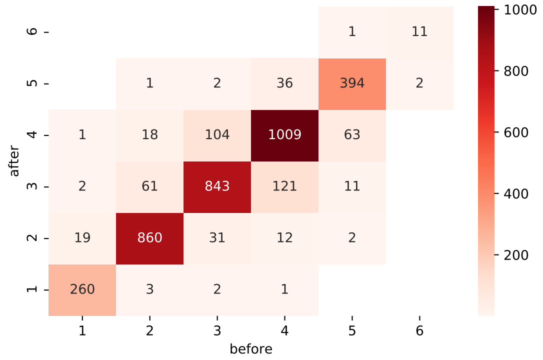

Figure 3: Before vs after rebuttal `OVAL`.

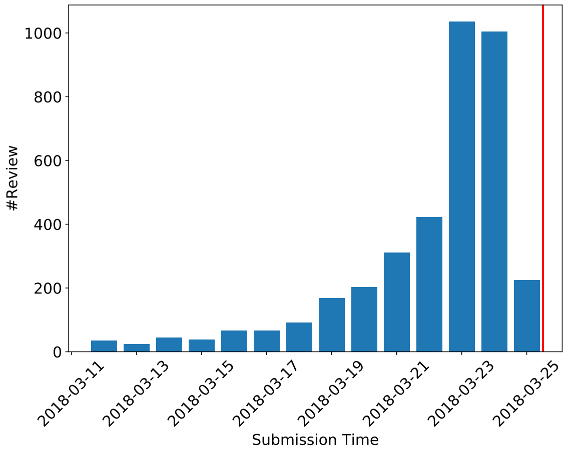

Figure 4: Distribution of review submission time. The review submission deadline (26th March 2018) is marked as the red vertical line towards the right end.

A reason why early submitters have lower scores may be that it takes less time to reject a paper, as the majority of papers is rejected anyway.

Criticism in Reviews. To study the most common paper weaknesses identified in reviews, we manually assess about 300 weakness statements from the reviews. Table 4 summarizes the main results, excluding concerns about *Technical weaknesses*. In our sample, most weaknesses refer to *Evaluation & Analysis*, i.e., criticize the lack of: error analysis, ablation tests, significance tests, human evaluations (opposed to indirect measures such as BLEU) and strong baselines as well as insufficient comparisons (either external or internal). Other frequent targets of criticism are *Writ-*

Eval	Writing	Nov	Data	Motivation
28%	18%	8%	8%	5%

Table 4: Frequent weakness types identified in reviews.

Type	Num.	Length (token)
iResp	100	373±191
dResp	80	260 ±140
kResp	1047	297±182
Total	1227	300±181

Table 5: Statistics of author responses (mean±standard deviation for Length).

ing quality, as well as *Data*: e.g., too few datasets being used (only English data or only synthetic data), missing agreement scores for newly labeled datasets, and resources not being publicly available. Reviewers also criticize the lack of *Novelty* and proper *Motivation* of approaches.

3.3 Author Responses

We align author responses with their corresponding reviews (if opted in), and term the author responses corresponding to INC, DEC and KEEP reviews as iResp, dResp and kResp, respectively. Table 5 presents an overview on these groups.

To qualitatively compare iResps and dResps, we extract and rank n-grams in both iResps and dResps according to the *log-likelihood ratio* (LLR) statistic (Dunning, 1993), treating iResps and dResps as two corpora[2]. The results are reported in Table 6. We find both iResps and dResps express gratitude and promise revisions in the final versions, but iResps address review questions and criticisms by referring back to certain lines and tables in the original paper while dResps fail to do so. We revisit these differences in §4.2.

iResps	dResps
the final version	thanks for your
in line DIGIT	DIGIT reply to
in table DIGIT	to question DIGIT
in the final	will add more
for example the	DIGIT we will
in order to	thank the reviewer
final version EOS	argument DIGIT reply
due to space	due to the
for your comments	paper is accepted
camera ready version	the revised version
DIGIT and DIGIT	we agree that

Table 6: Top trigrams based on LLR ranking. All digits were replaced by DIGIT. EOS: end of sentence.

To gain further insights, we analyze the *quality* of the author responses to the 300 weakness statements from Table 4. We advertised no formal definition of quality, and assessed a subjective, perceived quality score in a range from 1 (low) to 10 (high). We find that the *weak* author responses (scores 1-3) are substantially shorter than the *strong* ones (scores 8-10): the average token number in weak and strong responses are 53 and 90, respectively. Responses evaluated as weak are less specific and make vague promises (*"Thanks for the suggestion, we will try this in the camera-ready"*), off-topic (addressing different points than those raised by the reviewer), or apologetic (*"the deadline was very close", "our native language is not English"*). Interestingly, with some exceptions (*"We take your review as an example of bad writing"*), the weak responses are usually polite and admit the weaknesses suggested by the reviewers, but they tend not to detail how they would address the weaknesses. Strong responses, in contrast, are specific (referring to specific line numbers in the submission, as well as providing numerical values), detailed, longer, and often do not agree with the criticism, but explain why the reviewer's requirement is hard to meet or beyond the scope of the work.

4 After-Rebuttal Score Prediction

To measure the influence of different factors on the score update decisions, we propose and study the *after-rebuttal score prediction* task. Because most score updates after rebuttal do not exceed 1 point (see Fig. 3), we formulate this problem as a classification task. Specifically, given a before-rebuttal review, its corresponding author response and other peer reviews, we try to predict whether the reviewer will increase (INC), decrease (DEC) or keep (KEEP) her overall score after the rebuttal. We avoid predicting the final accept/reject decisions because they are not only based on the final scores (see Fig. 1, where a few low-score papers are accepted while some high-score papers are rejected), but also based on additional factors such as the balance of areas and diversity of papers, which are difficult to measure. The score updating of reviews, in contrast, only depends on the peer reviews and the authors responses.

We choose a classic feature-rich classification model for this task, for two reasons: a) model capacity is lower compared to, e.g., a deep neural network, which is beneficial in our small data scenario, and b) the results are easier to interpret.

---

[2] We only include n-grams that appear in at least 7 different author responses.

4.1 Features

Score features (`Score`). We use all peer review scores for a given submission to build an array of score-based features. These include review i's before-rebuttal `OVAL` (`self_score`), statistics of the other peer reviews' `OVAL` (denoted by `oth_X`, where `X` can be `max`/`min`/`mean`/`median`/`std`), statistics of all peer reviews' `OVAL` (`all_X`), and elementary arithmetic operations on the above features (e.g., `oth_mean-self` denotes the mean `OVAL` of the peer reviews minus review i's before-rebuttal `OVAL`). `CONF` are considered in a similar manner. We do not consider aspect scores such as `ORG` because they yielded no improvements in our preliminary experiments. The full list of features can be found in the supplementary material. We also include features based on the author response texts, as detailed below.

Length of response (`log_leng`). We have found that high-quality author responses are usually longer than the low-quality ones (see §3.3). We use the logarithm of the number of tokens in author responses as a feature.

Review-Response Similarity (`sim`). Lack of similarity between a review and its response may indicate that the response is "off-topic". To measure similarity, we have trained 300-dimensional skip-gram word embeddings on 5611 papers extracted from the cs.CL (computational and language) and cs.LG (learning) categories of ArXiv which were published between January 1, 2015 and December 31, 2017. We represent reviews and responses by averaging the embeddings of their words, and measure semantic similarity by cosine similarity.[3] We find it important to use word embeddings trained on *CL/LG* domain data: for example, nearest neighbors of "neural" in a model trained on Wikipedia are "axonal", "salience", while on Arxiv its nearest neighbors are "feedforward" and "deep". We find that iResps are more similar to their reviews than dResps and kResps: the average cosine similarity between the reviews and iResps, dResps and kResps are .38, .30 and .29, respectively.

Specificity (`spec`). In our human annotation experiments, unspecific responses were typically judged as weak because they did not address specific questions or weaknesses given by reviews. To measure the specificity of author responses, we use a feature-rich sentence-level specificity model by Li and Nenkova (2015) trained on multiple news corpora. The produced scores are in the $[0, 1]$ range, with higher values meaning higher specificity. iResps are slightly more specific than the other responses: the mean specificity scores for iResps, dResps and kResps are .29, .24 and .28, respectively. For each author response, we compute the `spec` scores for all their sentences and use statistics (`max`/`min`/`mean`/`median`/`std`) of the `spec` scores as features. The same strategy is used to build the politeness and convincingness features introduced below.

Politeness (`plt`). We employ the sentence-level politeness framework suggested by Danescu-Niculescu-Mizil et al. (2013) to quantify the politeness of the author responses. We have trained a simple bag-of-words based multi-layer perceptron (MLP) model using their Wikipedia and StackExchange data and applied it to the author responses, generating a politeness score in $[-1, 1]$ for each sentence in author responses, where higher scores mean higher politeness. While the mean politeness scores in iResps, dResps and kResps have no marked differences (all around 0.19), the score for the most polite sentence in iResps (.91) is higher than that of dResps (.68) and kResps (.90).

Convincingness (`cvc`). To approximate rebuttal convincingness we use the sentence-level convincingness model developed by Simpson and Gurevych (2018), trained on ∼1.2k argument pairs from web debate forums. We normalize all convincingness scores to $[0, 1]$, where larger scores mean higher convincingness. Mean convincingness scores for iResps, dResps and kResps are .60, .49 and .58, respectively.

Score validation. Since the `spec`, `plt` and `cvc` models are not trained on review-rebuttal data, we need to perform human evaluations to validate the produced scores. We rank the sentences in author responses in terms of their `spec`, `plt` and `cvc` scores and analyze the top and bottom 10 sentences in each ranking (see the supplementary material). We find that the scores successfully distinguish the most and least specific/polite/convincing sentences. To further validate the scores, for each type of score, we have randomly sampled 15 pairs of sentences from author responses and presented the pairs to 3 ex-

---

[3] We also used ROUGE (Lin, 2004) to measure the similarity but find the ROUGE scores to be highly correlated with the cosine similarities (Pearson correlation > 0.9), so we include only the cosine similarities in our models.

	`spec`	`plt`	`cvc`
Inter-User	.87	.87	.64
User-Score	.93	.87	.67

Table 7: Percentage of agreement for `spec`, `plt` and `cvc` scores. "User-Score" means the agreement between the aggregated (by majority voting) users' preferences and score-induced preferences.

perienced annotators, asking them to indicate the more specific/polite/convincing sentence in each pair. The agreement is presented in Table 7. The agreement between the users' aggregated preferences and score-induced preferences is quite high for all three types, confirming the validity of the scores. Note that the agreement for `cvc` is lower than the other two; the reason might be that it is difficult even for humans to judge convincingness of arguments, particularly when evaluated on the sentence level without surrounding context nor the corresponding review. The distribution of the `spec`, `plt` and `cvc` scores for iResps, dResps and kResps is in the supplementary material.

4.2 Results and Analyses

We perform experiments on a subset of the corpus which only includes the submissions that have author responses and three or more reviews opted in. We term this subset of the corpus *Submissions with Complete Reviews (Full)*. Training models on submissions with fewer reviews would bias certain features (e.g. `all_mean`) and thus bias the trained models. Also, we separate out the submissions from the Full set whose before-rebuttal average `OVAL` are between 3 and 4.5 (note that `OVAL` are in $[1, 6]$), so as to train and test a model specifically on borderline submissions for which score changes may be decisive for an accept or reject decision. We term this subset *Borderline Submissions (BRD)*. Full includes 791 submissions (80 INC, 60 DEC, 652 KEEP) and BRD includes 590 (69 INC, 48 DEC and 474 KEEP). All results and weights presented in this section are averaged over 5000 repeats of 10-fold cross validation; data entries are randomly shuffled for each repeat.

Feature Selection. We filter out features whose information gain is ranked in the bottom 50% of all features on the training set. For highly correlated features in the upper 50% (i.e. Pearson correlation ≥ 0.5), we filter out all but the one with the highest information gain. Remaining features are used to train a multinomial logistic regression model (i.e., MLP with no hidden layer and softmax activation function in the output layer). To balance the number of instances for the three classes, on the training set, in each fold of cross-validation we randomly down-sample cases with class KEEP to ensure that the number of KEEP is the same as the sum of INC and DEC. We also tried random forest, decision tree, support vector machines and Gaussian processes as classifiers, but their performances were similar or worse than that of logistic regression.

Feature Set	BRD	Full
`spec`	.324	.309
`plt`	.306	.310
`cvc`	.303	.304
`log_leng`	.340	.341
`sim`	.323	.302
`Score`	**.495**	**.526**
All but `Score`	.343	.336
All	**.522**	**.540**
Majority Baseline	.297	.301
Random Baseline	.258	.251

Table 8: Macro F-1 scores.

Results. Classification results are presented in Table 8. In addition, we compare to two baselines: the *majority baseline* always picks the majority decision (in our case, KEEP); the *random baseline* selects an action at random. Full results, including precision, recall and F1-scores for each label, can be found in the supplementary material.

We find that score-based features are most effective among all features. However, text-based features are also useful, supported by the observations that: **(i)** models using only text features all significantly (p-value < 0.01, double-tailed t-test) outperform the majority and random baseline; and **(ii)** using all features gives the best performance, significantly (p-value < 0.01) better than using any feature set alone.

Among the non-`Score` features, `log_leng` performs best. But we find it has high correlation with multiple `Score` features, and hence when all features are used, it is filtered out. The features `spec` and `sim` perform much better in BRD than in Full, which suggests that, for borderline papers, more weight is placed on whether the response explicitly addresses the points raised in reviews (similarity) and the specificity of the response.

Analysis. To interpret our results, we study the weights of the features in our logistic regression model shown in Tables 9 and 10. We observe the following trends:

- **"Peer pressure" is the most important factor of score change**: in both Full and BRD, features reflecting the gap between own and others' review scores (`oth_mean-self` and `self-oth_min`) have by far the largest weights compared to other feature groups. For example, in Full, the `Score` features have (absolute) weights of 0.4 or higher for the class INC, while all other features are substantially below 0.2. The weights make intuitive sense: e.g., when the mean of the other reviewers' scores is above a reviewer's initial score, she has a strong tendency to increase her own score and not to decrease her own score. Similarly, when a review contains a very convincing sentence, this substantially decreases the probability of a score decrease.

- **To improve the score for a borderline paper, a more convincing, specific and explicit response may be helpful**: in Full, no weight of a text-based feature is above 0.2 for INC; however, in BRD, the weights for `cvc_min`, `spec_median` and `sim` are all above 0.2. This asymmetry of the text-based features across Full and BRD also suggests that reviewers do appear to pay more attention to the author responses in situations where they may matter (e.g., make the difference between accept or reject decisions).

- **An impolite author response may harm the final score**: in both Full and BRD, the weight of `plt_max` is negative for DEC. In addition, in Full a more polite response helps increase the final score (positive weight for INC, close to 0 weight for KEEP). In BRD, in contrast, a more polite response may not increase the score but only keep it unchanged (positive weight for KEEP, close to 0 weight for INC). If we take BRD papers as those for which the author responses really matter, this means that politeness has an asymmetrical effect: it may push a paper below the acceptance threshold, but not above it. Indeed, `plt_max` is the second best text-feature for predicting decrease for BRD papers.

Feature	INC	DEC	KEEP
`oth_mean-self`	1.044	-1.265	.221
`self-oth_min`	-.378	.188	.190
`cvc_max`	.078	-.271	.193
`spec_median`	.159	-.224	-.065
`plt_max`	.170	-.174	.004
`sim`	.019	.099	-.119
`spec_max`	.022	.029	-.051

Table 9: Feature weights in multinomial logistic regression trained on Full.

Feature	INC	DEC	KEEP
`oth_mean-self`	.855	-1.026	.171
`self-oth_min`	-.372	.191	.181
`cvc_min`	.224	-.258	-.034
`spec_median`	.293	-.122	-.171
`sim`	.214	-.161	-.053
`cvc_max`	.117	-.085	-.033
`plt_max`	.016	-.192	.176

5 Discussion

The opinion update process we have described in §4.2 is closely related to the work on *opinion dynamics* (DeGroot, 1974; Acemoglu and Ozdaglar, 2011), which studies how human subjects change their opinions as a reaction to those of peers.

The "peer pressure" effect (opinions being updated to mean opinions) is widely observed in opinion formation of human subjects in controlled experiments. Lorenz et al. (2011) find that in simple estimation tasks ("What's the population density of Switzerland?"), human subjects tend to lean towards a consensus once they are exposed to the opinions of others. Similarly, Moussaid et al. (2013) find two dominant effects for simple factual questions: human subjects tend towards the mean opinion and towards the opinions of highly confident individuals. Our experiments also show that the mean opinion plays a very prominent role in peer reviews, but they show no evidence supporting the confidence effect: features based on the confidence scores do not play a significant role in deciding the final scores (see §4.2). We believe this is due to two main differences between peer reviewing and the controlled experiments in the above works: (i) there does not exist a ground-truth score for a submission, while such true answers about factual questions do exist in the controlled experiments; and (ii) participants of the controlled experiments lose money if they give incorrect answers, but a reviewer loses nothing when she does not adjust to a (self-assessed) expert.

Three types of *biases* have been studied in explanatory models of opinion dynamics in recent years. The first is opposition between members of different groups (e.g., due to *group-identity*) leading to distancing from certain subjects' opinions (Altafini, 2013; Eger, 2016). The second is *homophily*: individuals ignore opinions too different from their own (Deffuant et al., 2000; Hegselmann and Krause, 2002). The third is *conformity* (Buechel et al., 2015), i.e., the desire to conform to a group norm/opinion. Conformity bias can be strong and persist even in the presence of overwhelming evidence that a group opinion is wrong (Asch, 1951). Our observation that reviewers tend to converge to the mean of all reviews (§4.2) suggests that conformity bias also plays a prominent role in peer reviewing. We found no evidence (on an aggregate level) for the other two biases.

To summarize, conformity bias is the main bias we identified in the peer reviewing process. However, conformity bias has a negative effect on crowd-wisdom in estimation tasks (Lorenz et al., 2011), which strengthens confidence of human subjects in the correctness of their converged answer, while the actual correctness of their consensus is often even worse than the mean of multiple independent answers. A simple method to reduce conformity bias is to blind reviewers from each other, only allowing reviewers to update their reviews based on the author responses; the area chair (who can see all reviews for a paper) is then responsible for considering all (possibly conflicting) reviews and making the accept/reject recommendation. We believe that peer reviewing is to a large degree an opinion dynamics process, a neglected insight hitherto, and that lessons from this field should therefore be beneficial for peer reviewing for NLP conferences and beyond.

Finally, concerning the helpfulness of individual review based feature groups, we believe it reflects a weakness of the current rebuttal stage that politeness does matter, because this is *merely* a social aspect unrelated to the quality of the assessed papers. However, we also showed that filling up author responses with "thank you"s is unlikely to increase a reviewer's score for a borderline paper—so at least, authors do not seem to be able to sneak their papers in via social effects.

6 Conclusion

We presented a review corpus consisting of over 4k reviews and 1.2k author responses from ACL-2018. To the best of our knowledge, it is the first corpus that includes both before- and after-rebuttal reviews for both accepted and rejected papers in a major NLP conference. We qualitatively and quantitatively analyzed the corpus, including a manual classification of paper weaknesses outlined by reviewers and a quality rating study of the corresponding author responses.

In addition, we proposed a classification model to predict whether a reviewer will increase/decrease/keep her overall score after rebuttal. By analyzing the feature weights in our model, we quantitatively measured the importance of different decision variables for score updates. We found that the gap between a reviewer's initial score and her peers' scores is the main explanatory variable. Rebuttal-related factors like convincingness, specificity and politeness of responses are considerably less important but still have a statistically significant effect, especially for borderline papers.[4] Our findings shed light on the predominant role of the *conformity bias* in peer reviewing (see §5), and we discuss alternative peer review models addressing this bias. We hope our analyses will help the community better understand the strengths and weaknesses of the current peer review workflow, spurring further discussions.

Finally, provided that the rebuttal phase remains a key feature in many peer reviewed conferences, we think that our novel after-rebuttal score change prediction task can be practically beneficial for authors to restructure their author responses and thereby make them more effective.

Acknowledgements

The authors thank the anonymous reviewers and Dan Jurafsky for constructive comments and helpful remarks. This work has been supported by the ArguAna Project GU 798/20-1 (DFG), the German Research Foundation through the German-Israeli Project Cooperation (DIP, grant DA 1600/1-1 and grant GU 798/17-1), and the DFG-funded research training group "Adaptive Preparation of Information from Heterogeneous Sources" (AIPHES, GRK 1994/1). Appendicies

A Consent Message

Before a reviewer or an author enters her reviews or author responses, the following message appears to ask for her consent for data sharing:

> ATTENTION: this time, we plan to do some analytics on anonymized reviews and rebuttal statements, upon the agreement of the reviewers and authors, with the purpose of improving the quality of reviews. The data will be compiled into a unique corpus, which we potentially envisage as a great resource for NLP, e.g. for sentiment analysis and argumentation mining, and made available to the community properly anonymized at earliest in 2 years. We hope to provide data on ”how to review” to younger researchers, and improve transparency of the reviewing process in ACL in general.
>
> By default, you agree that your anonymised rebuttal statement can be freely used for research purposes and published under an appropriate open-source license within at earliest 2 years from the acceptance deadline.
>
> Place an ’x’ mark in the NO box if you would like to opt out of the data collection.
>
> `[x]`: YES
> `[ ]`: NO

Analyses on Submissions

We rank n-grams in both accepted and rejected papers according to the *log-likelihood ratio* (LLR) statistic, taking both accepted and rejected papers as one big corpus, respectively. The goal is to find n-grams that occur unusually frequently in one of the two groups, relative to the respective other.

Table 11 shows a few hand-selected n-grams with highest LLR for *accepted papers*; high-LLR n-grams for rejected papers are not presented due to licensing. To filter out noise, we only include n-grams that occur in at least 7 different papers. We can observe some interesting patterns: accepted papers appear to cite recent work, which reflects potential novelty and appropriate comparison to state of the art; tend to use more mathematics (of a particular kind); have an appendix; do significance testing; release code upon publication; and have multiple figures including subfigures.

Hot n-grams	Possible Interpretation
(2017)	Cite recent work
($z\|x$)	Math
artetxe et al	Authors working on a hot topic
dozat and manning	Authors of an influential method
in the supplementary	Paper has appendix
contextualized word representations	Trendy method
upon publication .	Code/data will be released
statistical significance of	Mathematically rigorous
figure 3 (	Multiple figures with subfigures

Table 11: Selected 3-grams that distinguish accepted from rejected papers based on the LLR statistics.

B Statistics on Reviewer Information

In this section, we present some statistics of all 1440 reviewers of ACL-18.

Country. The reviewers work in 53 different countries. The top 10 countries where the reviewers work are presented in Fig. 5. The distribution of the reviewer working places is heavily long-tailed: the United States alone contributes 36.9% of all reviewers, followed by China (8.7%), the United Kingdom (7.8%) and Germany (7.6%). Seven countries have more than 50 reviewers, and 19 countries have more than 10 reviewers.

Affiliation. The reviewers are from around 700 organisations. But as reviewers use different names to refer to the same organisation (e.g., both MIT and Massachusetts Institute of Technology are used), the real number of organisations can be much lower. The top 10 organisations and their reviewers numbers are presented in Fig. 6. Nine organisations contribute more than 20 reviewers, and 19 organisations contribute more than 10 reviewers.

Seniority. Most reviewers (69.9%) do not report their seniority levels. Among those that

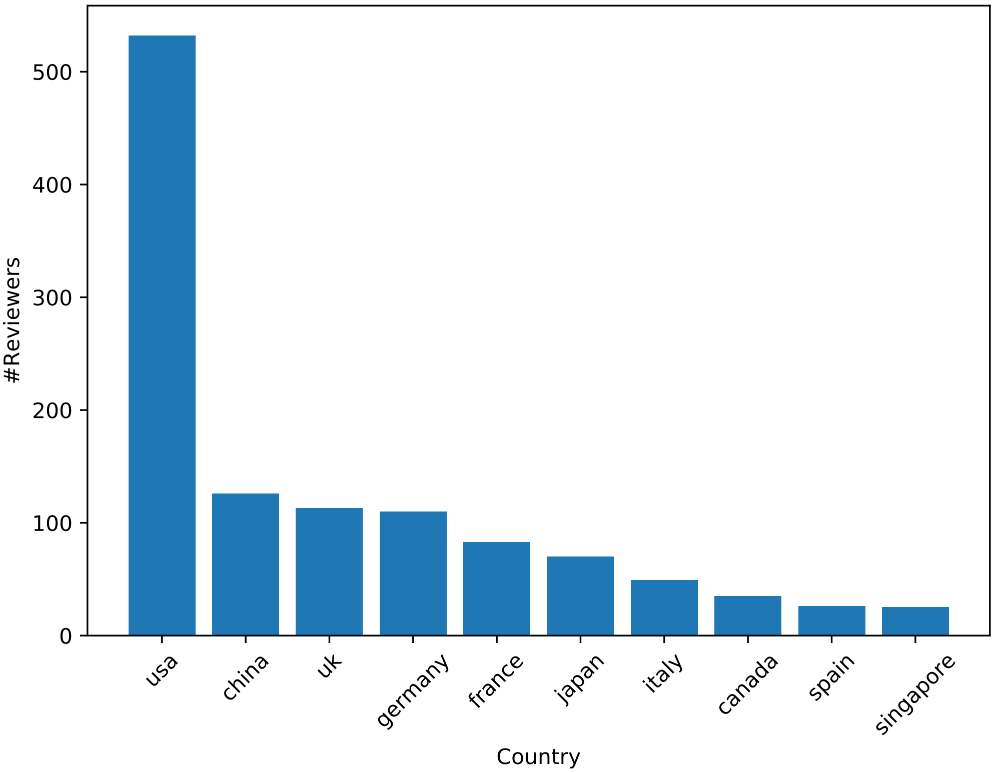

Figure 5: Distribution of countries where reviewers work.

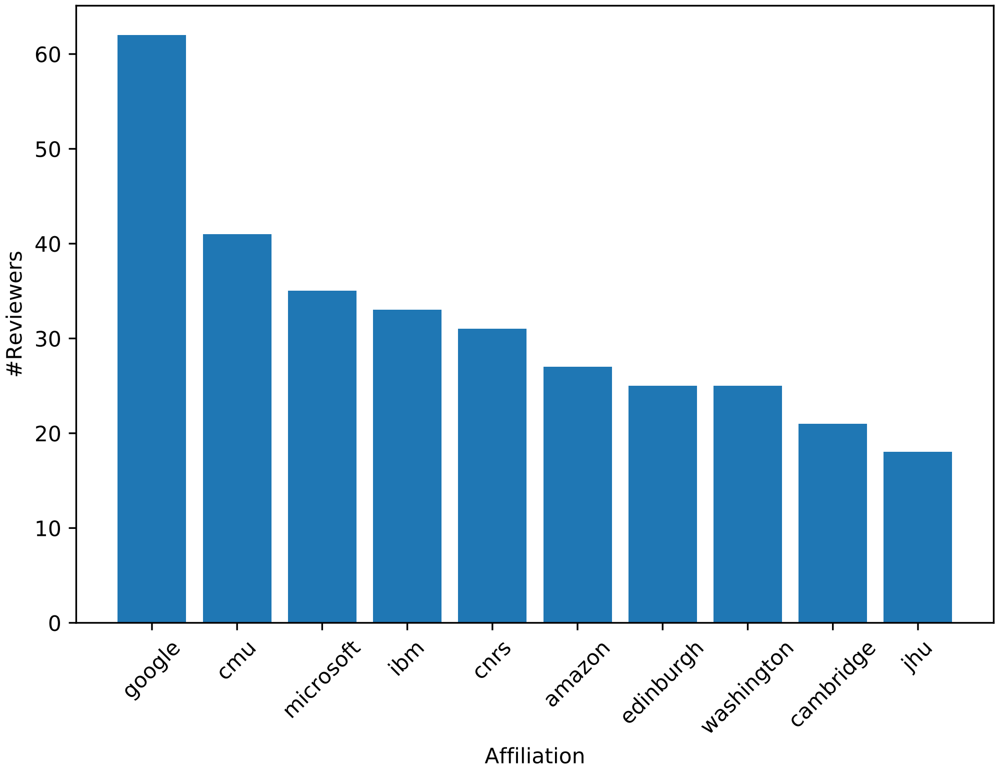

Figure 6: Distribution of organisations where reviewers work.

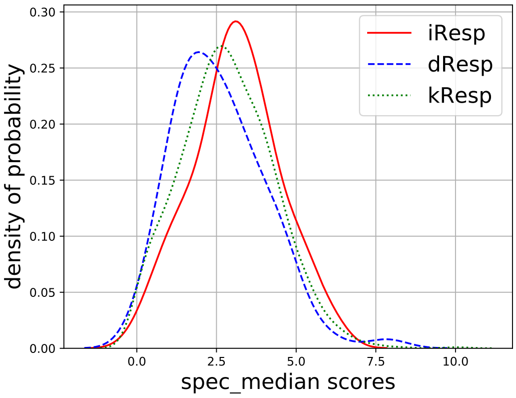

Figure 7: Smoothed distribution of specificity scores.

have reported their seniority, 50.2% are Professors, 27.6% are PhD students, and 22.2% are Post-Doc/Assistant-Professor.

Gender. We estimate the gender of the reviewers from their first names, using the tool available at `https://github.com/kensk8er/chicksexer`. 73.4% reviewers are estimated to be male and the rest 26.6% are estimated to be female.

C Full Results

The precision, recall and F1-scores for each label in both Full and BRD are presented in Table 12 and 13, respectively.

D Features

The full list of our hand-crafted features is presented in Table 14.

E Specificity Scores

We tokenize author responses with `nltk`, remove sentences with fewer than 10 tokens and rank the remaining sentences by their specificity scores. All scores are normalized to $[0, 10]$, with higher scores meaning higher specificity. The distribution of the specificity scores for author responses leading to increased, decreased and unchanged scores is illustrated in Fig. 7.

Top 10 sentences are presented below[5], and they all receive a specificity score 10.

- *We have already checked it. We can change the sentence in the last paragraph of Section ### to ''Since the proposed method only substituted ### based on ###, then the naturalness of ### using the proposed method is better than ###. This method was used because we have to maintain the context; The result can be more than 100% because we assume that the ### of original was 100% while based on human judgement, there are possibility that the ### of resulting sentences using the proposed method is better than the original one.*
- *###| ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# |*
- *###| ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# |*
- *There are two reasons why we mention that: (i) many papers exist, however, many previous papers made the same (or similar) conclusions, so some are picked up as representatives and (ii) because ### is a high-level conference, it's thought that there was no need to explain too much, and also because there are limited pages, space was wanted to be left to explain the analysis as detailed as possible and put focus on the analysis.*
- *Other external knowledge sources apart from ### do not add much: In principle, all resources we used originate in ###, the difference is the degree of knowledge we use. The novelty in this work does not lie in the use of ### as a knowledge resource but more generally in the principled ### of the classes.*
- *We will include this discussion in the paper. Other ### models (e.g., ###; ###) can in theory predict ###, however, they are not directly applicable to ### since they cannot handle ### representations, i.e., variables can refer to a ### representation (e.g., variable ### refers to an entire proposition and variable ### refers to a segment of meaning).*
- *As noted in our response to reviewer 3 - our results on the ### dataset of ### are on par with the ### model stated in the ### paper provided by reviewer 3 (which is a SOTA non-neural ### model) - although we used a very basic set of features and apply very limited task-specific tuning to our models.*

---

[5] The examples are anonymized by replacing citations, venues, method names, exact scores, etc. with placeholders; we also include cases where our system has erroneously rated non-text data (i.e. tables).

Table 14: The full list of hand-crafted features.

- *Although the models used are general to all seq2seq generation problems, the heuristics we used to select ### are specific to generating the ### (take for example, the heuristic based on ### - it was motivated by the fact that ### have a higher readability, hence the network has to focus towards better readable information in the ### in order to generate ###).*

- *Because the size of the training data for ### task is very small, ### instances for ### task and ### instances for ### task, whereas the number of the parameters of the whole network is very big, we pre-training the ### network based on ###, released for ### task, and pre-training the ### network based on the training data for ### task.*

- *Related workshop and share tasks, including ### (collocated with ###), ### (collocated with ###), ### (collocated with ###), and ### (collocated with ###), show a great potential on applying NLP technologies to the ### domain.*

Bottom 10 sentences are presented below. Their specificity scores are all smaller than 0.001.

- *It would be a little difficult to build this connection.*

- *It is not accurate and we will use 'obvious' instead.*

- *We are not quite sure which part is not identical.*

- *I will check that again and will write it as you said*

- *Therefore we can see that they have no relation with each other.*

- *We will try to do this in our future work.*

- *But we do not see this as a weakness of our approach.*

- *That is why we do not do that in the first submission.*

- *So this is really true for all the "models".*

- *Thank you very much for the reviews and for the very useful*

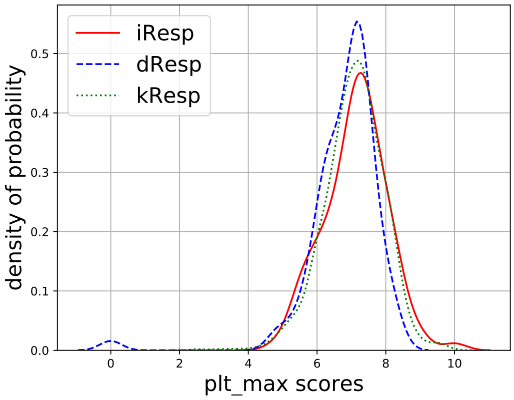

Figure 8: Smoothed distribution of politeness scores.

F Politeness Scores

We use the politeness scorer to rate the same set of sentences as in the specificity evaluation. We normalize all politeness scores to [0,10], with higher values meaning higher politeness. The distribution of the politeness scores is illustrated in Fig. 8. **Top 10 sentences** and their politeness scores are presented below.

- *(9.6) We thank this reviewer for his helpful comments that help improving the paper.*

- *(9.5) Thanks for the suggestion, we found that in many cases the two sentences that are separated by ### also have similar patterns to ###, and the size of the dataset would be too small to train a representative ### model if we only picked out the separate sentences examples.*

- *(9.5) Thank you for the helpful suggestion of including more qualitative results to more thoroughly understand the proposed approach.*

- *(9.4) We again thank the reviewer for the detailed and carefully constructed review and assure that the main concerns raised by the reviewer are fixable and we will fix them in the final version of the paper.*

- *(9.4) Meanwhile, thanks for your suggestion for more in-depth discussion on ###*

- *(9.3) We apologize for this error, and will correct this in the final version of the paper upon acceptance.*

- *(9.3) An interesting alternative approach would be the one proposed by the reviewer, but we chose this model because we wanted to encourage the model to aggregate information from a variety of positions, and in our experience ### has trouble learning to ### in this way because by design ### focuses on one position only.*
- *###| ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# |*
- *###| ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# | ##.# |*
- *(9.2) Depends on the task and the characteristic of two datasets, each proposed method shows its effectiveness, e.g., the ### using the ### between two entities is appropriate for the ### task since ### is systematically organized.*

Bottom 10 sentences and their politeness scores are presented below.

- *(1.7) By comparing ### with ###-, we know whether employing a ### helps; By comparing ### with ###, we know whether employ a ### helps; By comparing ### with ###, we know whether the ### helps.*
- *(2.2) ### = ### ∗ ###, where ### is a matrix of n samples with ### features followed by ### features, hence the size of ### is ###.*
- *(2.3) In other words, our coverage is ### times larger than theirs, so our proposed system can deal much better with the noise when learning ###.*
- *(2.4) And another difference lies in the ### layer, which contains ###, so when we process ### in ### independently which encourages our model to learn diverse features.*
- *(2.4) We will implement their method on our corpora and make some comparison with our method in the next version of our manuscript.*
- *(2.4) We are not giving up ### nor are we claiming that ### is more powerful.*

G Convincingness Scores

We use the convincingness scorer to rate the same set of sentences as in the previous two studies. The convincingness scores are normalized to $[0, 10]$, with higher values meaning higher convincingness. The distribution of the convincingness scores is illustrated in Fig. 9. **Top 10 sentences** in terms of convincingness are presented below. All top 10 sentences' convincingness scores are above 9.8.

- *In the revision, we perform the evaluation of the model with ### and ###, respectively.*
- *Deepening the ### system would inevitably increase model parameters, and slow the training and decoding, which is not what we expect.*
- *A technical document is defined as the document that assumes sufficient background*

knowledge and familiarity with the key technical or central/important terms in the document.

- *As reported in our paper, the success rate of our optimization algorithm is ### while, on average, only ###% of words are altered.*
- *The focus of this work is not a comparison of ### methods with ### methods, but how to mitigate the lack of labeled data problem in learning of a ### model.*
- *Our model works well on datasets that are deemed small for deep architectures to work and belong to special domains for which ### is not possible.*
- *We conduct t-test and get the p value as ###, which shows good agreement.*
- *Particularly, we will strive to improve the presentation quality and to make the draft more readable and better organized for more potential readers.*
- *Furthermore, ### can help ### to alleviate the performance degradation by ###.*
- *The ### experiments in Section ### show that our ### framework can achieve higher accuracy than the methods that rely on the same set of resources, while the state-of-the-art ### methods also require some other resources.*

Bottom 10 sentences in terms of convincingness scores are presented below[6]. Their convincingness scores are all below 0.01.

- *"Weakness 3:""why ... report on ... the '###' if you then dismiss it"""*
- *It is **not** used in the **testing** (###).*
- *Annotator 1: "Are you a citizen?" No =¿ Answer: No*
- *"Rev: ""It seems that ...""""*

Casting Light on Invisible Cities:
Computationally Engaging with Literary Criticism

Shufan Wang
University of Massachusetts, Amherst
shufanwang@cs.umass.edu

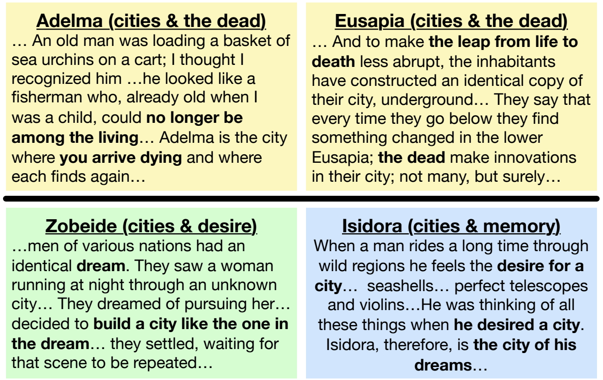
Mohit Iyyer
University of Massachusetts, Amherst
miyyer@cs.umass.edu

Abstract

Literary critics often attempt to uncover meaning in a single work of literature through careful reading and analysis. Applying natural language processing methods to aid in such literary analyses remains a challenge in digital humanities. While most previous work focuses on "distant reading" by algorithmically discovering high-level patterns from large collections of literary works, here we sharpen the focus of our methods to a single literary theory about Italo Calvino's postmodern novel *Invisible Cities*, which consists of 55 short descriptions of imaginary cities. Calvino has provided a classification of these cities into eleven thematic groups, but literary scholars disagree as to how trustworthy his categorization is. Due to the unique structure of this novel, we can computationally weigh in on this debate: we leverage pretrained contextualized representations to embed each city's description and use unsupervised methods to cluster these embeddings. Additionally, we compare results of our computational approach to similarity judgments generated by human readers. Our work is a first step towards incorporating natural language processing into literary criticism.

1 Introduction

Literary critics form interpretations of meaning in works of literature. Building computational models that can help form and test these interpretations is a fundamental goal of digital humanities research (Benzon and Hays, 1976). Within natural language processing, most previous work that engages with literature relies on "distant reading" (Jockers, 2013), which involves discovering high-level patterns from large collections of stories (Bamman et al., 2014; Chaturvedi et al., 2018). We depart from this trend by showing that computational techniques can also engage with literary criticism at a closer distance: concretely, we use recent advances in text representation learning to test a single literary theory about the novel *Invisible Cities* by Italo Calvino.



Adelma (cities & the dead)
… An old man was loading a basket of sea urchins on a cart; I thought I recognized him …he looked like a fisherman who, already old when I was a child, could **no longer be among the living**… Adelma is the city where **you arrive dying** and where each finds again…

Eusapia (cities & the dead)
… And to make **the leap from life to death** less abrupt, the inhabitants have constructed an identical copy of their city, underground… They say that every time they go below they find something changed in the lower Eusapia; **the dead** make innovations in their city; not many, but surely…

Zobeide (cities & desire)
…men of various nations had an identical **dream**. They saw a woman running at night through an unknown city… They dreamed of pursuing her… decided to **build a city like the one in the dream**… they settled, waiting for that scene to be repeated…

Isidora (cities & memory)
When a man rides a long time through wild regions he feels the **desire for a city**… seashells… perfect telescopes and violins…He was thinking of all these things when **he desired a city**. Isidora, therefore, is **the city of his dreams**…

Figure 1: Calvino labels the thematically-similar cities in the top row as *cities & the dead*. However, although the bottom two cities share a theme of desire, he assigns them to different groups.

Framed as a dialogue between the traveler Marco Polo and the emperor Kublai Khan, *Invisible Cities* consists of 55 prose poems, each of which describes an imaginary city. Calvino categorizes these cities into eleven thematic groups that deal with human emotions (e.g., desires, memories), general objects (eyes, sky, signs), and unusual properties (continuous, hidden, thin). Many critics argue that Calvino's labels are not meaningful, while others believe that there is a distinct thematic separation between the groups, including the author himself (Calvino, 2004). The unique structure of this novel — each city's description is short and self-contained (Figure 1) — allows us to computationally examine this debate.

As the book is too small to train any models, we leverage recent advances in large-scale language model-based representations (Peters et al., 2018a; Devlin et al., 2018) to compute a representation of each city. We feed these representa-

Proceedings of NAACL-HLT 2019, pages 1291–1297
Minneapolis, Minnesota, June 2 - June 7, 2019.

tions into a clustering algorithm that produces exactly eleven clusters of five cities each and evaluate them against both Calvino's original labels and crowdsourced human judgments. While the overall correlation with Calvino's labels is low, both computers and humans can reliably identify some thematic groups associated with concrete objects.

While prior work has computationally analyzed a single book (Eve, 2019), our work goes beyond simple word frequency or n-gram counts by leveraging the power of pretrained language models to engage with literary criticism. Admittedly, our approach and evaluations are specific to *Invisible Cities*, but we believe that similar analyses of more conventionally-structured novels could become possible as text representation methods improve. We also highlight two challenges of applying computational methods to literary criticisms: (1) text representation methods are imperfect, especially when given writing as complex as Calvino's; and (2) evaluation is difficult because there is no consensus among literary critics on a single "correct" interpretation.

2 Literary analyses of *Invisible Cities*

Before describing our method and results, we first review critical opinions on both sides of whether Calvino's thematic groups meaningfully characterize his city descriptions.

The groups are meaningful: Some scholars believe that the thematic grouping imposed by Calvino reflects properties of the cities he describes; Vrbani (2012), for example, argues that Calvino's structure are "ontologically grounded in different ways". Buitendijk (2018) further provides examples of cities with the same label that are clearly thematically similar, pointing at the "cities of desire" as "informed by 20th century theories of desires associated with Sigmund Freud". Calvino (2004) himself claims that he creates most categorizations of cities with clear labels in mind, especially the cities of memory and desire, which he deemed as "fundamental cornerstones" of the novel. However, many critics argue that authorial intent is irrelevant when analyzing literature (Wimsatt and Beardsley, 1946; Barthes, 1994).

The groups are arbitrary: On the other hand, a large body of criticism focuses on the apparent mismatch between a city's assigned thematic group and the content of its descriptions. Bloom (2002) claims that the "cities are totally interchangeable"; Springer (1985) agrees, stating that "even the categories themselves seem both chosen and assigned arbitrarily". Teichert (1985) contends that "the catalogue is superimposed on, but does not cover, the elusive, fluid mass of an unwritten world".

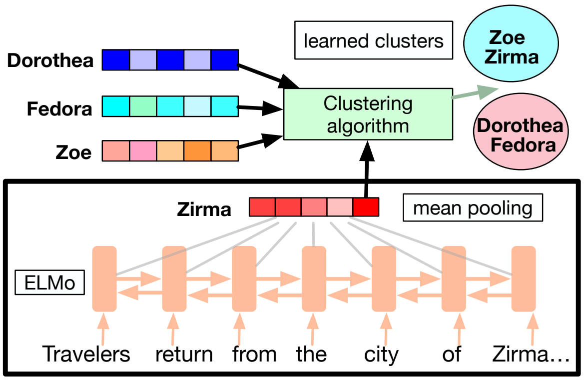


Figure 2: We first embed each city by averaging token representations derived from a pretrained model such as ELMo. Then, we feed the city embeddings to a clustering algorithm and analyze the learned clusters.

While out of scope for our computational analysis, many possible theories exist regarding *why* the groupings appear largely incoherent. For instance, Boeck (2004) posits that the structural incoherence exists because all of the cities actually describe different facets of Marco Polo's hometown of Venice. Breiner (1988) argues instead that Calvino's labels "may refer only to a projection of the Khan's occupational thirst for order, unrelated to the structure of the text", while Knowles (2015) hypothesizes that the mismatch is one of many obstacles that readers need to "untangle" to understand the central substance of the novel.

3 A Computational Analysis

We focus on measuring to what extent computers can recover Calvino's thematic groupings when given just raw text of the city descriptions. At a high level, our approach (Figure 2) involves (1) computing a vector representation for every city and (2) performing unsupervised clustering of these representations. The rest of this section describes both of these steps in more detail.

3.1 Embedding city descriptions

While each of the city descriptions is relatively short, Calvino's writing is filled with rare words, complex syntactic structures, and figurative language.[1] Capturing the essential components of each city in a single vector is thus not as simple as it is with more standard forms of text. Nevertheless, we hope that representations from language models trained over billions of words of text can extract some meaningful semantics from these descriptions. We experiment with three different pretrained representations: ELMo (Peters et al., 2018a), BERT (Devlin et al., 2018), and GloVe (Pennington et al., 2014). To produce a single city embedding, we compute the TF-IDF weighted element-wise mean of the token-level representations.[2] For all pretrained methods, we additionally reduce the dimensionality of the city embeddings to 40 using PCA for increased compatibility with our clustering algorithm.

3.2 Clustering city representations

Given 55 city representations, how do we group them into eleven clusters of five cities each? Initially, we experimented with a graph-based community detection algorithm that maximizes cluster modularity (Newman, 2006), but we found no simple way to constrain this method to produce a specific number of equally-sized clusters. The brute force approach of enumerating all possible cluster assignments is intractable given the large search space ($\frac{55!}{(5!)^{11}}$ possible assignments). We devise a simple clustering algorithm to approximate this process. First, we initialize with random cluster assignments and define "cluster strength" to be the relative difference between "intra-group" Euclidean distance and "inter-group" Euclidean distance.[3] Then, we iteratively propose random exchanges of memberships, only accepting these proposals when the cluster strength increases, until convergence. To evaluate the quality of the computationally-derived clusters against those of Calvino, we measure *cluster purity* (Manning et al., 2008):[4] given a set of predicted clusters M and ground-truth clusters D that both partition a set of N data points,

$$\text{purity} = \frac{1}{N}\sum_{m\in M} max_{d\in D}|m \cap d|.$$

Method	Purity	Accuracy
Random	0.32	33.3
GloVe	0.35	35.9
BERT	0.40	39.3
ELMo	0.42	44.6
Human	-	48.8

Table 1: Results from cluster purity and accuracy on the "odd-one-out" task suggests that Calvino's thematic groups are not completely arbitrary.

4 Evaluating clustering assignments

While the results from the above section allow us to compare our three computational methods against each other, we additionally collect human judgments to further ground our results. In this section, we first describe our human experiment before quantitatively analyzing our results.

Human clustering: We conduct a crowdsourced experiment to measure how well humans can disambiguate thematically different cities. Filling in the entire 55×55 adjacency matrix with human similarity judgments is expensive and time-consuming. Thus, we instead design a proxy "odd-one-out" task for collecting human judgments: given three city descriptions, two of which come from the same ground-truth thematic group and the other from a different group, workers are asked to identify the *intruder* city. We use the Figure Eight crowdsourcing platform[5] to collect three annotations each for 100 different city triples. Our interface initially displays only the first and last sentences of each city's description; workers can optionally click to reveal the full description. As workers are likely unfamiliar with *Invisible Cities* and its different thematic groups, this crowdsourced task provides a fair comparison to our computational approaches.

4.1 Quantitative comparison

We compare clusters computed on different representations using community purity; additionally, we compare these computational methods to humans by their accuracy on the odd-one-out task.

---

[1] The book contains a vocabulary of 5,372 word types, and the average length of a city description is 380 tokens.

[2] Using other composition functions such as the span representation of Peters et al. (2018b) had little impact on the learned clusters.

[3] The choice of distance metric (e.g., cosine, word mover) did not meaningfully impact our results.

[4] Purity ranges between 0 and 1, and a larger purity indicates a higher degree of agreement.

[5] Workers were restricted to English-speaking countries and paid $0.30 per judgment.

Purity of learned clusters: City representations computed using language model-based representation (ELMo and BERT) achieve significantly higher purity than a clustering induced from random representations, indicating that there is at least some meaningful coherence to Calvino's thematic groups (first row of Table 1). ELMo representations yield the highest purity among the three methods, which is surprising as BERT is a bigger model trained on data from books (among other domains). Both ELMo and BERT outperform GloVe, which intuitively makes sense because the latter do not model the order or structure of the words in each description.

Comparison to humans: While the purity of our methods is higher than that of a random clustering, it is still far below 1. To provide additional context to these results, we now switch to our "odd-one-out" task and compare directly to human performance. For each triplet of cities, we identify the intruder as the city with the maximum Euclidean distance from the other two. Interestingly, crowd workers achieve only slightly higher accuracy than ELMo city representations; their inter-annotator agreement is also low,[6] which indicates that close reading to analyze literary coherence between multiple texts is a difficult task, even for human annotators. Overall, results from both computational and human approaches suggests that the author-assigned labels are not entirely arbitrary, as we can reliably recover some of the thematic groups.

5 Examining the learned clusters

Our quantitative results suggest that while vector-based city representations capture some thematic similarities, there is much room for improvement. In this section, we first investigate whether the learned clusters provide evidence for any arguments put forth by literary critics on the novel. Then, we explore possible reasons that the learned clusters deviate from Calvino's.

Do learned clusters support existing analyses? The argument that *cities of desire* constitute a particularly coherent thematic group (Buitendijk, 2018) is partially supported by our clustering results. Three of the five *cities of desire* are grouped into the same cluster using BERT (two for ELMo), which makes it one of the most "internally coherent" groups. Similarly, some literary critics along with Calvino himself (Calvino, 2004) describe the *thin cities* as a fairly arbitrary group, which is supported by our results: when using BERT, no two *thin cities* are grouped into the same cluster. However, Calvino also suggests that the *cities of memory* group is a "fundamental substance" of the book and therefore should be highly coherent. Our computational methods cannot pick up this theme, instead scattering all *cities of memory* into different clusters.

Why do computers disagree with Calvino? In cases where the learned clusters deviate from the opinions of Calvino or literary critics, identifying the cause of the discrepancy is difficult: our computational methods are flawed, but there is also no one "correct" literary interpretation. Here we qualitatively analyze some of the learned clusters in an attempt to understand why the algorithm arrived at a particular assignment. First, we examine two cities from different thematic groups, *Beersheba* from "cities and the sky" and *Valdrada* from "cities and eyes", that belong to the same learned cluster (and are each other's nearest neighbors). The first two paragraphs of *Beersheba* describe a noble city "suspended in the heavens" with an identical but immoral "fecal" city underground, while the remaining paragraphs focus on the heavenly city. The description of *Valdrada*, which is built on a lake, shares this theme of twin cities: arriving travelers see "two cities: one erect above the lake, and the other reflected, upside down". While Calvino likely classified *Beersheba* based on its location in the sky, the two cities share undeniable thematic similarities. Rerunning the clustering algorithm after removing the first two paragraphs of *Beersheba* results in each city being assigned to a different cluster, which supports our hypothesis.

Another interesting case is the previously-mentioned "thin cities", supposedly bound together by airy and ambiguous themes (Knowles, 2015), which Calvino (2004) states were written after all of the other cities and are more incoherent than the other groups. While BERT does not group any thin cities together, ELMo categorizes *Isaura* and *Armilla* into the same learned cluster. The two cities appear largely dissimilar: *Isaura* is a city with a thousand wells dug by its inhabitants, while *Armilla* is an "unfinished" city without walls, ceilings, or floors. However, both cities' descriptions

---

[6] Fleiss $\kappa = 0.14$, indicating slight agreement, and two or more workers agreed on the intruder only 64% of the time.

mention supernatural beings living underground. In *Isaura*, some people believe "gods live in the depths" and "in the black lake that feeds the underground streams", while the last paragraph of *Armilla*'s description conjectures that it is "in the possession of nymphs and naiads" who "travel along underground veins". Removing these descriptions on underground gods and nymphs and rerunning our clustering algorithm yields a new assignment in which each of these cities belongs to different clusters.

When do humans and computers agree? Our computational approach yields generally comparable accuracies and more consistent results than human annotators in the "odd-one-out" task. On cities with concrete themes such as sky and trading, our approach with BERT and ELMo obtains accuracy of 0.44 and 0.45 respectively, (0.47 and 0.48 for humans). ELMo also performs on par with humans in some case: for example, humans achieve an accuracy of 42% on "cities and eyes", compared to ELMo's 43%. On groups where the theme word frequently occurs in the passage, such as "eyes", our approach even slightly outperforms the human readers. However, human readers are better at recognizing abstract intangible topics, such as memory.

6 Related work

Most previous work within the NLP community applies distant reading (Jockers, 2013) to large collections of books, focusing on modeling different aspects of narratives such as plots and event sequences (Chambers and Jurafsky, 2009; McIntyre and Lapata, 2010; Goyal et al., 2010; Eisenberg and Finlayson, 2017), characters (Bamman et al., 2014; Iyyer et al., 2016; Chaturvedi et al., 2016, 2017), and narrative similarity (Chaturvedi et al., 2018). In the same vein, researchers in computational literary analysis have combined statistical techniques and linguistics theories to perform quantitative analysis on large narrative texts (Michel et al., 2011; Franzosi, 2010; Underwood, 2016; Jockers and Kirilloff, 2016; Long and So, 2016), but these attempts largely rely on techniques such as word counting, topic modeling, and naive Bayes classifiers and are therefore not able to capture the meaning of sentences or paragraphs (Da, 2019). While these works discover general patterns from multiple literary works, we are the first to use cutting-edge NLP techniques to engage with specific literary criticism about a single narrative.

There has been other computational work that focuses on just a single book or a small number of books, much of it focused on network analysis: Agarwal et al. (2013) extract character social networks from *Alice in Wonderland*, while Elson et al. (2010) recover social networks from 19th century British novels. Wallace (2012) disentangles multiple narrative threads within the novel *Infinite Jest*, while Eve (2019) provides several automated statistical methods for close reading and test them on the award-winning novel *Cloud Atlas* (2004). Compared to this work, we push further on modeling the content of the narrative by leveraging pretrained language models.

7 Conclusion

Our work takes a first step towards computationally engaging with literary criticism on a single book using state-of-the-art text representation methods. While we demonstrate that NLP techniques can be used to support literary analyses and obtain new insights, they also have clear limitations (e.g., in understanding abstract themes). As text representation methods become more powerful, we hope that (1) computational tools will become useful for analyzing novels with more conventional structures, and (2) literary criticism will be used as a testbed for evaluating representations.

PAWS: Paraphrase Adversaries from Word Scrambling

Yuan Zhang **Jason Baldridge** **Luheng He**
Google AI Language
{zhangyua,jridge,luheng}@google.com

Abstract

Existing paraphrase identification datasets lack sentence pairs that have high lexical overlap without being paraphrases. Models trained on such data fail to distinguish pairs like *flights from New York to Florida* and *flights from Florida to New York*. This paper introduces PAWS (**P**araphrase **A**dversaries from **W**ord **S**crambling), a new dataset with 108,463 well-formed paraphrase and non-paraphrase pairs with high lexical overlap. Challenging pairs are generated by controlled word swapping and back translation, followed by fluency and paraphrase judgments by human raters. State-of-the-art models trained on existing datasets have dismal performance on PAWS (<40% accuracy); however, including PAWS training data for these models improves their accuracy to 85% while maintaining performance on existing tasks. In contrast, models that do not capture non-local contextual information fail even with PAWS training examples. As such, PAWS provides an effective instrument for driving further progress on models that better exploit structure, context, and pairwise comparisons.

1 Introduction

Word order and syntactic structure have a large impact on sentence meaning. Even small perturbation in word order can completely change interpretation. Consider the following related sentences.

(1) Flights from New York to Florida.
(2) Flights to Florida from NYC.
(3) Flights from Florida to New York.

All three have high bag-of-words (BOW) overlap. However, (2) is a paraphrase of (1), while (3) has a very different meaning from (1).

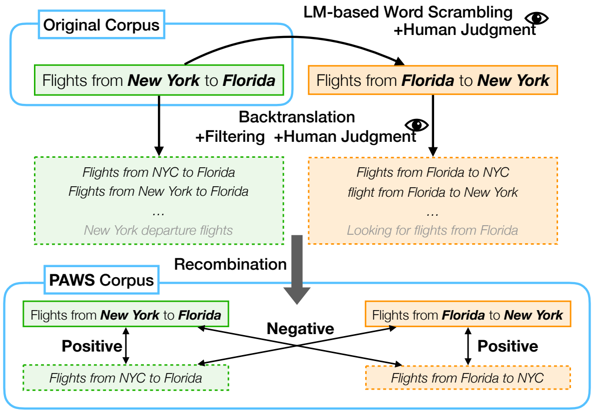

Figure 1: PAWS corpus creation workflow.

Existing datasets lack non-paraphrase pairs like (1) and (3). The Quora Question Pairs (QQP) corpus contains 400k real world pairs, but its negative examples are drawn primarily from related questions. Few have high word overlap, and of the ∼1,000 pairs with the same BOW, only 20% are not paraphrases. This provides insufficient representative examples to evaluate models' performance on this problem, and there are too few examples for models to learn the importance of word order. Table 1 shows that models trained on QQP are inclined to mark any sentence pairs with high word overlap as paraphrases despite clear clashes in meaning. Models trained or evaluated with only this data may not perform well on real world tasks where such sensitivity is important.

To address this, we introduce a workflow (outlined in Figure 1) for generating pairs of sentences that have high word overlap, but which are balanced with respect to whether they are paraphrases or not. Using this process, we create PAWS (**P**araphrase **A**dversaries from **W**ord **S**crambling), a dataset constructed from sentences in Quora and

Table 1: Paraphrase/Non-paraphrase (Y/N) pairs with high bag-of-words (BOW) overlap. (1)-(5) are drawn from PAWS, and (6) is from Mitchell and Lapata (2008). Both a simple BOW and the state-of-the-art BERT (Devlin et al., 2018) models, if trained/fine-tuned on the Quora Question Pairs (QQP) corpus, classify all of them (with one exception) as paraphrases (Y). A BERT model fine-tuned on both QQP and PAWS examples (BERT+PAWS), however, is able to get them correct.

Wikipedia. Examples are generated from controlled language models and back translation, and given five human ratings each in both phases. A final rule recombines annotated examples and balances the labels. Our final PAWS dataset will be released publicly with 108,463 pairs at `https://g.co/dataset/paws`.

We show that existing state-of-the-art models fail miserably on PAWS when trained on existing resources, but some perform well when given PAWS training examples. BERT (Devlin et al., 2018) fine-tuned on QQP achieves over 90% accuracy on QQP, but only 33% accuracy on PAWS data in the same domain. However, the accuracy on PAWS boosts to 85% by including 12k PAWS training pairs (without reducing QQP performance). Table 1 also shows that the new model is able to correctly classify challenging pairs. Annotation scale is also important: our learning curves show strong models like BERT improve with tens of thousands of training examples.

Our experimental results also demonstrate that PAWS effectively measures sensitivity of models to word order and structure. Unlike BERT, a simple BOW model fails to learn from PAWS training examples, demonstrating its weakness at capturing non-local contextual information. Our experiments show that the gains from PAWS examples correlate with the complexity of models.

2 Related Work

Existing data creation techniques have focused on collecting paraphrases, e.g. from co-captions for images (Lin et al., 2014), tweets with shared URLs (Lan et al., 2017), subtitles (Creutz, 2018), and back translation (Iyyer et al., 2018). Unlike all previous work, we emphasize the collection of challenging negative examples.

Our work closely relates to the idea of crafting adversarial examples to break NLP systems. Existing approaches mostly focused on adding label-preserving perturbations to inputs, but with the effect of distracting systems from correct answers. Example perturbation rules include adding noise to inputs (Jia and Liang, 2017; Chen et al., 2018), word replacements (Alzantot et al., 2018; Ribeiro et al., 2018), and syntactic transformation (Iyyer et al., 2018). A notable exception is Glockner et al. (2018): they generated both entailment and contradiction examples by replacing words with their synonyms or antonyms. Our work presents two main departures. We propose a novel method that generates challenging examples with balanced class labels and more word reordering variations than previous work. In addition, we release to public a large set of 108k example pairs with high-quality human labels. We believe the new dataset will benefit future research on both adversarial example generation and improvement of model robustness.

In our work, we demonstrate the importance of capturing non-local contextual information in the problem of paraphrase identification. This relates to prior work on probing sentence representations for their linguistic properties, such as how much syntactic information is encoded in representations (Conneau et al., 2018; Tenney et al.,

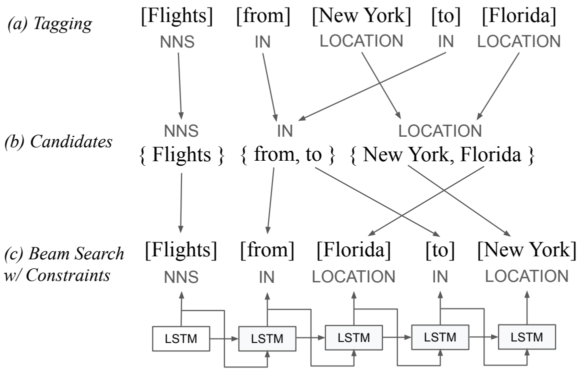

Figure 2: Illustration of the generation method in three steps. (a) Tag words and phrases with part-of-speech (POS) and named entities. (b) Build candidate sets by grouping words and phrases with the same tag. (c) Under the constraints of tag sequence template and candidate sets, find sentences with high language model scores using beam search.

2019; Ettinger et al., 2018). There also exists prior work that directly uses structural information in modeling (Filice et al., 2015; Liu et al., 2018). All these prior approaches were evaluated on existing datasets. In contrast, we perform studies on PAWS, a new dataset that emphasizes the importance of capturing structural information in representation learning. While developing new models is beyond the scope of this paper, this new dataset can facilitate research in this direction.

3 PAWS Example Generation

We define a **PAWS pair** to be a pair of sentences with high bag-of-words (BOW) overlap but different word order. In the Quora Question Pairs corpus, 80% of such pairs are paraphrases. Here, we describe a method to automatically generate non-trivial and well-formed PAWS pairs from real-world text in any domain (this section), and then have them annotated by human raters (Section 4).

Our automatic generation method is based on two ideas. The first swaps words to generate a sentence pair with the same BOW, controlled by a language model. The second uses back translation to generate paraphrases with high BOW overlap but different word order. These two strategies generate high-quality, diverse PAWS pairs, balanced evenly between paraphrases and non-paraphrases.

3.1 Word Swapping

Our first phase generates well-formed sentences by swapping words in real world text. Most text generation models rely on large amount of training data (Iyyer et al., 2018; Guu et al., 2018; Gupta et al., 2018; Li et al., 2018), which is unfortunately not available in our case. We thus propose a novel generation method based on language modeling and constrained beam search. The goal is to find a sentence that achieves high language model score as well as satisfying all constraints. High scores indicate that generated sentences are natural and well-formed, and constraints ensure generated pairs have the same BOW.

Figure 2 illustrates the generation procedure. First, given an input sentence, a CRF-based part-of-speech tagger tags each word. We further detect person names, locations, and organizations using a named entity recognizer, and replace POS with entity tags if probability scores are above 95%.[1] The sequence of tags of words and phrases form a template for the input.

Our beam search method then fills in each slot of the template from left to right, scoring each state by a language model trained on one billion words (Chelba et al., 2014). The candidate words and phrases for each slot are drawn from the input based on its tag. In Figure 2, for example, the second slot must be filled with a LOCATION from two candidate *New York* and *Florida*. Candidates are drawn without replacement so the generated sentence and the input have exactly the same bag-of-words. Note that this template-based constraint is more restrictive than the BOW requirement, but we choose it because it significantly reduces the search space. With this constraint, the method achieves high generation quality without a large beam. In practice, beam size is set to 100, which produces near-optimal results in most cases.

Let s' be the best sentence in the beam other than the input sentence s, and $LM(\cdot)$ be their log-likelihood by the language model. We take (s, s') as a good word-swapping pair if $LM(s') \geq LM(s) - t$.[2] We manually pick the threshold t=3.0 for a good balance between generation quality and coverage. Examples (1) and (2) in Table 2 are representative examples from this generation method.

---

[1] We pick this threshold to achieve about 95% precision.

[2] In a preliminary stage, we noticed that many pairs were simply a permutation of a list, like "A and B" changed to "B and A". For the diversity of the dataset, 99% of these are pruned via hand-crafted, heuristic rules.

	Sentence 1	Sentence 2	Generation Type
(1)	Can a **bad** person become **good**?	Can a **good** person become **bad**?	Adjective swap
(2)	**Jerry** looks over **Tom**'s shoulder and gets punched.	**Tom** looks over **Jerry**'s shoulder and gets punched.	Named entity swap
(3)	The team also toured in Australia **in 1953**.	**In 1953,** the team also toured in Australia.	Temporal phrase swap
(4)	Erikson **formed** the rock band Spooner with two fellow musicians.	Erikson **founded** the rock band Spooner with two fellow musicians.	Word replacement

Table 2: Examples of typical types of generation. (1) and (2) are from the word swapping method, while (3) and (4) are from the back translation method. Boldface indicates changes in each example.

3.2 Back Translation

Because word order impacts meaning, especially in English, the swapping method tends to produce non-paraphrases. Our preliminary results showed that the distribution of paraphrase to non-paraphrases from this method is highly imbalanced (about 1:4 ratio). However, we seek to create a balanced dataset, so we use an additional strategy based on back translation—which has the opposite label distribution and also produces greater diversity of paraphrases while still maintaining a high BOW overlap.

The back translation method takes a sentence pair and label (s_1, s_2, l) as input. For each sentence, the top-k translations are obtained from an English-German neural machine translation model (NMT); then each of these is translated back to English using another German-English NMT model, providing a resulting top-k results. We chose German as the pivot language because it produced more word reordering variations than other languages and the translation quality was good. Both models have the same architecture (Wu et al., 2016) and are trained on WMT14. This results in k^2 back translations before deduplication. We chose k=5. To obtain more pairs with the PAWS property, we further filter back translations by their BOW similarities to the input and their word-order inversion rates, as described below.

We define BOW similarity as the cosine similarity α between the word count vectors of a sentence pair. Pairs generated from the swapping strategy have score $\alpha = 1.0$, but here we relax the threshold to 0.9 because it brings more data diversity and higher coverage, while still generating paraphrases of the input with high quality.

To define the word-order inversion rate, we first compute word alignments between a sentence pair in a heuristic way by assuming they are one-to-one mapping and are always monotonic. For example, if the first sentence has three instances of *dog* and the second has two, we align the first two instances of *dog* in the same order and skip the third one. The inversion rate is then computed as the ratio of cross alignments. Figure 3 is an example pair with six alignments. There are 15 alignment pairs in total and 9 of them are crossed, e.g. alignments of *on* and *married*. The inversion rate of this example is therefore $9/15 = 0.6$. We sample back translation results such that at least half of the pairs have inversion rate over 0.02; this way, the final selected pairs cover interesting transformations of both word-order changes and word replacement. Examples (3) and (4) in Table 2 are representative examples from back translation.

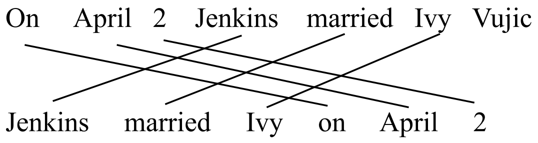

Figure 3: An example of how to compute inversion rate.

Label Balancing Figure 1 illustrates the process of constructing the final label-balanced set based on human annotations. The set first includes all pairs from back translation, which are mostly paraphrases. For each labeled pair (s_1, s_2) from swapping and a labeled pair (s_1, s'_1) from back translation, the set further includes the pair (s_2, s'_1) based on the rules: (1) (s_2, s'_1) is paraphrase if both (s_1, s_2) and (s_1, s'_1) are paraphrases; (2) (s_2, s'_1) is non-paraphrase if exactly one of (s_1, s_2) and (s_1, s'_1) is non-paraphrase; (3) otherwise (s_2, s'_1) is not included because its label is unknown. We also consider pairs (s'_2, s_1) and (s'_2, s'_1) in the similar way if s'_2 is a back translation of s_2 with human labels.

4 PAWS Dataset

Using the example generation strategies described in Section 3 combined with human paraphrase an-

Table 3: Detailed counts for examples created via the swapping strategy, followed by human filtering and paraphrase judgments.

notations, we create a large new dataset, **PAWS** that contains both paraphrase and non-paraphrase pairs that have both high bag-of-words overlap and word reordering. Source sentences are drawn from both the Quora Question Pairs (QQP) corpus (Iyer et al., 2017) and Wikipedia.[3] From these, we produce two datasets, PAWS_{QQP} and $\text{PAWS}_{\text{Wiki}}$.

We start by producing swapped examples from both QQP and Wikipedia. Both sources contain naturally occurring sentences covering many topics. On both corpora only about 3% of candidates are selected for further processing—the rest are filtered because there is no valid generation candidate that satisfies all swapping constraints or because the language model score of the best candidate is below the threshold. The remaining pairs (16,280 for QQP and 50k for Wikipedia) are passed to human review.

Sentence correction The examples generated using both of our strategies are generally of high quality, but they still need to be checked with respect to grammar and coherence. Annotators evaluate each generated sentence without seeing its source sentence. The sentence is accepted as is, fixed, or rejected. Table 3 shows the number of pairs of each action on each domain. Most of fixes are minor grammar corrections like *a apple→an apple*. Accepted and fixed sentences are then passed to the next stage for paraphrase annotation.

Total # back translation pairs	26,897
paraphrase	25,521
non-paraphrase	1,376
Human agreement	94.8%

Table 4: Paraphrase judgments on example pairs generated by back translation on Wikipedia sentences.

Overall 88% of generated examples passed the human correction phase on both domains.

Paraphrase identification Sentence pairs are presented to five annotators, each of which gives a binary judgment as to whether they are paraphrases or not. We choose binary judgments to make our dataset have the same label schema as the QQP corpus. Table 3 shows aggregated annotation statistics on both domains, including the number of paraphrase (positive) and non-paraphrase (negative) pairs and human agreement, which is the percentage ratio of agreement between each individual label and the majority vote of five labels on each example pair. Overall, human agreement is high on both Quora (92.0%) and Wikipedia (94.7%) and each label only takes about 24 seconds. As such, answers are usually straightforward to human raters.

To ensure the data is comprised of clearly paraphrase or non-paraphrase pairs, only examples with four or five raters agreeing are kept.[4] An example of low agreement is *Why is the 20th-century music so different from the 21st music?* v.s. *Why is the 21st century music so different from the 20th century music?*, where three out of five raters gave negative labels on this pair. The bottom block of Table 3 shows the final number of pairs after this filtering, and human agreement further goes up to over 95%. Finally, source and generated sentences are randomly flipped to mask their provenance.

The swapping strategy generally produces non-paraphrase examples—67% for QQP and 88% for Wikipedia. Because (a) the label imbalance is less pronounced for QQP and (b) NMT models perform poorly on Quora questions due to domain mismatch, we only apply the back translation strategy to Wikipedia pairs. Doing so creates 26,897 candidate example pairs after filtering. As before, each pair is rated by five annotators on the paraphrase identification task.[5] Table 4 shows that

---

[3] `https://dumps.wikimedia.org`

[4] We exclude low agreement pairs from our experiments, but we include them in our data release for further study.

[5] Sentence correction was not necessary for these because

	Train	Dev	Test	Yes%
PAWS$_{\text{QQP}}$	11,988	677	–	31.3%
PAWS$_{\text{Wiki}}$	49,401	8,000	8,000	44.2%
PAWS$_{\text{Wiki-Swap}}$	30,397	–	–	9.6%

Table 5: Counts of experimental split for each PAWS dataset. The final column gives the proportion of paraphrase (positive) pairs. There are 108,463 PAWS pairs in total.

most of the examples (94.9%) are paraphrases (as expected), with high human agreement (94.8%). Finally, we expand the pairs using the the rules described in Section 3.2.

Table 5 provides counts for each split in the final PAWS datasets. The training portion of PAWS$_{\text{QQP}}$ is a subset of the QQP training set; however, PAWS$_{\text{QQP}}$'s development set is a subset of both QQP's development and test sets because there are only 677 pairs. PAWS$_{\text{Wiki}}$ randomly draws 8,000 pairs for each of its development and test sets and takes the rest as its training set, with no overlap of source sentences across sets. Finally, any trivial pairs with identical sentences from development and test sets are removed.[6] The final PAWS$_{\text{QQP}}$ has a total of 12,665 pairs (443k tokens), where 31.3% of them have positive labels (paraphrases). PAWS$_{\text{Wiki}}$ has a total of 65,401 pairs (2.8m tokens), where 44.2% of them are paraphrases.

Note that we have human annotations on 43k pairs generated by the word swapping method on Wikipedia, but 30k of them have no back translation counterparts and therefore they are not included in our final PAWS$_{\text{Wiki}}$ dataset. Nevertheless, they are high-quality pairs with manual labels, so we include them as an auxiliary training set (PAWS$_{\text{Wiki-Swap}}$ in Table 5), and empirically show its impact in Section 6.

Unlabeled PAWS$_{\text{Wiki}}$ In addition to the fully labeled PAWS$_{\text{Wiki}}$ dataset, we also construct an unlabeled PAWS$_{\text{Wiki}}$ set at large scale. The idea is to simply treat all pairs from word swapping as non-paraphrases and all pairs from back translation as paraphrase, and construct the dataset in the same way as labeled PAWS$_{\text{Wiki}}$. The result is a total of 656k pairs with silver labels. We show empirically the impact of using this silver set in pre-training in Section 6.

	BOW	BiLSTM & ESIM	DecAtt	DIIN & BERT
Non-local context	×	✓	×	✓
Word interaction	×	×	✓	✓

Table 6: Complexity of each evaluated model.

5 Evaluated Models

PAWS is designed to probe models' ability to go beyond recognizing overall sentence similarity or relatedness. As noted in the introduction, models—even the best avaliable—trained on existing resources tend to classify any example with high BOW overlap as a paraphrase. Can any of these models learn finer structural sensitivity when provided with PAWS examples as part of their training?

We consider six different models that cover a wide range of complexity and expressiveness: two baseline encoders and four recent advanced models that achieved state-of-the-art or strong performance on paraphrase identification. Table 6 summarizes the models with respect to whether they represent non-local contexts or support cross-sentential word interaction.

The baseline models use cosine similarity with simple sentence encoders: a bag-of-words (**BOW**) encoder based on token unigram and bigram encodings and a bi-directional LSTM (**BiLSTM**) that produces a contextualized sentence encoding. A cosine value above .5 is taken as a paraphrase.

ESIM. The Enhanced Sequential Inference Model (Chen et al., 2017) achieved competitive performance on eight sentence pair modeling tasks (Lan and Xu, 2018). It encodes each sentence using a BiLSTM, concatenates the encodings for each sentence in the pair, and passes them through a multi-layer perceptron (MLP) for classification. The additional layers allow ESIM to capture more complex sentence interaction than cosine similarity in the baseline models.

DecAtt. The Decomposable Attention Model (Parikh et al., 2016) is one of the earliest models to introduce attention for paraphrase identification. It computes word pair interaction between two sentences and aggregates aligned vectors for final classification. This model achieved state-of-the-art results without explicitly modeling word

---

NMT generates fluent output.

[6] Such trivial examples exist because annotators sometimes fix a swapped sentence back to its source. We keep such examples in the training set (about 8% of the corpus) because otherwise a trained model would actually predict low similarity scores to identical pairs.

order. In our experiments, we show the limitations of this modeling choice on PAWS pairs.

DIIN. The Densely Interactive Inference Network (Gong et al., 2018) adopts DenseNet (Huang et al., 2017), a 2-dimensional convolution architecture, to extract high-order word-by-word interaction between n-gram pairs. This model achieved state-of-the-art performance without relying on pre-trained deep contextualized representations like ELMo (Peters et al., 2018). It outperformed ESIM and DecAtt models by a large margin on both paraphrase identification and natural language inference tasks.

BERT. The Bidirectional Encoder Representations from Transformers (Devlin et al., 2018) recently obtained new state-of-the-art results on eleven natural language processing tasks, including pushing the GLUE benchmark to 80.4% (7.6% absolute improvement). BERT involves pre-training a Transformer encoder (Vaswani et al., 2017) on a large corpus with over three billion words. This large network is then fine-tuned with just one additional output layer.

6 Experiments

We seek to understand how well models trained on standard datasets perform on PAWS pairs and to see which models are most able to learn from PAWS pairs. A strong model should improve significantly on PAWS when trained on PAWS pairs without diminishing performance on existing datasets like QQP. Overall, both DIIN and BERT prove remarkably able to adapt to PAWS pairs and perform well on both PAWS$_{\text{QQP}}$ and PAWS$_{\text{Wiki}}$ while the other models prove far less capable.

6.1 Experimental Setup

We use two metrics: classification accuracy and area-under-curve (AUC) scores of precision-recall curves. For all classification models, 0.5 is the threshold used to compute accuracy. We report results on testing sets for QQP and PAWS$_{\text{Wiki}}$, and on the development set for PAWS$_{\text{QQP}}$ (which has no test set).

For BERT, we use the implementation provided by the authors[7] and apply their default fine-tuning configuration. We use the provided BERT$_{\text{BASE}}$ pre-trained model instead of BERT$_{\text{LARGE}}$ due to GPU memory limitations. For all other models, we use our own (re-)implementations that matched reported performance on QQP. We use 300 dimensional GloVe embeddings (Pennington et al., 2014) to represent words and fix them during training.

6.2 Results

Main Results on PAWS$_{\text{QQP}}$ Table 7 summarizes results on the Quora domain. We first train models on the Quora Question Pairs (QQP) training set, and column "QQP→QQP" shows that all models achieve over 83% accuracy on QQP. However, when evaluating on PAWS$_{\text{QQP}}$, all models, including BERT, obtain abysmal accuracy under 40% (column "QQP→PAWS$_{\text{QQP}}$").

We hypothesize the performance on PAWS$_{\text{QQP}}$ relies on two factors: the number of representative training examples, and the capability of models to represent complex interactions between words in each sentence and across the sentences in the pair. To verify that, we further train models on a combination of QQP and PAWS$_{\text{QQP}}$ training sets and the last two columns of Table 7 show the results on PAWS$_{\text{QQP}}$. As expected, all models benefit from new training examples, but to different extents. Gains are much larger on state-of-the-art models like BERT, while the BOW model learns almost nothing from new examples. As a consequence, performance changes are more drastic on PAWS$_{\text{QQP}}$ than on QQP. For example, the absolute difference between BiLSTM and BERT is 4.2% on QQP, but it goes up to 27% on PAWS$_{\text{QQP}}$, which is a 60% relative reduction in error.

It is also noteworthy that adding PAWS$_{\text{QQP}}$ training examples has no negative impact to QQP performance at all. For example, a BERT model fine-tuned on QQP+PAWS$_{\text{QQP}}$ achieves the same 90.5% classification accuracy as training on QQP alone. We therefore obtain a single model that performs well on both datasets.

Main Results on PAWS$_{\text{Wiki}}$ In our second experiment we train and evaluate models on our PAWS$_{\text{Wiki}}$ dataset. Table 8 presents the results. DIIN and BERT outperform others by a substantial margin (>17% accuracy gains). This observation gives more evidence that PAWS data effectively measures models' sensitivity to word order and syntactic structure.

One interesting observation is that DecAtt performs as poorly as BOW on this dataset. This is likely due to the fact that DecAtt and BOW both consider only local context information. We there-

Table 7: **Acc**uracy (%) of classification and **AUC** scores (%) of precision-recall curves on Quora Question Pairs (**QQP**) testing set and our PAWS$_{QQP}$ development set. QQP→PAWS$_{QQP}$ indicates that models are trained on QQP and evaluated on PAWS$_{QQP}$. Other columns are defined in a similar way. QQP+PAWS$_{QQP}$ is a simple concatenation of the two training sets. Boldface numbers indicate the best accuracy for each testing scenario. Numbers in parentheses indicate absolute gains from adding PAWS$_{QQP}$ training data.

MODELS	Supervised (Acc)	Supervised (AUC)	Pretrain+Fine-tune (Acc)	Pretrain+Fine-tune (AUC)
BOW	55.8	41.1	55.6	44.9
BiLSTM	71.1	75.6	80.8	87.6
ESIM	67.2	69.6	81.9	85.8
DecAtt	57.1	52.6	55.8	45.4
+BiLSTM	68.6	70.6	88.8	92.3
DIIN	88.6	91.1	91.8	**94.4**
BERT	**90.4**	**93.7**	**91.9**	94.3

Table 8: Accuracy (%) and AUC scores (%) of different models on PAWS$_{Wiki}$ testing set. **Supervised** models are trained on human-labeled data only, while **Pretrain+Fine-tune** models are first trained on noisy unlabeled PAWS$_{Wiki}$ data and then fine-tuned on human-labeled data.

fore tested an enhancement of DecAtt by replacing its word representations with encodings from a BiLSTM encoder to capture non-local context information. The enhanced model significantly outperforms the base, yielding an 11.5% (57.1% vs. 68.6%) absolute gain on accuracy.

We further evaluate the impact of using silver PAWS$_{Wiki}$ data in pre-training, as discussed in Section 4. The last two columns of Table 8 show the results. Comparing to supervised performance, pre-training with silver data gives consistent improvements across all models except BOW and vanilla DecAtt. Perhaps surprisingly, adding silver data gives more than 10% absolute improvements on AUC scores for BiLSTM and ESIM, much higher than the gains on DIIN and BERT.

Size of Training Set To analyze how many PAWS examples are sufficient for training, we train multiple models on QQP plus different number of PAWS$_{QQP}$ examples. Figure 4 plots AUC score curves of DIIN and BERT as a function of the number of PAWS$_{QQP}$ training examples. $x = 0$ corresponds to models trained on QQP only, and the rightmost points correspond to models trained on QQP and full PAWS$_{QQP}$. Both models improve from 30% to 74% AUC scores with 6,000 PAWS$_{QQP}$ examples. Furthermore, neither curve reaches convergence, so they would likely still benefit from more PAWS training examples.

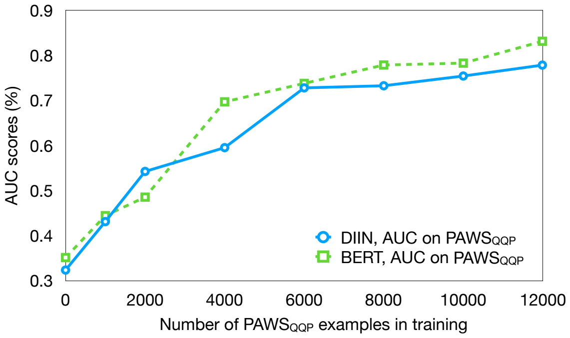

Figure 4: AUC scores (y-axis) as a function of the number of PAWS$_{QQP}$ examples in the training set (x-axis).

Cross-domain Results The PAWS datasets cover two domains: Quora and Wikipedia. Here we demonstrate that a model trained on one domain also generalizes to another domain, although not as well as training on in-domain data. Table 9 shows that a DIIN model trained on Quora (QQP+PAWS$_{QQP}$) achieves 70.5% AUC on the Wikipedia domain. This is lower than training on in-domain data (92.9%), but higher than the model trained without any PAWS data (46.0%). We also observe similar patterns when

TRAINING DATA	QQP (Test)	PAWS_{QQP} (Dev)	$\text{PAWS}_{\text{Wiki}}$ (Test)
QQP (Train)	95.2	32.4	46.0
$\text{QQP+PAWS}_{\text{QQP}}$	**95.3**	77.8	70.5
$\text{QQP+PAWS}_{\text{Wiki}}$	**95.3**	58.5	92.9
$\text{+PAWS}_{\text{Wiki-Swap}}$	**95.3**	70.6	93.5
$\text{QQP+PAWS}_{\text{QQP+Wiki}}$	95.1	87.0	93.4
$\text{+PAWS}_{\text{Wiki-Swap}}$	**95.3**	**89.9**	**93.8**

Table 9: AUC scores (%) when training DIIN models on different sets of training data. Boldface numbers indicate the best accuracy for each testing set.

training on Wikipedia ($\text{QQP+PAWS}_{\text{Wiki}}$) and testing on PAWS_{QQP}. Interestingly, using out-of-domain data also boosts in-domain performance. As Table 9 shows, training on both domains ($\text{QQP+PAWS}_{\text{QQP+Wiki}}$) leads to 9.2% absolute AUC gains on PAWS_{QQP} over the model trained only on $\text{QQP+PAWS}_{\text{QQP}}$.

The auxiliary training set on Wikipedia ($\text{PAWS}_{\text{Wiki-Swap}}$) helps further. As Table 9 shows, adding this auxiliary training set is particularly helpful to the performance on PAWS_{QQP}, yielding a 12.1% (70.6% vs 58.5%) gain on AUC when training on $\text{QQP+PAWS}_{\text{Wiki}}$. On $\text{PAWS}_{\text{Wiki}}$, this addition lifts the (no pre-training) DIIN model AUC from 91.1% (Table 8) to 93.8% (Table 9).

BERT vs DIIN Both models achieve top scores on PAWS, but interestingly, the two models disagree on many pairs and are not correlated in their errors. For example, of 687 of BERT's mistakes on the $\text{PAWS}_{\text{Wiki}}$ test set, DIIN got 280 (41%) correct. As such, performance might improve with combinations of these two existing models.

It is also worth noting that the DIIN model used in our experiments has only 590k model parameters, whereas BERT has over 100m. Furthermore, the computational cost of BERT is notably higher than DIIN. Given this, and the fact that DIIN is competitive with BERT (especially when pre-trained on noisy pairs, see Table 8), DIIN is likely the better choice in computationally constrained scenarios—especially those with strict latency requirements.

7 Conclusion

Datasets are insufficient for differentiating models if they lack examples that exhibit the necessary diagnostic phenomena. This has led, for example, to new datasets for noun-verb ambiguity (Elkahky et al., 2018) and gender bias in coreference (Webster et al., 2018; Rudinger et al., 2018; Jieyu Zhao, 2018). Our new PAWS datasets join these efforts and provide a new resource for training and evaluating paraphrase identifiers. We show that including PAWS training data for state-of-the-art models dramatically improves their performance on challenging examples and makes them more robust to real world examples. We also demonstrate that PAWS effectively measures sensitivity of models on word order and syntactic structure.

Abstract

This study explores the necessity of performing cross-corpora evaluation for grammatical error correction (GEC) models. GEC models have been previously evaluated based on a single commonly applied corpus: the CoNLL-2014 benchmark. However, the evaluation remains incomplete because the task difficulty varies depending on the test corpus and conditions such as the proficiency levels of the writers and essay topics. To overcome this limitation, we evaluate the performance of several GEC models, including NMT-based (LSTM, CNN, and transformer) and an SMT-based model, against various learner corpora (CoNLL-2013, CoNLL-2014, FCE, JFLEG, ICNALE, and KJ). Evaluation results reveal that the models' rankings considerably vary depending on the corpus, indicating that single-corpus evaluation is insufficient for GEC models.

1 Introduction

Grammatical error correction (GEC) is the task of correcting various grammatical errors in a given text, which is typically written by non-native speakers. Previous studies focused on typical errors such as those in the use of articles (Han et al., 2006), prepositions (Felice and Pulman, 2008), and noun numbers (Nagata et al., 2006). Machine translation approaches are being presently applied for GEC (Junczys-Dowmunt et al., 2018; Chollampatt and Ng, 2018; Ge et al., 2018; Junczys-Dowmunt and Grundkiewicz, 2016). In these approaches, GEC is treated as a translation problem from the erroneous text to the correct text (Mizumoto et al., 2012; Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014).

However, the evaluation of GEC performance is unfortunately not complete because researchers tend to evaluate their models on a single corpus. The CoNLL-2014 shared task dataset (Ng et al., 2014) has been recently used for such evaluation.

Single-corpus evaluation may be insufficient in cases wherein a GEC model generally aims to robustly correct grammatical errors in *any* written text partly because the task difficulty varies depending on proficiency levels and essay topics. Although a model outperforms a baseline in one corpus, the model in another corpus may perform better, leading to different conclusions from what we know. This study explores the necessity of performing cross-corpora evaluation for GEC models. The performance of four recent models, namely three neural machine translation (NMT)-based models (LSTM, CNN, and transformer) and a statistical machine translation (SMT)-based model is evaluated against six learner corpora (CoNLL-2014, CoNLL-2013 (Ng et al., 2013), FCE (Yannakoudakis et al., 2011), JFLEG (Napoles et al., 2017), KJ (Nagata et al., 2011), and ICNLAE (Ishikawa, 2013)). Evaluation results show that the models' rankings considerably vary depending on the corpus. Empirical results reveal that models must be evaluated using multiple corpora from different perspectives.

The contributions of this study are as follows:

- We first explore the necessity of performing cross-corpora evaluation for GEC models.
- We empirically show that the single-corpus evaluation may be unreliable.
- Our source code is published for cross-corpora evaluation so that researchers in the community can adequately and easily evaluate their models based on multiple corpora. [1]

2 Related Work

We are motivated by the issue of robustness in the parsing community. This field pre-

Proceedings of NAACL-HLT 2019, pages 1309–1314
Minneapolis, Minnesota, June 2 - June 7, 2019.

viously focused on improving parsing accuracy on Penn Treebank (Marcus et al., 1993). However, robustness was largely improved by evaluation using multiple corpora including Ontonotes (Hovy et al., 2006) and Google Web Treebank (Petrov and McDonald, 2012). A situation similar to this might also occur in GEC. In other words, evaluation in GEC has relied heavily on the CoNLL-2014 benchmark, which implies that the field is overdeveloping on this dataset.

Other corpora are used for evaluation, such as KJ (Mizumoto et al., 2012) and JFLEG (Sakaguchi et al., 2017; Junczys-Dowmunt et al., 2018; Chollampatt and Ng, 2018; Ge et al., 2018; Xie et al., 2018). However, these corpora still depend on one or at most two corpora.

3 Experimental Setup

3.1 Corpora for Evaluation

Cross-corpora evaluation is discussed herein using six corpora, namely CoNLL-2014, CoNLL-2013, FCE, JFLEG, KJ, and ICNALE. The following conditions were considered when selecting corpora:

- The corpus must be used at least once in the GEC community.
- Based on the hypothesis that writers' proficiency affects the error distribution of any given text, we add a corpus with relatively low proficiency (KJ) compared to CoNLL-2014.

We explicitly describe each learner corpus as follows:

CoNLL-2014 (Ng et al., 2014), the official dataset of CoNLL-2014 shared task, is a collection of essays written by students at the National University of Singapore and is commonly used as test data for the CoNLL-2014 benchmark. This dataset contains only two essay topics.

CoNLL-2013 (Ng et al., 2013), the official dataset of CoNLL-2013 shared tasks, is commonly used as the development data for the CoNLL-2014 benchmark and contains only two essay topics.

Cambridge ESOL First Certificate in English (FCE) (Yannakoudakis et al., 2011) is a dataset containing 1,244 examination scripts of the Cambridge FCE examination. Topics and first languages (L1s) in the dataset are diversified because it contains essays for 10 topics written by non-native speakers from various countries.

JHU FLuency-Extended GUG Corpus (JFLEG) (Napoles et al., 2017) contains approximately 1,500 sentences from an English proficiency test. It contains sentences written by learners of the English language having various L1s and proficiency levels.

Konan-JIEM Learner Corpus (KJ) (Nagata et al., 2011) contains 233 essays written on 10 topics by students of a Japanese college, which are manually error-tagged and shallow-parsed.

International Corpus Network of Asian Learners of English, Written Essays (ICNALE) (Ishikawa, 2013) contains essays written by college and graduate students from ten Asian countries/regions (China, Hong Kong, Indonesia, Japan, Korea, Pakistan, the Philippines, Singapore, Taiwan, and Thailand). The original ICNALE is not error annotated. Therefore, we sampled a total number of 1,736 sentences, which are manually annotated with grammatical errors based on KJ 's annotation scheme.

Table 1 summarizes the properties of these corpora. Let N and M denote the total number of source words and sentences in a corpus, respectively. Word error rate (WER) is defined as follows:

$$\mathrm{WER} = \frac{\sum_{m=1}^{M} d(X^m, Y^m)}{\sum_{m=1}^{M} N^m}$$

where X^m denotes each source sentence, Y^m denotes each corrected sentence, and $d(X^m, Y^m)$ denotes the edit distance between X^m and Y^m using dynamic programming.

The following conclusions are derived: (1) CoNLL-2014 has narrow coverage of topics, proficiency and L1s compared with other corporas such as JFLEG and FCE. (2) Several learner corpora are available for the evaluation of GEC models. These corpora can help investigate the performance of GEC models under different conditions.

3.2 Models

The following factors are considered while selecting our model.

- The models must be recent and commonly used.

Corpus	# sent.	# refs.	WER	# topics	Multiple L1	Multiple proficiency	Public available
CoNLL-2014	1,312	2	12.35	2	No	No	Yes
CoNLL-2013	1,381	1	14.85	2	No	No	Yes
FCE	32,199	1	12.00	10	Yes	Yes	Yes
JFLEG	747	4	20.86	Many	Yes	Yes	Yes
KJ	3,081	1	13.53	10	No	No	Yes
ICNALE	1,736	1	7.64	2	Yes	Yes	No

Table 1: Properties of evaluation corpora. Yes/No indicates whether the corpus exhibits each property in terms of multiple L1, multiple proficiency and public available.

- Each model must be implemented to have a competitive performance on CoNLL-2014.

We employed the following models based on the aforementioned factors:

LSTM: We use a bi-directional LSTM in the encoder and an LSTM with an attention mechanism in the decoder. Both the encoder and the decoder comprise two layers. The LSTM hidden state and word embedding sizes are set to be 500.

CNN: We follow the previous study (Chollampatt and Ng, 2018), namely a fully convolutional encoder–decoder architecture with seven convolutional layers. The hyperparameters used in a previous study are used herein (Chollampatt and Ng, 2018).

Transformer: Transformer is the self-attention-based model proposed by Vaswani et al. (2017). Six layers are used for both the encoder and decoder along with eight attention heads. The word embedding size is set to 1024 dimensions, and the size of position-wise feed-forward networks is set to 4096 dimensions at each inner layer.

SMT: We essentially follow the idea used in a previous study (Junczys-Dowmunt and Grundkiewicz, 2016), with some key differences. Specifically, we only use English Wikipedia for language model training and only the NUS Corpus of Learner English (NUCLE) and the Lang-8 Learner Corpora (Lang-8) for translation model training to make the experimental settings equal in all models.

3.3 Experimental Settings

We use two public datasets, namely Lang-8 (Mizumoto et al., 2011) and NUCLE (Dahlmeier et al., 2013), for training. Our pre-processing and experimental setup is similar to that reported previously (Chollampatt and Ng, 2018). In particular, a subset of NUCLE (5.4K) is utilized as the development data for selecting the model; the remaining subset (1.3M) is utilized as the training data. All the models are trained, tuned, and tested in the same way. The models are tested on each test data shown in Table 1. As an evaluation metric, we use $F_{0.5}$ score computed by applying the MaxMatch scorer (Dahlmeier and Ng, 2012) and GLEU (Napoles et al., 2015). We determine the average $F_{0.5}$ and average GLEU scores of the four models, which are trained with different random initializations, following a previously reported approach (Chollampatt and Ng, 2018).

4 Cross-Corpora Evaluation

Figure 1 shows the performance of each model sorted from best to worst based on their $F_{0.5}$ score, revealing that the performance substantially varies depending on the corpus. For example, the performance of the transformer ranges from the score of $F_{0.5}$, which is as low as 36.20 on CoNLL-2013, to as high as 60.06 on JFLEG. Notably, their rankings also considerably vary. Transformer performs best on CoNLL-2014. However, it exhibits third-best performance among FCE, KJ, and ICNALE; LSTM outperforms the other models by a large margin of up to 5.3 $F_{0.5}$ points. Some examples of the model outputs are presented in Table 2 and Table 3. Some situations are successfully corrected using transformer (Table 2), whereas it failed to perform in other situations (Table 3). The reason for difference in the model rankings cannot be generally stated because it is influenced by various factors such as the learner's proficiency, essay topic, and L1. The experimental results show, however, that discussions based on the performance on CoNLL-2014 may only hold under certain conditions.

Figure 2 shows the performance measured in GLEU having a similar trend. However, their

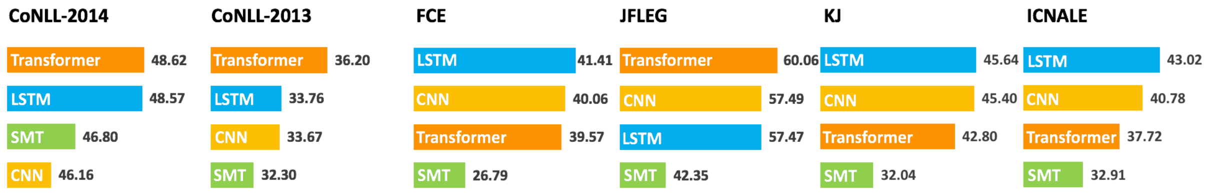

Figure 1: Average $F_{0.5}$ of the four models (trained with different random initializations), ranked best to worst.

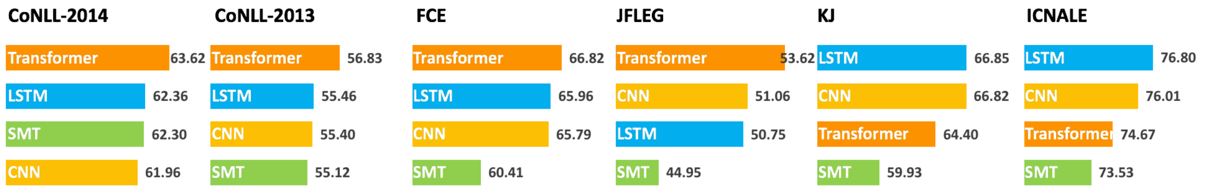

Figure 2: Average GLEU of the four models (trained with different random initializations), ranked best to worst.

rankings on FCE show different trends in Figure 1 and Figure 2. This is partly because $F_{0.5}$ and GLEU evaluate different perspectives of the models. Furthermore, evaluation data and metric must be appropriately set depending on the factors that need to be evaluated in the model.

5 Discussion

5.1 Is Diverse Single-Corpus Evaluation Sufficient?

Experimental results indicate that the benchmark single-corpus evaluation is not robust; however, more diverse corpora remain undetermined. Both JFLEG and FCE can be diverse corpora because they contain examination scripts written by language learners from all over the world. JFLEG is particularly designed to contain more diverse corpus for developing and evaluating GEC models (Napoles et al., 2017). If a diverse single-corpus evaluation suffices, the rankings of the models will remain the same. However, experimental results have shown that the model rankings on both JFLEG and FCE are different (Figure 1). Thus, single-corpus evaluation is deemed weak regardless of its diversity.

5.2 Advantage of Cross-Corpora Evaluation

This study discusses the importance of evaluating GEC models from various perspectives using multiple corpora. Multi-perspective evaluation does not necessarily mean using multiple corpora. Many aspects in a corpus can be used for analysis, such as the proficiency of the writers, essay topics, and the writer 's native language. As a case study, we evaluate and analyze the models regarding the essay WER. Table 4 shows the performance (in precision, recall, and $F_{0.5}$) of all the models when WER is the lowest (7.64 % for ICNALE) and the highest (20.86 % for JFLEG). Transformer and LSTM outperform all the other models in the highest and the lowest error-rated corpora, respectively. Experimental results show that LSTM and transformer may be more precision-oriented and recall-oriented, respectively. Further, precision-oriented models have an advantage over recall-oriented models when a given text contains several errors, and vice versa. This knowledge enables choosing a model based on the task that has to be completed.

6 Conclusion

This study explored the necessity of performing cross-corpora evaluation for GEC models, for which the performance of several GEC models was investigated against various learner corpora. Empirical evaluation results revealed that the model performance and rankings considerably vary depending on the corpus, suggesting that a single-corpus evaluation can be unreliable. Therefore, cross-corpora evaluation should be applied to GEC models. We also published our source code for the cross-corpora evaluation framework so that researchers in the community can adequately and easily evaluate their models based on multiple corpora. Our future study will further examine the robustness of several existing evaluation metrics and explore new metrics appropriate for cross-corpora and/or cross-domain evaluation.

Abstract

Although *Transformer* has achieved great successes on many NLP tasks, its heavy structure with fully-connected attention connections leads to dependencies on large training data. In this paper, we present *Star-Transformer*, a lightweight alternative by careful sparsification. To reduce model complexity, we replace the fully-connected structure with a star-shaped topology, in which every two non-adjacent nodes are connected through a shared relay node. Thus, complexity is reduced from quadratic to linear, while preserving the capacity to capture both local composition and long-range dependency. The experiments on four tasks (22 datasets) show that Star-Transformer achieved significant improvements against the standard Transformer for the modestly sized datasets.

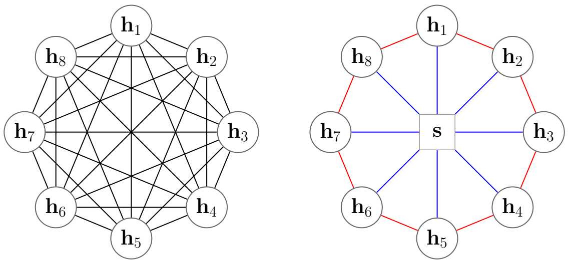

Figure 1: Left: Connections of one layer in Transformer, circle nodes indicate the hidden states of input tokens. Right: Connections of one layer in Star-Transformer, the square node is the virtual relay node. Red edges and blue edges are ring and radical connections, respectively.

1 Introduction

Recently, the fully-connected attention-based models, like Transformer (Vaswani et al., 2017), become popular in natural language processing (NLP) applications, notably machine translation (Vaswani et al., 2017) and language modeling (Radford et al., 2018). Some recent work also suggest that Transformer can be an alternative to recurrent neural networks (RNNs) and convolutional neural networks (CNNs) in many NLP tasks, such as GPT (Radford et al., 2018), BERT (Devlin et al., 2018), Transformer-XL (Dai et al., 2019) and Universal Transformer (Dehghani et al., 2018).

More specifically, there are two limitations of the Transformer. First, the computation and memory overhead of the Transformer are quadratic to the sequence length. This is especially problematic with long sentences. Transformer-XL (Dai et al., 2019) provides a solution which achieves the acceleration and performance improvement, but it is specifically designed for the language modeling task. Second, studies indicate that Transformer would fail on many tasks if the training data is limited, unless it is pre-trained on a large corpus. (Radford et al., 2018; Devlin et al., 2018).

A key observation is that Transformer does not exploit prior knowledge well. For example, the local compositionality is already a robust inductive bias for modeling the text sequence. However, the Transformer learns this bias from scratch, along with non-local compositionality, thereby increasing the learning cost. The key insight is then whether leveraging strong prior knowledge can help to "lighten up" the architecture.

To address the above limitation, we proposed a new lightweight model named "Star-Transformer". The core idea is to sparsify the

architecture by moving the fully-connected topology into a star-shaped structure. Fig-1 gives an overview. Star-Transformer has two kinds of connections. The radical connections preserve the non-local communication and remove the redundancy in fully-connected network. The ring connections embody the local-compositionality prior, which has the same role as in CNNs/RNNs. The direct outcome of our design is the improvement of both efficiency and learning cost: the computation cost is reduced from quadratic to linear as a function of input sequence length. An inherent advantage is that the ring connections can effectively reduce the burden of the unbias learning of local and non-local compositionality and improve the generalization ability of the model. What remains to be tested is whether one shared relay node is capable of capturing the long-range dependencies.

We evaluate the Star-Transformer on three NLP tasks including Text Classification, Natural Language Inference, and Sequence Labelling. Experimental results show that Star-Transformer outperforms the standard Transformer consistently and has less computation complexity. An additional analysis on a simulation task indicates that Star-Transformer preserve the ability to handle with long-range dependencies which is a crucial feature of the standard Transformer.

In this paper, we claim three contributions as the following and our code is available on Github [1]:

- Compared to the standard Transformer, Star-Transformer has a lightweight structure but with an approximate ability to model the long-range dependencies. It reduces the number of connections from n^2 to $2n$, where n is the sequence length.

- The Star-Transformer divides the labor of semantic compositions between the radical and the ring connections. The radical connections focus on the non-local compositions and the ring connections focus on the local composition. Therefore, Star-Transformer works for modestly sized datasets and does not rely on heavy pre-training.

- We design a simulation task "Masked Summation" to probe the ability dealing with long-range dependencies. In this task, we verify that both Transformer and Star-Transformer are good at handling long-range dependencies compared to the LSTM and BiLSTM.

2 Related Work

Recently, neural networks have proved very successful in learning text representation and have achieved state-of-the-art results in many different tasks.

Modelling Local Compositionality A popular approach is to represent each word as a low-dimensional vector and then learn the local semantic composition functions over the given sentence structures. For example, Kim (2014); Kalchbrenner et al. (2014) used CNNs to capture the semantic representation of sentences, whereas Cho et al. (2014) used RNNs.

These methods are biased for learning local compositional functions and are hard to capture the long-term dependencies in a text sequence. In order to augment the ability to model the non-local compositionality, a class of improved methods utilizes various self-attention mechanisms to aggregate the weighted information of each word, which can be used to get sentence-level representations for classification tasks (Yang et al., 2016; Lin et al., 2017; Shen et al., 2018a). Another class of improved methods augments neural networks with a re-reading ability or global state while processing each word (Cheng et al., 2016; Zhang et al., 2018).

Modelling Non-Local Compositionality There are two kinds of methods to model the non-local semantic compositions in a text sequence directly.

One class of models incorporate syntactic tree into the network structure for learning sentence representations (Tai et al., 2015; Zhu et al., 2015).

Another type of models learns the dependencies between words based entirely on self-attention without any recurrent or convolutional layers, such as Transformer (Vaswani et al., 2017), which has achieved state-of-the-art results on a machine translation task. The success of Transformer has raised a large body of follow-up work. Therefore, some Transformer variations are also proposed, such as GPT (Radford et al., 2018), BERT (Devlin et al., 2018), Transformer-XL (Dai et al., 2019) , Universal Transformer (Dehghani et al., 2018) and CN^3 (Liu et al., 2018a).

---

[1] `https://github.com/dmlc/dgl` and `https://github.com/fastnlp/fastNLP`

However, those Transformer-based methods usually require a large training corpus. When applying them on modestly sized datasets, we need the help of semi-supervised learning and unsupervised pretraining techniques (Radford et al., 2018).

Graph Neural Networks Star-Transformer is also inspired by the recent graph networks (Gilmer et al., 2017; Kipf and Welling, 2016; Battaglia et al., 2018; Liu et al., 2018b), in which the information fusion progresses via message-passing across the whole graph.

The graph structure of the Star-Transformer is star-shaped by introducing a virtual relay node. The radical and ring connections give a better balance between the local and non-local compositionality. Compared to the previous augmented models (Yang et al., 2016; Lin et al., 2017; Shen et al., 2018a; Cheng et al., 2016; Zhang et al., 2018), the implementation of Star-Transform is purely based on the attention mechanism similar to the standard Transformer, which is simpler and well suited for parallel computation.

Due to its better parallel capacity and lower complexity, the Star-Transformer is faster than RNNs or Transformer, especially on modeling long sequences.

3 Model

3.1 Architecture

The Star-Transformer consists of one relay node and n satellite nodes. The state of i-th satellite node represents the features of the i-th token in a text sequence. The relay node acts as a virtual hub to gather and scatter information from and to all the satellite nodes.

Star-Transformer has a star-shaped structure, with two kinds of connections in the: the radical connections and the ring connections.

Radical Connections For a network of n satellite nodes, there are n radical connections. Each connection links a satellite node to the shared relay node. With the radical connections, every two non-adjacent satellite nodes are two-hop neighbors and can receive non-local information with a two-step update.

Ring Connections Since text input is a sequence, we bake such prior as an inductive bias. Therefore, we connect the adjacent satellite nodes to capture the relationship of local compositions. The first and last nodes are also connected. Thus, all these local connections constitute a ring-shaped structure. Note that the ring connections allow each satellite node to gather information from its neighbors and plays the same role to CNNs or bidirectional RNNs.

With the radical and ring connections, Star-Transformer can capture both the non-local and local compositions simultaneously. Different from the standard Transformer, we make a division of labor, where the radical connections capture non-local compositions, whereas the ring connections attend to local compositions.

3.2 Implementation

The implementation of the Star-Transformer is very similar to the standard Transformer, in which the information exchange is based on the attention mechanism (Vaswani et al., 2017).

Multi-head Attention Just as in the standard Transformer, we use the scaled dot-product attention (Vaswani et al., 2017). Given a sequence of vectors $\mathbf{H} \in \mathbb{R}^{n \times d}$, we can use a query vector $\mathbf{q} \in \mathbb{R}^{1 \times d}$ to soft select the relevant information with attention.

$$\mathrm{Att}(\mathbf{q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}(\frac{\mathbf{q}\mathbf{K}^T}{\sqrt{d}})\mathbf{V}, \quad (1)$$

where $\mathbf{K} = \mathbf{H}\mathbf{W}^K, \mathbf{V} = \mathbf{H}\mathbf{W}^V$, and $\mathbf{W}^K, \mathbf{W}^V$ are learnable parameters.

To gather more useful information from $\mathbf{H}$, similar to multi-channels in CNNs, we can use multi-head attention with k heads.

$$\mathrm{MultiAtt}(\mathbf{q}, \mathbf{H}) = (\mathbf{a}_1 \oplus \cdots \oplus \mathbf{a}_k)\mathbf{W}^O, \quad (2)$$

$$\mathbf{a}_i = \mathrm{Att}(\mathbf{q}\mathbf{W}_i^Q, \mathbf{H}\mathbf{W}_i^K, \mathbf{H}\mathbf{W}_i^V), i \in [1, k] \quad (3)$$

where $\oplus$ denotes the concatenation operation, and $\mathbf{W}_i^Q, \mathbf{W}_i^K, \mathbf{W}_i^V, \mathbf{W}^O$ are learnable parameters.

Update Let $\mathbf{s}^t \in \mathbb{R}^{1 \times d}$ and $\mathbf{H}^t \in \mathbb{R}^{n \times d}$ denote the states for the relay node and all the n satellite nodes at step t. When using the Star-Transformer to encode a text sequence of length n, we start from its embedding $\mathbf{E} = [\mathbf{e}_1; \cdots; \mathbf{e}_n]$, where $\mathbf{e}_i \in \mathbb{R}^{1 \times d}$ is the embedding of the i-th token.

We initialize the state with $\mathbf{H}^0 = \mathbf{E}$ and $\mathbf{s}^0 = average(\mathbf{E})$.

The update of the Star-Transformer at step t can be divided into two alternative phases: (1) the update of the satellite nodes and (2) the update of the relay node.

At the first phase, the state of each satellite node $\mathbf{h}_i$ are updated from its adjacent nodes, including the neighbor nodes $\mathbf{h}_{i-1}, \mathbf{h}_{i+1}$ in the sequence, the relay node $\mathbf{s}^t$, its previous state, and its corresponding token embedding.

$$\mathbf{C}_i^t = [\mathbf{h}_{i-1}^{t-1}; \mathbf{h}_i^{t-1}; \mathbf{h}_{i+1}^{t-1}; \mathbf{e}^i; \mathbf{s}^{t-1}], \quad (4)$$

$$\mathbf{h}_i^t = \mathrm{MultiAtt}(\mathbf{h}_i^{t-1}, \mathbf{C}_i^t), \quad (5)$$

where $\mathbf{C}_i^t$ denotes the context information for the i-th satellite node. Thus, the update of each satellite node is similar to the recurrent network, except that the update fashion is based on attention mechanism. After the information exchange, a layer normalization operation (Ba et al., 2016) is used.

$$\mathbf{h}_i^t = \mathrm{LayerNorm}(\mathrm{ReLU}(\mathbf{h}_i^t)), i \in [1, n]. \quad (6)$$

At the second phase, the relay node $\mathbf{s}^t$ summarizes the information of all the satellite nodes and its previous state.

$$\mathbf{s}^t = \mathrm{MultiAtt}(\mathbf{s}^{t-1}, [\mathbf{s}^{t-1}; \mathbf{H}^t]), \quad (7)$$

$$\mathbf{s}^t = \mathrm{LayerNorm}(\mathrm{ReLU}(\mathbf{s}^t)). \quad (8)$$

By alternatively updating update the satellite and relay nodes, the Star-Transformer finally captures all the local and non-local compositions for an input text sequence.

Position Embeddings To incorporate the sequence information, we also add the learnable position embeddings, which are added with the token embeddings at the first layer.

The overall update algorithm of the Star-Transformer is shown in the Alg-1.

3.3 Output

After T rounds of update, the final states of $\mathbf{H}^T$ and $\mathbf{s}^T$ can be used for various tasks such as sequence labeling and classification. For different tasks, we feed them to different task-specific modules. For classification, we generate the fix-length sentence-level vector representation by applying a max-pooling across the final layer and mixing it with $\mathbf{s}^T$, this vector is fed into a Multiple Layer Perceptron (MLP) classifier. For the sequence labeling task, the $\mathbf{H}^T$ provides features corresponding to all the input tokens.

Algorithm 1 The Update of Star-Transformer

Input: Number of layers T, embedding of input tokens $e_1, \cdots, e_n$

```
// Initialization
$\mathbf{h}_1^0, \cdots, \mathbf{h}_n^0 \leftarrow \mathbf{e}_1, \cdots, \mathbf{e}_n$
$\mathbf{s}^0 \leftarrow average(\mathbf{e}_1, \cdots, \mathbf{e}_n)$
for $t$ from $1$ to $T$ do
    // update the satellite nodes
    for $i$ from $1$ to $n$ do
        $\mathbf{C}_i^t = [\mathbf{h}_{i-1}^{t-1}; \mathbf{h}_i^{t-1}; \mathbf{h}_{i+1}^{t-1}; \mathbf{e}^i; \mathbf{s}^{t-1}]$
        $\mathbf{h}_i^t = \mathrm{MultiAtt}(\mathbf{h}_i^{t-1}, \mathbf{C}_i^t)$
        $\mathbf{h}_i^t = \mathrm{LayerNorm}(\mathrm{ReLU}(\mathbf{h}_i^t))$
    // update the relay node
    $\mathbf{s}^t = \mathrm{MultiAtt}(\mathbf{s}^{t-1}, [\mathbf{s}^{t-1}; \mathbf{H}^t])$
    $\mathbf{s}^t = \mathrm{LayerNorm}(\mathrm{ReLU}(\mathbf{s}^t))$
```

4 Comparison to the standard Transformer

Since our goal is making the Transformer lightweight and easy to train with modestly sized dataset, we have removed many connections compared with the standard Transformer (see Fig-1). If the sequence length is n and the dimension of hidden states is d, the computation complexity of one layer in the standard Transformer is $O(n^2 d)$. The Star-Transformer has two phases, the update of ring connections costs $O(5nd)$ (the constant 5 comes from the size of context information $\mathbf{C}$), and the update of radical connections costs $O(nd)$, so the total cost of one layer in the Star-Transformer is $O(6nd)$.

In theory, Star-Transformer can cover all the possible relationships in the standard Transformer. For example, any relationship $\mathbf{h}_i \rightarrow \mathbf{h}_j$ in the standard Transformer can be simulated by $\mathbf{h}_i \rightarrow \mathbf{s} \rightarrow \mathbf{h}_j$. The experiment on the simulation task in Sec-5.1 provides some evidence to show the virtual node s could handle long-range dependencies. Following this aspect, we can give a rough analysis of the path length of dependencies in these models. As discussed in the Transformer paper (Vaswani et al., 2017), the maximum dependency path length of RNN and Transformer are $O(n)$, $O(1)$, respectively. Star-Transformer can pass the message from one node to another node via the relay node so that the maximum dependency path length is also $O(1)$, with a constant two comparing to Transformer.

Compare with the standard Transformer, all positions are processed in parallel, pair-wise connec-

MTL-16† consists of 16 datasets, each of them has 1400/200/400 samples in train/dev/test.

tions are replaced with a "gather and dispatch" mechanism. As a result, we accelerate the Transformer 10 times on the simulation task and 4.5 times on real tasks. The model also preserves the ability to handle long input sequences. Besides the acceleration, the Star-Transformer achieves significant improvement on some modestly sized datasets.

5 Experiments

We evaluate Star-Transformer on one simulation task to probe its behavior when challenged with long-range dependency problem, and three real tasks (Text Classification, Natural Language Inference, and Sequence Labelling). All experiments are ran on a NVIDIA Titan X card. Datasets used in this paper are listed in the Tab-1. We use the Adam (Kingma and Ba, 2014) as our optimizer. On the real task, we set the embedding size to 300 and initialized with GloVe (Pennington et al., 2014). And the symbol "Ours + Char" means an additional character-level pre-trained embedding JMT (Hashimoto et al., 2017) is used. Therefore, the total size of embedding should be 400 which as a result of the concatenation of GloVe and JMT. We also fix the embedding layer of the Star-Transformer in all experiments.

Since semi- or unsupervised model is also a feasible solution to improve the model in a parallel direction, such as the ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), we exclude these models in the comparison and focus on the relevant architectures.

5.1 Masked Summation

In this section, we introduce a simulation task on the synthetic data to probe the efficiency and non-local/long-range dependencies of LSTM, Transformer, and the Star-Transformer. As mentioned in (Vaswani et al., 2017), the maximum path length of long-range dependencies of LSTM and Transformer are $O(n)$ and $O(1)$, where n is the sequence length. The maximum dependency path length of Star-Transformer is $O(1)$ with a constant two via the relay node. To validate the ability to deal with long-range dependencies, we design a simulation task named "Masked Summation". The input of this task is a matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$, it has n columns and each column has d elements. The first dimension indicates the mask value $\mathbf{X}_{i0} \in \{0, 1\}$, 0 means the column is ignored in summation. The rest $d-1$ elements are real numbers in drawn uniformly from the range $[0, 1)$. The target is a $d-1$ dimensional vector which equals the summation of all the columns with the mask value 1. There is an implicit variable k to control the number of 1 in the input. Note that a simple baseline is always guessing the value $k/2$.

The evaluation metric is the Mean Square Error (MSE), and the generated dataset has (10k/10k/10k) samples in (train/dev/test) sets. The Fig-2 show a case of the masked summation task.

The mask summation task asks the model to recognize the mask value and gather columns in different positions. When the sequence length n is significantly higher than the number of the columns k, the model will face the long-range dependencies problem. The Fig-3a shows the per-

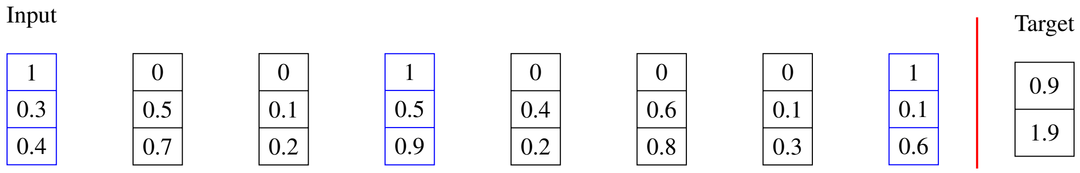

Figure 2: An example of the masked summation task, the input is a sequence of n vectors, each vector has d dimension, and there are total k vectors which have the mask value equals 1. The target is the summation of such masked vectors. In this figure, $n = 8, k = 3, d = 3$.

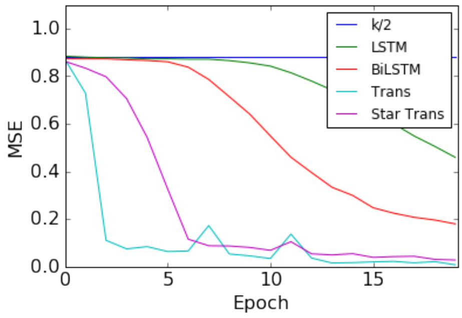
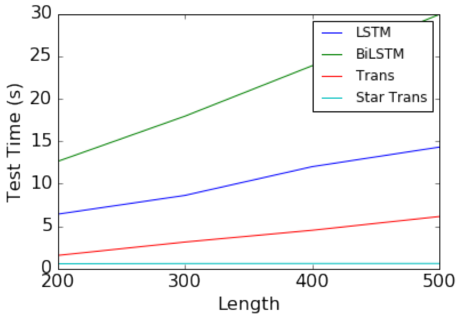


(a) MSE loss on the masked summation when $n = 200, k = 10, d = 10$. The $k/2$ line means the MSE loss when the model always guess the exception value $k/2$.



(b) Test Time, $k = 10, d = 10$

formance curves of models on various lengths. Although the task is easy, the performance of LSTM and BiLSTM dropped quickly when the sequence length increased. However, both Transformer and Star-Transformer performed consistently on various lengths. The result indicates the Star-Transformer preserves the ability to deal with the non-local/long-range dependencies.

Besides the performance comparison, we also study the speed with this simulation task since we could ignore the affection of padding, masking, and data processing. We also report the inference time in the Fig-3b, which shows that Transformer is faster than LSTM and BiLSTM a lot, and Star-Transformer is faster than Transformer, especially on the long sequence.

Table 2: Test Accuracy on SST dataset.

5.2 Text Classification

Text classification is a basic NLP task, and we select two datasets to observe the performance of our model in different conditions, Stanford Sentiment Treebank(SST) dataset (Socher et al., 2013) and MTL-16 (Liu et al., 2017) consists of 16 small datasets on various domains. We truncate the sequence which its length higher than 256 to ensure the standard Transformer can run on a single GPU card.

For classification tasks, we use the state of the relay node $\mathbf{s}^T$ plus the feature of max pooling on satellite nodes $\max(\mathbf{H}^T)$ as the final representation and feed it into the softmax classifier. The description of hyper-parameters is listed in Tab-1 and Appendix.

Results on SST and MTL-16 datasets are listed in Tab-2,3, respectively. On the SST, the Star-Transformer achieves 2.5 points improvement against the standard Transformer and beat the most models.

Also, on the MTL-16, the Star-Transformer outperform the standard Transformer in all 16 datasets, the improvement of the average accuracy is 4.2. The Star-Transformer also gets better results compared with existing works. As we mentioned in the introduction, the standard Transformer requires large training set to reveal its power. Our experiments show the Star-

Table 3: Test Accuracy over MTL-16 datasets. “Test Time” means millisecond per batch on the test set (batch_size is 128). “Len.” means the average sequence length on the test set.

Transformer could work well on the small dataset which only has 1400 training samples. Results of the time-consuming show the Star-Transformer could be 4.5 times fast than the standard Transformer on average.

5.3 Natural Language Inference

Natural Language Inference (NLI) asks the model to identify the semantic relationship between a premise sentence and a corresponding hypothesis sentence. In this paper, we use the Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) for evaluation. Since we want to study how the model encodes the sentence as a vector representation, we set Star-Transformer as a sentence vector-based model and compared it with sentence vector-based models.

In this experiment, we follow the previous work (Bowman et al., 2016) to use concat($\mathbf{r}_1, \mathbf{r}_2, \|\mathbf{r}_1 - \mathbf{r}_2\|, \mathbf{r}_1 - \mathbf{r}_2$) as the classification feature. The $\mathbf{r}_1, \mathbf{r}_2$ are representations of premise and hypothesis sentence, it is calculated by $\mathbf{s}^T + \max(\mathbf{H}^T)$ which is same with the classification task. See Apendix for the detail of hyper-parameters.

As shown in Tab-4, the Star-Transformer outperforms most typical baselines (DiSAN, SPINN) and achieves comparable results compared with the state-of-the-art model. Notably, our model beats standard Transformer by a large margin, which is easy to overfit although we have made a careful hyper-parameters' searching for Transformer.

Model	Acc
BiLSTM (Liu et al., 2016)	83.3
BiLSTM + self-att (Liu et al., 2016)	84.2
300D SPINN-PI (Bowman et al., 2016)	83.2
Tree-based CNN (Mou et al., 2016)	82.1
4096D BiLSTM-max (Conneau et al., 2017)	84.5
300D DiSAN (Shen et al., 2018a)	85.6
Residual encoders (Nie and Bansal, 2017)	86.0
Gumbel TreeLSTM (Choi et al., 2018)	86.0
Reinforced self-att (Shen et al., 2018b)	86.3
2400D Multiple DSA (Yoon et al., 2018)	87.4
Transformer	82.2
Star-Transformer	**86.0**

Table 4: Test Accuracy on SNLI dataset.

The SNLI dataset is not a small dataset in NLP area, so improving the generalization ability of the Transformer is a significant topic.

The best result in Tab-4 (Yoon et al., 2018) using a large network and fine-tuned hyper-parameters, they get the best result on SNLI but an undistinguished result on SST, see Tab-2.

5.4 Sequence Labelling

To verify the ability of our model in sequence labeling, we choose two classic sequence labeling tasks: Part-of-Speech (POS) tagging and Named Entity Recognition (NER) task.

Three datasets are used as our benchmark: one POS tagging dataset from Penn Treebank (PTB) (Marcus et al., 1993), and two NER datasets from CoNLL2003 (Sang and Meulder, 2003), CoNLL2012 (Pradhan et al., 2012). We use the fi-

Table 5: Results on sequence labeling tasks. We list the "Advanced Techniques" except widely-used pre-trained embeddings (GloVe, Word2Vec, JMT) in columns. The "Char" indicates character-level features, it also includes the Capitalization Features, Suffix Feature, Lexicon Features, etc. The "CRF" means an additional Conditional Random Field (CRF) layer.

Model	SNLI Acc	CoNLL03 Acc	MS MSE
Star-Transformer	86.0	90.93	0.0284
variant (a) -radical	84.0	89.35	0.1536
variant (b) -ring	77.6	79.36	0.0359

Table 6: Test Accuracy on SNLI dataset, CoNLL2003 NER task and the Masked Summation $n = 200, k = 10, d = 10$.

nal state of satellite nodes $\mathbf{H}^T$ to classify the label in each position. Since we believe that the complex neural network could be an alternative of the CRF, we also report the result without CRF layer.

As shown in Tab-5, Star-Transformer achieves the state-of-the-art performance on sequence labeling tasks. The "Star-Transformer + Char" has already beat most of the competitors. Star-Transformer could achieve such results without CRF, suggesting that the model has enough capability to capture the partial ability of the CRF. The Star-Transformer also outperforms the standard Transformer on sequence labeling tasks with a significant gap.

5.5 Ablation Study

In this section, we perform an ablation study to test the effectiveness of the radical and ring connections.

We test two variants of our models, the first variants (a) remove the radical connections and only keep the ring connections. Without the radical connections, the maximum path length of this variant becomes $O(n)$. The second variant (b) removes the ring connections and remains the radical connections. Results in Tab-6 give some insights, the variant (a) loses the ability to handle long-range dependencies, so it performs worse on both the simulation and real tasks. However, the performance drops on SNLI and CoNLL03 is moderate since the remained ring connections still capture the local features. The variant (b) still works on the simulation task since the maximum path length stays unchanged. Without the ring connections, it loses its performance heavily on real tasks. Therefore, both the radical and ring connections are necessary to our model.

6 Conclusion and Future Works

In this paper, we present Star-Transformer which reduce the computation complexity of the standard Transformer by carefully sparsifying the topology. We compare the standard Transformer with other models on one toy dataset and 21 real datasets and find Star-Transformer outperforms the standard Transformer and achieves comparable results with state-of-the-art models.

This work verifies the ability of Star-Transformer by excluding the factor of unsupervised pre-training. In the future work, we will investigate the ability of Star-Transformer by unsupervised pre-training on the large corpus. Moreover, we also want to introduce more NLP prior knowledge into the model.

Abstract

We address the problem of speech act recognition (SAR) in asynchronous conversations (forums, emails). Unlike synchronous conversations (e.g., meetings, phone), asynchronous domains lack large labeled datasets to train an effective SAR model. In this paper, we propose methods to effectively leverage abundant unlabeled conversational data and the available labeled data from synchronous domains. We carry out our research in three main steps. First, we introduce a neural architecture based on hierarchical LSTMs and conditional random fields (CRF) for SAR, and show that our method outperforms existing methods when trained on in-domain data only. Second, we improve our initial SAR models by semi-supervised learning in the form of pretrained word embeddings learned from a large unlabeled conversational corpus. Finally, we employ adversarial training to improve the results further by leveraging the labeled data from synchronous domains and by explicitly modeling the distributional shift in two domains.

1 Introduction

With the ever-increasing popularity of Internet and mobile technologies, communication media like emails and forums have become an integral part of people's daily life where they discuss events, issues and experiences. Participants interact with each other *asynchronously* in these media by writing at different times, generating a type of conversational discourse that is different from synchronous conversations such as meeting and phone conversations (Louis and Cohen, 2015). In the course of the interactions, the participants perform certain communicative acts like asking questions, requesting information, or suggesting something, which are known as **speech acts** (Austin, 1962). For example, consider the forum conversation in Figure 1. The participant who posted the initial comment **C$_1$**, describes his situation and asks a couple of *questions*. Other participants *respond* to the initial post with more information and provide *suggestions*. In this process, the participants get into a conversation by taking turns, each of which consists of one or more speech acts.

C$_1$: hoping to do the XinJiang Tibet Highway. [Statement]
Has anyone done it? [Question]
Am hoping to hire a 4-wheel drive. [Statement]
I know the roads are bad and I would need an experienced driver and guide - any recommendations? [Question]

C$_2$: I never done this routine,however i been to Xinjiang twice,in my opinion the local people not friendly, not safe to do this. [Response]
I still have relative stay in Xinjiang, however don't know what they can offer for help... [Response]

C$_3$: I'm not sure if travelling overland from Xinjiang to Tibet is officially legal yet. [Response]
You might want to post your question on the North-East Asia branch of Lonely Planet's ThornTree forum for more (useful) answers. [Suggestion]

C$_4$: a frend and i are trying this route as well, we will likely be in urumuqi and northern part of xinjiang from 8th apr to end apr; looking at doing the xin jiang tibet highway from end apr. (truncated) [Statement]
contact me at [email] if you want to hook up for possible transport sharing [Suggestion]
cheers. [Polite]

Figure 1: Example of speech acts in a forum thread.

Speech act recognition (SAR) is an important step towards deep conversational analysis, and can benefit many downstream applications. Availability of large labeled datasets such as the Switchboard-DAMSL (SWBD) (Jurafsky et al., 1997) and the Meeting Recorder Dialog Act (MRDA) (Dhillon et al., 2004) corpora has fostered research in data-driven SAR methods in synchronous domains. However, such large corpora

---

[*] All authors contibuted equally.

Proceedings of NAACL-HLT 2019, pages 1326–1336
Minneapolis, Minnesota, June 2 - June 7, 2019.

are not available in the asynchronous domains, and many of the existing (small-sized) ones use task-specific tagsets as opposed to a standard one. The unavailability of large annotated datasets with standard tagsets is one of the main reasons for SAR not getting much attention in asynchronous domains, and it is often quite expensive to annotate such datasets for each domain of interest.

SAR methods proposed before the neural 'tsunami', *e.g.,* (Qadir and Riloff, 2011; Jeong et al., 2009; Tavafi et al., 2013), used mostly bag-of-ngram representation (*e.g.,* unigram, bigram) of a sentence, and most of these methods disregard conversational dependencies (discourse structure) between sentences. Recently, Joty and Hoque (2016) proposed a neural-CRF framework for SAR in forum conversations. In their approach, a bi-LSTM (trained on the SAR task) first encodes the sentences separately into task-specific embeddings, which are then used in a separate CRF model to capture the conversational dependencies between sentences. They also use labeled data from the MRDA meeting corpus, without which their LSTMs perform worse than simple feed-forward networks. Although their method attempts to model sentence structure (using LSTM) and conversational dependencies (using CRF), the approach has several limitations.

First, the LSTM-CRF framework was disjoint, and thus cannot be trained end-to-end. Second, when using the MRDA meeting data, their method simply concatenates it with the target domain data assuming they have the same distribution. However, asynchronous domains (forum, email) differ from synchronous (MRDA) in their underlying conversational structure (Louis and Cohen, 2015), in style (spoken vs. written), and in vocabulary usage (meetings on some focused agenda vs. conversations on any topic of interests in a public forum). Therefore, we hypothesize that to make the best use of labeled data from synchronous domains, one needs to model the shift in domains.

In this work, we advance the state-of-the-art of SAR in asynchronous conversations in three main steps. First, we introduce an end-to-end neural architecture based on a hierarchical LSTM encoder with a Softmax or CRF output layer. Second, we improve our initial SAR model by semi-supervised learning in the form of word embeddings learned from a large unlabeled conversational corpus. Most importantly, we adapt our hierarchical LSTM encoder using domain adversarial training (Ganin et al., 2016) to leverage the labeled data from synchronous domains by explicitly modeling the shift in the two domains.

We evaluate our models on three different asynchronous datasets containing forum and email conversations, and on the MRDA meeting corpus. Our main findings are: (*i*) the hierarchical LSTMs outperform existing methods when trained on in-domain data for both synchronous and asynchronous domains, setting a new state-of-the-art; (*ii*) conversational word embeddings yield significant improvements over off-the-shelf ones; and (*iii*) domain adversarial training improves the results by inducing domain-invariant features. The source code, the conversational word embeddings, and the datasets are available at `https://ntunlpsg.github.io/demo/project/speech-act/`.

2 Related Work

Previous studies on **SAR in asynchronous conversation** have used supervised, semi-supervised and unsupervised methods. Cohen et al. (2004) classify emails into acts like 'deliver' and 'meeting'. Their approach however does not take email context into account. Carvalho and Cohen (2005) use an iterative algorithm containing two different classifiers: the content classifier that only looks at the content of the message, and the context classifier that takes into account both the content and contextual speech acts in the email thread structure. Other supervised approaches use classifiers and sequence taggers with hand-crafted features (Qadir and Riloff, 2011; Tavafi et al., 2013).

Jeong et al. (2009) use semi-supervised boosting to induce informative patterns from labeled spoken domains (MRDA, SWBD). Given a sentence represented as a set of trees (dependency, POS tags, n-grams), the boosting algorithm iteratively learns the sub-tree features. This approach does not consider the dependencies between the act types, something we successfully exploit in our work. Also, we leverage labeled data from synchronous conversations while adapting our model to account for the domain shift. Joty and Hoque (2016) use a bi-LSTM to encode a sentence, then use a separate CRF to model conversational dependencies. To learn an effective bi-LSTM model, they use the MRDA meeting data; however, without modeling the domain differences.

The unsupervised methods use variations of Hidden Markov Models (HMM) including HMM-Topic (Ritter et al., 2010), HMM-Mix (Joty et al., 2011), and Mixed Membership (Paul, 2012).

Several neural methods have been proposed in recent years for **SAR in synchronous conversations**. Kalchbrenner and Blunsom (2013) use a simple recurrent neural network (RNN) to model sequential dependencies between act types in phone conversations. They use a convolutional network to compose sentence representations from word vectors. Lee and Dernoncourt (2016) use a similar model, but also experiment with RNNs to compose sentence representations. Khanpour et al. (2016) use a stacked LSTM to compose word vectors into a sentence vector. Kumar et al. (2018) also use a hierarchical LSTM-CRF. However, none of these methods were applied to asynchronous conversations, where not much labeled data is available. Also to the best of our knowledge, no prior work attempted to do domain adaptation from the synchronous conversation, which is our main contribution in this paper.

3 The Base Model

We use a bidirectional long short-term memory or bi-LSTM (Hochreiter and Schmidhuber, 1997) to encode each sentence into a vector representation. Given an input sentence $\mathbf{x}_i = (w_1, \cdots, w_m)$ of length m, we first map each word w_t to its corresponding vector representation $\mathbf{v}_t$ by looking up the word embedding matrix. The LSTM recurrent layer then computes a compositional representation $\mathbf{z}_t$ at every time step t by performing nonlinear transformations of the current input $\mathbf{v}_t$ and the output of the previous time step $\mathbf{z}_{t-1}$. The output of the last time step $\mathbf{z}_m$ is considered as the representation of the sentence. A bi-LSTM composes a sentence in two directions: left-to-right and right-to-left, yielding a representation $\mathbf{h}_i = [\overrightarrow{\mathbf{z}_m}; \overleftarrow{\mathbf{z}_m}]$, where ';' denotes concatenation. Similar to (Joty and Hoque, 2016), we could use $\mathbf{h}_i$ to classify sentence $\mathbf{x}_i$ into one of the speech act types using a Softmax output layer. However, in that case, we would disregard the discourse-level dependencies between sentences in a conversation. To take conversational dependencies into account, we explore two methods as we describe below.

3.1 Hierarchical LSTM

We consider a conversation as a sequence of utterances (sentences). Given an input sequence of n sentences $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_n)$, the sentence-level bi-LSTM generates a sequence of n vectors $\mathbf{H} = (\mathbf{h}_1, \cdots, \mathbf{h}_n)$. To consider interdependencies between sentences, we place another bi-LSTM layer on top of $\mathbf{H}$ to connect the sentence vectors sequentially in both directions, and encode each sentence within its left and right contexts. As shown in Figure 2, the upper bi-LSTM combines the current input $\mathbf{h}_i$ with its previous hidden state $\overrightarrow{\mathbf{u}}_{i-1}$ (resp., $\overleftarrow{\mathbf{u}}_{i+1}$) to generate a representation for the current sentence $\overrightarrow{\mathbf{u}}_i$ (resp., $\overleftarrow{\mathbf{u}}_i$). The hierarchically encoded sentence vectors $\mathbf{U} = (\mathbf{u}_1, \cdots, \mathbf{u}_n)$ (where $\mathbf{u}_i = [\overrightarrow{\mathbf{u}_i}; \overleftarrow{\mathbf{u}_i}]$) are fed into a Softmax classifier for speech act classification.

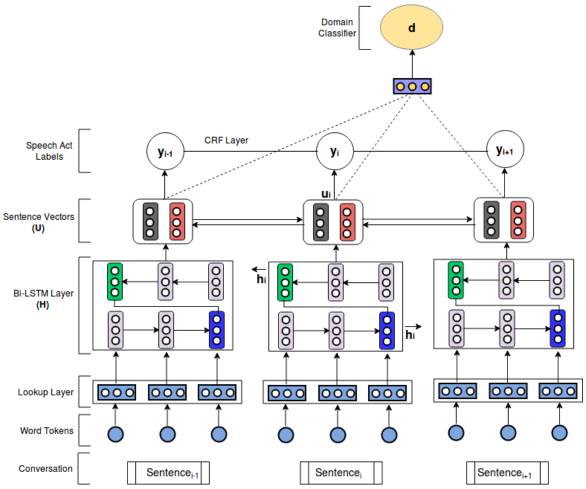

Figure 2: Hierarchical bi-LSTM-CRF model with domain adversarial training for speech act recognition.

$$p(y_i = k|\mathbf{X}, W, \theta) = \frac{\exp\ (\mathbf{w}_k^T \mathbf{u}_i)}{\sum_{k=1}^{K} \exp\ (\mathbf{w}_k^T \mathbf{u}_i)}$$

where W are the classifier weights, and θ are the parameters of the hierarchical LSTM encoder. We train the model by minimizing the cross entropy:

$$\mathcal{L}_c(W, \theta) = -\sum_{i=1}^{n}\sum_{k=1}^{K} y_{i,k} \log p(y_i = k|\mathbf{X}, W, \theta)$$

with $y_{i,k}$ being the one-hot encoding of the label.

3.2 Hierarchical LSTM with CRF

The hierarchical LSTM (H-LSTM) captures contextual information by propagating information through hidden layers, and has been shown to be effective in similar tasks such as context encoding in dialog systems (Serban et al., 2016). Despite this, its modeling strength is limited compared to structured models that use global inference to model consistency in the output, especially when there are strong dependencies between output labels (Collobert et al., 2011). Therefore, instead of classifying sentences independently with a Softmax layer, our second method is to model them jointly with a CRF layer (Lafferty et al., 2001). For an input-output sequence pair $(\mathbf{X}, \mathbf{y})$, we define the joint probability distribution:

$$p(\mathbf{y}|\mathbf{X}) = \frac{1}{Z(\mathbf{U}, A, V, \theta)} \prod_{i=1}^{n} \underbrace{\psi_n(y_i|\mathbf{u}_i, V)}_{\text{node factor}} \prod_{i=0}^{n} \underbrace{\psi_e(y_{i,i+1}|A)}_{\text{edge factor}}$$

where $\mathbf{U} = (\mathbf{u}_1, \cdots, \mathbf{u}_n)$ is the hierarchically encoded sentence vectors as before, and $\psi_n(y_i = k|\mathbf{u}_i, V) = \exp(V_k^T \mathbf{u}_i)$ is the node-level score with V being the weight matrix, ψ_e is the transition matrix parameterized by A, and $Z(.)$ is the global normalization constant that ensures a valid probability distribution. The cross entropy loss for the $(\mathbf{X}, \mathbf{y})$ sequence pair can be written as:

$$\mathcal{L}_c(V, A, \theta) = -\sum_{i=1}^{n} \log \psi_n(y_i|\mathbf{u}_i, V) - \sum_{i=0}^{n} \log A_{i,i+1} + \log Z$$

We use Viterbi decoding to infer the most probable tag sequence for an input sequence of sentences, $\mathbf{y}* = \text{argmax}_{\mathbf{y}}\, p(\mathbf{y}|\mathbf{X}, V, A, \theta)$. We will demonstrate later in our experiments that a CRF layer helps the H-LSTM to adapt quickly (*i.e.,* with less labeled data) to a target domain by exploiting the tag dependencies in the source domain.

4 Adaptation Methods

The hierarchical models have many parameters. Given enough training data, they should be able to encode a sentence, capturing its syntactic and semantic properties, and discourse-level dependencies. However, when it comes to SAR in asynchronous domains, not many large annotated corpora are available. Because of the large number of parameters, the models usually overfit when trained on small datasets of asynchronous conversations (shown in Sec. 6). We propose two solutions to address this problem. Our first (simple but effective) solution is to leverage large unlabeled conversational corpus to learn better task-agnostic word embeddings, and use it to initialize our models for better generalization. In the interests of coherence, we present this method in Section 5.

Our second solution is to leverage data from synchronous domains for which large annotated corpus is available (*e.g.,* MRDA corpus). However, as we will see, simple concatenation of the datasets is not quite effective in our case, because the conversations in synchronous and asynchronous domains differ in their conversational structures, modality (spoken vs. written), and vocabulary usage. To get the best out of the available synchronous domain data, we need to adapt our models by explicitly modeling the domain shift. More precisely, our goal is to adapt the hierarchical encoder so that it learns to encode sentence representations $\mathbf{U}$ (*i.e.,* features used for classification) that is not only discriminative for the act classification, but also invariant across the domains. We propose to use the **domain adversarial training** proposed by Ganin et al. (2016).

Let $\mathcal{D}_S = \{\mathbf{X}_p, \mathbf{y}_p\}_{p=1}^{P}$ denote the set of P labeled training conversations in the **source** domain (MRDA). We consider two adaptation scenarios.

***(i)* Unsupervised adaptation:** In this scenario, we have only *unlabeled* examples in the **target** domain (*e.g.,* forum). Let $\mathcal{D}_T^u = \{\mathbf{X}_p\}_{p=P+1}^{Q}$ be the set of $(Q - P - 1)$ unlabeled training instances in the target domain with Q being the total number of training instances in the two domains.

***(ii)* Semi-supervised/supervised adaptation:** In addition to the unlabeled instances $\mathcal{D}_T^u$, here we have access to some *labeled* training instances in the target domain, $\mathcal{D}_T^l = \{\mathbf{X}_p, \mathbf{y}_p\}_{p=Q+1}^{R}$, with R being the total number of training examples in the two domains. Depending on the amount of labeled data in the target domain, this setting is referred to as semi-supervised or supervised adaptation.

4.1 Unsupervised Adaptation

The dashed lines in Figure 2 show the extension of our base model for adaptation. The input conversation $\mathbf{X}$ is sampled either from a synchronous domain (*e.g.,* meeting) or from an asynchronous domain (*e.g.,* forum). Our goal is to adapt the H-LSTM encoder (parameterized by θ) to generate $\mathbf{U}$ such that it is not only informative for the SAR task but also invariant across domains. Upon achieving this, we can use the adapted encoder to encode a target sentence, and use the source classifier (Softmax or CRF) to classify the sentences.

We achieve this by adding a domain discriminator (dashed lines in Figure 2), another neural network that takes $\mathbf{U}$ as input, and tries to discriminate the domains of the input conversation $\mathbf{X}$ (*e.g.,* meeting vs. forum). The output of the discriminator is defined by a sigmoid function:

$$\hat{d}_\omega = p(d = 1|\mathbf{u}_i, \omega, \theta) = \text{sigm}(\mathbf{w}_d^T \mathbf{h}_d) \quad (1)$$

where $d \in \{0, 1\}$ denotes the domain (1 for meeting, 0 for forum), $\mathbf{w}_d$ are the final layer weights of the discriminator, and $\mathbf{h}_d = g(U_d \mathbf{u}_i)$ defines the hidden layer of the discriminator with U_d being the layer weights, and $g(.)$ being the activations. We use cross entropy as the discrimination loss:

$$\mathcal{L}_d(\omega, \theta) = -d \log \hat{d}_\omega - (1 - d) \log \left(1 - \hat{d}_\omega\right) \quad (2)$$

The composite network has three players: the hierarchical **LSTM encoder**, the **classifier** (Softmax or CRF), and the domain **discriminator**. During training, the encoder and the classifier play a co-operative game, while the encoder and the discriminator play an adversarial game. The training objective $\mathcal{L}(W, \theta, \omega)$ of the composite model is:

$$\underbrace{\sum_{p=1}^{P} \mathcal{L}_c^p(W, \theta)}_{\text{act classif (src)}} - \lambda \Big[\underbrace{\sum_{p=1}^{P} \mathcal{L}_d^p(\omega, \theta)}_{\text{domain disc (src)}} + \underbrace{\sum_{p=P+1}^{Q} \mathcal{L}_d^p(\omega, \theta)}_{\text{domain disc (tar)}} \Big] \quad (3)$$

where θ are the parameters of the encoder, W are the classifier weights, and $\omega = \{U_d, \mathbf{w}_d\}$ are the parameters of the discriminator.[1] The hyper-parameter λ controls the relative strength of the act classifier and the discriminator. We learn θ that optimizes the following **min-max** criterion:

$$\theta^* = \underset{W,\theta}{\text{argmin}} \max_{U_d, \mathbf{w}_d} \mathcal{L}(W, \theta, \omega) \quad (4)$$

Note that the updates of the shared encoder for the two networks (classifier and discriminator) work *adversarially* with respect to each other. Algorithm 1 provides pseudocode of our training method. The main challenge in adversarial training is to balance the networks (Arjovsky et al., 2017). In our experiments, we found the discriminator to be weaker initially. To balance the two components, we would need the error signals from the discriminator to be fairly weak initially, with full power unleashed only as the classification errors start to dominate. We follow the weighting schedule proposed in (Ganin et al., 2016, p. 21), which initializes λ to 0, and then changes it gradually to 1 as training progresses.

Algorithm 1: Adversarial training with SGD.

```
Input  : Data $\mathcal{D}_S$, $\mathcal{D}_T^u$, and batch size $b$
Output: Adapted model parameters $\theta$, W
1. Initialize model parameters;
2. repeat
    (a) Randomly sample $\frac{b}{2}$ labeled examples from $\mathcal{D}_S$
    (b) Randomly sample $\frac{b}{2}$ unlabeled examples from
        $\mathcal{D}_T^u$
    (c) Compute $\mathcal{L}_c(W, \theta)$ and $\mathcal{L}_d(\omega, \theta)$
    (d) Set $\lambda = \frac{2}{1+\exp(-10*p)} - 1$; $p$ is the training
        progress linearly changing form 0 to 1.
   // Classifier & Encoder
    (e) Take a gradient step for $\frac{2}{b} \nabla_{W,\theta} \mathcal{L}_c(W, \theta)$
   // Discriminator
    (f) Take a gradient step for $\frac{2\lambda}{b} \nabla_{U_d, \mathbf{w}_d} \mathcal{L}_d(\omega, \theta)$
   // Gradient reversal
    (g) Take a gradient step for $-\frac{2\lambda}{b} \nabla_\theta \mathcal{L}_d(\omega, \theta)$
until convergence;
```

4.2 Semi-supervised/supervised Adaptation

It is straight-forward to extend our adaptation method to a semi-supervised/supervised setting. Similar to the instances in the source domain, the labeled instances in the target domain $\mathcal{D}_T^l$ are used for act classification and domain discrimination. The total training loss in this case is

$$\mathcal{L}(W, \theta, \omega) = \underbrace{\sum_{p=1}^{P} \mathcal{L}_c^p(W, \theta)}_{\text{act classif. (source)}} + \underbrace{\sum_{p=Q+1}^{R} \mathcal{L}_c^p(W, \theta)}_{\textit{act classif. (target)}} -$$
$$\lambda \Big[\underbrace{\sum_{p=1}^{P} \mathcal{L}_d^p(\omega, \theta)}_{\text{dom classif. (source)}} + \underbrace{\sum_{n=P+1}^{R} \mathcal{L}_d^p(\omega, \theta)}_{\text{dom classif. (target)}} \Big]$$

where the second term is the classification loss on the target dataset $\mathcal{D}_T^l$, and the last term is the discrimination loss on both labeled and unlabeled data in the target domain.

5 Corpora

We now describe the datasets and the act tagset that we use, and the conversational word embeddings that we learn from a large unlabeled corpus.

5.1 Labeled Datasets

As mentioned, asynchronous domains lack large corpora that are annotated with a standard speech act tagset. Jeong et al. (2009) annotated sentences in TripAdvisor **(TA) forum** threads with the standard 12 act types defined in MRDA. They also remapped the **BC3 email** corpus (Ulrich et al., 2008) according to these tags. Subsequent studies (Tavafi et al., 2013; Oya and Carenini, 2014; Joty

---

[1] For simplicity, we describe adaptation of the encoder with Softmax output, but this generalizes naturally to CRF.

	Asynchronous			Synchronous

Table 4: Datasets and their statistics used for training the conversational word embeddings.

and Hoque, 2016) used these datasets but grouped the 12 acts into 5 coarser classes. Joty and Hoque (2016) also created a new dataset of QatarLiving[2] **forum** threads called **QC3**.[3] We use these three asynchronous datasets in our experiments. For our experiments on synchronous domains, we use the **MRDA meeting** corpus that was also used in related studies (Jeong et al., 2009; Joty and Hoque, 2016). Tables 1 and 2 show some basic statistics of the datasets and the tag distributions. Note that the tagset used by us and other related studies in asynchronous (written) conversation is different from the one used in synchronous spoken conversations (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Kumar et al., 2018). The later tagset contains acts like *backchannel*, *filter* and *disruption* that are more specific to speech.

The train-dev-test splits of the asynchronous datasets are done uniformly at random at the **conversation level**. Since the asynchronous datasets are quite small in size, to have a reliable test set, we create the train:test splits with an equal number of conversations (Table 3). Joty and Hoque (2016) also created conversation level datasets to train and test their CRF models. Their test sets however contain only 20% of the conversations, providing only 5 conversations for QC3 and BC3, and 20 for TA. Our experiments on these small test sets showed unstable results for all the models. Therefore, we use a larger test set (50%), and we report more general results on the whole corpus based on **2-fold** cross-validation, where the second fold was created by interchanging the train and test splits in Table 3. The same development set was used to tune the hyperparameters of the models for experiments on each fold. For experiments on MRDA, we use the same train:test:dev split as in (Jeong et al., 2009; Joty and Hoque, 2016).

5.2 Conversational Word Embeddings

One simple and effective approach to semi-supervised learning is to use word embeddings pretrained from a large unlabeled corpus. In our work, we use generic *off-the-shelf* pretrained embeddings to boost the performance of our models. In addition, we have also trained word embeddings from a large conversational corpus to get more relevant **conversational** word embeddings.

We use Glove (Pennington et al., 2014) to train our word embeddings from a corpus that contains 24K email threads from W3C (w3c.org), 25K threads from TripAdvisor, 220K threads from QatarLiving, and all conversations from SWBD and MRDA (a total of 120M tokens). Table 4 shows some statistics of the datasets used for training the conversational word embeddings. We also trained skip-gram word2vec (Mikolov et al., 2013), but its performance was worse than Glove.

6 Experiments

We followed similar preprocessing steps as Joty and Hoque (2016); specifically: normalize all characters to lower case, spell out digits and URLs, and tokenize the texts using TweetNLP (Gimpel et al., 2011). For performance compar-

ison, we use **accuracy** and **macro-F$_1$**. Like other related studies, we consider macro-F$_1$ as the main metric (more appropriate when class distributions are imbalanced), and select our model based on the best F_1 on the development set. Due to space limitations, we report only macro-F$_1$ here. Please refer to the Appendix for the accuracy numbers.

6.1 Experiments on In-domain Training

We first evaluate our base models on in-domain datasets by comparing with state-of-the-art models. In the next subsection, we evaluate our adaptation method in the three adaptation scenarios.

Settings. To validate the efficacy of our model, we compare it with two baselines: a Support Vector Machine (**SVM**) and a feed-forward network (**FFN**). In one setting, we use the concatenated word vectors as the input sentence representation, while in another, we use the pretrained skip-thought vectors (Kiros et al., 2015). We also compare our models with the bi-LSTM (**B-LSTM**) model of Joty and Hoque (2016) and the stacked LSTM (**S-LSTM**) of Khanpour et al. (2016).

We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001, and use dropout to avoid over-fitting. We use the Xavier initializer (Glorot and Bengio, 2010) to initialize the weights, and uniform $\mathcal{U}(-0.05, 0.05)$ to initialize the word vectors randomly. For pretrained word embeddings, we experiment with off-the-shelf embeddings that come with Glove as well as with our conversational word embeddings. For both random and pretrained initialization, we **fine-tune** our word embeddings on the SAR task.

We construct sequences from the **chronological order** of the sentences in a conversation. Since MRDA conversations are much longer compared to those in asynchronous domains (955 vs. 18-34 sentences in Table 1), we split the MRDA conversations into smaller parts containing a maximum of 100 sentences.[4] The number of epochs and batch size were fixed to 30 and 5 (conversations), respectively. We ran each experiment 5 times, each time with a different random seed, and report the average of the (2-fold×5=10) runs along with the standard deviation. Recently, Crane (2018) show that the main source of variability in results for neural models come from the random seed, and the author has recommended to report the distribution of results from a range of seeds.

Results. We present the results in Table 5. From the **first block** of results, we notice that both SVM and FFN baselines perform poorly compared to other models that tune the word embeddings and learn the sentence representation on the SAR task.

The **second block** contains five LSTM variants: (*i*) **B-LSTM$_{\text{rand}}$**, referring to bi-LSTM with *random* initialization; (*ii*) **B-LSTM$_{\text{gl}}$**, referring to bi-LSTM initialized with *off-the-shelf* Glove embeddings; (*iii*) **B-GRU$_{\text{c-gl}}$**, referring to bidirectional Gated Recurrent Unit (Cho et al., 2014) initialized with our *conversational* Glove; (*iv*) **B-LSTM$_{\text{c-gl}}$**, referring to bi-LSTM initialized with *conversational* Glove, and (*v*) **S-LSTM$_{\text{c-gl}}$**, referring to a 2-layer stacked LSTM with *conversational* Glove.[5] From the results, we can make the following conclusions. First, B-LSTM$_{\text{rand}}$ overfits extremely on

---

[4] In a different setting, we created sequences by connecting each non-initial comment with the initial comment generating many 2-comment sequences. This is considering the fact that in many QA forums, users mostly answer to the questions asked in the initial post. In our experiments on in-domain training, we found this competitive with our 'one long-chain' structure. However, the adaptation in this setting was much worse because of the mismatch in discourse structures of synchronous and asynchronous conversations.

[5] Increasing the number of layers in **S-LSTM$_{\text{c-gl}}$** did not give any gain (see Table 2 in the Appendix).

the asynchronous datasets, giving the worst results among the LSTMs. Second, pretrained vectors help to achieve better results, however, compared to the off-the-shelf vectors, our conversational word vectors yield much higher F_1, especially, in the asynchronous datasets that are smaller in size (5 - 11% absolute gains). This demonstrates that pretrained word embeddings provide an effective method to perform semi-supervised learning, when they are learned from relevant datasets.

The **last block** shows the results of our models. It is evident that both H-LSTM and H-LSTM-CRF outperform other models in all the datasets except QC3 where the difference is very small. They also give the best F_1 reported so far on MRDA, outperforming the B-LSTM models of Joty and Hoque (2016) and S-LSTM model of Khanpour et al. (2016). When we compare the two models, we notice that H-LSTM outperforms H-LSTM-CRF in all the datasets. A reason for this could be that the contextual dependency is already captured by the upper LSTM layer and the data may be too small for the CRF to offer anything more.

6.2 Experiments on Domain Adaptation

Settings. We compare our adversarial adaptation method with three baseline methods: Transfer, Merge and Fine-tune. **Transfer** models are trained on the source (MRDA) and tested on the target (QC3, TA, BC3). Our **adversarial unsupervised adaptation** method is comparable to the transfer method as they use labeled data only from the source domain. In **Merge**, models are trained on the concatenated training set of source and target datasets. **Fine-tune** is a widely used adaptation method for neural models (Chu and Wang, 2018). In this method, we first train a model on the source domain until convergence, then we fine-tune it on the target by training it further on the target dataset. Both merge and fine-tune are comparable to our **semi-supervised/supervised adaptation** as these methods use labeled data from the target domain. For semi-supervised experiments, we take smaller subsets (*e.g.,* 25%, 50%, and 75% of the labeled data) from the target domain.

We also compare our method with **Neural SCL** (Ziser and Reichart, 2017), which is another domain adaption method in the neural framework. We used the implementation made available by the authors.[6] For training our adaptation models, we use SGD (Algorithm 1 in the Appendix) with a momentum term of 0.9 and a dynamic learning rate as suggested by Ganin et al. (2016).

Method	**Model**	**QC3**	**TA**	**BC3**

Table 6: Domain adaptation results on our datasets. All models use conversational word embeddings. Results are averaged over (2 folds×5) 10 runs.

Results. The adaptation results are shown in Table 6. We observe that without any labeled data from the target (**Unsup. adap**), our adversarial adapted models (Adv-H-LSTM, Adv-H-LSTM-CRF) perform worse than the transfer baseline in all three datasets. In this case, since the out-of-domain labeled dataset (MRDA) is much larger, it overwhelms the model inducing features that are not relevant for the task in the target domain. However, when we provide the models with some labeled in-domain examples in the **semi-supervised (50%)** setting, we observe about 11% absolute gains in QC3 and BC3 over the corresponding Merge baselines, and 7 - 8% gains over the corresponding Fine-tune baselines. As we add more target labels (**100%**), performance of our adapted models (**Sup. adap**) improve further, yielding sizable improvements ($\sim$ 3% absolute) over the corresponding baselines in all datasets.

---

[6] https://github.com/yftah89/structural-correspondence-learning-SCL

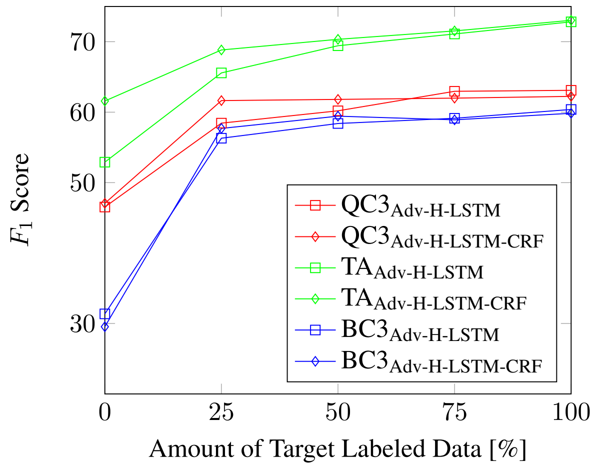

Figure 3: F_1 with varying amount of target labels.

Also notice that our adversarial adaptation outperforms Merge and Fine-tune methods for all models over all datasets, showing its effectiveness.

Figure 3 presents the F_1 scores of our adapted models with varying amount of labeled data in the target domain. We notice that the largest improvements for all three datasets come from the first 25% of the target labels. The gains from the second quartile are also relatively higher than the last two quartiles for TA and BC3. Another interesting observation is that H-LSTM-CRF performs better in unsupervised and semi-supervised settings (*i.e.,* with less target labels). In other words, H-LSTM-CRF adapts better than H-LSTM with small target datasets by exploiting the tag dependencies in the source. As we include more labeled data from the target, H-LSTM catches up with H-LSTM-CRF. Surprisingly, Neural SCL performs the worst. We suspect this is due to the mismatches between pivot features of the source and target domains.

If we compare our **adaptation results** with the **in-domain results** in Table 5, we notice that using the same amount of labeled data in the target, our supervised adaptation gives 3-4% gains across the datasets. Our semi-supervised adaptation using half of the target labels (50%) also outperforms the in-domain models that use all the target labels.

To further analyze the cases where our adapted models make a difference, Figure 4 shows the confusion matrices for the adapted H-LSTM and the non-adapted H-LSTM on the concatenated testsets of QC3, TA, and BC3. In general, our classifiers get confused between *Response* and *Statement*, and between *Suggestion* and *Statement* the most. We noticed similar phenomena in the human annotations, where annotators had difficulties with these three acts. It is however noticeable that the adapted H-LSTM is less affected by class imbalance, and it can detect the *Suggestion* and *Polite* acts more correctly than the non-adapted one.

7 Conclusion

We proposed an adaptation framework for speech act recognition in asynchronous conversation. Our base model is a hierarchical LSTM encoder with a Softmax or CRF output layer, which achieves state-of-the-art results for in-domain training. Crucial to its performance is the conversational word embeddings. We adapted our base model with adversarial training to effectively leverage out-of-domain meeting data, and to improve the results further. A comparison with existing methods and baselines in different training scenarios demonstrates the effectiveness of our approach.

Abstract

Advances in the automated detection of offensive Internet postings make this mechanism very attractive to social media companies, who are increasingly under pressure to monitor and action activity on their sites. However, these advances also have important implications as a threat to the fundamental right of free expression. In this article, we analyze which Twitter posts could actually be deemed offenses under German criminal law. German law follows the deductive method of the Roman law tradition based on abstract rules as opposed to the inductive reasoning in Anglo-American common law systems. This allows us to show how legal conclusions can be reached and implemented without relying on existing court decisions. We present a data annotation schema, consisting of a series of binary decisions, for determining whether a specific post would constitute a criminal offense. This schema serves as a step towards an inexpensive creation of a sufficient amount of data for automated classification. We find that the majority of posts deemed morally offensive actually do not constitute a criminal offense and still contribute to public discourse. Furthermore, laymen can provide sufficiently reliable data to an expert reference but are, for instance, more lenient in the interpretation of what constitutes a disparaging statement.

1 Introduction

The Internet is frequently used for discussing a variety of topics and an important medium for the exchange of opinions, considered crucial for healthy democratic societies. However, the rough tone in the Internet frequently leads to defamatory or abusive comments in these discussions. The EU has tried to tackle the problem by defining the term 'illegal hate speech'.[1] Additionally, in 2017, the European Commission published a communication entitled 'Tackling Illegal Content Online' aiming for enhanced responsibility of online platforms.[2] Independently from these recent developments on the EU level, Germany adopted the 'Network Enforcement Act'[3] in 2017. The Act provides for a regulatory framework for 'illegal content'[4] on social network platforms like Twitter or Facebook. It imposes the obligation on these providers to delete illegal content upon notification within seven days; in case of evidently illegal content within 24 hours.[5] From a practical point of view, given the number of statements on social media along with their possible notification, feasibility and accuracy of the required legal assessment becomes an important issue. Natural Language Processing might thus provide the necessary means to assist the legal assessment.

In this work, we investigate at which point morally offensive statements in social media constitute defamatory offenses under the German Criminal Code (StGB)[6], thus representing 'illegal content' according to the Network Enforcement Act and thereby triggering a deletion obligation for platform providers.[7] We analyze the legal decision-making process to determine defam-

[5] See § 3(2)(2),(3) of the Act. It is however doubtful whether these strict procedural requirements violate EU law, namely Art. 3, Art. 14 e-Commerce Directive (2000/31/EC) i.e. require acting 'expeditiously' after obtaining knowledge.

[6] Strafgesetzbuch v. 13.11.1998 (BGBl. I S. 3322).

[7] It is not guaranteed that a judge would necessarily arrive at the same conclusion, but a lawyer's expertise serves as a strong indicator for potentially punishable conduct.

Proceedings of NAACL-HLT 2019, pages 1337–1347
Minneapolis, Minnesota, June 2 - June 7, 2019.

atory offenses (§ 185 to § 187 StGB), which also clarifies the tension between the right to honor and the freedom of expression. Due to its additional complexity, we leave out incitement to hatred against a national, racial, religious or ethnic group or segments of the population (§ 130 StGB) as an offense against public peace in this paper. Furthermore, we investigate automated detection of postings protected by the freedom of expression in order to assist social media moderators. We focus in particular on the process of inexpensive and scalable data annotation, as access to legal expertise is a major bottleneck for providing a sufficient amount of data for classifier training.

2 Related Work

An automated detection of Internet discourse in which individuals or groups are verbally attacked has been intensively investigated under a variety of names, for instance: abusive language (Waseem et al., 2017), ad hominem arguments (Habernal et al., 2018), aggression (Kumar et al., 2018), cyberbullying (Xu et al., 2012; Macbeth et al., 2013), hate speech (Warner and Hirschberg, 2012; Ross et al., 2016; Del Vigna et al., 2017), offensive language usage (Razavi et al., 2010), profanity (Schmidt and Wiegand, 2017), threats (Oostdijk and van Halteren, 2013) or socially unacceptable discourse (Fišer et al., 2017).

The majority of the work focuses on the English language with few exceptions for instance for German (Ross et al., 2016), Dutch (Oostdijk and van Halteren, 2013), Italian (Del Vigna et al., 2017) or Slovene (Fišer et al., 2017). The dataset annotated in Fišer et al. (2017) is the only one that includes a coarse-grained binary annotation category indicating if an utterance violates Slovene law. To the best of our knowledge, automatic determination as to whether the (textual) content of a posting constitutes a criminal offense has never been previously attempted. Previous work focused on detecting postings with socially unacceptable content but without considering actual legal implications for freedom of expression.

Approaches that bring together Natural Language Processing with the legal perspective are in contrast significantly fewer, especially considering the fact that the legal evaluation depends on the applicable legal regime. Previous work focused on predicting the outcome of court trials, which all have in common that they derive their data from a rather large set of court-provided information. Bruninghaus and Ashley (2003) works on a combination of U.S. case law and normative rules: they experiment with clustering and regression models for predicting the outcome of U.S. cases. Katz et al. (2017) predicts U.S. supreme court rulings by using a random forest classifier; Kastellec (2010) investigates mappings from case facts to court decisions as outcomes. Waltl et al. (2017) predicts the outcome of decisions in German tax law. Aletras et al. (2016) predicts decisions of the European Court of Human Rights. Deriving data from court decisions might be an approach that is practical if relevant case law exists for the respective legal problem, which particularly makes sense from the perspective of the Anglo-American common law system.[8]

3 Operationalising Legal Assessment

Unlike under Anglo-American common law, for legal systems based on Roman law (‘civil law’ systems), the dogmatic perception of the respective legal disposition lies at the heart of legal decision-making. Our approach thus differs from the above-cited works by placing the focus on the abstract concept of an existing legal norm. The advantage of our approach is therefore that we pursue a solution to address legal problems by creating new data out of abstract legal rules, independently of whether they have been decided by a court. We rely solely on the Internet posting for this consideration, which is the same information available to moderators of social media platforms. To build the bridge from legal thinking to a technical implementation, we start by analyzing the legal requirements for social media content. We find that the decision-making process to determine criminal offenses can be formulated as a sequence of binary decisions when applying the legal dependencies between German criminal law and the fundamental rights of the individual as shown in Figure 1. The derived schema of binary decisions is shown in Figure 2, which we will use in the following section. We now turn to a discussion and analysis of the legal decision process to clarify how we derived this sequence of binary decisions.

---

[8] ‘Common law’ refers to the Anglo-American legal system that derives the law from judicial decisions, in contrast to the ‘civil law’ system of continental Europe that focuses on the abstraction of legal concepts in codified statutory law. See: B.A. Garner (2001) A Dictionary of Modern Legal Usage (2nd, revised ed.) New York: OUP.

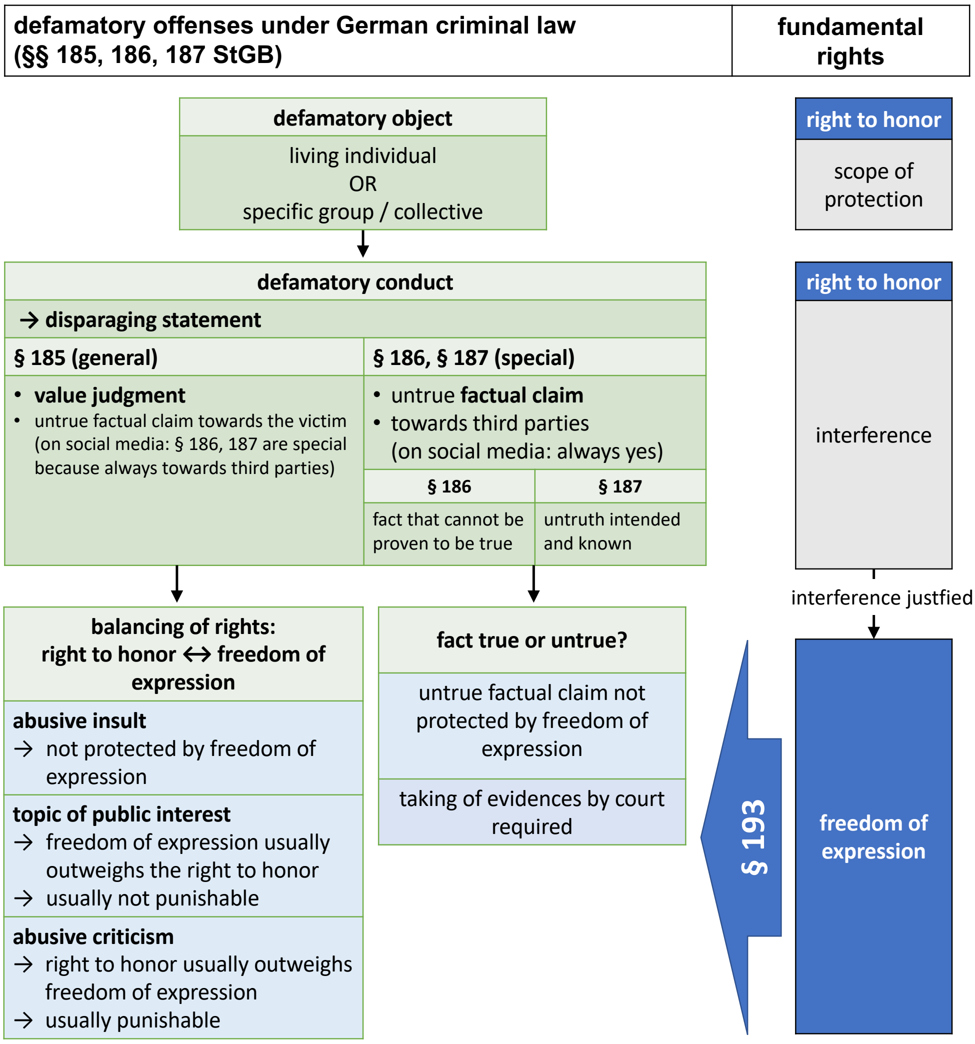

Figure 1: Conditions for defamatory offenses and fundamental rights' background under German law

Scope So what constitutes 'illegal content' that the Network Enforcement Act is targeting? The legal definition of the term 'illegal content'[9] is referring to offenses stipulated in the German Criminal Code. These references include, inter alia, defamatory offenses in § 185 to § 187 StGB[10] that cover the criminal punishment of insulting or defamatory statements. Accordingly, if a statement posted on social media fulfills the required elements of these offenses, the provider has the above-described obligation based on the Network Enforcement Act to delete said statement upon notification.[11] For this paper, we exclude § 130 StGB[12], that covers incitement to hatred against a national, racial, religious group or a group defined by their ethnic origins, due to an additional complexity of the assessment.

3.1 The Relevance of Fundamental Rights

To understand their elements in detail, it is crucial to refer to the more general legal concept behind these criminal offenses: as illustrated in Figure 1 the intention behind § 185 to § 187 StGB is leading to the protection of the victim's personality right, namely their right to honor under the German Constitution.[13] It is this right that is potentially at stake when social media users are disseminating statements with third parties as potential victims.

---

[9] See § 1(3) 'rechtswidrige Inhalte'.

[10] § 185: 'insult'(*Beleidigung*), § 186: 'defamation' *Üble Nachrede*) and § 187: 'intentional defamation' (*Verleumdung*). The reference to these defamatory offenses has however been criticized in literature, see: Erbs/Kohlhaas, Strafrechtliche Nebengesetze, 220. EL Juli 2018, § 1 NetzDG, Rn. 16-18.

[11] See § 3(2)(2),(3) of the Act.

[12] § 130, 'incitement to hatred' (*Volksverhetzung*).

[13] Derived from Art. 2(1) and Art. 1(1) of the German Constitution (Grundgesetz); BVerfGE 35, 202; E 54, 148, 155.

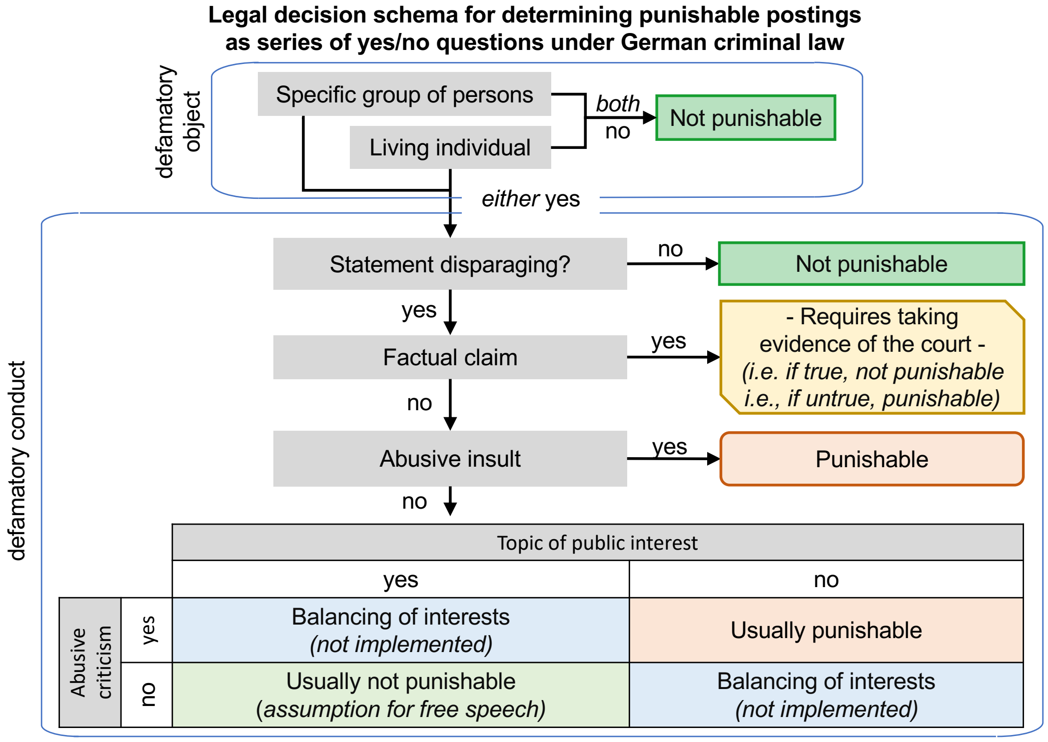

Figure 2: Series of binary decisions for determining criminal offenses under German criminal law

3.2 Defamatory Object

Consequently, the scope of protection of § 185 to § 187 StGB follows the respective interpretation of the right to honor. Thus, all three offenses share the approach to the possible victim as a holder of the right to honor: a **living individual** that might be addressed by a name, personal pronoun or user-mention as shown in Example 1.

(a) Are *you* kidding?
(b) *John* is this true?
(c) *@user* I don't believe you.

Example 1: Addressing living individuals

A **group of persons** can be considered as a potential victim if that group is distinguishable from the general public such that every member of that group could feel their honor is infringed as shown in Example 2.[14]

(a) *My school's language teachers* are all idiots.
(b) *The female students of this year's grad class* are all dump.

Example 2: Addressing distinguishable group of persons (highlighted in italic)

Consequently, only certain groups do qualify as potential defamatory object. Example 3 illustrates groups that would be too broad to be distinguishable from the general public.[15]

(a) All international conflicts are caused by *men*.
(b) *Refugees* out!!

Example 3: Counterexamples for addressing too unspecific or large groups

Collective entities such as governments or press companies with a recognized social role and who act with a collective, single will are included in the right to honor as shown in Example 4.[16]

(a) *The federal government* is lying.
(b) I don't like *the Christian Democratic Party*
(c) *The New York Times* got it all wrong.

Example 4: Addressing collective entities (highlighted in italic)

We translate these conditions of § 185 to § 187 StGB into an either/or-question, respectively whether *either* a living individual *or* a specific group is an object of the respective statement.

---

[14] BGHSt 19, 235, 238.

[15] These groups may, however, still qualify as a potential victim of 'incitement to hatred' (§ 130).

[16] See § 194 StGB; BGHSt 6, 186, 191, 192.

3.3 Defamatory Conduct

Disparaging Statement The next step in the legal assessment is then the existence of insulting or defamatory conduct with respect to the above-mentioned object, in the form of an expressed disparaging statement. This requirement is again shared by § 185 to § 187 StGB. It is already fulfilled by expressing contempt or disrespect through the allegation of shortcomings that could reduce the victim's social standing as shown in Example 5.[17]

(a) John is *an idiot.*
(b) The government is *lying*.
(c) Minister M *slept during the discussion.*

Example 5: Disparaging statements

From the perspective of the underlying fundamental rights, it is this disparaging statement which constitutes the interference with the potential victim's right to honor. The existence of a *disparaging statement* is implemented by a *yes/no-question.*[18]

Value Judgment or Factual Claim? As simplified in Figure 1, the legal assessment then varies between § 185 StGB as general disposition and § 186 and § 187 StGB with special rules and an increased penalty range.

For the different scope of these dispositions, the difference between the legal terms *'value judgment'* and *'factual claim'* (i.e. the assertion of facts, may they be true or untrue) is crucial. Value judgments constitute expressions of personal opinions as shown in Example 6:[19]

(a) *Merkels decisions are bullshit.*
(b) *@user I don't like you.*

Example 6: Value judgments

A factual claim can be clearly classified as true or untrue and is accordingly capable of proof as shown in Example 7.[20]

(a) *I saw Mr. A buying drugs yesterday evening.*
(b) *Minister M slept during the discussion.*

Example 7: Factual claim

§ 185 StGB, stipulating the insult ('Beleidigung'), comprises value judgments and untrue factual claims, irrespective of their dissemination towards third parties. § 186 and § 187 StGB on the other side provide for special rules for the assertion or dissemination of untrue facts, i.e. towards third parties. As the publication of statements on social media constitutes an 'assertion' or 'dissemination', untrue facts - for our study - are only treated by § 186, § 187 StGB. This reduces the scope of § 185 StGB to value judgments only.

From the perspective of the right to honor, only untrue factual claims may constitute a violation, while the assertion of true facts is always covered by the freedom of expression.[21] The distinction has consequences on the procedural level: because only the assertion of untrue facts violates the right to honor, during criminal proceedings, the court has to assess the truth by taking evidence. A technical implementation of this assessment would therefore require access to unlimited knowledge that goes beyond the textual information on which we work. Accordingly, we stop our examination in case of a factual claim.[22]

3.4 Value Judgments: Balancing of Rights

As the distinction between value judgment and factual claim is an alternative decision,[23] we continue our implementation for value judgments. In criminal proceedings, the court would have to consider at this point once more fundamental rights: value judgments - being not classifiable as untrue or true - generally fall under the scope of the freedom of expression of the potential offender.[24]

In the German Criminal Code, this is reflected by § 193 StGB: even if a statement falls under the scope of said criminal offenses, it might still be

---

[17] BGHSt 36, 145, 148.

[18] Regarding the mere *expression* of a statement, we assume a *yes-answer* for statements published on social media that are subject to this study, and therefore do not implement this condition.

[19] BVerfGE 61, 1; for Twitter postings: OLG Karlsruhe, 24.10.2018, 6 U 65/18.

[20] RG 41, 193; 55, 131; BVerfGE 94, 8.

[21] BVerfGE 99, 185, 197; E 97, 381, 403.

[22] Consequently, we do not implement subsequent conditions of § 186, § 187 StGB, as shown in Figure 1, respectively whether facts cannot be proven to be true (§ 186 StGB) or whether the untruth was intended and known (§ 187 StGB).

[23] Ambiguous statements that are based on facts, but are overall characterized by a valuation of these facts, fall under the category of 'value judgments'.

[24] Art. 5(1)1 of the German Constitution (Grundgesetz). According to Art. 5(2) the freedom of expression then again is limited by the right to honor.

justified based on § 193 StGB as exercise of legitimate interests. The most prominent example of one of these conflicting interests is the offender's freedom of expression. On the constitutional level, then, the decision of whether a social media posting constitutes a punishable criminal offense and leads to the platform provider's deletion obligation can thus ultimately be perceived as a balancing between freedom of expression and the right to honor.

Consequently, the court would have to balance these concurrent rights depending on the case at hand. But how could that balancing, usually comprising an evaluation of various factors, be carried over to a technical implementation? Over the years, German case law from the Federal Constitutional Court has developed guidelines for this balancing to be considered by the judge, which take the step of implying the typical outcome of the balancing. We implement these guidelines in three yes/no-questions:[25]

Abusive Insult Statements that constitute breaking a taboo by themselves and intend only the defamation of the victim without any substantiated contribution are classified as *'abusive insult' (Formalbeleidigung)*. According to settled case law, these statements are already excluded from the scope of freedom of expression.[26] Consequently, a justification based on § 193 StGB is, in this regard, denied and the elements of § 185 StGB are fulfilled along with a violation of the right to honor. Given these severe consequences for free speech, the German Constitutional Court has so far only once approved a statement as constituting an 'abusive insult' as shown in Example 8:[27]

A disabled person is called *"cripple"*

Example 8: Abusive insult

Topic of Public Interest For statements that contain a contribution to the public discourse with respect to a particular relevant topic of public interest, the settled case law of the German Federal Constitutional Court mandates a presumption in favor of free speech.[28]

Merkel prostitutes herself for the German car industry costing tax payers

Example 9: Topic of public interest

Example 9 comments on the right to stay of refugees, by this participating to the public debate in Germany about refugees from Syria. Accordingly, such statements usually outweigh the right to honor. They thus usually can be made, justified as having a legitimate interest based on § 193 StGB, therefore *usually not punishable*.

Abusive Criticism Finally, as *'abusive criticism' (Schmähkritik)* settled case law has defined statements that go beyond plausible criticism by primarily intending to abusively offend the victim, hereby neglecting a substantiated contribution.[29] In Example 10, the statement:

Minister M, that asshole, is lying to all of us!! noone has money to pay for this...

Example 10: No abusive criticism

despite the word 'asshole', still contributes to the public discourse, which is why its primary purpose is not (only) to abusively offend. Abusive criticism thus usually leads to favoring the right to honor over freedom of expression. Without justification pursuant to § 193 StGB, such statements are therefore *usually punishable*.

4 Proof of Concept

In this section, we now use the schema in Figure 2 to annotate data and learn more about the reliability of an automated classification.

4.1 Dataset

In order to legally assess social media postings, we first need to annotate a corpus as a starting point for an analysis. Randomly sampling postings from the Internet is a possible strategy to collect data for an annotation, but we would not have any certainty that enough offending postings occur. Therefore, we decide to use an existing corpus that has already been annotated for moral offensiveness. We use the corpus provided by the GermEval shared

---

[25] As illustrated in Figure 2, the judge would perform the balancing freely based on all circumstances (which we do not implement) if there is no *'abusive insult'* and if *'topic of public interest'* and *'abusive criticism'* are both yes or both no.

Factual claim	.925	.821
Abusive insult	.925	.820
Of public interest	.940	.855
Abusive criticism	.866	.678
Joint-decision	.821	.720

Table 1: Agreement between two legal experts on two-hundred randomly selected postings

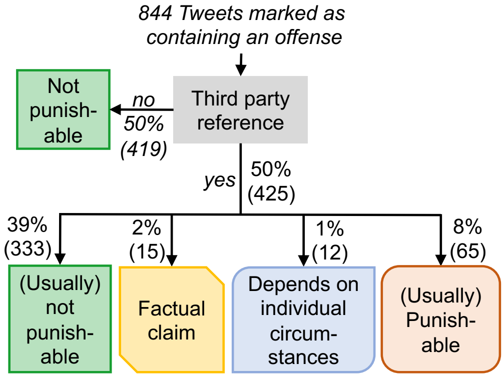

Figure 3: Legal categorization of annotated Tweets that were marked as containing an offense

task for *detecting offensive language usage* (Ruppenhofer et al., 2018). This dataset contains a mixture of German Twitter postings with a focus on German politics that are marked if the tweet is considered morally offensive from the subjective perception of the annotator. We work with a subset of 1,100 postings from this corpus, two-thirds of the postings (844) are marked as morally offensive. This enables us to investigate which statements commonly found in political debates are protected by the freedom of expression and which are not.

Annotation The reference annotation of these postings is provided by a fully-qualified lawyer of German law applying the schema in Figure 2. We additionally received 200 postings from a second fully-qualified lawyer in order to compute an agreement score between the two legal experts, which is shown in Table 1. We report accuracy and Cohen's κ (Cohen, 1960) for each decision and show the agreement for a *joint-decision* where we treat all decisions for a posting as a single decision. The legal experts disagree slightly on the assumption of abusive criticism. This is not surprising as the evaluation of courts might differ in different instances, especially regarding the balancing of interests in the case at hand.

Analysis Figure 3 shows the annotation results of the postings marked as *morally offensive*. We find that about half of the postings have to be categorized early on as *not punishable* for not containing a defamatory object, i.e. no living individual addressed or the addressed group is too unspecific. The remaining half is still to a large extent *usually not punishable*, mostly because the posts still contribute to a topic of public interest, despite of being disparaging. A small number of cases are either factual claims that would require taking evidence by the court or value judgments that do not concern topics of public interest. Thus, despite containing statements that may be deemed morally offensive, the vast majority of statements are legally acceptable, i.e. protected by the freedom of expression. The punishable cases often contain insulting buzzwords such as *slut, fat-ass* or *scumbag* when directed at a private individual, not at a person of public interest. Furthermore, punishable statements addressing a specific group use more frequently offending comparisons or descriptions but no typical single or two-word insults. However, it is important to recall that the dataset has a focus on political debates. Accordingly, most statements tackle a topic of public interest, and are thus considered *usually not punishable* granting a high degree of protection under the freedom of expression.

This analysis also shows that shared tasks such as *OffensEval* (Zampieri et al., 2019) tackle essentially only one step in the legal assessment, namely whether a statement is *disparaging*. Thus, they fall short of valuing the freedom of expression, which is in particular a problem for public discourse such as political debates, where opinions are often accompanied by 'bad' language.

4.2 Automated Detection

For an automated detection, it would seem straight forward to distinguish between *punishable* and *not punishable* postings. This approach requires an extremely large amount of data for each of the two classes, which we do not have. The data distribution is skewed with the *punishable* class being extremely small, which makes this direct ap-

	Decision	Acc	Class	F1

			No	.975

Table 2: Averaged 10-fold CV results for each decision on 1,100 Tweets, using an LSTM

proach infeasible. Instead, we investigate how well each of the binary decisions shown in Figure 2 can be learned independently, which has a less skewed distribution. We use a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) for classification.[30] We use the 300-dimensional German pre-trained word embeddings provided by Grave et al. (2018), which are trained on the German common crawl.

Table 2 shows averaged 10-fold CV results for each decision point. We observe that the accuracy is close to the underlying distribution of the two classes. The classification of the *defamatory object* has a mediocre performance. In particular, an insufficient coverage of group names and names of individuals in the dataset seem to be the main cause as the *no* classes usually perform considerably better than the *yes* classes. The classification of the decisions under *defamatory conduct* follows a similar trend. The few positive instances: *factual claim*, *abusive insult* and *abusive criticism* prevent a reliable distinction of these cases.

The next step would be to investigate how well the classification works in sequence, i.e. continuing the classification with the positively categorized instances of the previous step. However, the independent classification shows already that the amount of data is insufficient. Therefore, we turn next to the more pressing question of how to generate more data in a scalable way, especially without relying on expensive legal experts as annotators.

5 Data Annotation by Laymen

A scalable annotation of more data requires that laymen can be instructed in a way that enables them to solve the task at hand. Laymen are readily available, for instance via crowdsourcing but also as student assistants who can be more cheaply employed than legal experts for annotating data.

Setup We compare the annotation performance of both random crowd workers and student assistants. The crowd workers and the student assistants were required to speak German. We have no information on the educational background of the crowd workers, but we ensured that the student assistants were not students of law-related subjects. We prepared a simplified manual[31] based on Figure 2, which is supplemented with text examples for each decision to guide the layman through the annotation of each decision. We use the crowdsourcing platform figure-eight.com to let crowd workers and student assistants re-annotate the 1,100 postings for which we have a reference annotation by a legal expert. Each posting is annotated by three annotators.

The annotation results are shown in Table 3. It is to be expected that some annotators will perform better than others, but distinguishing the ‘good’ from the ‘bad’ is an additional challenge, which we will not deal with here. Instead, we aggregate the annotations of all participants in a voting-like fashion, taking in each case the majority vote for each decision.[32] This provides us with an approximation of the average layman performance on this task, which is the key information that we are interested in.

Analysis The results show that student assistants solve this task considerably better than crowd workers. In particular, the recognition of references to *specific group* poses the biggest challenges for crowd workers, which also explains why this group performs much more poorly than the student assistants. As shown in Figure 2, the evaluation for a post ends if neither a living individual nor specific group is addressed. If either of the first two decisions is incorrect, an annotator automatically makes up to five additional follow-up errors. The student assistants applied the manual considerably more consistently than the crowd

Joint-decision	.357	.201	.175	.050	.383	.250

Table 3: Agreement between the reference annotation by a legal expert and the aggregated laymen annotations of: *all users* (on 1,000 posts), only *crowd-workers* (on 402 posts) and only *student assistants* (on 390 posts). Results for *crowd-workers* and *student-assistants* are limited to postings where all three votes per posting were provided by users from the respective group.

workers, leading to fewer follow-up errors. Determining the referenced individual is also frequently challenging when several Twitter users are referenced by an at-mention, which introduces an uncertainty that the statement might refer to one of the linked users. We also find that the laymen tend to apply a more lenient interpretation of what is *disparaging* and consider many statements as non-disparaging, i.e. already an allegation of shortcomings[33], which could reduce the victim's social standing is disparaging in the legal sense.

The annotation results of the student assistants are encouraging for obtaining sufficient training data for a larger study on automated classification, i.e. a correct automated classification of the first two decisions would already be able to exclude many cases that do not have to be deleted based on the Network Enforcement Act.

6 Conclusion

We investigated which offenses found in German political Tweets constitute defamatory offenses under German criminal law, that social media operators are obliged to delete under the Network Enforcement Act. Following the dogmatic approach of civil law systems, we started with an analysis of the legal framework for defamatory offenses in the German Criminal Code along with its foundations in the balancing between the potential offender's freedom of expression and the potential victim's right to honor. We derived from this consideration a schema suited for data annotation consisting of a sequence of binary decisions to determine if a statement constituted a defamatory offense, which we used for annotating data. We find that the majority of the morally offensive postings in our dataset still contribute to the public discourse and are, hence, protected by the freedom of expression. We also investigated if laymen can be instructed to use this annotation schema to facilitate an inexpensive annotation of more data for classifier training. We find that laymen suited to the task can be found, but in particular the legal notions of a specific *group of persons* and the scope of what is considered *disparaging* are challenging for them.

In future work, we will investigate the usefulness of layman-annotated data for an automated classification. Furthermore, we will expand our work by investigating additionally the criminal offense of *incitement to hatred* (§ 130 StGB) and its implication on the freedom of expression.

Acknowledgements

We would like to thank Tatiana Günster for taking the time to provide us with a second legal opinion. Furthermore, we would like to thank Emilie Mathieu for helpful corrections and Michael Wojatzki for the helpful discussions about the user-study design.

Abstract

We propose a novel attention network for document annotation with user-generated tags. The network is designed according to the human reading and annotation behaviour. Usually, users try to digest the title and obtain a rough idea about the topic first, and then read the content of the document. Present research shows that the title metadata could largely affect the social annotation. To better utilise this information, we design a framework that separates the title from the content of a document and apply a title-guided attention mechanism over each sentence in the content. We also propose two semantic-based loss regularisers that enforce the output of the network to conform to label semantics, i.e. similarity and subsumption. We analyse each part of the proposed system with two real-world open datasets on publication and question annotation. The integrated approach, Joint Multi-label Attention Network (JMAN), significantly outperformed the Bidirectional Gated Recurrent Unit (Bi-GRU) by around 13%-26% and the Hierarchical Attention Network (HAN) by around 4%-12% on both datasets, with around 10%-30% reduction of training time.

1 Introduction

Social annotation, or tagging, is a popular functionality allowing users to assign "keywords" to online resources for better semantic search and recommendation (Vander Wal, 2007; Singer et al., 2014; Gedikli and Jannach, 2014). Common socially annotated textual resources include questions, papers, (micro-)blogs, product reviews, etc. In practice, however, only a limited number of resources is annotated with tags. Annotating a large number of documents requires much cognitive effort and can be time-consuming. This has driven research on document annotation based on existing tag sets (Belém et al., 2017; Nie et al., 2014).

Recent studies formalise the automated social annotation task as a multi-label classification problem (Gibaja and Ventura, 2015) and apply deep learning approaches (Li et al., 2016; Huang et al., 2016; Hassan et al., 2018). A strong baseline is the use of Bi-directional RNN (Schuster and Paliwal, 1997) with GRU (Cho et al., 2014) or LSTM (Hochreiter and Schmidhuber, 1997). Another more recent improvement is achieved through Hierarchical Attention Network (HAN) (Yang et al., 2016) which discriminates important words and sentences from others, as adapted in (Hassan et al., 2018) for annotation. These models, however, suffer from two issues: (i) simply scanning over the words and sentences, the models do not fully mimic the way users read and annotate documents, and (ii) semantic relations, similarity and subsumption, among the labels are not considered.

Our model focuses on simulating users' reading and annotation behaviour with attention mechanisms. The title of a document is highly abstract while informative about the topics and has a direct impact on users' annotation choice (Lipczak and Milios, 2010), showing high descriptive capacity and effectiveness for annotation (Figueiredo et al., 2013); the content provides complementary information for annotation. Usually, users firstly read the title, and based on their understanding of the title, proceed to the content of the document. To simulate this behaviour, we propose an attention network with separated inputs (title and content) and parallelled attention layers at both the word-level and the sentence-level. One major distinction to previous approaches is to represent the content with a title-guided attention mechanism; this enables the network to discriminate among sentences based on its understanding of the title.

In addition, in the social context, users tend to annotate documents collectively with tags of

Proceedings of NAACL-HLT 2019, pages 1348–1354
Minneapolis, Minnesota, June 2 - June 7, 2019.

various semantic forms and granularities (Peters, 2009; Heymann and Garcia-Molina, 2006). One challenging issue is how to exploit the relations among labels (user-generated tags) (Zhang and Zhou, 2014; Gibaja and Ventura, 2015) to improve the learning performance. Among neural network based methods, a recent attempt is to initialise weights for dedicated neurons in the last layer to memorise the label relations (Kurata et al., 2016; Baker and Korhonen, 2017), however, the limitation is the large number of neurons to be assigned, making it inefficient (or inapplicable) for systems with large number of labels. To incorporate the label semantics inferred from the data or from external knowledge bases into the network, we design two loss regularisers, for similarity and subsumption relations, respectively. The regularisers enforce the output layer of the network to satisfy the semantic constraints of the labels.

2 Proposed Method

We propose a parallelled two-layered attention network that simulates users' reading and annotation behaviour for document annotation. The proposed Joint Multi-label Attention Network (JMAN) approach is depicted in Figure 1. The model inputs the title and content separately into two Bidirectional-RNNs with word-level attention and sentence-level attention mechanisms to capture the important words and sentences. Each target is a multi-hot (as opposed to an one-hot) representation of the labels in the label set $y_d \in \{0,1\}^{|T|}$, where T is a list all labels, "1" indicates that a label appears in the label set of the document d, "0" otherwise. In Figure 1, attention mechanisms are indicated with dotted edges. One key distinction from the HAN model (Yang et al., 2016) is the title-guided sentence-level attention that models the reading order for annotation (the dotted edges linking c_t and c_{ta}). The output layer $s_d = \sigma(W_c c_d + b_c)$, activated with the sigmoid function σ, is further constraint by two loss regularisers, emphasising two types of label relations, similarity and subsumption, respectively.

For the RNN encoder, we apply the Gated Recurrent Unit (GRU) which can capture long term dependencies and is usually more time-efficient than LSTM (Hochreiter and Schmidhuber, 1997) in training. The Bidirectional-GRU (Bi-GRU) encoder (Cho et al., 2014) concatenates the hidden states generated from two GRUs, one reading the words (or sentences) forward and the other reading them backwards. This helps form a more complete understanding of the current word (or sentence).

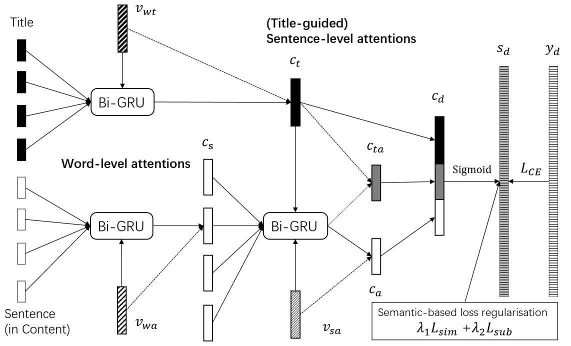

Figure 1: The Proposed Joint Multi-label Attention Network (JMAN) for Social Text Annotation

2.1 Hierarchical Attention

Hierarchical Attention captures the structure of a document by a word-level attention on each word's hidden state to create a sentence representation, then a sentence-level attention to form a content representation (Yang et al., 2016). The attention coefficients are computed based on the dot product between a non-linearly transformed weight vector of the hidden state and an "informative" vector, which encodes "what is the most informative word (or sentence)" in the sequence. This "informative" vector is commonly treated as a sequence of weights (Yang et al., 2016; Kumar et al., 2018; Hassan et al., 2018), trained along with other weights in the network. We applied parallelled word-level attention on the title and each sentence in the content. The attention coefficient and the final representation of a sequence is calculated as (taking words in title as an example):

$$c_t = \sum_i \alpha_i h_i = \sum_i \frac{\exp(v_{wt} \bullet v_i)}{\sum_j \exp(v_{wt} \bullet v_j)} h_i \tag{1}$$

where $v_i = \tanh(W_t h_i + b_t)$ is the output of a fully-connected layer of the hidden state h_i for each word in the title, v_{wt} is the "informative" vector for titles, and c_t is the resulting title representation. We can compute each sentence representation c_s and the content representation c_a in a similar manner (see Figure 1).

2.2 Title-guided Sentence-level Attention

The attention mechanisms above do not capture the interaction between the title and content of the document. Title represents highly abstract while important information about the topics of a document. Selection of the important sentences in the content should conform to the document's general topic, e.g. title. We can thus model the title-guided sentence-level attention as:

$$c_{ta} = \sum_{r} \alpha_r h_r = \sum_{r} \frac{\exp(c_t \bullet v_r)}{\sum_k \exp(c_t \bullet v_k)} h_r \tag{2}$$

where $v_r = \tanh(W_s h_r + b_s)$ is a fully connected layer with the hidden state of the rth sentence h_r as input and c_t is the title representation obtained from Equation 1.

Guiding sentence reading through title representation facilitates content understanding, but may lead to an overemphasis on the title in the annotation. In fact, the content itself, carrying more terms, conveys detailed information not covered by the title and may help suggest further tags for annotation (Figueiredo et al., 2013). We thus concatenate the title guided content representation c_{ta} and the content representation c_a from the original sentence-label attention, to form a more comprehensive representation of the content. The final content representation is then concatenated with the title representation $c_d = [c_t, c_{ta}, c_a]$. In the experiment, we will show the effectiveness of this design against several variations of the model.

2.3 Semantic-based Loss Regularisers

Users tend to annotate documents collectively with semantically related tags. Two major semantic relations in user-generated tags are similarity and subsumption (Stock, 2010; Peters, 2009). To deal with this label correlation issue, we propose two loss regularisers jointly learned with the binary cross entropy loss function. The intuition is that the output values of the neural network s_d, having the dimensions as the label space $|T|$, should satisfy semantic relations among labels. Such relations can be inferred from the label sets or observed in external knowledge bases. The whole joint loss is defined as $L = L_{CE} + \lambda_1 L_{sim} + \lambda_2 L_{sub}$. L_{CE} is the binary cross entropy loss adopted for multi-label text classification (Nam et al., 2014). L_{sim} and L_{sub} are defined as:

$$\begin{aligned} L_{sim} &= \frac{1}{2} \sum_{d} \sum_{(j,k)|T_j,T_k \in y_d} Sim_{jk} |s_{dj} - s_{dk}|^2 \\ L_{sub} &= \frac{1}{2} \sum_{d} \sum_{(j,k)|T_j,T_k \in y_d} Sub_{jk} R(s_{dj})(1 - R(s_{dk})) \end{aligned} \tag{3}$$

where y_d is the label set (annotated tags) of the document d. T is a list of all labels, where j and k are the indices of the list T, corresponding to the indices of nodes s_{dj} and s_{dk} in the output layer s_d. $R()$ is the rounding function for binary prediction, $R(s_{dj}) = 0$ if $S_{dj} < 0.5$, otherwise $R(s_{dj}) = 1$.

The similarity matrix $Sim \in (0,1)^{|T|*|T|}$ indicates pairwise similarity between labels, the larger the value of Sim_{jk}, the more similar the labels T_j and T_k are. Each element Sub_{jk} in the subsumption matrix $Sub \in \{0,1\}^{|T|*|T|}$ indicates whether the label T_j is a child label of T_k. Both the Sim and Sub matrix can be inferred from the training data or from external knowledge bases before training. In implementation, Sim (if thresholded) and Sub can be treated as sparse matrix to reduce computational complexity. We also used an adapted version of the loss regularisers in mini-batch training (the same set of label pairs that co-occurred within all documents in the same batch) to further to reduce computational complexity.

The rationale is that the less the difference of the two outputs of the similar labels is, the lower the L_{sim}. On the contrary, for output values not reflecting the label similarity, i.e. large $|s_{dj} - s_{dk}|^2$ when Sim_{jk} is close to 1, the error will be penalised with higher L_{sim}.

Given a document and a subsumption pair of labels, if the child label is used for annotation, its parent label has a relatively higher chance being used as well. In L_{sub}, if a subsumption relation $< T_j \rightarrow T_k >$ presents in the label set y_d, the case that the parent label T_k is predicted as false, i.e. $R(s_{dk}) = 0$, when its child label T_j is predicted as true, i.e. $R(s_{dj}) = 1$, will be penalised. Such a case will result in a positive penalty, while the penalty will be 0 in all other cases.

Thus, L_{sim} constrains similar labels to have similar outputs, while L_{sub} reinforces each co-occurring subsumption pair to satisfy the dependency of the parent label on the child label.

3 Experiments

3.1 Datasets

We evaluate our proposed approach for automated social annotation on two representative open datasets in social tagging, Bibsonomy[1] (academic publication annotation) and Zhihu[2] (general domain social question annotation). For Bibsonomy, we used the cleaned dataset from (Dong et al.,

Table 2: Comparison Results on the Zhihu dataset

2017) and further selected the tags related to Computer Sciences according to the ACM Computing Classification System[3] and selected the document that have both title and abstract (content); for Zhihu, we randomly sampled around 100,000 questions from the original data dump.

The cleaned Bibsonomy dataset has 12,101 documents, 17,619 vocabularies and 5,196 labels; the average number of labels per document is 11.59. The sample Zhihu dataset has 108,168 documents (questions), 62,519 vocabularies and 1,999 labels; the average number of labels per document is 2.45.

3.2 Implementation Details

To calculate Sim, we used cosine similarity, normalised to between 0 and 1, of self-trained skip-gram embedding (Mikolov et al., 2013) on all label sets in each dataset. To obtain Sub, about subsumption relations, for Bibsonomy, we resorted to an external knowledge source Microsoft Concept Graph[4] for label mapping and semantic grounding; for Zhihu, we used the provided crowd-sourced label subsumption relations. We tuned the λ_1 and λ_2 in L based on 10-fold cross-validation[5].

We implemented the proposed Joint Multi-label Attention Network (JMAN) model in Figure 1 on Tensorflow (Abadi et al., 2016) along with the baselines[6] based on brightmart's implementation[7] of TextRNN and HAN under the MIT license. Two strong baselines were chosen **Bi-GRU** (Schuster and Paliwal, 1997; Cho et al., 2014) and **HAN** (Yang et al., 2016; Hassan et al., 2018). Several variations of **JMAN** were also considered: (i) **JMAN-s**, the proposed model without semantic-based loss regularisers; (ii) **JMAN-s-tg**, the proposed model without semantic-based regularisers and title guided sentence-level attention, $c_d = [c_t, c_a]$; (iii) **JMAN-s-att**, the proposed model without semantic-based regularisers and the original sentence-level attention, $c_d = [c_t, c_{ta}]$.

We optimised the joint loss L using the Adam optimiser (Kingma and Ba, 2014) and set the number of hidden units as 100, learning rate as 0.01 and dropout rate as 0.5 (Srivastava et al., 2014) for all models. The batch sizes for Bibsonomy and Zhihu were set as 128 and 1,024, respectively. The sequence lengths of the title (also the length of each sentence) and the content were padded to 30 and 300 for Bibsonomy and 25 and 100 for Zhihu. Non-static input embedding for the title and the sentences were initialised as 100-dimension self-trained skip-gram embedding (Mikolov et al.,

[7] https://github.com/brightmart/text_classification

2013). We decayed the learning rate by half when the loss on validation set increased and set an early stopping point when learning rate is below 2e-5. All experiments were run on a GPU server, NVIDIA GeForce GTX 1080 Ti.

3.3 Results

We report the mean and the standard deviation of the testing results on models trained with 10-fold cross-validation. The cleaned user-generated tags, i.e. labels, for each dataset were taken as the ground truth and the widely used example-based metrics, Precision, Recall and F_1 score (Godbole and Sarawagi, 2004; Tsoumakas et al., 2010; Zhang and Zhou, 2014), were adopted. The average training time per fold was also recorded.

The results with respect to the two datasets are presented in the Table 1 and 2 respectively. Our proposed JMAN model significantly outperforms Bi-GRU and HAN. In terms of F_1, with the Bibsonomy dataset, the proposed JMAN model provides a 7.8% absolute increase (by 25.5%) over Bi-GRU and 4.0% (by 11.6%) over HAN; on the Zhihu dataset, our model is 2.5% absolutely (by 13.4%) better than Bi-GRU and 0.9% (by 4.4%) than HAN. This is mostly attributed to the boost of recall through modeling the title metadata and the title-guided attention mechanism. The JMAN model also converges ("understands") much faster than HAN with around 10.3% (for Bibsonomy) and 18.2% (for Zhihu) less training time per fold and converges even faster than Bi-GRU (by 29.5% and 22.0% for the Bibsonomy and Zhihu dataset in terms of training time, respectively). Recall and F_1 score drop significantly, with training time increased, when the title-guided or the original sentence-level attention is removed. Adding semantic-based loss regularisers further boosts the precision, recall and F_1 of the model.

We also noticed that, compared to the results on the Bibsonomy dataset, the improvement on the Zhihu dataset with the proposed model is less significant. This may be related to the characterstics of the dataset: Zhihu has shorter texts (padded to 1/3 of the Bibsonomy dataset), more vocabularies (over 3 folds), less number of labels (about 40%) and less average number of labels per document (about 1/5) than the Bibsonomy dataset. This would warrant further study on the datasets and on validating the model with datasets from other social media platforms.

4 Conclusion

We proposed a parallelled two-layer attention network for text annotation based on user-generated tags. It models the behaviour how human users read and understand document with the title-guided attention mechanism and leverages label semantics through two loss regularisers to constrain the network outputs. Experimental results show the effectiveness of this method with superior performance and training speed. This system can be applied to various types of social media platforms to support document organisation.

Future studies will explore the possibility of applying the title-guided attention mechanism to other large datasets on major social media platforms. It is also interesting to see whether the semantic-based loss regularisers can be adapted to improve the performance of the recent pre-trained transferable deep learning models, such as the Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018).

Acknowledgments

We thank all the anonymous reviewers for their constructive feedback. The implementation is based on brightmart's TextRNN and Hierarchical Attention Network under the MIT license[8]. Abstract

The advent of micro-blogging sites has paved the way for researchers to collect and analyze huge volumes of data in recent years. Twitter, being one of the leading social networking sites worldwide, provides a great opportunity to its users for expressing their states of mind via short messages which are called tweets. The urgency of identifying emotions and sentiments conveyed through tweets has led to several research works. It provides a great way to understand human psychology and impose a challenge to researchers to analyze their content easily. In this paper, we propose a novel use of a multi-channel convolutional neural architecture which can effectively use different emotion and sentiment indicators such as hashtags, emoticons and emojis that are present in the tweets and improve the performance of emotion and sentiment identification. We also investigate the incorporation of different lexical features in the neural network model and its effect on the emotion and sentiment identification task. We analyze our model on some standard datasets and compare its effectiveness with existing techniques.

1 Introduction

Social networking sites (e.g., Twitter) have become immensely popular in the last decade. User generated content (e.g., blog posts, statuses, tweets etc.) in social media provides a wide range of opinionated, emotional and sentimental content which gives researchers a massive data source to explore. For example, Twitter, being one of the leading social networking giants, provides an online environment that allows people of various backgrounds and locations to share their opinions and views on different matters. As of July 2018, over 500 million tweets are sent per day having over 300 million monthly active users.[1]

There is often a misconception about sentiments and emotions as these subjectivity terms have been used interchangeably (Munezero et al., 2014). Munezero et al. (2014) differentiate these two terms along with other subjectivity terms and provide the computational linguistics community with clear concepts for effective analysis of text. While sentiment classification tasks deal with the polarity of a given text (whether a piece of text expresses positive, negative or neutral sentiment) and the intensity of the sentiment expressed, emotion mining tasks naturally deal with human emotions which in some end purposes are more desirable (Ren and Quan, 2012; Desmet and Hoste, 2013; Mohammad et al., 2015). Detecting emotion and sentiment from noisy twitter data is really challenging due to its nature. Tweets tend to be short in length and have a diverse vocabulary making them harder to analyze due to the limited contextual information they contain. In this study, we are interested in tackling these two tasks with a novel use of a single neural network architecture.

A number of emotion theories are available which suggest different sets of basic emotions. Interestingly, *joy, sadness, anger, fear* and *surprise* are common to all. To the best of our knowledge, the model suggested by Ekman (1999) is the most broadly used emotion model. In this study, we use Ekman's basic emotions together with other sets of emotions (Plutchik, 1984; Shaver et al., 1987).

In early textual emotion mining and sentiment analysis research, the usefulness of using external lexicons along with predefined rules has been demonstrated (Aman and Szpakowicz, 2008; Neviarouskaya et al., 2007; Bandhakavi et al., 2017; Thelwall et al., 2010; Gilbert, 2014). Aman and Szpakowicz (2008) used *Roget's Thesaurus* along with *WordNet-Affect* for fine-grained emotion prediction from blog data. Bandhakavi et al. (2017) propose a unigram mixture model (UMM)

Minneapolis, Minnesota, June 2 - June 7, 2019.

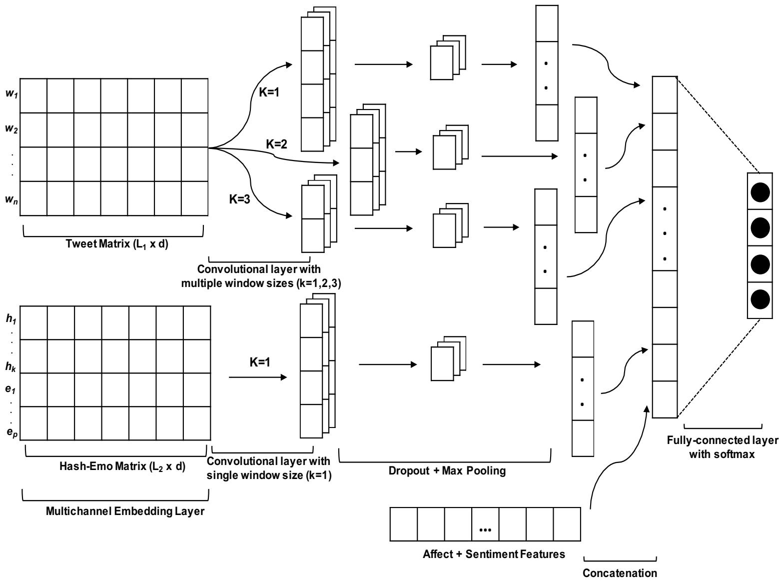

Figure 1: Overview of the MC-CNN model

to create a domain-specific lexicon which performs better in extracting features than Point-wise Mutual Information and supervised Latent Dirichlet Allocation methods. Neviarouskaya et al. (2007) propose a rule-based system which can handle informal texts in particular. They built a database of abbreviations, emoticons, affect words, etc., in which each entry is labeled with an emotion and its intensity. Thelwall et al. (2010) propose an algorithm, *SentiStrength*, which utilizes a dictionary of sentiment words associated with strength measures to deal with short informal texts from social media. Gilbert (2014) propose *VADER*, a rule-based model for sentiment analysis. They built a lexicon which is specially attuned to microblog-like contexts and their model outperforms individual human raters. More recently, deep learning models have proven to be very successful when applied on various text-related tasks (Kim, 2014; Kalchbrenner et al., 2014; dos Santos and Gatti, 2014; Tai et al., 2015; Wang et al., 2016; Felbo et al., 2017; Abdul-Mageed and Ungar, 2017). Kim (2014) showed the effectiveness of a simple CNN model that leverages pre-trained word vectors for a sentence classification task. Kalchbrenner et al. (2014) propose a dynamic CNN model using a dynamic k-max pooling mechanism which is able to generate a feature graph which captures a variety of word relations. They showed the efficacy of their model by achieving high performances on binary and multi-class sentiment classification tasks without any feature engineering. dos Santos and Gatti (2014) propose a deep CNN model that uses both character and word-level information allowing them to achieve state-of-the-art performance on both binary and fine-grained multi-class sentiment classification for one of the twitter datasets. Tai et al. (2015) propose a Tree-LSTM model which captures syntactic properties in text. Their model performs particularly well on sentiment classification. Wang et al. (2016) propose a regional CNN-LSTM model for dimensional sentiment analysis. Their proposed model computes *valence-arousal* ratings from texts and outperforms several regression-based methods. Felbo et al. (2017) propose a bi-directional LSTM model with attention showing that their model learns better representations when distant supervision is expanded to a set of noisy labels. Abdul-Mageed and Ungar (2017) also used distant supervision to build a large twitter dataset and proposed a Gated Recurrent Neural Network model for fine-grained emotion detection.

The recent success of neural based models motivated us to take a different look at the sentiment and emotion prediction from the noisy twitter data task. Compared with sequential models, CNN models train relatively faster and seem to work very well on noisy data such as tweets which are grammatically error-prone. We decided to work with CNN models after our initial experiments suggested that they perform comparatively better than a simple BiLSTM model on twitter dataset. We address the following questions in this paper:

- Can CNN models be used in a way that can improve the performance of detecting emotion and sentiment from noisy Twitter data?
- How important are hashtag words, emoticons and emojis as predictors of emotion and sentiment in micro-blogging sites? How can we encode them in a multi-channel convolutional neural network?
- How can we add external features to a CNN model effectively?

The remainder of the paper is organized as follows: We describe our model architecture in detail in Section 2. In Section 3, we describe the datasets and lexicons used in our experiments. As well, we describe the experimental setup required for working with Twitter data. In Section 4, we discuss the results from our experiments. In Section 5, we discuss our findings with particular attention paid to answering the above questions. Finally, in Section 6, we give a summary of our work followed by our remarks on future studies.

2 Multi-channel CNN Model

We represent the architecture of our model in Fig. 1. The model consists of an embedding layer with two channels, a convolution layer with different kernel sizes and multiple filters, a dropout layer for regularization, a max pooling layer, multiple hidden layers and a softmax layer. We now describe each of these layers in detail.

2.1 Embedding Layer

In this layer, two embedding matrices, the Tweet Matrix and the Hash-Emo Matrix, are passed through two different channels of our convolutional neural network. The first matrix represents a particular tweet. Each tweet t_i consists of a sequence of tokens $w_1, w_2, \ldots, w_{n_i}$. L_1 is the maximum tweet length. The height of the Tweet Matrix is L_1. Short tweets are padded using zero padding.

In the Tweet Matrix, every word is represented as a d-dimensional word vector. Since tweets are usually noisy, short in length, and have different kinds of features other than text, it's useful to have a word embedding specially trained on a large amount of Tweet data (Tang et al., 2014). Previous research (Collobert et al., 2011; Socher et al., 2011) has shown the usefulness of using pre-trained word vectors to improve the performance of various models. As a result, in our experiments, we have used the publicly available pre-trained `GloVe` word vectors for Twitter by (Pennington et al., 2014a). The word vectors are trained on 27B word tokens in an unsupervised manner.

In this layer, we also pass another matrix called the Hash-Emo Matrix through a different channel in our network. This matrix is composed of three different sets of features: hashtags, emoticons and emojis. These are considered as distinguishable traits to showcase one's mood (Zhao et al., 2012). People like to use hashtags to express their emotional state through various micro-blogging sites (e.g., Twitter) (Qadir and Riloff, 2014). Also graphical emoticons or emojis can convey strong emotion or sentiment. So for each tweet t_i, we extract hashtags $h_1, h_2, \ldots, h_{k_i}$ and emoticons/emojis $e_1, e_2, \ldots, e_{p_i}$. We concatenate the hashtags and emoticon/emoji vectors for each tweet t_i to get the Hash-Emo Matrix. We introduce a hyper-parameter L_2 as a threshold on the height of the Hash-Emo Matrix. Tweets with the number of hash-emo features less than L_2 are padded with zero while tweets with more hash-emo features than L_2 are truncated. We use word vectors from `GloVe` with dimension d for hashtags words. In the case that no word vector is found for a particular word we randomly initialize it. We also do random initialization of word vectors for emoticons. For emojis, we first map it to something descriptive (to be discussed in more detail in Section 3.2) and then generate random word vectors. These word vectors are tuned during the training phase.

2.2 Convolutional Layer

In this layer, we apply m filters of varying window sizes over the Tweet Matrix from the embedding layer. Here, window size (k) refers to the number of adjacent word vectors in the Tweet Matrix that are filtered together (when $k > 1$). Sliding our filter down we repeat this for the rest of the word vectors. Let $w_i \in \mathbb{R}^d$ be the d-dimensional word vector corresponding to the i-th word in a tweet. Also let $w_{i:i+j}$ denote the concatenation of word vectors $w_i, w_{i+1}, \ldots, w_{i+j}$ and $F \in \mathbb{R}^{k \times d}$ denote the filter matrix. Thus a feature f_i is generated by:

$$f_i = F \otimes w_{i:i+k-1} + b \tag{1}$$

where b is a bias term and $\otimes$ represents the convolution action (a sum over element-wise multiplications). At this stage, we apply a nonlinear activation function such as *ReLU* (Nair and Hinton, 2010) before passing it through the dropout layer. We use multiple filters with the same window size in order to learn complementary features from the same window. Different window sizes (k) allow us to extract active local k-gram features.

For the Hash-Emo Matrix, we apply m filters to each vector to generate local unigram features in different scales before passing it to the next layer.

2.3 Pooling Layer

In this layer, employing a max-over pooling operation (Collobert et al., 2011) on the output from the previous layer for each channel extracts the most salient features. In this way, for each filter, we get the maximum value. So we get features equal to the number of filters in this stage. We chose max pooling instead of other pooling schemes because Zhang and Wallace (2017) showed that max pooling consistently performs better than other pooling strategies for various sentence classification tasks.

2.4 Hidden Layers

We concatenate all the feature vectors from the previous layer. In addition, we concatenate additional sentiment and affect feature vectors (which are described in detail in Section 3.2) as well which forms a large feature vector. This is then passed through a number of hidden layers. A non-linear activation function (i.e., ReLU (Nair and Hinton, 2010)) is applied in each layer before the vector is finally passed through the output layer. We tried a different activation function (tanh) as well, but ReLU worked the best for us.

2.5 Output Layer

This is a fully connected layer which maps the inputs to a number of outputs corresponding to the number of classes we have. For multi-class classification task, we use softmax as the activation function and categorical cross-entropy as the loss function. The output of the softmax function is equivalent to a categorical probability distribution which generally indicates the probability that any of the classes are true. For binary classification task, we use sigmoid as the activation function and binary cross-entropy as our loss function.

3 Experiments

In this section, we describe in detail the datasets and experimental procedures used in our study.

Table 1: (a) Basic statistics of the emotion datasets used in our experiments. (b) Basic statistics of sentiment labeled datasets used in our experiments.

3.1 Datasets

We used a number of emotion and sentiment datasets for our experiments. A description of each dataset is given below:

BTD. Big Twitter Data is an emotion-labeled Twitter dataset provided by Wang et al. (2012). The dataset had been automatically annotated based on the seven emotion category seed words (Shaver et al., 1987) being a hashtag and the quality of the data was verified by two annotators as described in (Wang et al., 2012). We were only able to retrieve a portion of the original dataset as many tweets were either removed or not available at the time we fetched the data using the Twitter API. We applied the heuristics from (Wang et al., 2012) to remove any hashtags from the tweets which belong to the list of emotion seed words.

TEC. Twitter Emotion Corpus has been published by Mohammad (2012) for research purposes. About 21,000 tweets were collected based on hashtags corresponding to Ekman's (1999) six basic emotions. The dataset has been used in related works (Shahraki and Zaiane, 2017; Balahur, 2013; Mohammad and Kiritchenko, 2015).

CBET. The Cleaned Balanced Emotional Tweet dataset is provided by Shahraki and Zaiane (2017). To the best of our knowledge, this is one of the largest publically available balanced datasets for twitter emotion detection research. The dataset contains 80,937 tweets with nine emotion categories including Ekman's six basic emotions.

SE. The SemEval-2018 Task 1 - Affect dataset was provided by Mohammad et al. (2018). The SemEval task was to estimate the intensity of a given tweet and its corresponding emotion. However, in this study, we utilize the labeled dataset only to classify the tweets into four emotion categories and use the training, development and test sets provided in this dataset in our experiments.

STS-Gold. This dataset was constructed by Saif et al. (2013) for Twitter sentiment analysis. The dataset contains a total of 2,034 tweets labeled (positive/negative) by three annotators. This dataset has been extensively used in several works for model evaluation (Saif et al., 2014b; Krouska et al., 2017; Saif et al., 2014a).

STS. The Stanford Twitter Sentiment dataset was introduced by Go et al. (2009). It consists of a training set and a test set. The training set contains around 1.6 million tweets, whereas the test set contains 498 tweets. The training set was built automatically based on several emoticons as potential identifiers of sentiment. However, the test set was manually annotated and heavily used for model evaluation in related research. We perform one experiment with all three labels (positive/negative/neutral) to compare the performance of different variants of our model and another one with two labels (positive/negative) to make comparison with related works (Jianqiang et al., 2018; dos Santos and Gatti, 2014; Go et al., 2009).

SS-Twitter. The Sentiment Strength Twitter dataset was constructed by Thelwall et al. (2012) to evaluate SentiStrength. The tweets were manually labeled by multiple persons. Each tweet is assigned a number between 1 and 5 for both positive and negative sentiments, 1 represents weak sentiment strength and 5 represents strong sentiment strength. We followed the heuristics used by Saif et al. (2013) to obtain a single sentiment label for each tweet, giving us a total of $4,242$ positive, negative and neutral tweets. The transformed dataset has been used in other literature (Go et al., 2009; Zhang et al., 2018).

We provide basic statistics of the datasets used in our experiments in Table 1.

3.2 Experimental Setup

Data Cleaning. Twitter data is unstructured and highly informal (Yoon et al., 2013) and thus it requires a great deal of effort to make it suitable for any model. NLTK (Bird and Loper, 2004) provides a regular-expression based tokenizer for Twitter, TweetTokenizer, which preserves user mentions, hashtags, urls, emoticons and emojis in particular. It also reduces the length of repeated characters to three (i.e. "Haaaaaapy" will become "Haaapy")". In our experiments, we utilized the TweetTokenizer to tokenize tweets.

To accommodate the pretrained word vectors from (Pennington et al., 2014b), we pre-processed each tweet in a number of ways. We lowercased all the letters in the tweet. User mentions have been replaced with <user> token (i.e. @username1 will become <user>). In addition, we also removed urls from the tweets as urls do not provide any emotional value. We also normalized certain negative words (e.g., "won't" will become "will not"). Using slang words is a very common practice in social media. We compiled a list of the most common slang words from various online resources[2] and replaced all of the occurrences with their full form (e.g., "nvm" will become "never mind"). Our list of slang words doesn't contain any word which has multiple meanings. Usage of certain punctuation is often crucial in social media posts as it helps the user to emphasize certain things. We found that two punctuation symbols (! and ?) are common among social media users to express certain emotional states. We kept these symbols in our text and normalized the repetitions (e.g., "!!!" will become "! <repeat>").

The use of emojis and emoticons has increased significantly with the advent of various social media sites. Emoticons (e.g., :-D) are essentially a combination of punctuation marks, letters and numbers used to create pictorial icons which generally display an emotion or sentiment. On the other hand, emojis are pictographs of faces, objects and symbols. The primary purpose of using emojis and emoticons is to convey certain emotions and sentiments (Dresner and Herring, 2010). One advantage of using the TweetTokenizer is that it gives us emoticons and emojis as tokens. Though we use the emoticons as is in our experiment, we utilize a python library called "emoji" to get descriptive details about the pictorial image. For example, "☺" represents *"smiling_face"*.

In our experiments, we removed stop-words and replaced numbers occurring in the tweets with the token <number>. We also stripped off "#" symbols from all the hashtags within the tweets (e.g.,

"#depressed" will become "depressed") and used the stripped version of hashtags on the second channel of our model. We only kept tokens with more than one character.

Input Features. Along with word embeddings, we used additional affect and sentiment features in our network. In our experiments, we used a feature vector V_f where each value in the vector corresponds to a particular lexical feature ranging between $[0, 1]$. We utilized a number of publicly available lexicons which are described briefly below to construct the vector.

Warriner et al. (2013) provides a lexicon consisting of 14,000 English lemmas with valence, arousal and dominance scores. Three components of emotion are scored for each word between 1 and 9 in this lexicon. We calculate the average score for each component across all tokens in a tweet and normalize them in the range [0, 1]. Gilbert (2014) provides a list of lexical features along with their associated sentiment intensity measures. We use this lexicon to calculate the average of positive, negative, and neutral scores over all the tokens in a tweet. In addition, we used the *NRC Emotion Lexicon* provided by Mohammad and Turney (2013) which consists of a list of unigrams and their association with one of the emotion categories (anger, anticipation, disgust, fear, joy, sadness, surprise, trust). We use the percentage of tokens belonging to each emotion category as features. We also used the *NRC Affect Intensity Lexicon* provided by Mohammad and Bravo-Marquez (2017) and *NRC Hashtag Emotion Lexicon* provided by Mohammad and Kiritchenko (2015) which contain real-valued fine-grained word-emotion association scores for words and hashtag words.

We combined two lexicons *MPQA* and *BingLiu* provided by Wilson et al. (2005) and Hu and Liu (2004), respectively, and used them to calculate the percentage of positive and negative tokens belonging to each tweet. We also used *AFINN* (Nielsen, 2011) which contains a list of English words rated for valence with an integer between −5 (negative) to +5 (positive). We first normalized the scores in the range [0,1] and then calculated the average of this score over all the tokens in a tweet. Lastly, we detect the presence of consecutive exclamation (!) and question marks (?) in a tweet and use them as boolean features.

Network Parameters and Training. Zhang and Wallace (2017) performed a sensitivity analysis on various parameters of a one-layer CNN model and showed how tuning the parameters can affect the performance of a model. Inspired by the work done by (Zhang and Wallace, 2017), we also searched for the optimal parameter configurations in our network. Table 3 shows different hyper-parameter configurations that we tried and the final configuration that was used in our model. The final configuration was based on both performance and training time. The embedding dimension has been set to 100 for both channels of our network as it worked best for us among other dimensions. We also experimented with a different number of fil-

ters and varying kernel sizes. The combination of kernel sizes, $(k = 1, 2, 3)$ in the first channel and $k = 1$ in the second channel worked the best for us. We also experimented with various batch sizes and the performance of the model remained reasonably constant, though the training time varied significantly. In our network, we used three hidden layers. In addition, we used the Adam optimizer (Kingma and Ba, 2014) and the back-propagation (Rumelhart et al., 1986) algorithm for training our model. Keras 2.2.0 was used for implementing the model.

Regularization. In order to reduce overfitting, it is a common practice to employ regularization strategies in CNNs. In our experiments, we used dropout regularization (Srivastava et al., 2014) for both of the channels after the convolutional layer. We experimented with three different dropout rates as seen in Table 3 and also with no dropout at all. The model works better when we apply dropouts after the convolutional layer.

4 Results

In this section, we describe the results obtained in our experiments. We use precision, recall, F1-score and accuracy as our evaluation metrics.

In recent emotion category recognition studies on Twitter data, people tend to construct their own dataset by collecting tweets from Twitter for their experiments. Hence, it is hard to find a large enough benchmark dataset to compare the performance with other people's work. In this study, we experimented with four emotion labeled datasets which have been made publicly available by their authors. Table 2 shows the results for each emotion category for all of the datasets. For the BTD dataset, we trained our model with $1,136,305$ tweets, while we used $140,979$ and $142,602$ tweets as development and test data respectively. We used the same training, development and test sets as (Wang et al., 2012) except that our retrieved dataset contains fewer samples. We achieved relatively high F1-scores of $\mathbf{72.6\%}, \mathbf{73.6\%}$ and $\mathbf{76.8\%}$ for *joy, sadness* and *anger*, respectively, whereas for *surprise* we get a low F1-score of $\mathbf{27.1\%}$. This is probably due to the imbalanced nature of the dataset as can be seen in Table 1. The number of samples for *joy, sadness* and *anger* is much higher than for *surprise*. Our model achieves an accuracy of $\mathbf{69.2\%}$, whereas Wang et al. (2012) reported an accuracy of $\mathbf{65.6\%}$ when trained on a much larger dataset. We can not make direct comparison with (Wang et al., 2012) since we were not able to retrieve the full test set due to the unavailability of some tweets at the time of fetching data from Twitter. For the TEC dataset, we evaluated our model with 10-fold cross validation. Mohammad (2012) reported an F1-score of $\mathbf{49.9\%}$ with SVM, whereas our model achieves an F1-score of $\mathbf{55.6\%}$. For the CBET dataset, we used 80% of the data as the training set and the remaining 20% as the test set. We get an average F1-score of $\mathbf{56.5\%}$. We also used 10-fold cross-validation for the SemEval dataset and achieved an F1-score of $\mathbf{61.3\%}$. Table 4 shows the performance of our model with 10-fold cross-

validation on different sentiment datasets with two classes (positive and negative). For the STS-Gold dataset, our model achieves an accuracy of $\mathbf{90.7\%}$ whereas the previous best accuracy ($\mathbf{86.0\%}$) was reported by Jianqiang et al. (2018) with a deep CNN model. Our model achieves the best accuracy ($\mathbf{90.3\%}$) for the STS-Test dataset as well, while the previous best ($\mathbf{87.6\%}$) was reported in (Jianqiang et al., 2018). dos Santos and Gatti (2014) also experimented with the same dataset with their Character to Sentence CNN model, reporting an accuracy of $\mathbf{86.4\%}$. Lastly, for the SS-Twitter dataset, our model achieves an accuracy of $\mathbf{79.3\%}$ whereas Zhang et al. (2018) and Saif et al. (2013) reported an accuracy of $\mathbf{61.9\%}$ and $\mathbf{73.4\%}$, respectively.

Tables 5 and 6 show the performance of three variants of our model on the sentiment labeled datasets and the emotion labeled datasets respectively. The first variant is a basic CNN model without hash-emo embedding or any additional features. The second variant includes the hash-emo embedding, while the last variant combines additional lexical features as well. It can be observed that when we introduce the second channel with hash-emo embedding, we get a significant increase in accuracy for most of the datasets. We can see in Table 5 that, for STS-Test and SS-Twitter datasets, we get better F1-scores for all three sentiment labels when we include the hash-emo embedding along with external lexical features. In Table 6, we can see that, inclusion of hash-emo embedding in the network gives us $\mathbf{2.4}, \mathbf{3.3}, \mathbf{2.3}$ and $\mathbf{3.5}$ percentage points increase in accuracy and the inclusion of additional features as well gives us $\mathbf{3.1}, \mathbf{4.6}, \mathbf{2.6}$ and $\mathbf{5.7}$ percentage points increase in accuracy for BTD, TEC, CBET and SE datasets, respectively, over the base models.

Models	Dataset

5 Discussion

In this study, we have showed the effectiveness of encoding hashtags, emoticons and emojis through a separate channel in a CNN network for emotion and sentiment detection tasks. Our MC-CNN model with hash-emo embedding performs well when compared to the basic CNN model. To the best of our knowledge, our model achieves the best accuracies on the three sentiment datasets, and has significant improvement in performance on the four emotion labeled datasets over the basic CNN model. The results show the importance of hashtags, emoticons and emojis in social media as predictors of emotion and sentiment. The model performs even better when additional lexical features are introduced into the network.

6 Conclusions and Future Work

In this paper, we propose a novel use of a multi-channel convolutional neural architecture which effectively encodes different types of emotion indicators which are found in social media posts. Results suggest that encoding the emotion indicators through a separate channel provides significant improvement over the traditional CNN based models. We also demonstrate a simple approach to incorporate different lexical features in the network giving us comparatively better results when used along with our MC-CNN model. Our model performs particularly well on two important tasks in social media: emotion detection and sentiment analysis. This model can be extended to perform other tasks as well. In future, we would like to explore character embedding as this can give us crucial linguistic features from noisy twitter data.

Abstract

It is very critical to analyze messages shared over social networks for cyber threat intelligence and cyber-crime prevention. In this study, we propose a method that leverages both domain-specific word embeddings and task-specific features to detect cyber security events from tweets. Our model employs a convolutional neural network (CNN) and a long short-term memory (LSTM) recurrent neural network which takes word level meta-embeddings as inputs and incorporates contextual embeddings to classify noisy short text. We collected a new dataset of cyber security related tweets from Twitter and manually annotated a subset of 2K of them. We experimented with this dataset and concluded that the proposed model outperforms both traditional and neural baselines. The results suggest that our method works well for detecting cyber security events from noisy short text.

1 Introduction

Twitter has become a medium where people can share and receive timely messages on about anything. People share facts, opinions, broadcast news and communicate with each other through these messages. Due to the low barrier to tweeting, and growth in mobile device usage, tweets might provide valuable information as people often share instantaneous updates such as the breaking news before even being broadcasted in the newswire *c.f.* Petrović et al. (2010). People also share cyber security events in their tweets such as zero day exploits, ransomwares, data leaks, security breaches, vulnerabilities *etc*. Automatically detecting such events might have various practical applications such as taking the necessary precautions promptly as well as creating self-awareness as illustrated in Fig. 1. Recently, working with the cyber security related text has garnered a lot of interest in both computer security and natural language processing (NLP) communities (*c.f.* Joshi et al. (2013); Ritter et al. (2015); Roy et al. (2017)). Nevertheless, detecting cyber security events from tweets pose a great challenge, as tweets are noisy and often lack sufficient context to discriminate cyber security events due to length limits. Recently, deep learning methods have shown to be outperforming traditional approaches in several NLP tasks (Chen and Manning, 2014; Bahdanau et al., 2014; Kim, 2014; Hermann et al., 2015). Inspired by this progress, our goal is to detect cyber security events in tweets by learning domain-specific word embeddings and task-specific features using neural architectures. The key contribution of this work is two folds. First, we propose an end-to-end learning system to effectively detect cyber security events from tweets. Second, we propose a noisy short text dataset with annotated cyber security events for unsupervised and supervised learning tasks. To our best knowledge, this will be the first study that incorporates domain-specific meta-embeddings and contextual embeddings for detecting cyber security events.

> Dear @AppleSupport, we noticed a *HUGE* security issue at MacOS High Sierra. Anyone can login as "root" with empty password after clicking on login button several times. Are you aware of it @Apple?

Figure 1: A cyber security event. A recently discovered security issue has been reported on Twitter which caught public attention. A security fix has been published right afterward.

2 Method

In the subsequent sections, we address the challenges to solve our task. The proposed system overview is illustrated in Fig. 2.

Minneapolis, Minnesota, June 2 - June 7, 2019.

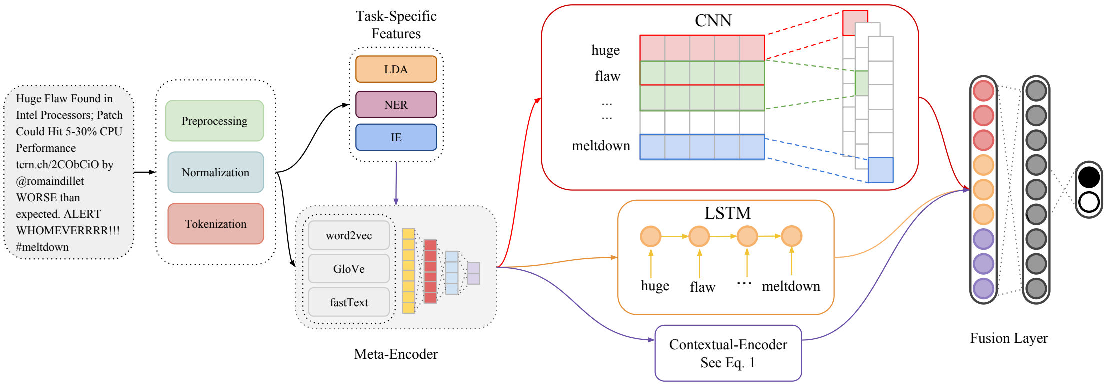

Figure 2: System Overview. A tweet is first pre-processed, then task-specific features and word level meta-embeddings are extracted to represent tokens. Finally, a Bi-LSTM, CNN, and Contextual Encoder are fused to classify the encoded tweet.

2.1 Meta-Embeddings

Word embedding methods might capture different semantic and syntactic features about the same word. To exploit this variety without losing the semantics, we learn meta-embeddings for words.

Word Embeddings. Word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and fastText (Joulin et al., 2016; Bojanowski et al., 2016) are trained for learning domain specific word embeddings on the unlabeled tweet corpus.

Meta-Encoder. Inspired by Yin and Schütze (2015) we learn meta-embeddings for words with the aforementioned word embeddings. We use a Convolutional Autoencoder (Masci et al., 2011) for encoding $3xD$ size embeddings to a $1xD$ dimensional latent variable and to reconstruct the original embeddings from this latent variable. Both encoder and decoder are comprised of 2 convolutional layers where 32 neurons are used on each. The encoder part is shown in Fig. 3. We argue that this network learns a much simpler mapping while capturing the semantic and syntactic relations from each of these embeddings, thus leading to a richer word-level representation. Another advantage of learning meta-embeddings for words is that the proposed architecture alleviates the Out-of-Vocabulary (OOV) embeddings problem, as we still get embeddings from the fastText channel, in contrast to GloVe and word2vec, where no embeddings are available for OOV words.

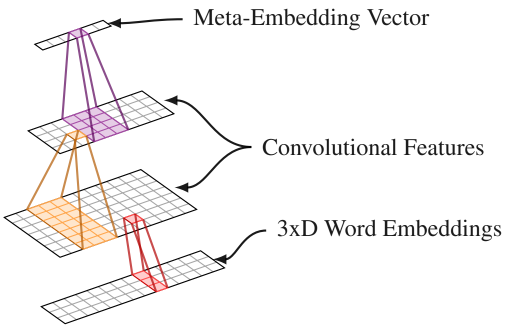

Figure 3: Convolutional encoder as a feature extractor. The decoder is symmetric to the encoder, and in inference time we drop the decoder and use only the encoder network.

2.2 Contextual Embeddings

To capture the contextual information, we learn task-specific features from tweets.

LDA. Latent Dirichlet Allocation (LDA) is a generative probabilistic model to discover topics from a collection of documents (Blei et al., 2003). LDA works in an unsupervised manner and learns a finite set of categories from a collection, thus represents documents as mixtures of topics. We train an LDA model to summarize each tweet by using the topic with the maximum likelihood *e.g.* with the topic “vulnerability” for the tweet in Fig 1.

NER. Named Entity Recognition (NER) tags the specified named entities from raw text into predefined categories. Named entities could be more general categories such as people, organizations, or specific entities can be learned by creating a dataset containing specific entity tags. We employ an automatically annotated dataset that contains entities from cyber security domain (Bridges et al., 2013) to train our Conditional Random Field model using handcrafted features, *i.e.*, uni-gram, bi-gram, and gazetteers. The dataset comprises of 850K tokens that contain named entities such as ‘Relevant Term’, ‘Operating System’,‘Hardware’, ‘Software’, ‘Vendor’, in the standard IOB-tagging format. Our NER model tags “password” as ‘Relevant Term’ and “Apple” as ‘Vendor’ for the tweet in Fig 1.

IE. Uncovering entities and the relations between those entities is an important task for detecting cyber security events. In order to address this we use Information Extraction (IE), in particular OpenIE annotator(Angeli et al., 2015) from the Stanford CoreNLP (Manning et al., 2014). Subsequently, we extract relations between noun phrases with the following dependency triplet $\langle arg_1, rel, arg_2 \rangle$, where arg_1, arg_2 denote the arguments and rel represents an implicit semantic relation between those arguments. Hence, the following triplet is extracted from the tweet in Fig. 1, $\langle we, noticed, huge\ security\ issue \rangle$.

Contextual-Encoder. We use the outputs of LDA, NER and IE algorithms to obtain a combined vector representation using meta-embeddings described in Sec. 2.1. Thus, contextual embeddings are calculated as follows[1].

$$\gamma(\tau) = \frac{f(\varphi(\tau)) + \sum_{i=1}^{N} f(\varsigma(\tau)^i) + \sum_{j=1}^{M} f(\delta(\tau)^j)}{N + M + 1} \quad (1)$$

where γ function extracts contextual embeddings and τ denotes a tweet, f, φ, ς and δ represent meta-embedding, LDA, NER, and IE functions, respectively. Lastly, N and M denote the output tokens.

2.3 Event Detection

Inspired by the visual question answering task (Antol et al., 2015), where different modalities are combined by CNNs and RNNs, we adopt a similar network architecture for our task. Prior to training, and inference we preprocess, normalize and tokenize each tweet as described in Sec. 3.

CNN. We employ a CNN model similar to that of (Kim, 2014) where we feed the network with static meta-embeddings. Our network is comprised of one convolutional layer with varying filter sizes, that is $2, 3, 5$. All tweets are zero padded to the maximum tweet length. We use $ReLU$ as activation and global max pooling at the end of CNN.

RNN. We use a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) and read the input in both directions and concatenate forward and backward hidden states to encode the input as a sequence. Our LSTM model is comprised of a single layer and employs 100 neurons.

3 Experiments

Data Collection. We collected $2.5M$ tweets using the Twitter's streaming API over a period from `2015-01-01` to `2017-12-31` using an initial set of keywords, henceforth referred as *seed keywords* to retrieve cyber security related tweets. In particular, we use the main group names of cyber security taxonomy described in Le Sceller et al. (2017) as seed keywords e.g. 'denial of service', 'botnet', 'malware', 'vulnerability', 'phishing', 'data breach' to retrieve relevant tweets. Using seed keywords is a practical way to filter out noise considering sparsity of cyber security related tweets in the whole tweet stream. After the initial retrieval, we use `langid.py` (Lui and Baldwin, 2012) to filter out non-English tweets.

Data Preprocessing. We substitute user handles with $\$mention\$$, and hyperlinks with $\$url\$$. We remove *emoticons* and reserved keyword RT which denotes retweets. We substitute hashtags by removing the prefix # character. We limit characters that repeat more than two times, remove capitalization and tokenize tweets using the Twitter tokenizer in `nltk` library. We normalize non-standard forms, *i.e.* writing *cu tmrrw* instead of *see you tomorrow*. Although there are several reasons for that, the most prominent one is that people tend to mimic prosodic effects in speech (Eisenstein, 2013). To overcome this, we use lexical normalization, where we substitute OOV tokens with in-Vocabulary (IV) standard forms, *i.e.* a standard form available in a dictionary. In particular we use UniMelb (Han et al., 2012), UTDallas (Liu et al., 2011) datasets. Lastly, we remove identical tweets and check the validity by removing tweets with less than 3 non-special tokens.

Data Annotation. We instructed cyber security domain experts for manual labelling of the dataset. Annotators are asked to provide a binary label for whether there is a cyber security event in the given tweet or not. Annotators are told to skip tweets if they are unsure about their decisions. Finally, we validated annotations by only accepting annotations if at least 3 among 4 annotators agreed on. Therefore, we presume the quality of attained ground truth labels is dependable. Overall, $2K$ tweets are annotated.

Dataset Statistics. After preprocessing, our initial $2.5M$ tweet dataset is reduced to $1.7M$ tweets where $2K$ of them are labeled[2]. The labeled dataset is somewhat balanced as there are 843 event-related tweets and 1157 non-event tweets. The training and testing sets have 1600 and 400 samples, respectively.

---

[1] We used zero vectors for the non-existent relations.

[2] Available at `http://stmai.github.io/cydec`

Training. We used Keras with Tensorflow backend in our neural models. For fastText and word2vec embeddings we used Gensim, and for GloVe we used `glove-python` library. For training the word embeddings, we use the entire tweet text corpus and obtain 100 dimensional word embeddings. We set word2vec and fastText model's alpha parameter to 0.025 and window size to 5. For GloVe embedding model, we set the learning rate to 0.01, alpha to 0.75 and maximum count parameter to 100. For embedding models, we determined the minimum count parameter to 5, culminating in the elimination of infrequent words. Consequently, we have 3, 100-dimensional word embedding tensor in which first, second and third channels consist of word2vec, fastText and GloVe embeddings respectively. We then, encode these $3x100$ dimensional embeddings into $1x128$ dimensional representations by using our Meta-Encoder. We train our two channel architecture that combines both LSTM and CNN with 2 inputs: meta-embeddings and contextual embeddings. We use meta-embeddings for feature learning via LSTM and CNN, and their feature maps are concatenated with contextual embeddings in the Fusion Layer. In the end, fully connected layers and a softmax classifier are added, and the whole network is trained to minimize binary cross entropy loss with a learning rate of 0.01 by using the Adam optimizer (Kingma and Ba, 2014).[3]

Baselines. To compare with our results, we implemented the following baselines: `SVM with BoW`: We trained an SVM classifier using Bag-of-words (BoW) which provides a simplified representation of textual data by calculating the occurrence of words in a document. `SVM with meta-embeddings`: We trained an SVM classifier with the aforementioned meta-embeddings. `CNN-Static`: We used Kim (2014)'s approach using word2vec embeddings.

Results. Table 1 summarizes the overall performance of each method. To compare the models, we used four different metrics: accuracy, recall, precision and F1-score. Each reported result is the mean of a 5-fold cross validation experiment. It is clear that our method outperforms various simple and neural baselines. Also, in Table 2, we provide results of our proposed model along with the ground-truth annotations. We also provide results with the different combinations of contextual features, i.e., LDA, NER, IE[4].

Models	Accuracy	Precision	Recall	F1
SVM+BoW	0.75	0.71	0.70	0.70
SVM+Meta-Emcoder	0.71	0.64	0.61	0.63
CNN-static (Yoon Kim, 2014)	0.76	0.72	0.69	0.70
Human	0.65	0.70	0.87	0.59
CNN+Meta-Encoder	0.78	0.78	0.63	0.70
LSTM+Meta-Encoder	0.78	0.74	0.70	0.72
Ours (see Fig. 2)	**0.82**	**0.79**	**0.72**	**0.76**

Table 1: Results

Human Study. 8 different subjects are thoroughly instructed about what is considered as a cyber security event and individually asked to label 50 randomly selected tweets from the test set. The results are provided in Table 3.

Error Analysis. In order to understand how our system performs, we randomly select a set of erroneously classified instances from the test dataset.

Type I Errors. Our model identifies this tweet as an event "uk warned following breach in air pollution regulation \$url\$" whereas it is clearly about the a breach of a regulation. We hypothesize that this is due to the lack of sufficient training data. Following tweet is also identified as an event "wannacry ransomware ransomwareattack ransomwarewannacry malware \$url\$". We suspect that the weights of multiple relevant terms deceive the model.

Type II Errors. Our model fails to identify the following positive sample as an event. For "playstation network was the target of miraibotnet ddos attack guiding tech rss news feed search" our model fails to recognize the 'miraibotnet' from the tweet. We suspect this is due to the lack of hashtag decomposition; otherwise, the model could recognize 'mirai' and 'botnet' as separate words.

Discussions. Cyber security related tweets are complicated and analysing them requires in-depth domain knowledge. Although human subjects are properly instructed, the results of the human study indicate that our task is challenging and humans can hardly discriminate cyber security events amongst cyber security related tweets. To further investigate this, we plan to increase the number of human subjects. One limitation of this study is that we do not consider hyperlinks and user handles which might provide additional information. One particular problem we have not addressed in this work is hashtag decomposition. Error analysis indicates that our model might get confused by challenging examples due to ambiguities and lack of context.

4 Related Work

Event detection on Twitter is studied extensively in the literature (Petrović et al., 2010; Sakaki et al., 2010; Weng and Lee, 2011; Ritter et al., 2012; Yuan et al., 2013; Atefeh and Khreich, 2015). Banko et al. (2007) proposed a method to extract relational tuples from web corpus without requiring hand labeled data. Ritter et al. (2012) proposed a method for categorizing events in Twitter. Luo et al. (2015) suggested an approach to infer binary relations produced by open IE systems. Recently, Ritter et al. (2015) introduced the first study to extract event mentions from a raw Twitter stream for event categories DDoS attacks, data breaches, and account hijacking. Chang et al. (2016) proposed an LSTM based approach which learns tweet level features automatically to extract events from tweet mentions. Lately, Le Sceller et al. (2017) proposed a model to detect cyber security events in Twitter which uses a taxonomy and a set of seed keywords to retrieve relevant tweets. Tonon et al. (2017) proposed a method to detect events from Twitter by using semantic analysis. Roy et al. (2017) proposed a method to learn domain-specific word embeddings for sparse cyber security text. Prior art in this direction (Ritter et al., 2015; Chang et al., 2016) focuses on extracting events and in particular predicting the events' posterior given the presence of particular words. Le Sceller et al. (2017); Tonon et al. (2017) focus on detecting cyber security events from Twitter. Our work distinguishes from prior studies as we formulate cyber security event detection problem as a classification task and learn meta-embeddings from domain-specific word embeddings while incorporating task-specific features and employing neural architectures.

5 Conclusion

We introduced a novel neural model that utilizes meta-embeddings learned from domain-specific word embeddings and task-specific features to capture contextual information. We present a unique dataset of cyber security related noisy short text collected from Twitter. The experimental results indicate that the proposed model outperforms the traditional and neural baselines. Possible future research direction might be detecting cyber security related events in different languages.

Abstract

Adversarial examples are important for understanding the behavior of neural models, and can improve their robustness through adversarial training. Recent work in natural language processing generated adversarial examples by assuming white-box access to the attacked model, and optimizing the input directly against it (Ebrahimi et al., 2018). In this work, we show that the knowledge implicit in the optimization procedure can be distilled into another more efficient neural network. We train a model to emulate the behavior of a white-box attack and show that it generalizes well across examples. Moreover, it reduces adversarial example generation time by 19x-39x. We also show that our approach transfers to a black-box setting, by attacking The Google Perspective API and exposing its vulnerability. Our attack flips the API-predicted label in 42% of the generated examples, while humans maintain high-accuracy in predicting the gold label.

1 Introduction

Adversarial examples (Goodfellow et al., 2014) have gained tremendous attention recently, as they elucidate model limitations, and expose vulnerabilities in deployed systems. Work in natural language processing (NLP) either (a) used simple heuristics for generating adversarial examples (Jia and Liang, 2017; Belinkov and Bisk, 2017; Iyyer et al., 2018), or (b) assumed white-box access, where the attacker has access to gradients of the model with respect to the input (Feng et al., 2018; Ebrahimi et al., 2018). In this approach, adversarial examples are constructed through an optimization process that uses gradient descent to search for input examples that maximally change the predictions of a model. However, developing attacks with only black-box access to a model (no access to gradients) is still under-explored in NLP.

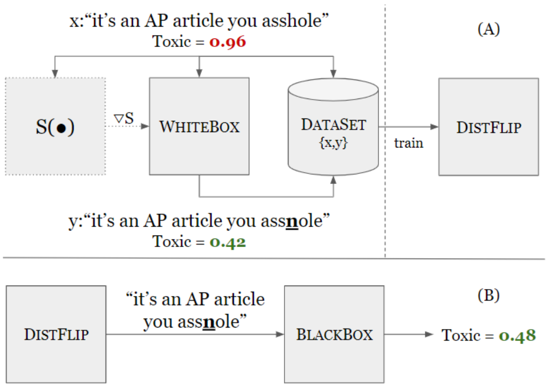

Figure 1: (A) Using a white-box attack we generate adversarial examples for a source toxicity model $S(\cdot)$. We train our black-box attacker, DISTFLIP, to emulate the white-box attack. (B) We use DISTFLIP to attack a black-box model.

Inspired by work in computer vision (Papernot et al., 2016; Liu et al., 2017), we show in this work that a neural network can learn to emulate the optimization process of a white-box attack and generalize well to new examples. Figure 1 gives a high-level overview of our approach. We assume a text classification model and a white-box attack that flips characters in the input to modify the model prediction (Ebrahimi et al., 2018). We generate output adversarial examples using the white-box attack and train a neural network from these input-output examples to imitate the white-box attack. This results in a much more efficient attack whose run-time is independent of the optimization process. Moreover, assuming adversarial examples transfer between different models, our distilled model can now be used to generate adversarial examples for black-box attacks directly.

We use our approach to attack a toxicity classifier, aimed at detecting toxic language on social media (Hosseini et al., 2017). We show that our model achieves a speed-up of 19x-39x in generating adversarial examples while maintaining similar attack quality, compared to an optimization-based

method. We then use our model for a black-box attack against Google Perspective API for detecting toxic sentences, and find that 42% of our generated sentences are misclassified by the API, while humans agree that the sentences are toxic.

Our code can be downloaded from `http://github.com/orgoro/white-2-black`.

2 Background

Adversarial examples have been extensively used recently in NLP for probing and understanding neural models (Jia and Liang, 2017; Weber et al., 2018). Methods for generating such examples include adding random or heuristically constructed noise (Belinkov and Bisk, 2017; Rodriguez and Rojas-Galeano, 2018; Gao et al., 2018), meaning-preserving modifications that change the surface form (Iyyer et al., 2018; Ribeiro et al., 2018), and human-in-the-loop generation (Wallace et al., 2018). A weakness of such models is that they do not directly try to modify the prediction of a model, which can reduce efficacy (Kurakin et al., 2016). In the white-box setting, Feng et al. (2018) have changed the meaning of an input without changing model output using access to gradients, and Ebrahimi et al. (2018) proposed HOTFLIP, the aforementioned white-box attack that we emulate for flipping input characters.

In computer vision, Papernot et al. (2016) and Liu et al. (2017) have shown that adversarial examples generated by a white-box model can be helpful for a black-box attack. Generating adversarial text examples is more challenging than adversarial images, because images are points in a continuous space, and thus it is easier to apply norm restrictions. Text examples have a discrete structure and thus such approaches have not been investigated for adversarial text generation yet.

3 HOTFLIP

HOTFLIP (Ebrahimi et al., 2018) is a white-box method for generating adversarial examples for a character-level neural model. It uses the gradient with respect to a 1-hot input representation to estimate the character flip that incurs the highest cost. We briefly describe HOTFLIP, which we use to generate training examples for our distilled model.

Let $\mathrm{x} = ((x_1^1, \ldots, x_1^n), \ldots, (x_m^1, \ldots, x_m^n))$ be a sentence represented as a sequence of m characters, encoded as 1-hot vectors over a vocabulary of size n. Define $L(\mathrm{x}, y)$ to be the loss of a trained model for the input x with respect to a label y.

HOTFLIP requires one function evaluation (forward pass) and one gradient computation (backward pass) to compute a first-order estimate of the best possible character flip in x. Flipping the i^{th} character from a to b can be represented by this vector: $\overrightarrow{v_{i_b}} = (\ldots, (0, \ldots, -1, \ldots, 1, \ldots, 0)_i, \ldots)$, where -1 and 1 are in the positions for the a^{th} and b^{th} characters respectively. A first-order estimate of the change in loss can be obtained by computing $\nabla_x L(\mathrm{x}, y)$ with back-propagation, and taking a directional derivative along $\overrightarrow{v_{i_b}}$:

$$\nabla_{\overrightarrow{v_{i_b}}} L(\mathrm{x}, y) = \nabla_x L(\mathrm{x}, y) \cdot \overrightarrow{v_{i_b}}.$$

We can now choose the character-flip a to b that maximizes this estimate using the gradients with respect to the input x:

$$\arg\max_{i,b} [\nabla L(\mathrm{x}, y) \cdot \overrightarrow{v_{i_b}}] = \arg\max_{i,b} [\frac{\partial L}{\partial x_i^b} - \frac{\partial L}{\partial x_i^a}].$$

To perform a sequence of flips, any search procedure can be applied. HOTFLIP uses beam search of r steps, keeping at each step the top-K flip sequences that increased $L(\mathrm{x}, y)$ the most. This require $O(K \cdot r)$ forward and backward passes. Character insertions and deletions are modeled as multiple flips, but for simplicity, we only consider *character flips* in our work.

The main drawbacks of HOTFLIP are that it does not gain any knowledge from optimizing over multiple examples, and that its efficiency is strongly tied to the search procedure used ($O(K \cdot r)$ forward and backward passes per example for beam-search). Next, we present our model that overcomes these limitations.

4 Distilling a Black-box Attack

We are interested in whether (a) the knowledge in the optimization process of HOTFLIP can be distilled into a neural model, and (b) whether this model can generalize to a black-box attack. Therefore, the outline of our approach is as follows:

1. Train a *source text classification model* on data from a similar distribution to the data used to train the *target black-box model*.
2. Generate adversarial examples by performing white-box optimization (with HOTFLIP) on the source model.
3. Train an efficient *attacker* to generate adversarial examples, and perform a black-box attack against the target model.

We assume a training set $\mathcal{D} = \{(\mathrm{x_i}, y_i)\}_{i=1}^{N}$ used to train a character-based source model $S(\cdot)$ that takes a character sequence x as input, and returns a distribution over the output space $\mathcal{Y}$ (details on the source model are in Section 5). We now elaborate on the processes of data generation and training of the attacker.

Data generation We take examples (x, y) from $\mathcal{D}$ and run HOTFLIP with search until we obtain an adversarial example $\bar{\mathrm{x}}$ such that the probability of the gold label is low, that is, $[S(\bar{\mathrm{x}})]_y < \tau$, where $[S(\bar{\mathrm{x}})]_y$ is the probability given by $S(\bar{\mathrm{x}})$ to $y \in \mathcal{Y}$ and τ is a threshold (we use $\tau = 0.15$).

Let $s = ((\mathrm{x}^{(0)} = \mathrm{x}), \mathrm{x}^{(1)}, \dots, (\mathrm{x}^{(l)} = \bar{\mathrm{x}}))$ be the sequence of sentences generating $\bar{\mathrm{x}}$, where every consecutive pair $(\mathrm{x}^{(\mathrm{i})}, \mathrm{x}^{(\mathrm{i}+1)})$ differs by a single character: the character in position $j^{(i)}$ was flipped to the character $c^{(i)}$. Our attacker is trained from examples $(\mathrm{x}^{(\mathrm{i})}, (j^{(i)}, c^{(i)}))$ generated from every pair of consecutive sentences in s. For example, if the sentence is the one-word sentence "Asshole", and after flipping one character it becomes "Assnole", the example would be ("Asshole", (4, 'n')).

Model training Our attacker takes a character sequence x as input and outputs a pair (j^*, c^*), where $j^* \in [1, \dots, m]$ is the position of the character to be flipped, and c^* is the target character.

Figure 2 describes the architecture of our model.

Our model embeds each character using a pre-trained 300-dimensional character embedding[1], and then passes the character sequence through a 1-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with 512-dimensional hidden states. The BiLSTM h_j hidden state in every position are passed through two feed-forward networks, one for replacement prediction (which character to flip) and one for target prediction (what target character to choose). The network that perfoms replacement prediction has 2 hidden layers of dimensions 100 and 50 with ReLU activations, and a single logit l_j as output per position. The output distribution over the sentence positions is given by a softmax over all character positions. At inference time j^* is computed with an argmax instead of a softmax.

The network that produces target prediction has two-hidden layers of dimensions 100 and 100 with ReLU activations and outputs a vector of logits $v_j \in \mathbb{R}^{96}$ per position with a softmax layer, which provides a distribution over the character vocabulary. The target character c^* is computed at inference time with an argmax over the target position $\mathrm{x}_{\mathrm{j}^*}$.

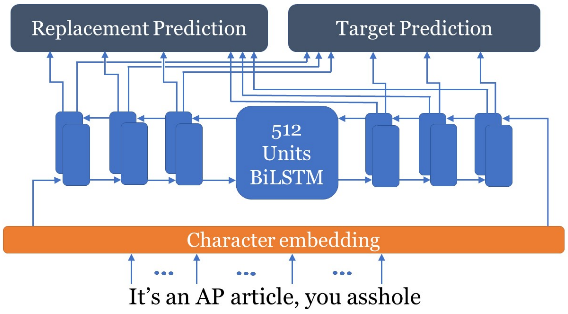

Figure 2: The architecture of our attacker network.

Our loss function is simply the sum of two cross-entropy terms: one for the gold position, and one for the gold character in the gold position.

Running our model is more efficient that HOTFLIP and run-time is independent of the optimization procedure. A forward pass in our model is equivalent to $2 \cdot K$ steps in HOTFLIP with beam-search. We show this leads to large practical speed-ups in Section 5.

5 Experiments

We now empirically investigate whether our method can be used to attack classifiers for detecting "toxic" language on social media. Recently a challenge by Alphabet aimed to improve labeling of toxic comments that are rude and disrespectful. Alphabet released a dataset[2] of 160K comments from Wikipedia discussions, and classified each comment to six labels. We focus on the *Toxic* label only, which represents 9.5% of the dataset.

We used the dataset to train the source model $S(\cdot)$, which runs a 2-layer bidirectional GRU (Cho et al., 2014) over the input x, and then uses an attention (Bahdanau et al., 2015) pooling layer to obtain a fixed dimensional vector for x. This vector is passed through a feed-forward layer to compute the probability that x is toxic. The accuracy of the source model is 96.5% AUC – comparable to the top submissions in the challenge.

We used the 13,815 toxic-labeled sentences from the training set to generate adversarial examples for training the attacker as described above. Dataset

---

[1] `https://github.com/minimaxir/char-embeddings/blob/master/glove.840B.300d-char.txt`

[2] `https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/data`

generation depends on the search procedure, and we experiment with 3 setups: (a) HOTFLIP-5: beam-search with K=5, (b) HOTFLIP-10: beam-search with K=10, and (C) HOTFLIP+: a more expensive search procedure that calls $S(\cdot)$ more frequently. We describe the details of this procedure in Appendix A. Because our attacker is independent of the search procedure, inference time is not affected by the search procedure at data generation time. This results in three distilled models: DISTFLIP-5, DISTFLIP-10, and DISTFLIP+.[3]

Attacking the source model We compare the performance of DISTFLIP variants against HOTFLIP variant, including HOTFLIP-1 (K=1). We also compare to a RANDOM baseline, which chooses a position and target character randomly, and to an ATTENTION baseline, which uses the attention layer of $S(\cdot)$ to choose the character position with maximum attention to flip, and selects a target character randomly.

Table 1 summarizes our results. We report the average number of flips required to change the prediction of toxic sentences in the source model, the slow-down per single character-flip, and the slow-down per attack, which is computed by multiplying slow-down per flip by the ratio of the number of flips required per attack. Because roughly 15% of the examples in the dataset mostly contain repeated profanities that require many flips, we also report the average number of flips for the other 85% of the examples.

We observe that HOTFLIP+ requires the fewest flips to change model prediction, but attacks are very slow. The number of flips per attack for DISTFLIP+ is comparable to HOTFLIP-5 and HOTFLIP-10, but it achieves a speed-up of 19x-39x. DISTFLIP-5 and DISTFLIP-10 require a few more flips compared to DISTFLIP+. Overall attack quality is high, with less than two flips necessary for 85% of the examples for DISTFLIP+.

Figure 3 provides a more fine-grained view of the results by showing the proportion of sentences classified as toxic as a function of the number of flips. Overall, the picture is similar to Table 1, with DISTFLIP+ being comparable to HOTFLIP-10.

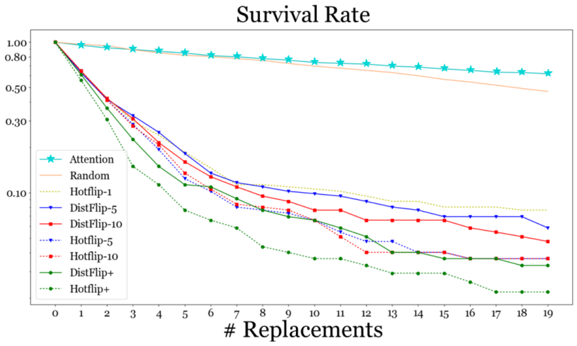

Figure 3: Proportion of sentences classified as toxic as a function of the number of flips for all models on the test set.

Attacking The Google Perspective API The Google perspective API[4] returns the probability that a sentence is toxic, where probability > 0.7 is classified as *toxic*, < 0.3 is *non-toxic*, and otherwise *uncertain*. The model itself is not publicly available. We randomly selected 136 toxic examples from the validation set and attacked them with DISTFLIP+ until the source model probability was < 0.5.

We measured the toxicity probability before and after our attack and found that the average toxicity probability decreased from 0.9 to 0.67, with an average of 5.0 flips per sentence. The label is flipped from *toxic* to *uncertain* or *non-toxic* in 42% of these examples.

Human validation To validate that toxic sentences remain toxic after our attack, we showed 5 independent annotators a total of 150 sentences from three classes: toxic sentences, non-toxic sentences, and attacked sentences (attacked by DISTFLIP-5). The same annotator was never shown a toxic sentence and its attacked counterpart. We asked annotators whether sentences are toxic, and measured average annotated toxicity.

We found that 89.8% of the toxic sentences were annotated as toxic, compared to 87.6% in the attacked toxic sentences. This shows that humans clearly view the sentences as toxic, even after our attack. Table 2 shows examples for sentences attacked by DISTFLIP-10 and the change in toxicity score according to The Google Perspective API.

6 Conclusion

In this work we present a general approach for distilling the knowledge in any white-box attack into a trained model. We show that this results in substantial speed-up (19x-39x) while maintaining comparable quality. Moreover, we show that our

A Appendix: HotFlip+

Algorithm 1 describes the search procedure of HOTFLIP+. The main motivation behind this search procedure is that HOTFLIP uses gradients to estimate the character-flip that maximally changes the predictions of a model, but this estimate is not guaranteed to be correct. In HOTFLIP+ we try to overcome this limitation by performing pruning with gradients, and then actually evaluating a larger number of possible flips by running the source model on many possible flips. This makes the search procedure slower, because we have to run the source model (forward pass) much more frequently. For this algorithm we use beam size 3.

In Algorithm 1, the *toxicity score* of a sentence is the result of running it through the source model, and the *beam score* is the first-order estimate described in Section 3.

Algorithm 1 HotFlip+

```
procedure HOTFLIP+(sentence)
    beam ← Initialize beam with the original sentence and its toxicity score.
    while True do
        $bf, tox$ ← Pop from the beam the flipped sentence with lowest toxicity, and its toxicity.
        if $tox < 0.5$ then
            $break$
        create a new beam.
        for every beam entry in the current beam do
            compute all possible flipped sentences and their beam score (as in HOTFLIP).
            for $flip\_sent, flip\_score$ in flipped sentences do
                $min\_score$ ← minimal beam score on the beam.
                if $flip\_score > min\_score$ then                ▷ Prune using beam score
                    $tox$ ← Compute the toxicity of $flip\_sent$ with a forward pass.
                    $max\_tox\_in\_beam$ ← Pop from the new beam the maximal toxicity score.
                    if $tox < max\_tox\_in\_beam$ then
                        push $flip\_sent, flip\_score, tox$ to the new beam.
    return $bf$
```

Analyzing the Perceived Severity of Cybersecurity Threats Reported on Social Media

Abstract

Breaking cybersecurity events are shared across a range of websites, including security blogs (FireEye, Kaspersky, etc.), in addition to social media platforms such as Facebook and Twitter. In this paper, we investigate methods to analyze the severity of cybersecurity threats based on the language that is used to describe them online. A corpus of 6,000 tweets describing software vulnerabilities is annotated with authors' opinions toward their severity. We show that our corpus supports the development of automatic classifiers with high precision for this task. Furthermore, we demonstrate the value of analyzing users' opinions about the severity of threats reported online as an early indicator of important software vulnerabilities. We present a simple, yet effective method for linking software vulnerabilities reported in tweets to Common Vulnerabilities and Exposures (CVEs) in the National Vulnerability Database (NVD). Using our predicted severity scores, we show that it is possible to achieve a Precision@50 of 0.86 when forecasting high severity vulnerabilities, significantly outperforming a baseline that is based on tweet volume. Finally we show how reports of severe vulnerabilities online are predictive of real-world exploits.[1]

1 Introduction

Software vulnerabilities are flaws in computer systems that leave users open to attack; vulnerabilities are generally unknown at the time a piece of software is first published, but are gradually identified over time. As new vulnerabilities are discovered and verified they are assigned CVE numbers (unique identifiers), and entered into the National Vulnerability Database (NVD).[2] To help prioritize response efforts, vulnerabilities in the NVD are assigned severity scores using the Common Vulnerability and Scoring System (CVSS). As the rate of discovered vulnerabilities has increased in recent years,[3] the need for efficient identification and prioritization has become more crucial. However, it is well known that a large time delay exists between the time a vulnerability is first publicly disclosed to when it is published in the NVD; a recent study found that the median delay between the time a vulnerability is first reported online and the time it is published in the NVD is seven days; also, 75% of threats are first disclosed online giving attackers time to exploit the vulnerability.[4]

[redacted]

Just tested the Dirty COW vulnerability. Nasty. Especially when thinking about all the devices that will never be patched, like in the IoT.

3:26 PM - 28 Oct 2016

Figure 1: Example tweet discussing the dirty copy-on-write (COW) security vulnerability in the Linux kernel.

In this paper we present the first study of whether natural language processing techniques can be used to analyze users' opinions about the severity of software vulnerabilities reported online. We present a corpus of 6,000 tweets annotated with opinions toward threat severity, and empirically demonstrate that this dataset supports automatic classification. Furthermore, we propose a simple, yet effective method for linking software vulnerabilities reported on Twitter to entries in the NVD, using CVEs found in linked URLs. We then use our threat severity analyzer to conduct a large-scale study to validate the accuracy of users' opinions online against experts' severity

ratings (CVSS scores) found in the NVD. Finally, we show that our approach can provide an early indication of vulnerabilities that result in real exploits in the wild as measured by the existence of Symantec virus signatures associated with CVEs; we also show how our approach can be used to retrospectively identify Twitter accounts that provide reliable warnings about severe vulnerabilities.

Recently there has been increasing interest in developing NLP tools to identify cybersecurity events reported online, including denial of service attacks, data breaches and more (Ritter et al., 2015; Chang et al., 2016; Chambers et al., 2018). Our proposed approach in this paper builds on this line of work by evaluating users *opinions* toward the severity of cybersecurity threats.

Prior work has also explored forecasting software vulnerabilities that will be exploited in the wild (Sabottke et al., 2015). Features included structured data sources (e.g., NVD), in addition to the volume of tweets mentioning a list of 31 keywords. Rather than relying on a fixed set of keywords, we analyze message content to determine whether the author believes a vulnerability is severe. As discussed by Sabottke et al. (2015), methods that rely on tracking keywords and message volume are vulnerable to adversarial attacks from Twitter bots or sockpuppet accounts (Solorio et al., 2013). In contrast, our method is somewhat less prone to such attacks; by extracting users' opinions expressed in individual tweets, we can track the provenance of information associated with our forecasts for display to an analyst, who can then determine whether or not they trust the source of information.

2 Analyzing Users' Opinions Toward the Severity of Cybersecurity Threats

Given a tweet t and named entity e, our goal is to predict whether or not there is a serious cybersecurity threat towards the entity based on context. For example, given the context in Figure 2, we aim at predicting the severity level towards *adobe flash player*. We define an author's perceived severity toward a threat using three criteria: (1) does the author believe that their followers should be worried about the threat? (2) is the vulnerability easily exploitable? and (3) could the threat affect a large number of users? If one or more of these criteria are met, then we consider the threat to be severe.

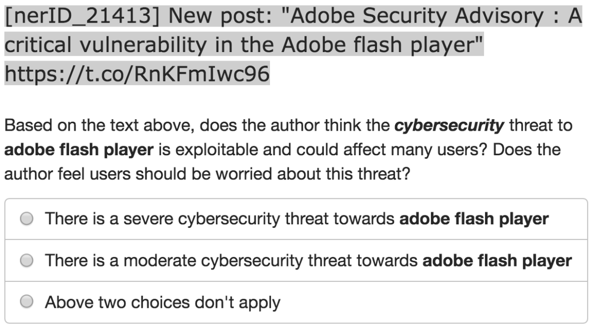
2.1 Data Collection

To collect tweets describing cybersecurity events for annotation, we tracked the keywords "ddos" and "vulnerability" from Dec 2017 to July 2018 using the Twitter API. We then used the Twitter tagging tool described by Ritter et. al. (2011) to extract named entities,[5] retaining tweets that contain at least one named entity. To cover as many linguistic variations as possible, we used Jaccard similarity with a threshold of 0.7 to identify and remove duplicated tweets with same date.[6]

2.2 Mechanical Turk Annotation

We paid crowd workers on Amazon Mechanical Turk to annotate our dataset. The annotation was performed in two phases; during the first phase, we asked workers to determine whether or not the tweet describes a cybersecurity threat toward a target entity, in the second phase the task is to determine whether the author of the tweet believes the threat is severe; only tweets that were judged to express a threat were annotated in the second phase. Each HIT contained 10 tweets to be annotated; workers were paid $0.20 per HIT. In pilot studies we tried combining these two annotations into a single task, but found low inter-rater agreement, especially for the threat severity judgments, motivating the need for separation of the annotation procedure into two tasks.

Figure 2 shows a portion of the annotation interface presented to workers during the second phase of annotation. Details of each phase are described below, and summarized in Table 1.



[nerID_21413] New post: "Adobe Security Advisory : A critical vulnerability in the Adobe flash player" https://t.co/RnKFmIwc96

Based on the text above, does the author think the ***cybersecurity*** threat to **adobe flash player** is exploitable and could affect many users? Does the author feel users should be worried about this threat?

○ There is a severe cybersecurity threat towards **adobe flash player**

○ There is a moderate cybersecurity threat towards **adobe flash player**

○ Above two choices don't apply

Figure 2: A portion of the annotation interface shown to MTurk workers during the threat severity annotation.

Threat existence annotation: Not all tweets in our dataset describe cybersecurity threats, for example many tweets discuss different senses of the

---

[5] https://github.com/aritter/twitter_nlp

[6] We sampled a dataset of 6,000 tweets to annotate.

Anno. Tweets Total	1st Annotation (5 workers per tweet)			2nd Annotation (10 workers per tweet)		
	Label	# Tweets	%	Label	# Tweets	%
6,000	With threat	2,543 (1,966 for 2nd anno.)	42.4	Severe threat	506	25.7
				Moderate threat	1,460	74.3
	Without threat	3,457	57.6	/		

Table 1: Number of annotated tweets with break-down percentages to each category. In 1st annotation, a tweet contains a threat if more than 3 workers vote for it. In 2nd annotation, a threat is severe if more than 6 workers agree on it. Number of workers cut-offs are determined by comparing to our golden annotations in pilot studies.

word "vulnerability" (e.g., "It's OK to show vulnerability"). During the first phase of our annotation process, workers judged whether or not there appears to be a cybersecurity threat towards the target entity based on the content of the corresponding tweet. We provide workers with 3 options: the tweet indicates (a) a cybersecurity threat towards given entity, (b) a threat, but not towards the target entity, or (c) no cybersecurity threat. Each tweet is annotated by 5 workers.

Threat severity annotation: In the second phase, we collect all tweets judged to contain threats by more than 3 workers in the first phase and annotated them for severity. 1,966 tweets were selected out of 6,000.[7] For each tweet we provided workers with 3 options: the tweet contains (a) a severe, (b) a moderate or (c) no threat toward the target entity. During our pilot study, we found this to be a more challenging annotation task, therefore we increased the number of annotators per tweet to 10 workers, which we found to improve agreement with our expert judgments.

Inter-annotator agreement: During both phases, we monitored the quality of workers' annotations using their agreement with each other. We calculated the annotation agreement of each worker against the majority vote of other workers. We manually removed data from workers who have an agreement less than 0.5, filling in missing annotations with new workers. We also manually removed data from workers who answered either uniformly or randomly for all HITs.

Agreement with expert judgments: To validate the quality of our annotated corpus we compared the workers' aggregated annotations against our own expert annotations. We independently annotated 150 randomly sampled tweets, 61 tweets of which are marked as containing severe or moderate threats. For threat existence annotation, we observe a 0.66 value of Cohen's κ (Artstein and Poesio, 2008) between the expert judgements and majority vote of 5 crowd workers. Although our threat severity annotation task may require some cybersecurity knowledge for accurate judgment, we still achieve 0.52 Cohen κ agreement by comparing majority vote from 10 workers with expert annotations.

2.3 Analyzing Perceived Threat Severity

Using the annotated corpus described in Section 2.2, we now develop classifiers that detect threats reported online and analyze users' opinions toward their severity. Specifically, given a named entity and tweet, $\langle e, t\rangle$, our goal is to estimate the probability the tweet describes a cybersecurity threat towards the entity, $p_{\text{threat}}(y|\langle e, t\rangle)$ and also the probability that the threat is severe, $p_{\text{severe}}(y|\langle e, t\rangle)$. In this section, we describe the details of these classifiers and evaluate their performance.

We experimented with two baselines to detect reports of cyberthreats and analyze opinions about their severity: logistic regression using bag-of-ngram features, and 1D convolutional neural networks. In the sections below we describe the input representations and details of these two models.

Logistic regression: We use logistic regression as our first baseline model for both classifiers. Input representations are bag-of-ngram features extracted from the entire tweet content. Example features are presented in Table 4. We use context windows of size 2, 3 and 4 to extract features. We map extracted n-grams that occur only once to a $\langle\texttt{UNK}\rangle$ token. In all our experiments, we replace named entities with a special token $\langle\texttt{TARGET}\rangle$; this helps prevent our models from biasing towards specific entities that appear in our training corpus. All digits are replaced with 0.

---

[7] We further deduplicate pairs of tweets where the longest common subsequence covers the majority of the text contents. During deduplication all hashtags and URLs were removed and digits were replaced with 0.

Convolutional neural networks: We also experimented with 1D convolutional neural networks (Collobert et al., 2011; Kim, 2014). Given a tweet, the model first applies convolutional operations on input sequences with various filters of different sizes. The intermediate representations for each filter are aggregated using max-pooling over time, followed by a fully connected layer. We choose convolution kernel sizes to be 3, 4 and 5-grams with 100 filters for each. We minimize cross-entropy loss using Adam (Kingma and Ba, 2015); the learning rate is set to 0.001 with a batch size of 1 and 5 epochs.

Word embeddings: We train our own cybersecurity domain word embeddings based on GloVe (Pennington et al., 2014), as 39.7% of our tokens are treated as OOV words in GloVe pre-trained Twitter embeddings. We used a corpus of 609,470 cybersecurity-related tweets (described in Section 2.1) as our training corpus. The dimension of word embeddings is 50. Table 2 shows nearest neighbors for some sampled cybersecurity terms based on the learned embeddings.

During network training, we initialize word embedding layer with our own embeddings. We initialize tokens not in our trained embeddings by randomized vectors with uniform distribution from -0.01 to 0.01. We fine-tune the word embedding layer during training.

Token	Nearest Neighbors
#ddos	attacks, ddos, datacenter-insider, attack, #cyberattack
#hackers	hackers, sec_cyber, #blackberryz00, #malware, #hacking
threats	defenses, cyberrisk, #cybersecurity, threat, #iot-based
vulnerability	risk, ..., #vulnerability, strength, critical

Table 2: Nearest neighbors to some cybersecurity related tokens in our trained word embeddings. Embeddings are trained by using GloVe. Similar tokens are sorted by cosine similarity scores.

2.3.1 Experimental Setup

For threat existence classification, we randomly split our dataset of 6,000 tweets into a training set of 4,000 tweets, a development set of 1,000 tweets, and test set of 1,000 tweets. For the threat severity classifier, we only used data from 2nd phase of annotation. This dataset consists of 1,966 tweets that were judged by the mechanical turk workers to describe a cybersecurity threat towards the target entity. We randomly split this dataset into a training set of 1,200 tweets, a development set of 300 tweets, and a test set of 466 tweets. We collapsed the three annotated labels into two categories based on whether or not the author expresses an opinion that the threat towards the target entity is severe.

2.3.2 Results

Threat existence classifier: The logistic regression baseline has good performance at identifying threats, which we found to be a relatively easy task; area under the precision-recall curve (AUC) on the development and test set presented in Table 5. This enables accurate detection of trending threats online by tracking cybersecurity keywords using the Twitter streaming API, following an approach that is similar to prior work on entity-based Twitter event detection (Ritter et al., 2012; Zhou et al., 2014; Wei et al., 2015). Table 3 presents an example of threats detected using this procedure on Nov. 22, 2018.[8]

Threat severity classifier: Figure 3 shows precision recall curves for the threat severity classifiers. Logistic regression with bag-of-ngram features provides a strong baseline for this task. Table 4 presents examples of high-weight features from the logistic regression model. These features often intuitively indicate severe threats, e.g. “critical vulnerability”, “a massive”, “million”, etc. Without much hyperparameter tuning on the development set, the convolutional neural network consistently achieves higher precision at the same level of recall as compared to logistic regression. We summarize the performance of our threat existence and severity classifiers in Table 5.

3 Forecasting Severe Cybersecurity Threats

In Section 2 we presented methods that can accurately detect threats reported online and analyze users’ opinions about their severity. We now explore the effectiveness of this model for forecasting. Specifically, we aim to answer the following questions: **(1)** To what extent do users’ opinions about threat severity expressed online align with expert judgments? **(2)** Can these opinions provide an early indicator to help prioritize threats based

on their severity?

A large corpus of users' opinions: We follow the same procedure described in Section 2.1 to prepare another dataset for a large-scale evaluation. For this purpose, we collected data from Jan 2016 to Nov 2017; this ensures no tweets overlap with those that were annotated in Section 2.2. We collect all English tweets that explicitly contain the keyword "vulnerability" within this time period, which results in a total number of 976,180 tweets. 377,468 tweets remain after removing tweets without named entities.

National Vulnerability Database (NVD): NVD is the U.S. government database of software vulnerabilities. Started in 2000, NVD covers over 100,000 vulnerabilities, assigning a unique CVE number for each threat. These CVE numbers serve as common identifiers. NVD uses the Common Vulnerability Scoring System (CVSS) to measure the severity of threats. CVSS currently has two versions: CVSS v2.0 and CVSS v3.0 standards. CVSS v3.0 is the latest version released in July 2015. We summarize the two standards in Table 6.[9]

Severity	Base Score	Severity	Base Score
		None	0.0
Low	0.0-3.9	Low	0.1-3.9
Medium	4.0-6.9	Medium	4.0-6.9
High	7.0-10.0	High	7.0-8.9
		Critical	9.0-10.0

Table 6: Qualitative severity rankings of vulnerabilities in NVD. (Left) CVSS v2.0 standards and (Right) CVSS v3.0 standards.

Matching tweets with NVD records: Evaluating our forecasts of high severity vulnerabilities

---

[9] https://nvd.nist.gov/vuln-metrics/cvss

relies on accurately matching tweets describing vulnerabilities to their associated NVD records. To achieve this we present a simple, yet effective method that makes use of content in linked webpages. We find that 82.4% of tweets contain external urls in our dataset.

Our approach to link tweets to CVEs is to search for CVE numbers either in url addresses or in corresponding web pages linked in tweets reporting vulnerabilities.[10] We ignore web pages that contain more than one unique CVE to avoid potential ambiguities. Using this approach, within our dataset, 79,383 tweets were linked to 10,565 unique CVEs. In order to stimulate a forecasting scenario, we only consider CVEs where more than two associated tweets were posted at least 5 days ahead of official NVD publication date. In our dataset, 13,942 tweets are finally selected for forecast evaluation, covering 1,409 unique CVE numbers. To evaluate the accuracy of this linking procedure, we randomly sampled 100 matched pairs and manually checked them. We find the precision of our matching procedure to be very high: only 2 mismatches out of 100 are found.

3.1 Forecasting Models

Now that we have a linking between tweets and CVE numbers, our goal is to produce a sorted list of CVEs with those that are indicated to be severe threats the top. We consider two ranking procedures, detailed below; the first is based on users' opinions toward the severity of a threat, and the second is a baseline that simply uses the volume of tweets describing a specific vulnerability to measure its severity. To simplify the exposition below, we denote each CVE number as CVE_i, and the collection of tweets linked to this CVE number as $T_{\text{CVE}_i} = \{k | \text{tweet } t_k \text{ is mapped to } \text{CVE}_i\}$.

Our model: Our severe threat classifier assigns a severity score $p_{\text{severity}}(y|\langle e, t\rangle)$ for each tuple of name entity e and corresponding tweet t. For a specific CVE, we define our severity forecast score to be the maximum severity scores among all tuples from matched tweets $\langle \cdot, t_k\rangle$ (a single tweet may contain more than one name entity):

$$(\text{CVE}_i)_{\text{forecast score}} = \max_{k \in T_{\text{CVE}_i}} p_{\text{severity}}(y|\langle \cdot, t_k\rangle).$$

Tweet volume baseline: Intuitively, the number of tweets and retweets can indicate people's concern about a specific event. Specifically, the severity for threat CVE_i according to the volume model is defined by the cardinality of T_{CVE_i}:

$$(\text{CVE}_i)_{\text{volume score}} = |T_{\text{CVE}_i}|.$$

3.2 Forecasting CVSS Ratings

In our first set of experiments, we compare our forecasted threat severity scores against CVSS ratings from the NVD. We define a threat as being severe if its CVSS score is ≥ 7.0. This cut-off corresponds to qualitative severity ratings provided by CVSS (marked as HIGH or CRITICAL in Table 6).[11] We use the newest v3.0 scoring system, which was developed to improve v2.0.[12] Large software vendors have announced of the adaptation of the CVSS v3.0 standards, including Cisco, Oracle, SUSE Linux, and RedHat.

We evaluate our models' performance at identifying severe threats five days ahead of the NVD publication date, within their top k predictions. Table 7 shows our results. We observe that tweet volume performs better than a random baseline; having a large number of tweets beforehand is a good indicator for high severity, however our approach which analyzes the content of messages discussing software vulnerabilities achieves significantly better performance; 86% of its top 50 forecasts were indeed rated as HIGH or CRITICAL severity in the NVD.

	P@10	P@50	P@100	AUC
Random	59.0	61.2	58.8	0.595
Volume model	70.0	68.0	70.0	0.583
Our model	100.0	86.0	78.0	0.658

Table 7: Model performance of identifying severe threats (CVSS scores $\geq$ 7.0) with Precision@k and area under the precision-recall curve (AUC) metrics. For majority random baseline, we average over 10 trails.

---

[10] Readers may be wondering why a CVE number has been generated before it is officially published in the database. This is due to the mechanism of assigning CVEs. Some identified companies have the right to assign CVEs or have already reversed some CVEs. When a threat appears, a CVE number is assigned immediately before any further evaluation. NVD only officially publishes a threat after all evaluations are completed. Therefore, there is a time delay between CVE entry established date and the official publication date.

[11] The Forum of Incident Response and Security Teams (FIRST) also provides an example guideline that recommends patching all vulnerabilities with CVSS scores $\geq$ 7.0. See https://www.first.org/cvss/cvss-based-patch-policy.pdf.

Table 8: Top 4 threats identified by our forecast model. Severity scores are generated by using threat severity classifier in Section 2.3.

Table 8 presents top 4 forecast results from our model. We observe that our model can predict accurate severity level even 19 days ahead of the official published date in NVD (Table 8(a), (c)).

3.3 Predicting Real-World Exploits

In addition to comparing our forecasted severity scores against CVSS, as described above, we also explored several alternatives suggested by the security community to evaluate our methods: (1) Symantec's anti-virus (AV) signatures[13] and intrusion-protection (IPS) signatures,[14] in addition to (2) Exploit Database (EDB).[15]

Sabottke et al. (2015) suggested Symantec's AV and IPS signatures are the best available indicator for real exploitable threats in the wild. We follow their method of explicitly querying for CVE numbers from the descriptions of signatures to generate exploited threats ground truth. Exploit Database (EDB) is an archive of public exploits and software vulnerabilities. We query EDB for all threats that have been linked into NVD.[16] In total we gathered 134 CVEs verified by Symantec and EDB to be real exploits within the 1,409 CVEs used in our forecasting evaluation.

We evaluate the number of exploited threats identified within our top ranked CVEs. Table 9 presents our results. We observe that 7 of top 10 threats from our model were exploited in the wild. We also observe that for the actual CVSS v3.0 scores, only 1 out of the top 10 vulnerabilities was

exploited.

	Top 10		Top 50		Top 100	
	P	R	P	R	P	R
True CVSS	10.0	0.7	16.0	6.0	16.0	11.9
Volume model	60.0	4.5	22.0	8.2	19.0	14.2
Our model	70.0	5.2	28.0	10.4	21.0	15.7

Table 9: Model performance against real-world exploited threats identified by Symantec and Exploit-DB. "True CVSS" refers to ranking CVEs based on actual CVSS scores in NVD. This model is only for reference and can not be used in real practice, as we do not know true CVSS scores when forecasting.

3.4 Identifying Accounts that Post Reliable Warnings

Finally we perform an analysis of the reliability of individual Twitter accounts. We evaluate all accounts with more than 5 tweets exceeding 0.5 confidence score from our severity classifier. Table 10 presents our results. Accounts in our data whose warnings were found to have highest precision when compared against CVSS include "@securityaffairs" and "@EduardKovacs", which are known to post security related information, and both have more than 10k followers.

Account Name	# Corr / # Fcst	Acc. (%)
jburnsconsult	15 / 15	100
securityaffairs	10 / 10	100
EduardKovacs	6 / 6	100
cripperz	5 / 5	100
cipherstorm	4 / 5	80

Table 10: List of users with top accuracies on forecasting severe cybersecurity threats.

4 Related Work

There is a long history of prior work on analyzing users' opinions online (Wiebe et al., 2004), a large body of prior work has focused on sentiment analysis (Pang et al., 2002; Rosenthal et al., 2015), e.g., determining whether a message is positive or negative. In this paper we developed annotated corpora and classifiers to analyze users' opinions toward the severity of cybersecurity threats reported online, as far as we are aware this is the first work to explore this direction.

Forecasting real-world exploits is a topic of interest in the security community. For example, Bozorgi et al. (2010) train SVM classifiers to rank the exploitability of threats. Several studies have also predicted CVSS scores from various sources including text descriptions in NVD (Han et al., 2017; Bullough et al., 2017).

Prior work has also explored a variety of forecasting methods that incorporate textual evidence (Smith, 2010), including the use of Twitter message content to forecast influenza rates (Paul et al., 2014), predicting the propagation of social media posts based on their content (Tan et al., 2014) and forecasting election outcomes (O'Connor et al., 2010; Swamy et al., 2017).

5 Conclusion

In this paper, we presented the first study of the connections between the severity of cybersecurity threats and language that is used to describe them online. We annotate a corpus of 6,000 tweets describing software vulnerabilities with authors' opinions toward their severity, and demonstrated that our corpus supports the development of automatic classifiers with high precision for this task. Furthermore, we demonstrate the value of analyzing users' opinions about the severity of threats reported online as an early indicator of important software vulnerabilities. We presented a simple, yet effective method for linking software vulnerabilities reported in tweets to Common Vulnerabilities and Exposures (CVEs) in the National Vulnerability Database (NVD). Using our predicted severity scores, we show that it is possible to achieve a Precision@50 of 0.86 when forecasting high severity vulnerabilities, significantly outperforming a baseline that is based on tweet volume. Finally we showed how reports of severe vulnerabilities online are predictive of real-world exploits.

Acknowledgments

We thank our anonymous reviewers for their valuable feedback. We also thank Tudor Dumitraş for helpful discussion on identifying real exploited threats. A Linking Algorithm

We describe our approach to match tweets with NVD records in full detail in Algorithm 1.

B Limitations of CVSS and Real-World Exploits Ground Truth

In Section 3.2 - Section 3.3, we compare our forecast results with (1) CVSS ratings, and (2) real exploited threats identified by Symantec signatures and Exploit Database. Each of these sources of ground truth have limitations, which we discuss below.

Algorithm 1 Linking tweets to NVD records.

```
// Linking
for every tweet $t$ do
    if CVE number in tweet context or in url links then
        match CVEs to this tweet
    else
        query webpage contents to search for CVEs

// Check linking results
Keep tweets that matched to only one unique CVE to avoid ambiguities

// Apply time constraints
Select out tweets that are posted at least 5 days ahead of official NVD publication date (at most 365 days[17])
```

CVSS ratings are widely used as standard indicators for risk measurement in practice. However, one problem of CVSS ratings is that high severity threats do not necessarily lead to real-world exploits. Allodi and Massacci (2012) show that only a small portion (around 2%) of reported vulnerabilities were found to be exploited in the wild. Furthermore, more than half of the threats in NVD are marked as HIGH or CRITICAL, causing a large burden on vendors to fix.[18] We also notice these CVSS scores are closely tied with specific categories of threats. For example, 85.6% of buffer errors are marked as HIGH or CRITICAL, while 72.5% of information leaks were marked as MEDIUM or LOW. All these issues post challenges on how to prioritize real exploitable threats, with the goal of reducing false positives and false negatives simultaneously. Our work provides one such additional source of information for helping to prioritize threats.

The ground truth we use for real exploited threats is still an incomplete list. For example, Linux kernel vulnerabilities are less likely to appear in Symantec signatures, as Symantec does not have a security product for Linux. Identifying real exploited threats is a difficult task; to the best of our knowledge, there does not exist an easy-to-access list covering all exploited threats currently.

C Additional Analysis of Results

In this section, we present further analyses of people's online behaviors when discussing cybersecurity threats on social media.

We find that the real severity of threats is pre-

---

[17] If a tweet or its associate urls explicitly contains a CVE number, then we ignore this maximum time range constraint.

Table 11: Some examples of forecast errors made by our model. (a) False negative examples: there is no clear language clue for demonstrating the severity of threats, experts are needed for threats of this kind. (b) False positive examples: there exist some signals captured by our model for being severe threats, but actual severity might be overestimated.

Adj.	Ratio	Adj.	Ratio	Adj.	Ratio
serious	2.01	aware	1.61	fast	1.39
pivotal	1.95	most	1.61	original	1.39
sure	1.95	vivid	1.61	able	1.39
free	1.95	accessible	1.39	blind	1.39
active	1.79	popular	1.39	arbitrary	1.35
intelligent	1.79	deep	1.39	high	1.30
static	1.79	black	1.39	incomplete	1.25
critical	1.67	top	1.39	malicious	1.20
severe	1.61	dangerous	1.39	wily	1.10
great	1.61	wild	1.39	evil	1.10

Table 12: Top ranked log-odds ratio of subjective adjectives describing severe threats (CVSS scores ≥ 7.0) versus non-severe threats (CVSS scores < 7.0). Subjective adjectives are identified by using Subjectivity Lexicon (SUB) (Wilson et al., 2005).

dictable based on users' opinions online. We observe several repeated patterns in how people describe severe threats. We summarize some of these patterns below:

- describing severity levels (see Appendix C.1), such as "critical", "serious", "highly";
- describing the number of users or devices affected, such as "millions of ⟨TARGET⟩ devices", "huge number of";
- potential consequences, such as "allows hackers to", "could allow for remote code execution", "malware";
- alerts or warnings, such as "please be aware", "warning";
- suggesting immediate actions, such as "patch now".

C.1 Usage of Subjective Adjectives

We notice people rely on adjectives for describing the level of severity for threats, rather than numerical scores. These subjective adjectives form our initial impressions on these threats.

We examine subjective adjectives people use for measuring threats. We run POS tagging to extract all tokens marked as `JJ`, `JJP`, and `JJS`. We then rank subjective adjectives in Subjectivity Lexicon (SUB) (Wilson et al., 2005) by log-odds ratio of their occurrences in NVD descriptions for HIGH or CRITICAL threats versus MEDIUM or LOW threats. Table 12 presents top ranked subjective adjectives. We observe variants people are using for severe threats, e.g. "serious", "severe", "malicious", etc.

C.2 Temporal Analysis

We collect all CVEs having matched tweets posted at least 1 day ahead of the official NVD publication date, resulting in a set of 3,678 CVEs. Within our dataset, 84.7% of CVEs are reported within 60 days after the first disclosure on social media. We observe a median of 5 days delay in our dataset, whereas some of threats have significant longer delays. For example, CVE-2016-2123[19] (Overflow Remote Code Execution Vulnerability) first appears at Twitter on Dec. 19, 2016[20], but is published in NVD on Nov. 1, 2018. It again shows the difficulty of threat evaluation and management.

C.3 Error Analysis

We evaluate two types of errors with respect to forecasting high severity vulnerabilities: false positive and false negative examples. We observe that some severe threats are difficult to predict based on contents in general, such as Table 11(a). There is no clear clue for estimating the severity level merely on tweet contents.

We present another incorrect example extracted by our forecast system in Table 11(b). We notice tokens like "expose users to attack", "opens up to a raft of problems", etc. This threat does seem to be exploitable and harmful to a lot of users. However, experts mark it as of medium severity. It might be the case that the actual severity level of some threats are overestimated by some accounts.

Abstract

Deep-learning-based models have been successfully applied to the problem of detecting fake news on social media. While the correlations among news articles have been shown to be effective cues for online news analysis, existing deep-learning-based methods often ignore this information and only consider each news article individually. To overcome this limitation, we develop a graph-theoretic method that inherits the power of deep learning while at the same time utilizing the correlations among the articles. We formulate fake news detection as an inference problem in a Markov random field (MRF) which can be solved by the iterative mean-field algorithm. We then unfold the mean-field algorithm into hidden layers that are composed of common neural network operations. By integrating these hidden layers on top of a deep network, which produces the MRF potentials, we obtain our deep MRF model for fake news detection. Experimental results on well-known datasets show that the proposed model improves upon various state-of-the-art models.

1 Introduction

The term “fake news” refers to news articles that is intentionally and verifiably false (Shu et al., 2017). The problem of fake news has existed since the appearance of the printing press, but only gained a lot of momentum and visibility during the age of social media. This is due to the large audience, easy access and fast dissemination mechanism of social media, where more and more users are consuming news in a daily basis (Shu et al., 2017). Traditional methods for verifying the veracity of news that rely on human experts, despite being reliable, do not scale well to the massive volume of news nowadays. This renders the automatic detection of fake news on social media an important problem, drawing a lot of attention from both the academic and industrial communities.

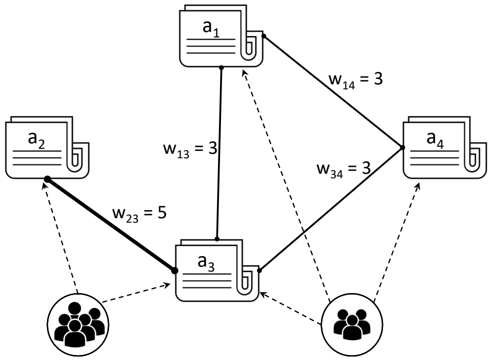

Figure 1: Modeling the relationship among news articles (or events): the dash lines represent engagements of users to articles, the solid lines represent the relationships between articles with weights determined by the number of common engaged users.

The recent literature has witnessed the success of deep learning models in detecting fake news on social media (Ma et al., 2016; Yu et al., 2017; Ruchansky et al., 2017; Rashkin et al., 2017; Ma et al., 2018a; Kochkina et al., 2018). By leveraging the capability of deep networks in learning high-level representations, these models have achieved state-of-the-art performance on various benchmark datasets. Nevertheless, one limitation of existing deep-learning-based methods is that they often ignore the correlations among news articles, which have been proved to be effective for analysing online events (Freire et al., 2016; Fairbanks et al., 2018).

To overcome this limitation, we aim at a model that leverages the capability of deep neural networks while effectively incorporating the correlations among articles when determining their credibility. To this end, we first model the relationship between two articles by the number of the com-

Proceedings of NAACL-HLT 2019, pages 1391–1400
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

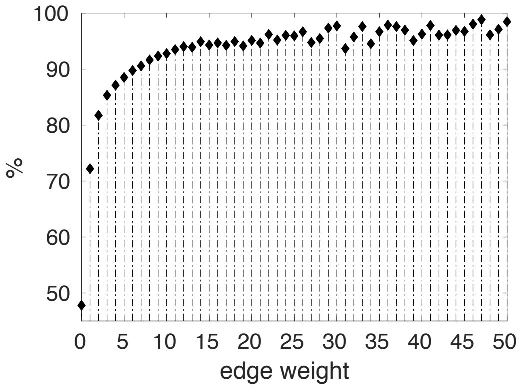

Figure 2: Percentage of edges having certain weights, which connects two articles with the same labels on the news graph constructed from the Weibo dataset (Ma et al., 2016).

mon users that engage to them, e.g., by means of tweeting, re-tweeting, commenting. An example is illustrated in Fig. 1: the articles a_2 and a_3 have a strong relationship as they are engaged to by 5 common users, whereas, there is no relationship between the articles a_1 and a_2 because there is no user engage to both of them. With this modeling, we can construct a *news graph*, where each node corresponds to an article and an edge encodes the relationship between two articles.

Our underlying assumption is that if there exists a strong relationship between two articles, they are likely to share the same labels. To verify this assumption, we calculate the percentages of the edges that connect two articles with the same labels, among those whose weights are equal to certain values, and plot the results for the news graph constructed from the Weibo dataset (Ma et al., 2016) in Fig. 2. It is clear from Fig. 2 that the higher the edge weight, the more likely it is that the corresponding articles share the same labels (*fake* or *true*). Similar patterns are observed on other datasets such as the Twitter (Ma et al., 2016) and the PHEME (Zubiaga et al., 2017) datasets. Evidently, these results support our assumption.

In order to incorporate the correlations among news articles, we formulate fake news detection as an inference problem in a Markov random field (MRF). Our motivation behind this formulation is to leverage the capability of MRF in capturing dependencies among random variables. We solve the resulting inference problem using the mean-field algorithm (Koller and Friedman, 2009). We then propose a method to unfold this algorithm into hidden layers that can be integrated on top of a deep network that computes the potentials of the MRF. By doing this, we obtain our deep MRF model for detecting fake news, referred to as the DMFN model. To the best of our knowledge, this is the first integration of deep networks and MRF for detecting fake news. Our main contributions are as follows:

- We formulate fake news detection as an inference problem in an MRF model. This allows us to incorporate the correlations among news articles when deciding their credibility.
- We propose a method to unfold the mean-field algorithm into specially-designed neural network layers, and build a deep MRF model for detecting fake news.
- We carry out comprehensive experiments on widely-used datasets collected from popular social networks. Experimental results show the effectiveness of the proposed model compared to various state-of-the-art models.

The remainder of the paper is organized as follows: we review the related work in Section 2, and describe our formulation of fake news detection as an inference problem MRF in Section 3. In Section 4, we describe our model in detail. We present our experimental studies in Section 5 and finally draw the conclusions in Section 6.

2 Related Work

Early work in fake news detection focused on finding a good set of features that are useful for separating fake news from genuine news. Linguistic patterns, such as special characters, specific keywords and expression types, have been explored to spot fake news (Castillo et al., 2011; Liu et al., 2015; Zhao et al., 2015). Different feature types have also been considered, such as the characteristics of users involved in spreading the news, e.g. the number of followers, the users' ages and genders (Castillo et al., 2011; Yang et al., 2012), and the news' propagation patterns (Castillo et al., 2011; Kwon et al., 2013). Instead of relying on a single feature type, existing works normally made use of multiple types of feature at the same time.

Recent years have witnessed the use of deep learning for fake news detection. The idea is to leverage deep neural networks to overcome the limitation of the *shallow* hand-craft features employed in the earlier methods (Ma et al., 2016).

Many works proposed to represent news articles as multivariate time series using the timestamp information and to formulate fake news detection as a sequence classification problem (Ma et al., 2016; Yu et al., 2017; Ma et al., 2018a; Liu and Brook Wu, 2018; Kochkina et al., 2018). As it is common in the literature to utilize multiple types of features in detecting fake news, deep networks with multiple branches to incorporate various feature types were also proposed (Ruchansky et al., 2017; Volkova et al., 2017; Yang et al., 2018). In general, deep learning based methods yield higher accuracy compared to shallow-feature-based approaches, leading to state-of-the-art performance.

The existing deep-learning models, however, often ignore the correlations among news articles which haven been shown to be effective cues for analysing online news and events (Freire et al., 2016; Fairbanks et al., 2018). Freire et al. proposed a method to detect breaking news on Wikipedia by exploring the graph of related events (Freire et al., 2016). This graph is built by connecting any pair of pages on Wikipedia which were edited by the same users in a small time window. In (Fairbanks et al., 2018), a graph of news was constructed by connecting the corresponding web pages using the links between them in form of `html` tags. The credibility of the news was assessed by applying the loopy belief propagation algorithm to perform semi-supervised learning on this graph. In their experiments, the authors showed that the correlations among the news, encoded in the constructed graph, were more effective than the textual content of the news for predicting their credibility.

In this work, we propose a deep MRF model for fake news detection. Apart from leveraging the power of deep networks, our model incorporates the correlations among news articles when determining their credibility. In this regard, our method shares a similar motivation with the graph-based methods for social event analysis as mentioned above. Nevertheless, while these graph-based methods do not utilize any information of the news articles beyond the labels, our model is more generic and allows incorporating an arbitrary number of features.

3 Fake News Detection on MRF

We employ a Markov random field (MRF) model (Freeman et al., 2000) to incorporate the correlations among the events due to its capability in capturing dependencies among random variables. To this end, we first construct an event graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with $\mathcal{V}$ the set of vertices and $\mathcal{E}$ the set of edges as described in Section 1. We then define an MRF model over $\mathcal{G}$. In this model a node k is associated with a random variable X_k, which represents the label of the k-th event. The random variables $X_k, \forall k \in \{1, \dots, n\}$ have domain $\mathcal{L} = \{\mathcal{L}_1, \mathcal{L}_2 \dots \mathcal{L}_s\}$, which represent the s possible labels. For notation brevity, we refer to the nodes in $\mathcal{V}$ by their indices, namely, $k \in \{1, \dots, n\}$. We are interested in inferring the distribution $P(X)$ of the MRF, from which the labels for the events can be obtained. In the MRF, the probability $P(X = \mathrm{x})$, with x a set of values of the random variables, is given by (Koller and Friedman, 2009)

$$P(X = \mathrm{x}) = \frac{1}{Z} \exp(-E(\mathrm{x})), \tag{1}$$

with Z the partition function ensuring a valid distribution and $E(\mathrm{x})$ the energy of the MRF, which has the following form

$$E(\mathrm{x}) = \sum_{k \in \mathcal{V}} \Phi\left(\mathrm{x}_k^u\right) + \lambda \sum_{k,l \in N} \Psi\left(\mathrm{x}_k^u, \mathrm{x}_l^v\right). \tag{2}$$

In (2), N is the set of nodes that are connected in the MRF . The *unary potential*, $\Phi\left(\mathrm{x}_k^u\right)$, measures the cost of assigning the label $\mathcal{L}_u$ to the node k, while the *pairwise potential*, $\Psi(\mathrm{x}_k^u, \mathrm{x}_l^v)$, measures the cost of assigning the nodes k and l respectively the labels $\mathcal{L}_u$ and $\mathcal{L}_v$. As such, the pairwise potentials capture the dependencies among the nodes of the MRF. λ is a hyperparameter.

As exactly computing $P(X)$ is intractable, we employ the mean-field algorithm (Koller and Friedman, 2009) to approximate $P(X)$ by a fully-factorized proposal distribution $Q(X) = \prod_{\forall k \in \mathcal{V}} Q_k(X_k)$. $Q_k(X_k = \mathcal{L}_u)$ is the probability that the node k have the label $\mathcal{L}_u$ according to the distribution Q_k. Denote $Q_k(X_k = \mathcal{L}_u)$ as q_k^u, the mean-field algorithm iteratively calculates $q_k^u, \forall k \in \{1, \dots, n\}$, $u \in \{1, \dots, s\}$ according to (Koller and Friedman, 2009)

$$\begin{aligned} q_k^u = \frac{1}{Z_k} \exp \Bigg\{ - \Bigg(& \Phi\left(\mathrm{x}_k^u\right) \\ & + \lambda \sum_{l \in N_k} \sum_{v \in \mathcal{L}} q_l^v \Psi\left(\mathrm{x}_k^u, \mathrm{x}_l^v\right) \Bigg) \Bigg\}, \end{aligned} \tag{3}$$

with N_k the set of nodes connected to k and $Z_k = \sum_{u \in \mathcal{L}} q_k^u$ the normalization factor ensuring $q_k^u, \forall u \in \{1, \dots, s\}$, add up to 1. The generic mean-field update in (3) requires the unary potentials and pairwise potentials. In Section 4, we show how we realize these potentials.

4 Deep MRF Model for Fake News Detection

In this section, we present our realizations of the unary and pairwise potentials, with which we obtain the final mean-field update equation. After that, we present a method to unfold the mean-field update into specially-designed neural network layers, and describe our deep MRF model for fake news detection.

4.1 Computing the Unary and Pairwise Potentials

We compute the unary potential $\Phi(\mathrm{x}_k^u)$ of the MRF as the negative log likelihood:

$$\Phi(\mathrm{x}_k^u) = -\ln p(X_k = \mathcal{L}_u), \tag{4}$$

with $p(X_k = \mathcal{L}_u)$ the likelihood that X_k has label $\mathcal{L}_u$. As such, $\Phi(\mathrm{x}_k^u)$ will be high if this node is not likely to have the label $\mathcal{L}_u$, and vice versa. The likelihood $p(X_k = \mathcal{L}_u)$ is computed as $p(X_k = \mathcal{L}_u) = \mathcal{F}_\theta(\mathcal{O}_k)$, where $\mathcal{F}_\theta$ is a non-linear function represented by a deep neural network parameterized by θ and O_k is the observations, i.e, features associated to the k-th event. The design of this network is described later in Section 4.

The pairwise potential is computed by

$$\Psi(\mathrm{x}_k^u, \mathrm{x}_l^v) = a(k,l) \times \mu(u,v), \tag{5}$$

where $a(k,l)$ is the weight of the edge between the nodes k and l, namely, $a(k,l)$ represents how strong the relationship between the nodes k and l is; and $\mu(u,v)$ is the *label compatibility*, which is calculated using the Pott model (Boykov et al., 1998):

$$\mu(u,v) = \begin{cases} 1, & \text{if } u \neq v, \\ 0, & \text{otherwise.} \end{cases} \tag{6}$$

Substituting the pairwise potential in (5) into (3), we obtain the final mean-field update equation:

$$q_k^u = \frac{1}{Z_k} \exp \Bigg\{ -\Phi\left(x_k^u\right) \\ - \lambda \sum_{l \in N_k} a(k,l) \sum_{v \in \mathcal{L}} q_l^v \times \mu\left(u,v\right) \Bigg\}. \tag{7}$$

We refer to the term $\sum_{v \in \mathcal{L}} q_l^v \times \mu(u,v)$ in (7) as the *compatibility transform* step, and to the term $\sum_{l \in N_k} a(k,l) \sum_{v \in \mathcal{L}} q_l^v \times \mu\left(u,v\right)$ summing up information from the nodes connected to the node k as the *message passing* step.

4.2 Mean-Field Updates as Neural Network Layers

We now describe a method to implement the update equation in (7) using operations that are common in the deep learning literature. Abusing the notation, we denote also by $Q \in \mathbb{R}^{n \times s}$ a matrix, with an entry $Q_{k,u}$ corresponding to the value q_k^u, i.e., the probability that the node k has the label $\mathcal{L}_u$. Denote by $A \in \mathbb{R}^{n \times n}$ the adjacency matrix, containing all the edge weights in $\mathcal{G}$. We set $A_{k,k} = 0, \forall k \in \{1, \dots, n\}$. We further denote by $M \in \mathbb{R}^{s \times s}$ a square matrix whose the entry $M_{u,v}$ corresponds the label compatibility $\mu(u,v)$ calculated using (6), and by $\Phi \in \mathbb{R}^{n \times s}$ the matrix containing the unary potentials $\Phi(\mathrm{x}_k^u)$, for all $k \in \{1, \dots, n\}$ and $u \in \{1, \dots, s\}$. Φ is calculated by taking the logarithm of Q element-wise.

4.2.1 The Compatibility Transform Step

The compatibility transform in (7) can be performed via a 1-D convolutional layer applied on the matrix Q. This convolutional layer has s filters of kernel size $1 \times s$. The weights of the u-th filter are set equal to the values along the u-th row of M. We do not employ any padding and set the stride to 1. When applying this operation, the u-th filter slides vertically across Q, and calculates the inner product between its weights and the rows of Q. The output is denoted as $\mathcal{Q}' \in \mathbb{R}^{n \times s}$, with an entry $Q'_{l,u}$ given by

$$\begin{aligned} Q'_{l,u} &= \sum_{v \in \mathcal{L}} Q_{l,v} \times M_{u,v} \\ &= \sum_{v \in \mathcal{L}} q_l^v \times \mu(u,v), \end{aligned} \tag{8}$$

for all $l \in \{1, \dots, n\}$, $u \in \{1, \dots, s\}$, which is equal to the result of the compatibility transform step in (7).

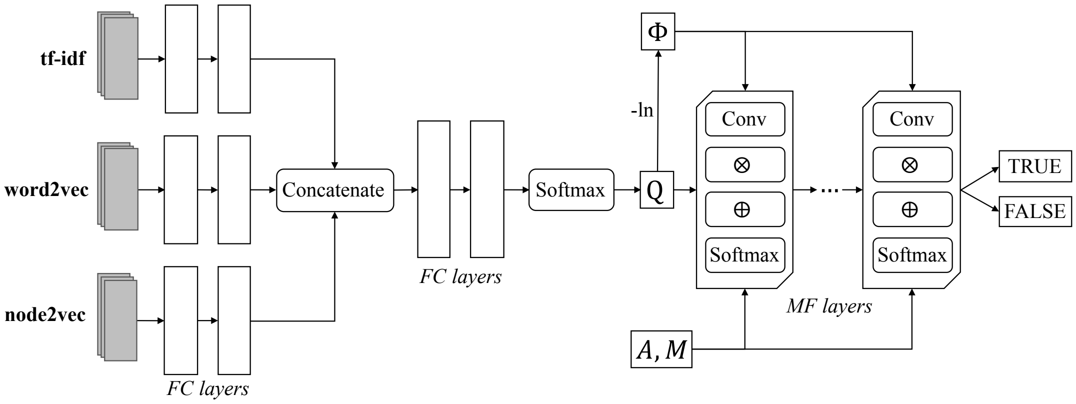

Figure 3: The architecture of the DMFN model: the first block consists of three feature branches, each with configurable numbers of fully-connected (FC) layers to process a type of feature, a concatenation layer and a number of FC layers with softmax activation function at the end to produce labels' probability matrix Q; Each *mean-field* (MF) layer consists of four main operations, namely convolution (conv), matrix multiplication ($\otimes$), point-wise addition ($\oplus$) and the softmax function. T MF layers are stacked one after another to implement the mean-field algorithm with T iterations. All MF layers share the same set of parameters, namely, the matrix of the unary potentials Φ, which is computed from Q, the adjacency matrix A encoding the relationships among the input events, and the compatibility matrix M.

4.2.2 The Message Passing Step

Given the adjacency matrix $A \in \mathbb{R}^{n \times n}$ and the output $Q^{'} \in \mathbb{R}^{n \times s}$ from the compatibility transform step, the message passing step can be performed simply by multiplying A with $Q^{'}$. This multiplication results in $Q^{''} \in \mathbb{R}^{n \times s}$, in which:

$$\begin{aligned} Q^{''}_{k,u} &= \sum_{l=1}^{n} A_{k,l} . Q^{'}_{l,u} \\ &= \sum_{l=1}^{n} a(k,l) \sum_{v \in \mathcal{L}} q_l^v \times \mu(u,v). \end{aligned} \tag{9}$$

As $A_{k,l} = 0$ if $l \notin N_k$, the operation in (9) is equivalent to the message passing step in (7).

4.2.3 The Mean-field Layer

To finish the update in (7), one needs to element-wise multiply $Q^{''}$ with λ, add Φ and negate the result. The exponential and normalization can be performed jointly using the *softmax* function, resulting in the new matrix $Q \in \mathbb{R}^{n \times s}$ whose entries correspond to the values of q_k^u after one mean-field iteration, for all $k \in \{1, \ldots, n\}$, $u \in \{1, \ldots, s\}$. We can consider these operations together with those implementing the compatibility transform and the message passing steps, as the operations of specially-designed a neural network layer, which we call the mean-field (MF) layer. As all the component operations are differentiable, the operation implemented by the MF layer is also differentiable. Each MF layer, hence, implements one iteration of the mean-field algorithm. Clearly, by stacking T MF layers, we can implement the mean-field algorithm with T iterations.

4.3 The DMFN Model

4.3.1 Model Architecture

The architecture of the DMFN model is illustrated in Figure 3, with two blocks: the first block corresponds to the deep network $\mathcal{F}_\theta$ that produces the unary potentials, and the second block is composed of T MF layers, which implements the T-iteration mean-field algorithm. The deep network $\mathcal{F}_\theta$ takes as inputs several feature types extracted to represent the given set of events. Each feature type is processed by a feature branch with a number of fully-connected (FC) layers. The outputs of the last layers in all feature branches are concatenated to produce high-level representations for all the events. These representations are then fed to another set of FC layers and a softmax function to produce the label probabilities. These label probabilities form the matrix Q, as described in Section 4.2. All the FC layers in the model are followed by a batch normalization layer (Ioffe and Szegedy, 2015), a ReLU activation function (Glorot et al., 2011), and the dropout regularization (Srivastava et al., 2014).

In the second block, all the MF layers share the same parameters, namely, the matrix Φ, the adjacency matrix A that encodes the relationships among the given events, and the label compatibility matrix M. The first MF layer takes as input the matrix Q, whereas, the later MF layers operate on the outputs from their previous MF layers. The output after the last MF layer is the final label probabilities predicted for the given events. It should be noted that the parameters of the MF layers are pre-computed and shared. As such, adding MF layers after the layers in the first block does not increase the the risk of overfitting of the model.

4.3.2 Feature Extraction

We extract multiple types of features to capture the characteristics of the events, namely, the textual contents and social engagements. For the textual features, we first group all the tweets related to an event into a document. We pre-process the documents by removing stop words, converting the words into lower case and tokenizing them. From the pre-processed documents, we extract the *term frequency - inverse document frequency* (tf-idf) (Wu et al., 2008), and *word2vec* (Mikolov et al., 2013) feature vectors. We use the word2vec model pre-trained on the Google News dataset to map each word in a document to a $300-$dimensional embedding vector, and then obtain the embedding for the document by taking the average of the word embeddings.

We use a graph embedding technique to capture the social engagements associated to the events. Concretely, we first build a graph of users from the given dataset. Two users are connected by an edge if they engage to at least one event in common, with the edge's weight determined by the total number of common engaged events. We then employ the *node2vec* algorithm (Grover and Leskovec, 2016) to learn an embedding for each user. The social engagement feature of an event is then calculated by taking the average of the embeddings of all users engaged to it. It is worth noting that the graph of users used in this step is different from the graph of events, constructed as described in Section 1.

4.3.3 Training and Testing the DMFN Model

We employ the weighted cross entropy loss function to train the DMFN model. When calculating the loss, the weight given to the training samples of a particular label is inversely proportional to the number of samples in the current batch which have this label. This technique is highly beneficial when dealing with imbalanced dataset, e.g., the PHEME dataset (Zubiaga et al., 2016). The model's parameters are learned by using the SGD algorithm with the Adam parameter update (Kingma and Ba, 2015).

At the testing stage, we select for the testing event k the label $\mathcal{L}_{\hat{u}} \in \mathcal{L}$ with $\hat{u}$ determined by $\hat{u} = \arg\max_{u \in \{1,\dots,s\}} q_k^u$. As we want to utilize the correlations among events in the prediction, we provide an adjacency matrix encoding the relationships among a set of events and run a forward pass with all their features as input. Without the adjacency matrix or when setting the adjacency matrix to the identity matrix, the model predicts the labels for each events without considering their correlations.

5 Experiments

5.1 Experimental Settings

We employ three well-known benchmark datasets, namely the Twitter, Weibo (Ma et al., 2016) and PHEME datasets (Zubiaga et al., 2017) for our experiments. The Twitter dataset consists of 992 events, involving 233.7 thousand users and 592.4 thousand tweets. The Weibo dataset is larger, with $4,664$ events, 2.8 million users and 3.8 million posts. Events in these datasets are labeled as either *fake* or *true*, and the two labels are relatively balanced. The PHEME dataset consists of $5,802$ comment threads collected from Twitter, with approximately 103 thousand tweets in total. This dataset is imbalanced, with $1,972$ threads labeled as *rumour* and $3,830$ threads labeled as *non-rumour*.

5.2 Hyperparameter Selection

For the DMFN model, we employ one hidden layer in each feature branch, and one hidden layer after the concatenation layer, all with 100 hidden units. We train the model for maximum 100 epochs with learning rate 0.001 and stop training early if the validation loss does not improve over the average of those of the previous 25 epochs. To control overfitting, we employ dropout with high dropping rate of 0.9.

We determine the values of λ which balance the weight between the unary and pairwise potentials in the MRF, and of the number of MF layers, T by cross validation on a separate split on the Weibo dataset. First, we fix T to 30, with which the mean-field algorithm is highly likely to converge (Krähenbühl and Koltun, 2011), and experi-

λ	0.005	0.050	0.100	0.500
Weibo	0.958	**0.960**	0.959	0.949

T	1	5	10	15
Weibo	0.949	0.960	0.960	0.960

Table 2: Accuracy of the DMFN model when varying T on the Weibo datasets (Ma et al., 2016).

ment with different values of λ. The result of this is presented in Table 1.

Fixing λ to 0.05, we experiment with different number of MF layers by varying T. The results are summarized in Table 2. As can be seen from the table, employing multiple MF layers improves the results over just one MF layer. Even though we still observe improvements in the performance with more than 5 MF layers, the difference is small. As a result, we select $T = 5$ as it produces the best trade-off between accuracy and computational complexity.

5.3 Experimental Results

We compare the results of different models in two experimental settings, namely *late detection* and *early detection*. The former setting allows the models to use all the available users posts in the entire time span of the given datasets, whereas in the latter setting, the models are only allowed to use posts that have appeared within a specific deadline (in hours) since the appearances of the events.

5.3.1 Late Detection Setting

We compare the results of the proposed models in the late detection setting with those of reference models, including the decision tree classifier (DTC) (Castillo et al., 2011), the SVM classifier (SVM-RBF) (Yang et al., 2012), the random forest classifier (RFC) (Kwon et al., 2013), the SVM classifier with timeseries features (SVM-TS) (Ma et al., 2015), the 2-layer GRU model (GRU-2) (Ma et al., 2016) and the convolutional neural network (CAMI) (Yu et al., 2017), the Tree-structured Recursive Neural Networks (TD-RvNN) (Ma et al., 2018b), and the CRF and Naive Bayes classifiers in (Zubiaga et al., 2017). The performance of the models is assessed using four metrics, namely, accuracy, average precision, average recall and macro F1 score. Similar to (Yu et al., 2017), on the Twitter and Weibo datasets, we randomly reserve 10% of the samples for parameter tuning and perform four-fold cross validation on the remaining. On the PHEME dataset, we follow the leave-one-event-out approach as in (Zubiaga et al., 2017). We report the average results for the models.

The results for different models on the Twitter and the Weibo datasets (Ma et al., 2016) are shown in Table 3. On these two datasets, we do not include the results of the TD-RvNN model (Ma et al., 2018b) as this model requires a tree-like connections among the tweets to represent an event. As can be seen from the table, the DMFN model consistently outperforms the reference models on both datasets. The results of all the models are better on the Weibo dataset than on the Twitter dataset. This is possibly because number of posts available on the Weibo dataset is much larger than that available on the Twitter dataset.

The results on the PHEME dataset is illustrated in Table. 4. As this dataset is imbalanced, the prediction accuracy is not a good metric for comparison. Similar to (Zubiaga et al., 2017), we focus on the other metrics, namely, precision, recall and macro F1 score in the comparison. The CRF model with content features (Zubiaga et al., 2017) yields the highest precision, whereas the Naive Bayes classifiers yield the highest recalls.. While the reference models are either biased toward high precision or high recall scores, the DMFN model produces more balanced precision and recall, and the best Macro F1 score. The DF-RvNN model (Ma et al., 2018a) also achieves balanced precision and recall, nevertheless its performance is lower than that of the DMFN model in all metrics (with p-values of 0.004, 0.04, 0.03 respectively for the precision, recall and macro f1 scores in a pairwise t-test).

On the PHEME dataset, the average number of tweets per event is 17.8, which is much smaller than those on the Twitter and Weibo datasets (805 and 815 posts per event respectively). The lower number of tweets, and the class imbalance render this dataset highly challenging. As such, the performance of all the considered models on this dataset is lower than that on the Twitter and Weibo datasets. Overall on all the considered datasets, we observe consistent performance of the DMFN model: The variance of the Macro F1 score over 10 repetitions are relatively low, which are equal to

Model	Twitter				Weibo

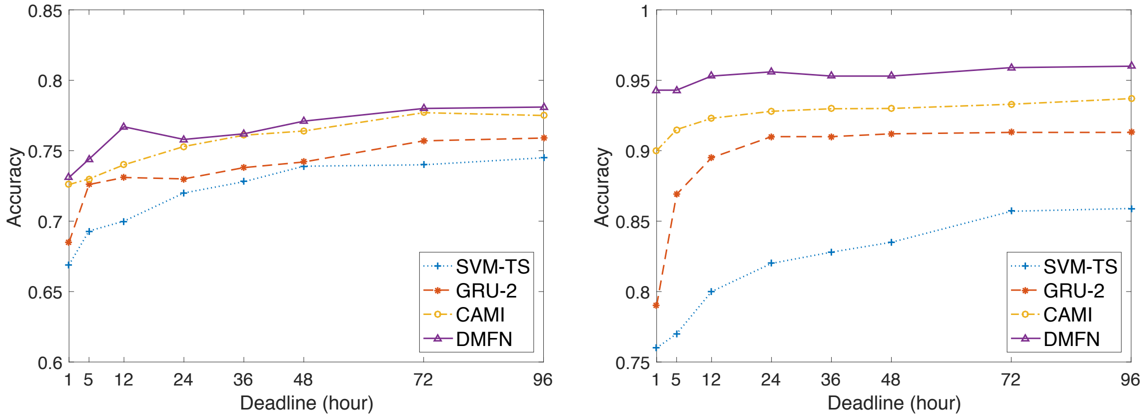
1e−4, 2e−4 and 6e−5 respectively on the Twitter, Weibo and PHEME datasets.

5.3.2 Early Detection Setting

We perform the early detection experiments on the Twitter and Weibo datasets with different deadlines, in $\{1, 5, 12, 24, 36, 48, 72, 96\}$ (hours). Fig. 4a and Fig. 4b illustrate the results on the Twitter and the Weibo datasets, respectively. As can be seen, on both datasets, the DMFN model performs the best among the selected models, followed by the CAMI model. On the Weibo dataset, the average number of posts per event is approximately 168, 353, 497 within the 1-hour, 5-hour and 12-hour deadlines respectively.These figures suggest that Weibo users are responsive and quickly react to a newly broadcasted event. The large number of posts per event, even at 1-hour deadline, gives enough information for the DMFN, as well as the CAMI models to produce good results, even within short deadlines.

5.3.3 The Effects of Jointly Training the Deep Network with Mean-field Inference

An advantage of the proposed model is that it allows training the deep network that produces the unary potentials with feedback from the mean-field inference. To verify this argument, we compare the performance when using different variants of the proposed model: (*i*) training and testing without the MF inference, (*ii*) training without the MF inference and testing with the MF inference, and (*iii*) training and testing with the MF inference (the full DMFN model). We denote the three variants as *DMFN-base*, *DMFN-separate* and *DMFN*. As can be seen from the table, applying the MF inference improves the results of the base model even if it has been trained without the MF inference. This proves the benefits of enforcing the dependencies between the events in the MRF when making predictions. Nevertheless, training and testing with MF inference consistently yields the best results among the three variants. This proves



(a) Twitter dataset (b) Weibo dataset

Figure 4: Accuracy of different models when considering only posts within specific deadlines on the Twitter and Weibo datasets.

the benefits of unfolding the MF inference and incorporate it on top of the base network.

6 Conclusion

We formulated the fake news detection on social media as an inference problem in an MRF model that can be solved using the mean-field algorithm. By translating each update step in this algorithm into common operations in the deep learning literature, we can unfold it into hidden layers that can be integrated on top of another deep neural network. This results in our deep MRF model (DMFN) for detecting fake news. As such, the DMFN carries the advantages of both deep neural networks in learning high-level representations, and of MRF in incorporating correlations among the news articles. Experiments on well-known benchmark datasets show that the proposed model consistently improves over the state of the art in fake news detection in both the late and early detection settings.

Abstract

In online discussion fora, speakers often make arguments for or against something, say birth control, by highlighting certain aspects of the topic. In social science, this is referred to as *issue framing*. In this paper, we introduce a new issue frame annotated corpus of online discussions. We explore to what extent models trained to detect issue frames in newswire and social media can be transferred to the domain of discussion fora, using a combination of multi-task and adversarial training, assuming only unlabeled training data in the target domain.

1 Introduction

The *framing* of an issue refers to a choice of perspective, often motivated by an attempt to influence its perception and interpretation (Entman, 1993; Chong and Druckman, 2007). The way issues are framed can change the evolution of policy as well as public opinion (Dardis et al., 2008; Iyengar, 1991). As an illustration, contrast the statement *Illegal workers depress wages* with *This country is abusing and terrorizing undocumented immigrant workers*. The first statement puts focus on the economic consequences of immigration, whereas the second one evokes a morality frame by pointing out the inhumane conditions under which immigrants may have to work. Being exposed to primarily one of those perspectives might affect the publics attitude towards immigration.

Computational methods for frame classification have previously been studied in news articles (Card et al., 2015) and social media posts (Johnson et al., 2017). In this work, we introduce a new benchmark dataset, based on a subset of the 15 generic frames in the *Policy Frames Codebook* by Boydstun et al. (2014). We focus on frame classification in *online discussion fora*, which have become crucial platforms for public dialogue on social and political issues. Table 1 shows example annotations, compared to previous annotations for news articles and social media. Dialogue data is substantially different from news articles and social media, and we therefore explore ways to transfer information from these domains, using multi-task and adversarial learning, providing non-trivial baselines for future work in this area.

Platform: Online discussions
Economic Frame, Topic: Same sex marriage `But as we have seen, supporting same-sex marriage saves money.`
Legality Frame, Topic: Same sex marriage `So you admit that it is a right and it is being denied?`
Platform: News articles
Economic Frame, Topic: Immigration `Study Finds That Immigrants Are Central to Long Island Economy`
Legality Frame, Topic: Same sex marriage `Last week, the Iowa Supreme Court granted same-sex couples the right to marry.`
Platform: Twitter
Legality Frame, Topic: Same sex marriage `Congress must fight to ensure LGBT people have the full protection of the law everywhere in America. #EqualityAct`

Table 1: Example instances from the datasets described in §2 and 3.

Contributions We present a new issue-frame annotated dataset that is used to evaluate issue frame classification in online discussion fora. Issue frame classification was previously limited to news and social media. As manual annotation is expensive, we explore ways to overcome the lack of labeled training data in the target domain with

multi-task and adversarial learning, leading to improved results in the target domain.[1]

Related Work Previous work on automatic frame classification focused on news articles and social media. Card et al. (2016) predict frames in news articles at the document level, using clusters of latent dimensions and word-based features in a logistic regression model. Ji and Smith (2017) improve on previous work integrating discourse structure into a recursive neural network. Naderi and Hirst (2017) use the same resource, but make predictions at the sentence level, using topic models and recurrent neural networks. Johnson et al. (2017) predict frames in social media data at the micro-post level, using probabilistic soft logic based on lists of keywords, as well as temporal similarity and network structure. All the work mentioned above uses the generic frames of Boydstun et al. (2014)'s Policy Frames Codebook. Baumer et al. (2015) predict words perceived as frame-evoking in political news articles with hand-crafted features. Field et al. (2018) analyse how Russian news articles frame the U.S. using a keyword-based cross-lingual projection setup. Tsur et al. (2015) use topic models to analyze issue ownership and framing in public statements released by the US congress. Besides work on frame classification, there has recently been a lot of work on aspects closely related to framing, such as subjectivity detection (Lin et al., 2011), detection of biased language (Recasens et al., 2013) and stance detection (Mohammad et al., 2016; Augenstein et al., 2016; Ferreira and Vlachos, 2016).

2 Online Discussion Annotations

We create a new resource of issue-frame annotated online fora discussions, by annotating a subset of the Argument Extraction Corpus (Swanson et al., 2015) with a subset of the frames in the Policy Frames Codebook. The Argument Extraction Corpus is a collection of argumentative dialogues across topics and platforms.[2] The corpus contains posts on the following topics: *gay marriage*, *gun control*, *death penalty* and *evolution*. A subset of the corpus was annotated with argument quality scores by Swanson et al. (2015), which we exploit in our multi-task setup (see §3).

We collect new issue frame annotations for each argument in the argument-quality annotated data.[3] We refer to this new issue-frame annotated corpus as *online discussion corpus* henceforth. Each argument can have one or multiple frames. Following Naderi and Hirst (2017), we focus on the five most frequent issue frames: *Economic*, *constitutionality and jurisprudence*, *policy prescription and evaluation*, *law and order/crime and justice*, and *political*. See Table 1 for examples and Table 2 for the class distribution in the resulting online discussions test set. Phrases which do not match the five categories are labeled as *Other*, but we do not consider this class in our experiments. The annotations were done by a single annotator. A second annotator labeled a subset of 200 instances that we use to compute agreement as macro-averaged F-score, assuming one of the annotations as gold standard. Results are 0.73 and 0.7, respectively. The averaged Cohen's Kappa is 0.71.

3 Additional Data

The dataset described in the previous section serves as evaluation set for the online discussions domain. As we do not have labeled training data for this domain, we exploit additional corpora and additional annotations, which are described in the next subsection. Statistics of the filtered datasets as well as preprocessing details are given in Appendix A.

Media Frames Corpus The Media Frames Corpus (Card et al., 2015) contains US newspaper articles on three topics: *Immigration*, *smoking* and *same-sex marriage*. The articles are annotated with the 15 framing dimensions defined in the Policy Frames Codebook.[4] The annotations are on

---

[1] Code and annotations are available at `https://github.com/coastalcph/issue_framing`.

[2] The corpus is a combination of dialogues from `http://www.createdebate.com/`, and Walker et al. (2012)'s Internet Argument Corpus, which contains dialogues from `4forums.com`.

[3] Topic cluster *Evolution* was dropped, because it contained too few examples matching our frame categories.

[4] We discard all instances that do not correspond to the frame categories in the online discussions data.

Model	Task	Domain	Labelset	# classes	# sequences
Baseline	Main task	News articles	Frames	5	10,480
	Target task	Online disc. (test)	Frames	5	692
Multitask	+Aux task	Tweets	Frames	5	1,636
	+Aux task	Online disc.	Argument quality	2	3,785
Adversarial	+Adv task	Online disc. + News articles	Domain	2	4,731 + 10,480
		Online disc. (dev)	Frames	5	176

Table 3: Overview over the data and labelsets for the different tasks. The baseline model trains on the main task and predicts the target task. The multi-task model uses one or both auxiliary tasks in addition to the main task. The adversarial model uses the adversarial task in addition to the main task. All models use the online disc. dev set for model selection.

span-level and can cross sentence boundaries. We convert span annotations to sentence-level annotations as follows: if a span annotated with label l lies within sentence boundaries and covers at least 50% of the tokens in the sentence, we label the sentence with l. We only keep sentence annotations if they are indicated by at least two annotators.

Congressional Tweets Dataset The congressional tweets dataset (Johnson et al., 2017) contains tweets authored by 40 members of the US Congress, annotated with the frames of the Policy Frames Codebook. The tweets are related to one or two of the following six issues: *abortion*, *the Affordable Care Act*, *gun rights vs. gun control*, *immigration*, *terrorism*, and *the LGBTQ community*, where each tweet is annotated with one or multiple frames.

Argument Quality Annotations The corpus of online discussions contains additional annotations that we exploit in the multi-task setup. Swanson et al. (2015) sampled a subset of 5,374 sentences, using various filtering methods to increase likelihood of high quality argument occurrence, and collected annotations for argument quality via crowdsourcing. Annotators were asked to rate argument quality using a continuous slider [0-1]. Seven annotations per sentence were collected. We convert these annotations into binary labels (1 if $\geq$ 0.5, 0, otherwise) and generate an approximately balanced dataset for a binary classification task that is then used as an auxiliary task in the multi-task setup. Balancing is motivated by the observation that balanced datasets tend to be better auxiliary tasks (Bingel and Søgaard, 2017).

4 Models

The task we are faced with is (multi-label) sequence classification for online discussions. However, we have no labeled training data (and only a small labeled validation set) for the target task in the target domain. Hence, we train our model on a dataset which is labeled with the target labels, but from a different domain. The largest such dataset is the news articles corpus, which we consequently use as main task. Our baseline model is a two-layer LSTM (Hochreiter and Schmidhuber) trained on only the news articles data. We then apply two strategies to facilitate the transfer of information from source to target domain, multi-task learning and adversarial learning. We briefly describe both setups in the following. An overview over tasks and data used in the different models is shown in Table 3.

Multi-Task Learning To exploit synergies between additional datasets/annotations, we explore a simple multi-task learning with hard parameter sharing strategy, pioneered by Caruana (1993), introduced in the context of NLP by Collobert et al. (2011), and to RNNs by Søgaard and Goldberg (2016), which has been shown to be useful for a variety of NLP tasks, e.g. sequence labelling (Rei, 2017; Ruder et al., 2019; Augenstein and Søgaard, 2017), pairwise sequence classification (Augenstein et al., 2018) or machine translation (Dong et al., 2015). Here, parameters are shared between hidden layers. Intuitively, it works by training several networks in parallel, tying a subset of the hidden parameters so that updates in one network affect the parameters of the others. By sharing parameters, the networks regularize each other, and the network for one task can benefit from repre-

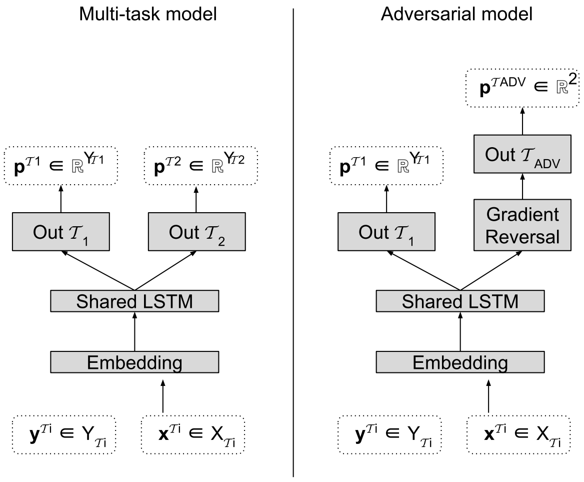

Figure 1: Overview over the multi-task model (left) and the adversarial model (right). The baseline LSTM model corresponds to the same architecture with only one task.

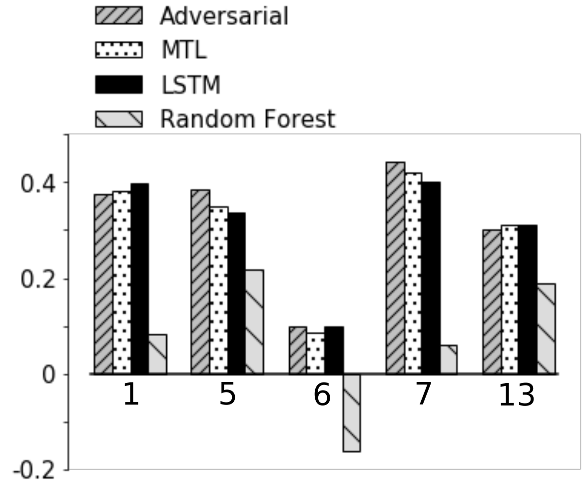

Figure 2: Improvement in F-score over the random baseline by class. The absolute F-scores for the best performing system for classes 1, 5, 6, 7, and 13, are 0.529, 0.625, 0.298, 0.655, and 0.499, respectively.

sentations induced for the others.

Our multi-task architecture is shown in Figure 1. We have N different datasets $\mathcal{T}_1, \cdots, \mathcal{T}_N$. Each dataset $\mathcal{T}_i$ consists of tuples of sequences $x^{\mathcal{T}_i} \in X_{\mathcal{T}_i}$ and labels $y^{\mathcal{T}_i} \in Y_{\mathcal{T}_i}$. A model for task $\mathcal{T}_i$ consists of an input layer, an LSTM layer (that is shared with all other tasks) and a feed forward layer with a softmax activation as output layer. The input layer embeds a sequence $x^{\mathcal{T}_i}$ using pretrained word embeddings. The LSTM layer recurrently processes the embedded sequence and outputs the final hidden state h. The output layer outputs a vector of probabilities $p^{\mathcal{T}_i} \in R^{Y_{\mathcal{T}_i}}$, based on which the loss $\mathcal{L}_i$ is computed as the categorical cross-entropy between prediction $p^{\mathcal{T}_i}$ and true label $y^{\mathcal{T}_i}$. In each iteration, we sample a data batch for one of the tasks and update the model parameters using stochastic gradient descent. If we sample a batch from the main task or an auxiliary task is decided by a weighted coin flip.

Adversarial Learning Ganin and Lempitsky (2015) proposed adversarial learning for domain adaptation that can exploit unlabeled data from the target domain. The idea is to learn a classifier that is as good as possible at assigning the target labels (learned on the source domain), but as poor as possible in discriminating between instances of the source domain and the target domain. With this strategy, the classifier learns representations that contain information about the target class but abstract away from domain-specific features. During training, the model alternates between 1) predicting the target labels and 2) predicting a binary label discriminating between source and target instances. In this second step, the gradient that is backpropagated is flipped by a Gradient-Reversal layer.[5] Consequently, the model parameters are updated such that the classifier becomes worse at solving the task. The architecture is shown in the right part of Figure 1. In our implementation, the model samples batches from the adversarial task or the main task based on a weighted coinflip.

5 Experiments

We compare the multi-task learning and the adversarial setup with two baseline models: (a) a Random Forest classifier using tf-idf weighted bag-of-words-representations, and (b) the LSTM baseline model. For the multi-task model, we use both the Twitter dataset and the argument quality dataset as auxiliary tasks. For all models, we report results on the test set using the optimal hyper-parameters that we found averaged over 3 runs on the validation set. For the neural models, we use 100-dimensional GloVe embeddings (Pennington et al., 2014), pre-trained on Wikipedia and Gigaword.[6] Details about hyper-parameter tuning and optimal settings can be found in Appendix B.

Results The results in Table 5 show that both the multi-task and the adversarial model improve over

---

[5] In the forward pass, this layer multiplies its input with the identity matrix.

[6] `https://nlp.stanford.edu/projects/glove/`

Nr.	Gold	Adv	MTL	LSTM	Sentence
(1)	5	5	5	7	But, star gazer, we had guns then when the Constitution was written and enshrined in the BOR and now incorporated into th 14th Civil Rights Amendment.
(2)	6	6	5	1	Gun control is about preventing such security risks.
(3)	7	7	5	1	First, you warn me of the dangers of using violent means to stop a crime .
(4)	5	6	6	6	So I don't see restrictions on handguns in D.C. as being a clear violation of the Second Amendment.

Table 4: Examples for model predictions on the online discussion dev set. The first column shows the gold label and the following columns the prediction made by the adversarial model (Adv), the Multi-Task model (MTL) and the LSTM baseline (LSTM).

Model	P_{ma}	R_{ma}	F_{ma}	F_{mi}
Random Baseline	0.196	0.198	0.189	0.196
Random Forest Baseline	0.496	0.335	0.267	0.279
LSTM Baseline	0.512	0.510	0.503	0.521
Multi-Task	0.526	0.525	0.505	0.534
Adversarial	**0.533**	**0.534**	**0.515**	**0.548**

Table 5: Macro- (ma) and micro-averaged (mi) scores for the online discussion test data averaged over 3 runs. The multi-task model uses the Twitter and argument quality datasets as auxiliary tasks. The micro-average F of a baseline that predicts the majority class is 0.307.

the baselines. The multi-task model achieves minor improvements over the LSTM baseline, with a bigger improvement in the micro-averaged score, indicating bigger improvements with frequent labels. The adversarial model performs best, with an error reduction in micro-averaged F over the LSTM baseline of 5.6%.

Figure 2 shows the system performances for each class. Each bar indicates the difference between the F-score of the respective system and the random baseline. The adversarial model achieves the biggest improvements over the baseline for classes 5 and 7, which are the two most frequent classes in the test set (cf. Table 6). For classes 1 and 13, the adversarial model is outperformed by the LSTM. Furthermore, we see that the hardest frame to predict is the *Policy prescription and evaluation frame* (6), where the models achieve the lowest improvement over the baseline and the lowest absolute F-score. This might be because utterances with this frame tend to address specific policies that vary according to topic and domain of the data, and are thus hard to generalize from source to target domain.

Analysis Table 4 contains examples of model predictions on the dialogue dev set. In Example (1), the adversarial and the multi-task model correctly predict a *Constitutionality* frame, while the LSTM model incorrectly predicts a *Crime and punishment* frame. In Examples (2) and (3), only the adversarial model predicts the correct frames. In both cases, the LSTM model incorrectly predicts an *Economic* frame, possibly because it is misled by picking up on a different sense of the terms *means* and *risks*. In Example (4), all models make an incorrect prediction. We speculate this might be because the models pick up on the phrase *restrictions on handguns* and interpret it as referring to a policy, whereas to correctly label the sentence they would have to pick up on the *violation of the Second Amendment*, indicating a *Constitutionality* frame.

6 Conclusion

This work introduced a new benchmark of political discussions from online fora, annotated with issue frames following the Policy Frames Cookbook. Online fora are influential platforms that can have impact on public opinion, but the language used in such fora is very different from newswire and other social media. We showed, however, how multi-task and adversarial learning can facilitate transfer learning from such domains, leveraging previously annotated resources to improve predictions on informal, multi-party discussions. Our best model obtained a micro-averaged F1-score of 0.548 on our new benchmark.

Appendix A Data Preprocessing

For the Twitter and news articles datasets, we remove all instances that do not correspond to the five target frames. Table 6 shows the class distributions in the filtered datasets. We tokenize all sequences using spaCy [7], which we also use for sentence splitting in the news articles dataset. For the Twitter dataset, we follow Johnson et al. (2017) in removing URLs and @-mentions.

Appendix B Hyperparameters in Experiments

The hyperparameters for all neural models were tuned on the online disc. dev set. We report test results for the optimal settings found by averaging over 3 training runs, which we determine by the best macro-averaged F-score and smallest variance between the runs. We set the DyNet weight decay parameter to 1e-7 for all neural models, batch size is 128, and the word embeddings are not updated during training.

For the multi-task and adversarial model, we do a grid-search over the weight of the coin flip used to decide on sampling from main/aux or main/adversarial task in the range of [0.1,0.2,0.3,0.4,0.5,0.6,0.7,0.8,0.9]. The optimal weight for sampling the main task is 0.5 for the multi-task model and 0.3 for the adversarial task.

All models are trained using early stopping (after at least 80 epochs of training) with a patience of 5 epochs. The number of iterations (updates) per epoch is a hyperparameter, that we set by default as twice the number of data batches for the main task. For a fair coin flip, the models hence see as much data for the main task as for the auxiliary/adversarial task per epoch.

Abstract

We present **V**ector of **L**ocally **A**ggregated **E**mbeddings (`VLAE`) for effective and, ultimately, lossless representation of textual content. Our model encodes each input text by effectively identifying and integrating the representations of its semantically-relevant parts. The proposed model generates high quality representation of textual content and improves the classification performance of current state-of-the-art deep averaging networks across several text classification tasks.

1 Introduction

Representation learning algorithms can reveal intrinsic low-dimensional structure in data (Rumelhart et al., 1986; Bengio et al., 2013; LeCun et al., 2015). In particular, deep averaging networks (DANs) are effective for text classification (Shen et al., 2018; Arora et al., 2017; Wieting et al., 2016; Iyyer et al., 2015). They achieve their improvement through use of word embeddings, weighted averaging, and deepening networks. The above works show that DANs can outperform RNNs and CNNs in text classification while taking only a fraction of their training time.

In this work, with a special focus on DANs, we study the effect of information loss associated with average word embeddings and develop algorithms that are robust against information loss for text representation. We show that divergence of word embeddings from their average can be considered as a good proxy to quantify information loss; in particular, longer documents suffer from significant information loss when represented by average word embeddings. These results inspire our work to develop a novel representation learning approach based on Vector of Locally Aggregated Descriptors (VLAD) (Jégou et al., 2010; Arandjelovic and Zisserman, 2013)–an effective approach to integrate image descriptors for large scale image datasets. Our model identifies semantically-relevant parts of documents and locally integrates their representations through clustering and autoencoding. In contrast to averaging, our model prevents larger semantically-relevant parts of inputs to dominate final representations. It improves DANs by 5.30 macro-F1 points in classifying longer texts and show comparable performance to them on shorter text.

2 Preliminary Analysis

How can information loss be quantified when word embeddings are averaged? How important it is to address information loss when representing textual content? Are representation learning algorithms robust against information loss? We conduct experiments to answer these questions with respect to deep averaging network (DANs). Our study can inspire works in more complex averaging approaches such as those reported in (Torabi Asr et al., 2018; Kiela et al., 2015) as well as recent works on unsupervised semantic similarity (Pagliardini et al., 2018). We use the DAN developed in (Joulin et al., 2017) and several datasets containing short and long documents to answer these questions.

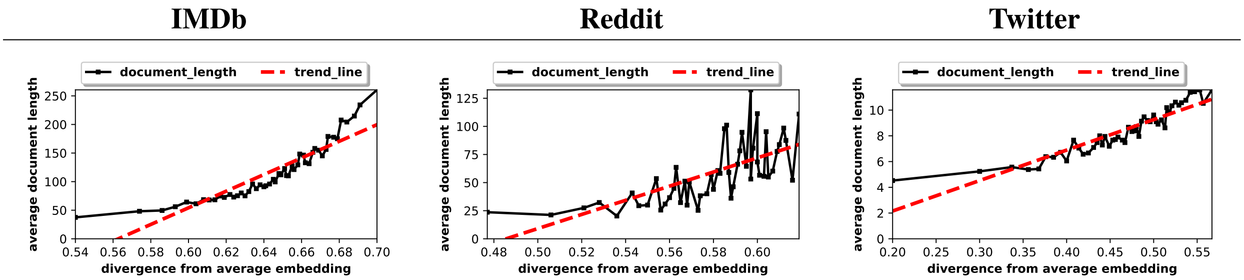
2.1 Quantifying Information Loss

Let's assume a d-dimensional word embedding space. We quantify the amount of information loss in the average word embedding vector of a given document $\mathbf{S} \in \mathbb{R}^{n \times d}$ by computing the average divergence (or distance) between its word embeddings, $\mathbf{w}_i \in \mathbb{R}^d \; \forall i \in \{1 \dots n\}$, and their average vector, $\bar{\mathbf{s}} = 1/n \sum_i \mathbf{w}_i$, $\bar{\mathbf{s}} \in \mathbb{R}^d$, as follows:

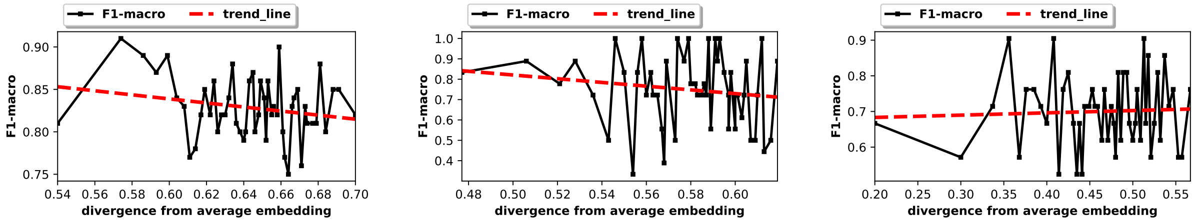
$$divergence = \frac{1}{n} \sum_i (1 - cosine(\bar{\mathbf{s}}, \mathbf{w}_i)). \quad (1)$$

Figures 1(a)–1(c) show strong positive correlation between divergence and document length

Proceedings of NAACL-HLT 2019, pages 1408–1414
Minneapolis, Minnesota, June 2 - June 7, 2019.



(a) divergence vs. length (b) divergence vs. length (c) divergence vs. length



(d) divergence vs. F1 (e) divergence vs. F1 (f) divergence vs. F1

Figure 1: Quantification of information loss associated with average word embeddings. Divergence indicates the average distance between individual word embeddings (of size $d = 300$) and their average embedding, see Equation (1). (a-c): show strong positive correlation between divergence and average document length (number of words in a document) across datasets. (d-f): show macro F1 performance of the deep averaging network developed in (Joulin et al., 2017) across datasets: performance considerably drops for higher values of information loss/divergence, e.g. divergence values above 0.55. Note that, we sort and bin instances based on their divergence values and report average length (a-c) and macro-F1 (d-f) for each bin.

across long and short text datasets. Given these results and if we assume longer documents should suffer from greater information loss if represented by average word embeddings, divergence from mean can be a good proxy to quantify information loss associated with average embeddings.

2.2 Effect of Information Loss

As Figures 1(d) and 1(e) show, DAN's macro-F1 classification performance considerably decreases as divergence (or text length) increases for IMDb and Reddit datasets; note that we sort and bin instances based on their divergence values and report average macro-F1 for each bin. In particular, as the trend lines in Figures 1(d) and 1(e) show, the average macro-F1 performance drops from 0.86 and 0.82 on shorter IMDb and Reddit posts to 0.82 and 0.71 on their longer posts respectively. In addition, the result on Twitter dataset, Figure 1(f), shows that DANs are robust against small information loss, i.e. small divergence values below 0.55 do not inversely affect macro-F1 performance. This result is also observed on the other two datasets, see macro-F1 performance for small divergence values (≤ 0.55) in Figures 1(d) and 1(e).

The above experiments show that (a): significant information loss can occur when word embeddings are averaged, in particular, when representing longer documents, and (b) such information loss can inversely affect the performance of downstream classifiers like DANs on longer texts. In this paper, we develop an effective representation learning model to tackle this problem.

3 Method

We propose to utilize semantically-relevant parts of inputs to tackle information loss associated with average word embeddings. Assuming that semantically-relevant words are closer to each other in semantic space (constructed over a global vocabulary), we expect divergence between words in semantically-relevant parts of inputs (i.e. information loss associated to their average word embedding) to be very small. Thus, as Figure 2 illustrates, we propose to cluster the semantic space to first identify semantically-relevant parts of inputs over a global vocabulary; we then effectively integrate these parts to represent documents.

Let's assume a global vocabulary $\mathcal{V}$ in which words are represented in a d-dimensional space, $\mathbf{w} \in \mathbb{R}^d$. As Figure 2 shows, we first cluster this semantic space into k clusters through the following objective function over $\mathcal{V}$:

$$min \sum_{\mathbf{w} \in \mathcal{V}} ||f(\mathcal{C}, \mathbf{w}) - \mathbf{w}||^2, \tag{2}$$

where $\mathcal{C}$ is the set of k cluster centers, $|\mathcal{C}| = k$, and $f(\mathcal{C}, \mathbf{w})$ returns the nearest cluster center $\mathbf{c} \in \mathcal{C}$ to the embedding vector $\mathbf{w}$ based on `cosine` similarity among embeddings or Euclidean distance in case of K-Means.[1]

Given a document $\mathbf{S} \in \mathbb{R}^{n \times d}$ with an arbitrary number of $n \geq 1$ words, and the above k cluster centers, we compute the representation of the document in each cluster $\mathbf{c}_i$, $i = 1 \ldots k$ as follows:

$$\mathbf{a}_i = \frac{1}{z_i} \sum_{j: f(\mathcal{C}, \mathbf{w}_j) = \mathbf{c}_i} \mathbf{w}_j \tag{3}$$

$$z_i = |j : f(\mathcal{C}, \mathbf{w}_j) = \mathbf{c}_i|,$$

where $\mathbf{a}_i \in \mathbb{R}^d$ indicates the representation of the document at cluster $\mathbf{c}_i$ and is obtained by taking the average embedding of words of the document that have been assigned to cluster $\mathbf{c}_i$ according to Equation (2), and z_i is the number of such words in cluster $\mathbf{c}_i$. To this end, each document can be represented by $\mathbf{A} \in \mathbb{R}^{d \times k}$ which is obtained by concatenating its cluster-level representations. Note that we didn't observe any performance difference between the above averaging process versus computing *residuals* (differences between word embeddings and corresponding cluster centroids) which is commonly used to represent cluster-level image descriptors (Jégou et al., 2010; Arandjelovic and Zisserman, 2013) in image processing.

Since $\mathbf{A}$s are of fixed length, they can be readily used as features in traditional classification and clustering algorithms. However, they can cause efficiency issues because of their large size ($d \times k$); note that the typical value for embedding dimension d is 300 (Pennington et al., 2014; Mikolov et al., 2013). To tackle this issue, we further integrate cluster-level representations, at the cost of some further information loss, to create representations of lower dimension for inputs.

In particular, given all input documents with k cluster-level representations $\mathbf{A} \in \mathbb{R}^{d \times k}$ for each document, we develop an autoencoder with one hidden layer that integrates these cluster-level representations to create a final representation for each document, vector $\mathbf{a} \in \mathbb{R}^{d \times m}$ where m is the dimensionality reduction parameter and $m \times d$ is length of the representation (final layer of the encoder) and is smaller than $d \times k$ for $m < k$. Training a single-layer autoencoder corresponds to optimizing the learning parameters to minimize the overall loss between inputs and their reconstructions. For real-valued $\mathbf{A}$, squared loss is often used (Vincent et al., 2010), i.e. $l(\mathbf{A}) = ||\mathbf{A} - \hat{\mathbf{A}}||^2$ where $\hat{\mathbf{A}} \in \mathbb{R}^{d \times k}$ is reconstruction of $\mathbf{A}$ and generated by the decoder from $\mathbf{a}$. Our intuition is that if $\mathbf{a}$ leads to a good reconstruction of $\mathbf{A}$, it has retained all information available in the input.

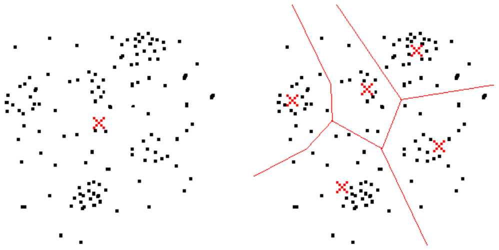


Figure 2: Illustration of VLAEs: squares show word embeddings of a hypothetical document and crosses show their corresponding average. (a): shows average word embedding in center - the case of high information loss or divergence from mean, (b): shows average word embeddings in corresponding word clusters; these embeddings are used to produce VLAEs.

We refer to $\mathbf{a} \in \mathbb{R}^{d \times m}$ as the Vector of Locally Aggregated Embeddings (VLAE). We expect this final representation to be robust against information loss due to its cluster-level local aggregation which prevents larger portions of semantically-similar words to dominate the representation.

4 Experiments

Data: We investigate VLAEs in three binary classification tasks: sentiment classification on IMDb (Maas et al., 2011), disease-text classification on Reddit, where the task is to classify reddit posts as relevant or irrelevant to specific diseases, and churn prediction on Twitter (Amiri and Daumé III, 2015), where the task is to classify/predict if given tweets indicate user intention about leaving brands, e.g. the tweet "my days with BRAND are numbered" is a *churny* tweet. See details in Table 1. For pre-processing, we change all texts to lowercase, and remove stop words, user names, and URLs from texts.

---

[1] This problem can be solved through gradient descent seeded with an initial set of k examples drawn uniformly at random from $\mathcal{V}$ (Bottou and Bengio, 1995; Sculley, 2010).

	Train	Val	Test	Unlabeled
IMDb	40K	5K	5K	50K
Reddit	2K	1K	1K	100K
Twitter	3K	1K	1K	100K

Table 1: Statistics of dataset used in experiments.

Settings: We use validation data for hyperparameter tuning and model selection. We use 300-dimensional word embeddings ($d = 300$) provided by Google (Mikolov et al., 2013), and for greater number of ds, we train `word2vec` on unlabeled data, see Table 1. In addition, we set the dimensionality reduction parameter m from $\{1 \dots 4\}$ using validation data. The best value of m is the same across tasks/datasets, $m = 2$. Furthermore, we determine the number of clusters k for VLAEs by choosing the optimal k from $\{2^i, i = \{1 \dots 7\}\}$ using validation data of each dataset. We learn optimal k with respect to task, but not embedding space, due to significant density of the semantic space of word embeddings, see Note on Clustering Word Embeddings.

Baselines: We consider two versions of DANs as baselines: `Avg_small` and `Avg_large` which represent documents by average word embedding of size $d = 300$ and $d = m \times 300$ respectively. Note that, for fair comparison, `Avg_large` has the exact same size as our model (`VLAE`); however, depending on m, their network size is 1.3-1.6 times greater than that of `Avg_small` due to difference in input dimensions. We use 3 hidden layers of size 300 for above networks. Also, to directly evaluate the effect of averaging, we do not adjust initial word embeddings during training.

Experimental Results: Table 2 shows the performance of different models across datasets. The results show that `VLAE` significantly outperforms `Avg_small` and `Avg_large` by 2.6 and 7.2 points in Macro-F1 on IMDb. The corresponding values on Reddit dataset are 6.7 and 3.4 points respectively. We believe these improvements are due to more effective and lossless representation of inputs. We note that `Avg_large` performs worse than `Avg_small` on IMDb. This could be attributed to the size of training data which may not be enough to train `Avg_large`, or to lower quality of input representations in `Avg_large` compared to `Avg_small` in case of IMDb. Note that although `VLAE` has the same number of parameters as `Avg_large`, it uses autoencoding to effectively filter redundant information. Verifying these hypotheses will be the subject of future work. In addition, `VLAE` show lower performance than `Avg_large` on Twitter dataset, F1 of 72.62 versus 73.08. We attribute this result to the shorter length of tweets for which, as we experimentally showed before, averaging does not cause major divergence in representations. On average, `VLAE` improves `Avg_small` and `Avg_large` by 4.7 and 5.3 F1 points on IMDb and Reddit (longer texts) respectively. It also shows comparable performance to best performing model on Twitter (shorter texts).

	Avg_small	Avg_large	VLAE
IMDb	83.11	78.52	**85.72***
Reddit	59.42	62.72	**66.10***
Twitter	61.42	**73.08***	72.62
AVG	67.98	71.44	**74.81**

Table 2: Macro-F1 performance of different models across datasets. Asterisk mark (*) indicates significant difference between top two systems. `VLAE` outperforms other models on longer texts, and show comparable performance to `Avg_large` on shorter text.

We also compare models in terms of the quality of their representations. For this comparison, we ignore input preparation time and assume a model that generates better representations should converge faster than other models; note that the overall turnaround time of `VLAE` is greater than that of `Avg_small` or `Avg_large` because of its input preparation time which we ignore for the purpose of this experiment. The result show that `VLAE` leads to 7.5, 1.3, and 1.3 times faster convergence than `Avg_small` and 14.9, 2.6, and 1.8 times faster convergence than `Avg_large` on IMDb, Reddit, and Twitter datasets respectively. Considering the size of these networks, these results indicate that representations obtained from VLAE are much better than those of its counterparts.

Note on Clustering Word Embeddings: In experiments, we observe clusters obtained from word embeddings are often very dense. This is a challenge for our model because with small number of clusters (ks) potentially dissimilar words can appear in the same cluster, while with large ks semantically-similar words may appear in different clusters. Neither of these are desired.

To illustrate the above challenge, we report Silhouette Coefficient (SC) (Rousseeuw, 1987) of k-means with different number of clusters obtained from words embeddings across datasets. SC indicates how well cluster boundaries are detected

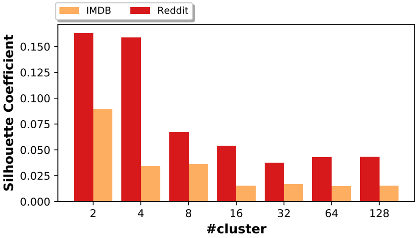

Figure 3: Mean Silhouette Coefficient computed for different number of clusters; a higher Silhouette Coefficient score indicates better defined clusters.

by a clustering model. It is calculated using the mean intra-cluster distance and the mean nearest-cluster distance for each sample. Specifically, the mean distance between each embedding and all other embeddings in the same cluster (mc), and the mean distance between the embedding and all other embeddings in the next nearest cluster (the nearest cluster that the embedding is not part of) (mn) are used to measure SC for the embedding:

$$\frac{mn - mc}{\max(mn, mc)}.$$

The best and worst SC scores are 1 and -1 which indicate ideal and worst clustering respectively. Also, values near 0 indicate overlapping clusters.

Figure 3 shows the mean SCs computed over all word embeddings for IMDb and Reddit datasets.[2] The results show that (a): the best number of clusters is $k = 2$ on both datasets, and (b): Silhouette Coefficient scores generally home in on values close to zero as the number of clusters increases. These results show significant density of embeddings in semantic space. Therefore, we optimize the number of clusters for creating `VLAEs` by resorting to validation data and measuring task-specific performance. From these results, we conclude that a hierarchical clustering approach that recursively combines pairs of semantically-similar clusters could help better defining these clusters and perhaps improve the performance of our model.

5 Related Work

Deep averaging networks (DANs) (Joulin et al., 2017; Iyyer et al., 2015; Arora et al., 2017; Shen et al., 2018) were developed based on the successes of vector operations in embedding space. In contrast to their simplicity, DANs showed high performance in text classification tasks.

Arora et al. (2017) showed that sentences can be effectively represented by the weighted average of their word embeddings modified by PCA/SVD. In addition, the DANs developed in (Iyyer et al., 2015), (Joulin et al., 2017), and (Shen et al., 2018) were feed-forward networks that used average word embeddings to represent inputs; they were effective for several NLP tasks such as document categorization, text pair similarity, and short sentence classification. Furthermore, feed-forward architectures like DANs have been used for language modeling (Bengio et al., 2003) and greedy transition-based dependency parsing (Chen and Manning, 2014) with fast turnaround time.

In addition, previous research investigated a variety of vector operations that could replace the averaging operation used in the DANs. Many of these operations have been studied in (Mitchell and Lapata, 2008) for modeling the compositionality of short phrases, or showing the utility of simple vector computations(Banea et al., 2014). The operations in (Mitchell and Lapata, 2008) were also extended to use syntactic relation between words and grammar (Erk and Padó, 2008; Collobert and Weston, 2008). Also, clustering semantic space was studied in (Mekala et al., 2017) to learn context information for words and for tasks like topic coherence and information retrieval.

In this work, we built on previous work on DANs and investigated and tackled information loss associated with average word embeddings.

6 Conclusion and Future Work

We investigate information loss associated with average word embeddings. We show that averaging lead to significant information loss and propose to tackle the issue by identify semantically-similar parts of documents through clustering of semantic space at word-level and integrating cluster-level representations through autoencoding. A promising future direction is to use hierarchical clustering to create better cluster-level representations.

Acknowledgments

We thank anonymous reviewers for their insightful comments and constructive feedback.

Abstract

As offensive content has become pervasive in social media, there has been much research in identifying potentially offensive messages. However, previous work on this topic did not consider the problem as a whole, but rather focused on detecting very specific types of offensive content, e.g., hate speech, cyberbulling, or cyber-aggression. In contrast, here we target several different kinds of offensive content. In particular, we model the task hierarchically, identifying the type and the target of offensive messages in social media. For this purpose, we complied the Offensive Language Identification Dataset (OLID), a new dataset with tweets annotated for offensive content using a fine-grained three-layer annotation scheme, which we make publicly available. We discuss the main similarities and differences between OLID and pre-existing datasets for hate speech identification, aggression detection, and similar tasks. We further experiment with and we compare the performance of different machine learning models on OLID.

1 Introduction

Offensive content has become pervasive in social media and thus a serious concern for government organizations, online communities, and social media platforms. One of the most common strategies to tackle the problem is to train systems capable of recognizing offensive content, which can then be deleted or set aside for human moderation. In the last few years, there have been several studies on the application of computational methods to deal with this problem. Prior work has studied offensive language in Twitter (Xu et al., 2012; Burnap and Williams, 2015; Davidson et al., 2017; Wiegand et al., 2018), Wikipedia comments,[1] and Facebook posts (Kumar et al., 2018).

Previous studies have looked into different aspects of offensive language such as the use of abusive language (Nobata et al., 2016; Mubarak et al., 2017), (cyber-)aggression (Kumar et al., 2018), (cyber-)bullying (Xu et al., 2012; Dadvar et al., 2013), toxic comments[1], hate speech (Kwok and Wang, 2013; Djuric et al., 2015; Burnap and Williams, 2015; Davidson et al., 2017; Malmasi and Zampieri, 2017, 2018), and offensive language (Wiegand et al., 2018).

Recently, Waseem et al. (2017) analyzed the similarities between different approaches proposed in previous work and argued that there was a need for a typology that differentiates between whether the (abusive) language is directed towards a specific individual or entity, or towards a generalized group, and whether the abusive content is explicit or implicit. Wiegand et al. (2018) further applied this idea to German tweets. They experimented with a task on detecting offensive vs. non-offensive tweets, and also with a second task on further sub-classifying the offensive tweets as profanity, insult, or abuse. However, to the best of our knowledge, no prior work has explored the target of the offensive language, which might be important in many scenarios, e.g., when studying hate speech with respect to a specific target. Below, we aim at bridging this gap.

More generally, in this paper, we expand on the above ideas by proposing a novel three-level hierarchical annotation schema that encompasses the following three general categories:

A: Offensive Language Detection

B: Categorization of Offensive Language

C: Offensive Language Target Identification

We further use the above schema to annotate a large dataset of English tweets, which we make publicly available online.[2]

The key contributions of this paper can be summarized as follows:

- We propose a new three-level hierarchical annotation schema for abusive language detection and characterization.
- We apply the schema to create *Offensive Language Identification Dataset (OLID)*, a new large-scale dataset of English tweets with high-quality annotation of the target and type of offenses.
- We perform experiments on OLID using different machine learning models for each level of the annotation, thus setting important baselines to compare to in future work.

While each of these sub-tasks tackles a particular type of abuse or offense, they share similar properties and the hierarchical annotation model proposed in this paper aims to capture this. Considering that, for example, an insult targeted at an individual is commonly known as cyberbulling and that insults targeted at a group are known as hate speech, we believe that OLID's use of a hierarchical annotation schema makes it a useful resource for various offensive language identification and characterization tasks.

2 Hierarchically Modelling Offensive Content

In the OLID dataset, we use a hierarchical annotation schema split into three levels to distinguish between whether the language is offensive or not (A), its type (B), and its target (C). Each level is described in more detail in the following subsections and examples are shown in Table 1.

2.1 Level A: Offensive language Detection

Level A discriminates between the following types of tweets:

- **Not Offensive (NOT):** Posts that do not contain offense or profanity;
- **Offensive (OFF):** Posts containing any form of non-acceptable language (profanity) or a targeted offense, which can be veiled or direct. This includes insults, threats, and posts containing profane language or swear words.

2.2 Level B: Categorization of Offensive Language

Level B categorizes the type of offense:

- **Targeted Insult (TIN):** Posts containing insult/threat to an individual, a group, or others;
- **Untargeted (UNT):** Posts containing non-targeted profanity and swearing. Posts with general profanity are not targeted, but they contain non-acceptable language.

2.3 Level C: Offensive Language Target Identification

Level C categorizes the targets of insults/threats:

- **Individual (IND):** Posts targeting an individual. This can be a famous person, a named individual or an unnamed participant in the conversation. Insults and threats targeted at individuals are often defined as cyberbulling.
- **Group (GRP):** Posts targeting a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or other common characteristic. Many of the insults and threats targeted at a group correspond to what is commonly understood as hate speech.
- **Other (OTH)** The target of these offensive posts does not belong to any of the previous two categories (e.g., an organization, a situation, an event, or an issue).

Keyword	**Offensive %**
medical marijuana	0.0
they are	5.9
to:NewYorker	8.3
you are	21.0
she is	26.6
to:BreitBartNews	31.6
he is	32.4
gun control	34.7
-filter:safe	58.9
conservatives	23.2
antifa	26.7
MAGA	27.7
liberals	38.0

Table 2: The keywords from the full dataset (except for the first three rows) and the percentage of offensive tweets for each keyword.

3 Data Collection

We retrieved the examples in OLID from Twitter using its API and searching for keywords and constructions that are often included in offensive messages, such as 'she is' or 'to:BreitBartNews'[3]. The full list of keywords we used is shown in Table 2.

We first carried out a round of trial annotation of 300 instances with six experts using nine keywords. The goal of the trial annotation was (*i*) to evaluate the proposed tagset, (*ii*) to evaluate the data retrieval method, and (*iii*) to create a gold standard with instances that could be used as test questions to ensure the quality of the annotators for the rest of the data, which was carried out using crowdsourcing. The keywords used in the trial annotation are shown in the first nine rows of Table 2. We included left (*@NewYorker*) and far-right (*@BreitBartNews*) news accounts because there tends to be political offense in the comments for such accounts. The keyword that resulted in the highest concentration of offensive content was the Twitter 'safe' filter, corresponding to tweets that were flagged as unsafe by Twitter (the '-' symbiol indicates 'not safe').

Since the vast majority of content on Twitter is not offensive, we tried different strategies to keep the distribution of offensive tweets at around 30% of the dataset. We excluded some keywords that were not high in offensive content during the trial annotation such as 'they are' and 'to:NewYorker'. Although 'he is' was poor in offensive content in the trial dataset (15%), we kept it as a keyword in order to avoid gender bias, and we found that in the full dataset it was more offensive (32.4%). The trial keywords that we ultimately decided to exclude due to low percentage of offensive tweets are shown in the top portion of Table 2.

We computed Fleiss' $kappa$ on the trial dataset for the five annotators on 21 of the tweets. The value was .83 for Layer A (OFF vs. NOT) indicating high agreement. As to normalization and anonymization, we did not store any user metadata or Twitter IDs, and we substituted the URLs and the Twitter mentions by placeholders.

During the full annotation task, we decided to search for more political keywords as they tend to be richer in offensive content. Thus, we sampled our full dataset, so that 50% of the tweets come from political keywords, and the other 50% come from non-political keywords. Within these two groups, tweets were evenly sampled for the keywords. In addition to 'gun control', and 'to:BreitbartNews' used during the trial annotation, four new political keywords were used to collect tweets for the full dataset: 'MAGA', 'antifa', 'conservatives', and 'liberals'. The breakdown of keywords and their offensive content in the full dataset is shown in the bottom of Table 2.

We follow prior work in related areas (Burnap and Williams, 2015; Davidson et al., 2017) and we annotate our data using crowdsourcing. We used Figure Eight[4] and we ensured data quality by (*i*) only hiring annotators who were experienced in the platform, and (*ii*) using test questions to discard annotations by individuals who did not reach a certain threshold. Each instance in the dataset was annotated by multiple annotators and inter-annotator agreement was calculated at the end.

We first acquired two annotations for each instance. In the case of disagreement, we requested a third annotation, and we then took a majority vote. The annotators were asked to label each tweet at all three levels of the annotation scheme, and we considered there to be agreement only when the annotators agreed on the labels for all levels. Approximately 60% of the time, the two annotators agreed, and thus no additional annotation was needed. A third annotation was requested for the rest of the tweets; there was no instance when more than three annotations were needed.

---

[3] *to* is a special Twitter API word indicating that the tweet was directed at a specific account (e.g., BreitBartNews).

A	B	C	Training	Test	Total
OFF	TIN	IND	2,407	100	2,507
OFF	TIN	OTH	395	35	430
OFF	TIN	GRP	1,074	78	1,152
OFF	UNT	—	524	27	551
NOT	—	—	8,840	620	9,460
All			13,240	860	14,100

Table 3: Distribution of label combinations in OLID.

The breakdown of the data into training and testing for the labels from each level is shown in Table 3. It is worth noting that one of the key challenges we observed when collecting for OLID was producing a dataset containing a sufficient number of instances for each class. This is particularly evident in the sizes for Subtasks B and C. Other studies also had this issue when collecting similar datasets. For example, in (Davidson et al., 2017), only 5% of the tweets were considered hate speech by the majority of the annotators, and in (Burnap and Williams, 2015) only 11.6% of the examples were labeled as hate speech.

4 Experiments and Evaluation

We experiment with various models:

SVM Our simplest machine learning model is a linear SVM trained on word unigrams. SVMs have achieved state-of-the-art results for many text classification tasks (Zampieri et al., 2018).

BiLSTM We also experiment with a bidirectional Long Short-Term-Memory (BiLSTM) model, which we adapted from a pre-existing model for sentiment analysis (Rasooli et al., 2018). The model consists of (*i*) an input embedding layer, (*ii*) a bidirectional LSTM layer, and (*iii*) an average pooling layer of input features. The concatenation of the LSTM layer and the average pooling layer is further passed through a dense layer, whose output is ultimately passed through a *softmax* to produce the final prediction. We set two input channels for the input embedding layers: pre-trained FastText embeddings (Bojanowski et al., 2017), as well as updatable embeddings learned by the model during training.

CNN Finally, we experiment with a Convolutional Neural Network (CNN) model based on the architecture of (Kim, 2014), and using the same multi-channel inputs as the above BiLSTM.

Our models are trained on the training dataset, and evaluated by predicting the labels for the held-out test set. As the label distribution is highly imbalanced (see Table 3), we evaluate and we compare the performance of the different models using macro-averaged F1-score. We further report per-class Precision (P), Recall (R), and F1-score (F1), and weighted average. Finally, we compare the performance of the models against simple majority and minority class baselines.

4.1 Offensive Language Detection

The performance on discriminating between offensive (OFF) and non-offensive (NOT) posts is reported in Table 4. We can see that all models perform significantly better than chance, with the neural models performing substantially better than the SVM. The CNN outperforms the RNN model, achieving a macro-F1 score of 0.80.

4.2 Categorization of Offensive Language

In this set of experiments, the models were trained to discriminate between targeted insults and threats (TIN) and untargeted (UNT) offenses, which generally refer to profanity. The results are shown in Table 5. We can see that the CNN performs better than the BiLSTM, with a macro-F1 score of 0.69. Note that all models perform better at identifying TIN compared to UNT.

4.3 Offensive Language Target Identification

The results for the offensive target identification experiment are shown in Table 6. Here the models were trained to distinguish between three targets: a group (GRP), an individual (IND), or others (OTH). We can see that all three models achieved similar results, far surpassing the random baselines, with a slight performance edge for the neural models.

The performance of all models for the OTH class is 0, which can be explained by two factors. First, unlike the two other classes, OTH is a heterogeneous collection of targets. It includes offensive tweets targeted at organizations, situations, events, etc., thus making it more challenging for models to learn discriminative properties for this class. Second, there are fewer training instances for this class compared to the other two: there are only 395 instances for OTH vs. 1,075 for GRP and 2,407 for IND.

	NOT			OFF			Weighted Average

5 Conclusion and Future Work

We presented OLID, a new dataset with annotation of type and target of offensive language. It is the official dataset of the shared task *SemEval 2019 Task 6: Identifying and Categorizing Offensive Language in Social Media* (OffensEval) (Zampieri et al., 2019).[5] In OffensEval, each annotation level in OLID is an independent sub-task. To the best of our knowledge, this is the first dataset to contain annotation of type and target of offenses in social media, and it opens interesting research directions.

We further presented baseline experiments using SVMs and neural networks, which have shown that this is a challenging, yet doable task.

In future work, we would like to make a cross-corpus comparison of OLID vs. datasets annotated for similar tasks such as aggression identification (Kumar et al., 2018) and hate speech detection (Davidson et al., 2017). We further plan to create similar datasets for other languages, following OLID's hierarchical annotation scheme.

Acknowledgments

We would like to thank the anonymous NAACL reviewers for their valuable suggestions and Nikola Ljubešić for the feedback provided.

This research presented was partially supported by an ERAS fellowship awarded to Marcos Zampieri by the University of Wolverhampton.

Biomedical Event Extraction Based on Knowledge-driven Tree-LSTM

Abstract

Event extraction for the biomedical domain is more challenging than that in the general news domain since it requires broader acquisition of domain-specific knowledge and deeper understanding of complex contexts. To better encode contextual information and external background knowledge, we propose a novel knowledge base (KB)-driven tree-structured long short-term memory networks (Tree-LSTM) framework, incorporating two new types of features: (1) dependency structures to capture wide contexts; (2) entity properties (types and category descriptions) from external ontologies via entity linking. We evaluate our approach on the BioNLP shared task with Genia dataset and achieve a new state-of-the-art result. In addition, both quantitative and qualitative studies demonstrate the advancement of the Tree-LSTM and the external knowledge representation for biomedical event extraction.

1 Introduction

Biomedical information extraction is widely used to assist the biology community on knowledge acquisition and ontology construction. Biomedical events generally refer to a change of status, particularly on proteins or genes. The goal of event extraction is to identify triggers and their arguments from biomedical text, and then assign an event type to each trigger and a role to each argument. For example, in the sentence shown in Figure 1, it includes a **gene expression** and a **positive regulation** event mention, both triggered by the word *transduced*. *Tax* is the **Theme** argument of the **gene expression** event. An event could also serve as an argument of another event, leading to a nested structure. For instance, the **gene expression** event triggered by *transduced* is also a **Theme** argument of the **positive regulation** event as shown in Figure 1.

Earlier studies on biomedical event extraction rely on kernel classification methods like the support vector machines (SVMs) (Björne and Salakoski, 2011; Venugopal et al., 2014) using hand-crafted features, which require high engineering effort and domain-specific knowledge. Recent distributional representation based approaches (Rao et al., 2017; Björne and Salakoski, 2018) explore deep neural networks which only require distributed semantic features. However, different from event extraction in the general news domain, biomedical event extraction requires broad acquisition of domain-specific knowledge and deep understanding of complex contexts. For example, in Genia event extracton of BioNLP shared task 2011 (Kim et al., 2011), about 80% of entity mentions are abbreviations of genes, proteins and diseases while more than 36% of event triggers and arguments are separated with more than 10 words.

In order to efficiently capture indicative information from broad contexts, we first adopt tree structure based long short-term memory (Tree-LSTM) networks. Compared to the linear chain structured LSTM, the Tree-LSTM takes tree-structured network topology into consideration. As shown in the top frame of Figure 1, Tree-LSTM takes the dependency tree structure of each sentence as input and gradually incorporates the information from the whole subtree into each node. Dependency tree structure can connect semantically related concepts, and thus shorten the distance between a trigger and its arguments significantly. For instance, in the following sentence "*... , which* **binds** *to the enhancer A located in the promoter of the mouse MHC class I gene* **H-2Kb**, ...", when determining the trigger type of *binds*, we need to carefully select its contextual words, such as *H-2Kb*, which indicates the object of *binds*. However, *binds* and *H-2Kb* are sepa-

Proceedings of NAACL-HLT 2019, pages 1421–1430
Minneapolis, Minnesota, June 2 - June 7, 2019.

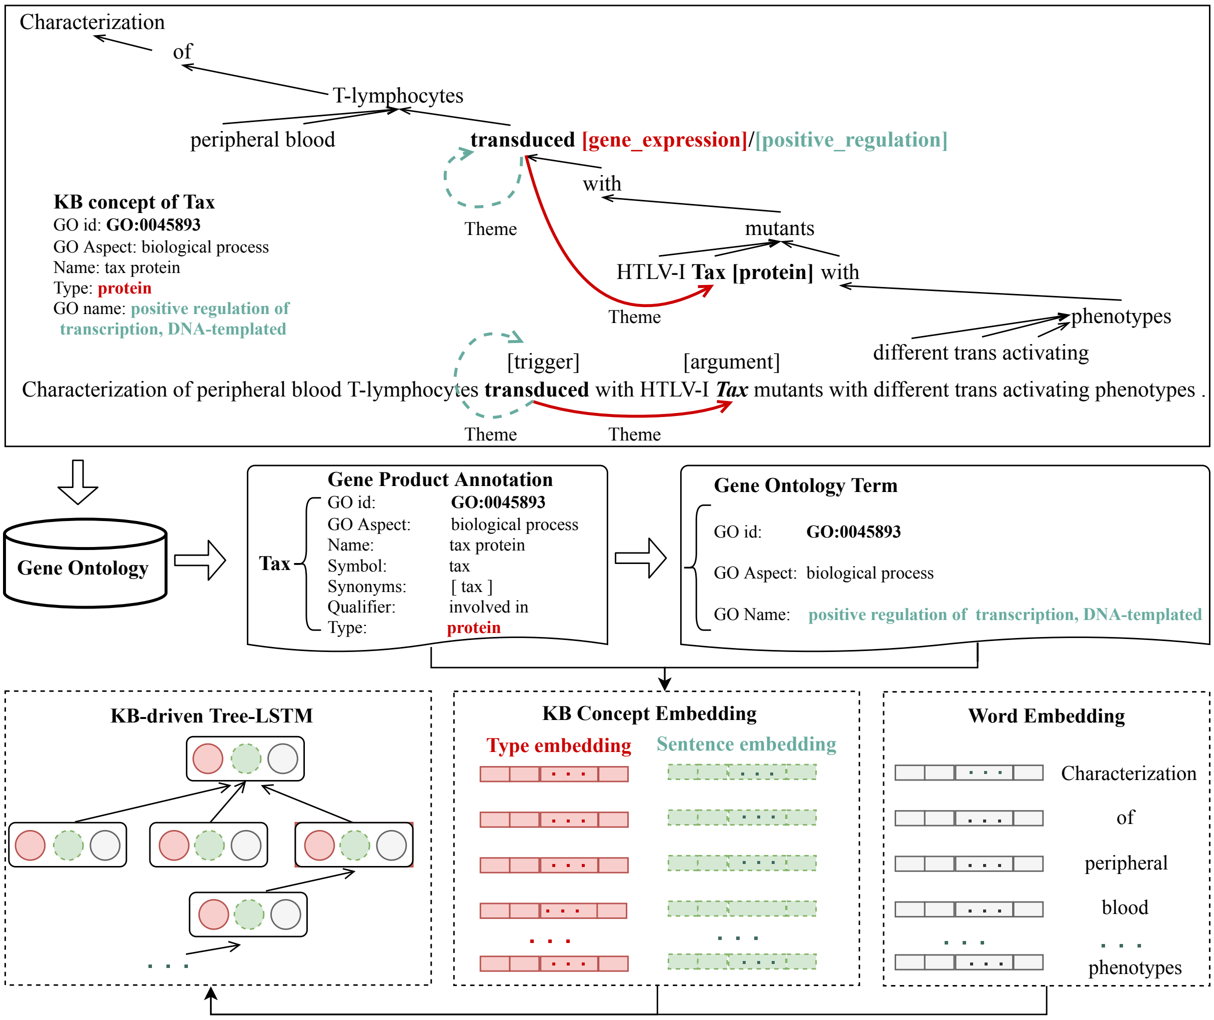

Figure 1: The framework of the KB-driven Tree-LSTM model. The upper frame shows the dependency tree structure and event annotations of a sentence; the middle frame demonstrates the knowledge base information obtained from the Gene Ontology for *Tax*; the bottom frame describes the KB-driven Tree-LSTM which takes the KB concept embedding and word embedding as input.

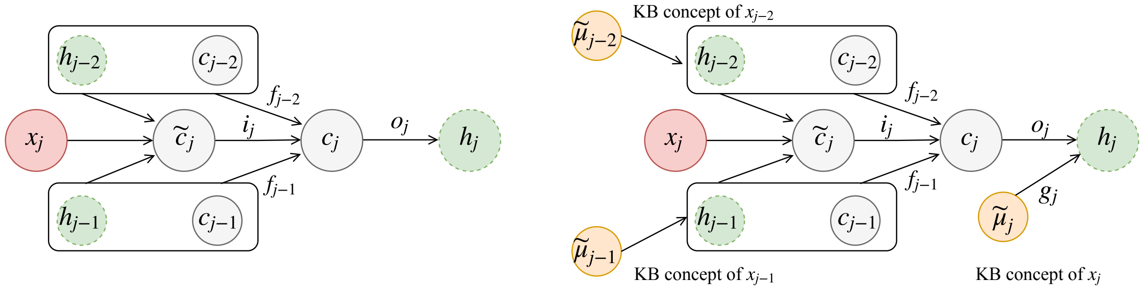
rated with 16 words which is difficult for a chain-structured LSTM to capture their long distance dependency, while within dependency tree structure, their distance is significantly shortened to 7.

Moreover, to better capture domain-specific knowledge, we further propose to leverage the external knowledge bases (KBs) to acquire properties of all the biomedical entities. The KB properties are extremely beneficial for our model to learn patterns more explicitly. Take the entity *Tax* in Figure 1 as an example, it's a protein often involved in the biological process of *positive regulation of transcription* referred to Gene Ontology (Ashburner et al., 2000). This function description provides crucial clues to determine the type of *transduced* as **positive regulation**. Therefore, to capture such knowledge from external KBs, for each entity, we first learn a KB concept embedding from its properties, and then automatically incorporate the KB representation into its Tree-LSTM hidden state with a gate function.

Our contributions are twofold: First, to the best of our knowledge, it's the first time to adopt Tree-LSTM for biomedical event extraction to effectively capture the wide contexts. Second, we further incorporate external knowledge from domain-specific KBs into the Tree-LSTM, which yields state-of-the-art performance on Genia event extraction shared task.

2 KB-driven Tree-LSTM for Event Extraction

In this section, we present our KB-driven Tree-LSTM approach for biomedical event extraction.



A. a Tree-LSTM unit **B. a KB-driven Tree-LSTM unit**

Figure 2: (A): a Tree-LSTM unit. (B): a KB-driven Tree-LSTM unit. The yellow circles with $\widetilde{\mu}$ notations denote external KB concept embeddings.

We first introduce the Tree-LSTM framework, and then describe the construction of KB concept embedding for each entity. Finally we incorporate the KB concept embedding into a Tree-LSTM and apply it for event trigger and argument extraction.

2.1 Tree-LSTM

The Tree-LSTM (Tai et al., 2015) is a variation of LSTM (Hochreiter and Schmidhuber, 1997) to a tree-structured network topology. It shows improvement in representing sentence semantic meaning compared to sequential LSTM such as Bidirectional LSTM (BiLSTM) (Graves et al., 2013). The main difference between sequential LSTM and Tree-LSTM is, at each time step, the former calculates its hidden state from the input at the current time step and the hidden state from previous step, while Tree-LSTM computes its hidden state from the input token and the hidden states of all its children nodes from the tree structure. A Tree-LSTM reduces to sequential LSTM when each node in the tree only has one child. Figure 2 (A) shows a Tree-LSTM unit. In order to obtain the hidden state h_j of an input token x_j, the unit calculates all of its children hidden states (h_{j-1}, h_{j-2}) through depth-first traversal.

2.2 Constructing KB Concept Embedding

For the biomedical event extraction, we mainly explore the Gene Ontology as our external KB since it provides detailed descriptions for each gene and gene product attributes across all species. It consists of two types of information: (1) the gene ontology (GO) defines all the gene functions, relations between these gene functions, and aspects used to describe the gene functions, including molecular function, cellular component and biological process. (2) the gene product annotations (GO Anno) provide all entity related attributes, such as the full entity name, entity type, as well as the gene functions it is related to. For example, in Figure 1, given the entity *tax*, from the gene product annotations, we can get its full entity name as *tax protein* which is a type of *proteins* and it's related to a function about *biological process*. From the gene ontology, we can further determine the specific function that *tax* is related to *positive regulation of transcription* in terms of *biological process* aspect.

In order to leverage the external KB information, we first apply QuickGO API (Binns et al., 2009) to link each entity mention to the Gene Ontology and retrieve all the KB annotations. For each entity, we carefully select two types of properties which are beneficial for event extraction task: the entity type (e.g., *protein* for *tax*) and the gene ontology function it is related to (e.g., *positive regulation of transcription* for *tax*). The entity type can facilitate the explicit pattern learning for argument role labeling, for example, the gene expression event pattern (Theme: Protein, Trigger: transduced) is more popular than (Theme: Tax, Trigger: transduced) in Figure 1. The gene ontology function can provide implicit clues to determine the trigger type as aforementioned in Section 1.

As shown in Figure 1, we assign a word embedding which pretrained on PubMed and PMC texts (Moen and Ananiadou, 2013) to represent each entity type. For each gene ontology function which is usually a long phrase, we use a state-of-the-art sentence embedding approach (Conneau et al., 2017) to automatically learn a vector representation. We then concatenate these two types of KB property representations as the final KB concept embedding.

2.3 Event Trigger Extraction

After obtaining the KB concept embeddings, we further incorporate them into the Tree-LSTM to leverage the domain-specific knowledge.

Given a sentence, for example the sentence shown in Figure 3, we first perform the dependency parsing with the Stanford dependency parser (Chen and Manning) and obtain a dependency tree structure. For each node j in the tree structure, $C(j)$ is the set of children nodes of node j and μ_k is the KB concept embedding of node k. We set μ_k to 0 if node k is not a biomedical entity. $\widetilde{\mu}_j$ denotes the sum of the KB concept embeddings of j's children nodes and $\widetilde{h}_j$ is the sum of the hidden states of j's children nodes:

$$\widetilde{h}_j = \sum_{k \in C(j)} h_k$$

$$\widetilde{\mu}_j = \sum_{k \in C(j)} \mu_k$$

where h_k is the hidden state of node k.

Then we incorporate the KB concept embeddings into the input, forget, and output gates of the Tree-LSTM:

$$\begin{aligned} i_j &= \sigma(W_i[x_j, \widetilde{h}_j, \widetilde{\mu}_j] + b_i) \\ f_{jk} &= \sigma(W_f[x_j, h_k, \widetilde{\mu}_k] + b_f) \\ o_j &= \sigma(W_o[x_j, \widetilde{h}_j, \widetilde{\mu}_j] + b_o) \end{aligned}$$

where i_j and o_j are the input gate and the output gate for node j respectively. f_{jk} is the forget gate for node j in terms of its child node k. W_i, W_f, and W_o are learnable parameters, b_i, b_f and b_o are bias terms. Thus, for each node j, the input gate gathers all KB information from its children nodes, and the output gate balances the meaningful information from its local contexts and the KB concept embeddings of its children nodes.

Besides adding the KB concept embeddings into the three gates to select useful KB formation implicitly, similar to Ma et al. (2018), we also introduce a knowledge specific output gate g_j to explicitly incorporate knowledge information into each node's hidden state. While different from Ma et al. (2018) which only considers the knowledge concept embedding of each node itself, we use the sum of the KB concept embeddings of the whole subtree instead:

$$g_j = \sigma(W_g[x_j, \widetilde{h}_j, \widetilde{\mu}_j] + b_g)$$

where W_g is a weight matrix to be learned, b_g is the bias term.

As demonstrated in Figure 2 (B), we eventually combine the implicit way of incorporating KB information into the input, output and forget gates and an explicit way of directly incorporating the KB information into a node's hidden state:

$$\begin{aligned} \widetilde{c}_j &= \tanh(W_c[x_j, \widetilde{h}_j] + b_c) \\ c_j &= \sum_{k \in C(j)} f_{jk} \odot c_k + i_j \odot \widetilde{c}_j \\ h_j &= o_j \odot \tanh(c_j) + g_j \odot \tanh(W_\mu \widetilde{\mu}_j) \end{aligned}$$

where c_j is the memory cell, W_c and W_μ are weight matrices to be learned.

After getting the hidden state h_j of each node j, we use a softmax classifier to predict a label for each node, and optimize the parameters by minimizing a negative log-likelihood loss.

2.4 Event Argument Role Labeling

After detecting all candidate triggers, we further extract arguments for each trigger. The Genia event extraction shared task provides the annotations of all entity mentions. Thus, for each trigger, we use all the entity mentions that occur in the same sentence as its candidate arguments, and then assign an argument role or *None*. Different from trigger extraction, we use the shortest dependency path (SDP) within the dependency tree structure instead of the surface contexts to better capture the dependency between the trigger and each argument.

Taking the sentence in Figure 3 as an example, given a trigger *transcription* and a candidate argument *OBF-1*, we first perform dependency parsing and extract the shortest dependency path between *transcription* and *OBF-1* with the Dijkstra's algorithm (Johnson, 1973) and obtain the shortest dependency path *transcription* → *of* → *genes* → *OBF-1*. We use the same KB-driven Tree-LSTM architecture as introduced in Section 2.3 to encode each node into a new hidden state representation. We use the hidden state of the root node h_0 as the overall vector representation of the whole dependency path. Finally, we feed the concatenation of h_0 with the hidden state of the trigger and argument as input to another softmax to predict the argument role. We also optimize the model by minimizing a negative log-likelihood loss.

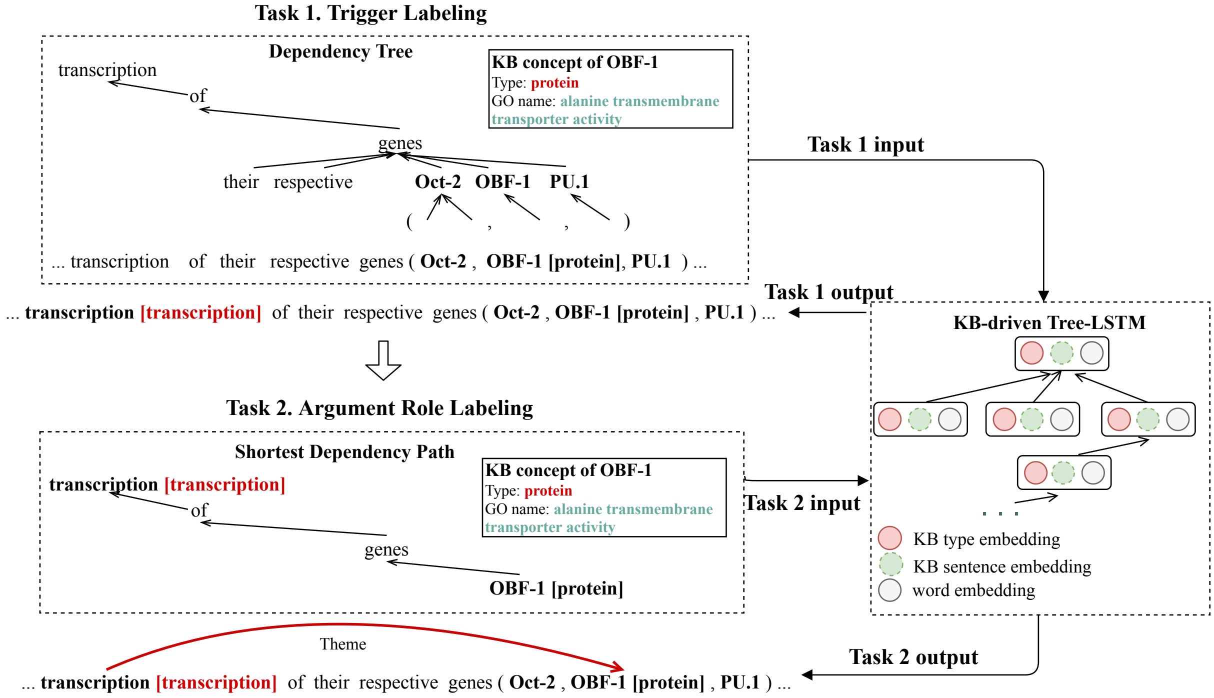


Figure 3: Examples of trigger labeling and argument role labeling via a KB-driven Tree-LSTM.

Event Type	Core Arguments
Gene expression	Theme(P)
Transcription	Theme(P)

Table 1: Predefined event types with accepted argument roles in Genia event extraction task, and data statistics of Genia event extraction 2011 dataset. P: protein; E: event.

3 Experiment

3.1 Task Description

The Genia Event Extraction task is the main task in the BioNLP Shared Task series (Kim et al., 2009, 2011; Nédellec et al., 2013). The Genia task defines 9 fine-grained event types as shown in Table 1. Note that a **Binding** event may take more than one protein as its **Theme** arguments. A **Regulation** event may take one protein or event as its **Theme** argument and also optionally take one protein or event as its **Cause** argument. A **Regulation** event taking an event as its argument will lead to a nested structure. 37.2% nested events are observed in Genia 2011 corpus (Björne and Salakoski, 2011). There are 6.0% inter-sentence events while our model only focuses on sentence-level event extraction.

3.2 Experimental Setup

We apply our KB-driven Tree-LSTM model on Genia 2011 data set. The entities in Genia data set are manually annotated and given as part of the input.

We evaluate our results on the test set using the official online tool provided by the Genia task organizers.[1] Following previous studies (Björne and Salakoski, 2011; Venugopal et al., 2014; Rao et al., 2017; Björne and Salakoski, 2018), we report scores obtained by the approximate span (allowing trigger spans to differ from gold spans by single words). As we only focus on matching core arguments, we use recursive matching criterion for evaluation which not requires matching of additional arguments for events referred from other events (Kim et al., 2011).

We use the word embedding pretrained on PubMed and PMC texts (Moen and Ananiadou,

---

[1] http://bionlp-st.dbcls.jp/GE/2011/eval-test/

2013) for word and type embeddings. The hyper-parameters are tuned on the development set and listed in Table 2. Word representations are updated during training with an initial learning rate of 0.1.

Parameter	Value
Word embedding size	200
Type embedding size	200
Sentence embedding size	4096
Tree-LSTM hidden size	100
Batch size	25
Epoch size	30
Dropout rate	0.5
Learning rate	0.05
Initial embedding learning rate	0.1
Optimizer	AdaGrad

Table 2: Hyper-parameters.

3.3 Results and Error Analysis

Table 3 shows the final event extraction results of applying our KB-driven Tree-LSTM model on Genia 2011 dataset with the comparison of only using Tree-LSTM and a standard BiLSTM model. Tree-LSTM outperforms the BiLSTM baseline which indicates the power of Tree-LSTM in dealing with long-distance dependency structure in biomedical literature. By incorporating external KB information, our approach achieves about 2.12% F-score gain comparing to Tree-LSTM, which demonstrates the effectiveness of the KB properties for biomedical event extraction. We will show detailed analysis in Section 3.4.

Table 4 presents the previous event extraction results from the BioNLP shared task using the same corpus. Our approach outperforms all previous methods. Among them, the systems TEES (Björne and Salakoski, 2011), EventMine-CR (Miwa et al., 2012) and Stacked Generalization (Majumder et al., 2016) are based on SVMs with well designed features. FAUST (Riedel and McCallum, 2011) and BioMLN (Venugopal et al., 2014) use jointed inference models. Björne and Salakoski (2018) adopts a convolutional neural networks (CNNs) with abundant features derived from TEES system. In our work, instead of using high-dimensional features with manual effort as in these previous models, our approach only requires pretrained distributed word representations as input features.

We notice that our approach achieves high scores on **Simple** event types but get relatively low scores on **Binding** event and **Regulation** event types. We analyze the results and find that **Binding** event extraction is more challenging since it usually has multiple arguments. For example, Figure 4 shows two sentences which are chosen from the output of the development data set. There are two **Binding** event mentions in the first sentence: E1 (Trigger: interacting, Type: Binding, Theme: RUNX1, Theme2: p3000) and E2 (Trigger: binding, Type: Binding, Theme: CREB). Our model mistakenly extracts *CREB* as a *Theme* of E1 since *CREB* is highly related to protein p300 in the dependency tree structure.

Regulation events are considered as the most challenging event type because they usually have an optional **Cause** argument and are involved in nested structures, which are not handled well by most of current event extraction approaches. In addition, intuitively, most trigger words are verbs or nouns. We rank all the trigger words in the train-

System	Event Type	Rec	Prec	F1

ing data set according to their frequency, and find that most of spurious errors for **Regulation** event trigger extraction occur when the trigger words are prepositions or conjunctions. For instance, in Figure 4, the second sentence contains two positive **Regulation** events triggered by a preposition *from* and a conjunction *rather than*. Such function words are rarely annotated as triggers and our KB-aware Tree-LSTM cannot well collect meaningful contexts from their subtrees.

3.4 Effect of KB concepts

As shown in Table 3, we achieve about 3.5% and 2.1% F1 score gain on **Binding** and **Regulation** event types by leveraging external KB information into the Tree-LSTM. In order to show the effect of KB concept embeddings, we visualize the probabilities of word *transcription* to be predicted for each event type. As Figure 5 shows, by adding KB concept embeddings, the function description *positive regulation of transcription, DNA-templated* provided by the biomedical entity *OBF-1* significantly enhances the probability of *transcription* being predicted to a *Transcription* event type.

Similarly, Figure 6 visualizes the probabilities of the E1 event mention (Trigger: transduced, Type: gene_expression, Theme: Tax) to be predicted as an argument of E2 event mention (Trigger: transduced, Type: positive regulation, Theme: E1). We can see that, without using KB information, the Tree-LSTM mistakenly predict the argument role of E1 as **None**. In contrast, by incorporating KB concept embeddings, especially

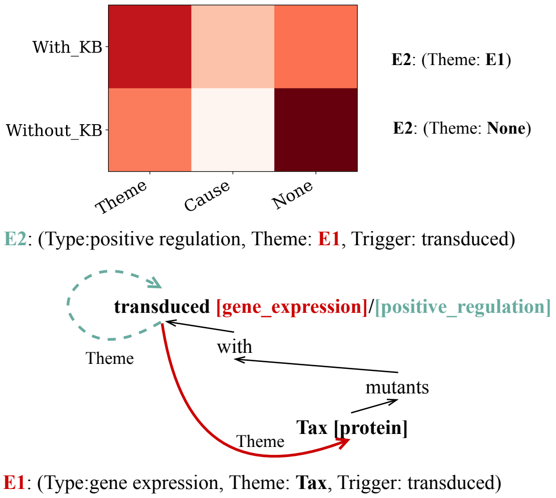

Figure 6: Visualization of the effect of KB concept embedding on argument role labeling for a Positive Regulation event triggered by *transduced* and a Gene Expression event E1 (Theme: Tax, Trigger: transduced).

the information from the function description *positive regulation of transcription, DNA-templated* for *Tax*, our approach successfully promotes the probability of E1 being predicted as the *Theme* of E2.

4 Related Work

As a crucial task in information extraction, event extraction has gained a lot of interest. In general news domain, previous work on event extraction can be divided into two main categories. The first is feature-based methods which mainly focus on feature design, leveraging local features (Grishman et al., 2005; Ahn, 2006) and global features (Ji and Grishman, 2008; Liao and Grishman, 2011; Huang and Riloff, 2012) to improve the performance. Some studies proposed joint models to overcome the error propagation problem (Poon and Vanderwende, 2010; Riedel et al., 2009; Li et al., 2013; Venugopal et al., 2014; Li et al., 2014). The second category includes distributional representation based methods which have been applied into event extraction extensively. Most of these approaches are based on the standard Convolutional Neural Networks (CNNs) (Chen et al., 2015; Nguyen and Grishman, 2015, 2016), Recurrent Neural Networks (RNNs) (Nguyen et al., 2016), generative adversarial networks (Hong et al., 2018), zero-shot learning (Huang et al., 2017) and advanced attention mechanisms (Liu et al., 2018b; Chen et al., 2018).

Our work is also related to the studies which leverage the external knowledge base for information extraction. Liu et al. (2017) takes advantage of external resources, such as FrameNet, to label events while Chen et al. (2017) adopts distance supervision to augment the training data. Liu et al. (2018a) develops an attention-based model for event extraction. What's more, shortest dependency path is broadly explored for information extraction, especially for relation classification (Xu et al., 2015; Miwa and Bansal, 2016) and shows promising benefits.

Biomedical event extraction task part of the BioNLP Shared Task series (Kim et al., 2009, 2011; Nédellec et al., 2013). Previous studies mainly explore local and global features with SVM model (Miwa et al., 2010, 2012; Björne and Salakoski, 2013; Majumder et al., 2016). Riedel and McCallum (2011) develop a joint model with dual decomposition. Cohen et al. (2009), Kilicoglu and Bergler (2011) and Bui et al. (2013) develop rule-based methods and achieve high precision. Venugopal et al. (2014) leverage Markov logic networks for joint inference. Rao et al. (2017) uses the Abstract Meaning Representations (AMR) to extract events based on the assumption that an event structure can be derived from an AMR subgraph. Recently, some representation-based models (Jagannatha and Yu, 2016; Rao et al., 2017; Björne and Salakoski, 2018) have been proposed while most of them adopt the widely used CNNs and RNNs with features derived from the biomedical text. Lim et al. (2018) implements a binary Tree-LSTM architecture for biomedical relation extraction. Compared with these methods, our approach only requires pre-trained distributed word representations as input features and incorporates meaningful KB information into a Tree-LSTM.

5 Conclusions and Future Work

In this paper, we show the effectiveness of using a KB-driven tree-structured LSTM for event extraction in biomedical domain. The Tree-LSTM can efficiently capture semantically related concepts for each node within the tree structure. By leveraging the external KB concept properties including the entity type and the function description, our approach is able to perform deep understanding of domain-specific expressions and connections. Without using manually designed high-dimensional features, our approach significantly outperforms all previous methods. In the future, we plan to explore a broader range of properties from KB to facilitate biomedical information extraction tasks.

Detecting Cognitive Impairments by Agreeing on Interpretations of Linguistic Features

Zining Zhu[1,2], **Jekaterina Novikova**[1], **Frank Rudzicz**[3,5,2,4,1]

Abstract

Linguistic features have shown promising applications for detecting various cognitive impairments. To improve detection accuracies, increasing the amount of data or the number of linguistic features have been two applicable approaches. However, acquiring additional clinical data can be expensive, and hand-crafting features is burdensome. In this paper, we take a third approach, proposing Consensus Networks (CNs), a framework to classify after reaching agreements between modalities. We divide linguistic features into non-overlapping subsets according to their modalities, and let neural networks learn low-dimensional representations that agree with each other. These representations are passed into a classifier network. All neural networks are optimized iteratively.

In this paper, we also present two methods that improve the performance of CNs. We then present ablation studies to illustrate the effectiveness of modality division. To understand further what happens in CNs, we visualize the representations during training. Overall, using all of the 413 linguistic features, our models significantly outperform traditional classifiers, which are used by the state-of-the-art papers.

1 Introduction

Alzheimer's disease (AD) and its usual precursor, mild cognitive impairment (MCI), are prevalent neurodegerative conditions that inhibit cognitive abilities. Cognitive impairments are traditionally diagnosed only with standard clinical tests like MoCA (Nasreddine et al., 2005) and the Rey-Auditory Verbal learning Test (Rey, 1941), but hiring clinicians to administer these tests and analyze their results is costly. Fortunately, many cognitive impairments can be observable in daily life, because they impact one's language abilities. For example, cognitively impaired people tend to use more pronouns instead of nouns, and pause more often between sentences in narrative speech (Roark et al., 2011).

This insight makes automatic detection possible. Machine learning classifiers can detect cognitive impairments given descriptive linguistic features. In recent work, linguistic features including pronoun-noun-ratios, pauses, and so on, are used to train classifiers to detect cognitive diseases in various tasks. For example, Fraser et al. (2015) achieved up to 82% accuracy on DementiaBank[1], the largest publicly available dataset on detecting cognitive impairments from speech, and Weissenbacher et al. (2016) achieved up to 86% accuracy on a corpus of 500 subjects. Yancheva et al. (2015) estimated Mini-Mental State Estimation scores (MMSEs), describing the cognitive status and characterizing the extent of cognitive impairment.

To improve the accuracy of automated assessment using engineered linguistic features, there are usually two approaches: incorporating more clinical data or calculating more features. Taking the first approach, Noorian et al. (2017) incorporated normative data from Talk2Me[2] and the Wisconsin Longitudinal Study (Herd et al., 2014) in addition to DementiaBank, which increased AD:control accuracy up to 93%, and moderateAD:mildAD:control three-way classification accuracy to 70%. Taking the second approach, Yancheva and Rudzicz (2016) used 12 features derived from vector space models and reached a .80 F-score on DementiaBank. Santos et al. (2017) calculated features depicting characteristics of co-occurrence graphs of narrative transcripts (e.g., the degree of each vertex in the graph). Their classifiers reached 65% accuracy on DementiaBank

(MCI versus a subset of Control).

There are limitations in either of the two approaches. On one hand, acquiring additional clinical data can be expensive (Berndt and Cockburn, 2013). Moreover, the additional data should be similar enough to existing training data to be helpful. On the other hand, crafting new features requires creativity and collaboration with subject matter experts, and the implementation can be time consuming. Neither of these approaches is satisfactory.

These limitations motivate us to take a third, novel approach. Instead of using new data or computing new features, we use the existing linguistic features.

If the speaker is cognitively impaired, and their language ability is affected, features from each of the acoustic, syntactic, and semantic modalities should reflect such change (Szatloczki et al., 2015; Moro et al., 2015; Fraser et al., 2015). We therefore need to distill the common information revealed by features from multiple, mainly distinct, modalities.

To utilize information common across different modalities, Becker and Hinton (1992) and de Sa (1994) let classifiers look at each modality and supervise each other. These examples illustrated the effectiveness of multi-view learning in utilizing common information among different observations, but their algorithms fail to train useful classifiers for cognitive impairments in our datasets. Without explicit supervision, self-supervised models almost always converge to a state producing the same predictions for all people, giving trivial classifiers.

Instead of aligning the predictions from modalities, we let the representations of the modalities agree. Generative adversarial networks (GANs) provide an approach. In GANs, a "discriminator" network is trained to tell whether a vector is drawn from the real world or produced synthetically by a "generator" neural network, while the generator is trained to synthesize images as close to real data as possible. We borrow this setting, and encourage the neural networks interpreting different modalities to produce representations of modalities as similar to each other as possible. This leads to our classifier framework, consensus networks (CNs).

Consensus networks constitute a framework using adversarial training to utilize common information among modalities for classification. In this framework, several neural networks ("ePhysicians") are juxtaposed, each learning the representation of a partition of linguistic features for each transcript. Being trained towards producing agreed representations, we show they are increasingly able to capture common information contained across disparate subsets of linguistic features.

We empirically add two extensions to CN that improve the classification accuracies, called the "noise modality" and "cooperative optimization" respectively, as explained below. To illustrate the effectiveness of the consensus mechanisms, we present two ablation studies. First, we compare neural networks built with consensus (CN) and those without (MLP). On partial or complete modalities, CN outperforms MLP significantly. Second, we compare CNs built with linguistic features divided into random subsets. Division according to their natural modalities train better consensus networks. We also visualize the representations during training procedure, and show that when the representations agree, their distributions appear symmetric.

Overall, taking all 413 linguistic features, our models significantly outperform traditional classifiers (e.g., support vector machines, quadratic discriminant analysis, random forest, Gaussian process), which are used by the state-of-the-art.

2 Related Works

Generative Adversarial Networks The idea of aligning representations by making them indistinguishable is inspired by GAN (Goodfellow et al., 2014), where a generator produces fake images (or other data) that are as similar to real data as possible. However, our model does not have a generator component as GANs do. Instead, we only compress features into representations while trying to align them.

Multi-view Learning Learning from multiple modalities is also referred to as multi-view learning. Becker and Hinton (1992) set up multiple neural networks to look at separate parts of random-dot stereograms of curved surfaces, and urge their prediction to equal each other. The trained neural networks were able to discover depth without prior knowledge about the third dimension. de Sa (1994) divided linguistic features into two modalities, and passed them to two separate neural networks. The two neural networks supervised each other (i.e., output labels that are used to train the other) during alternative optimization steps to reach a consensus. Their self-supervised system reached 79±2% accuracy using the Peterson-Barney vowel recognition dataset (Peterson and Barney, 1952). Benediktsson et al. (1997) computed multiple views from the same feature sets and classified by taking their majority votes. Pou-Prom and Rudzicz (2018) used canonical correlation analysis (CCA) to classify using multiple aspects. Contrary to that work, our consensus networks take in distinct subsets of features as modalities. Co-training (Blum and Mitchell, 1998) and tri-training (Zhou and Li, 2005) use distinct subsets of features, but they use them to train distinct classifiers, and let the results directly supervise each other. Their approach 'bootstrapped' classifications based on a few labeled data, but our method explicitly uses a modality discriminator that enforces alignments between modalities.

Domain Adaptation In domain adaptation and multi-task learning, there have been many attempts to learn indistinguishable embeddings between domains. For example, Ganin et al. (2016) and Joty et al. (2017) applied a gradient reversal layer to let encoders minimize the domain classification loss. Baktashmotlagh et al. (2013) minimized the maximum-mean discrepancy (MMD) loss in a reproductive kernel Hilbert space (RKHS) of the latent representations. Motiian et al. (2017) used semantic similarity loss between latent representations of different class data to encourage alignments between domains. Liu et al. (2017) and Chen and Cardie (2018) used shared and private networks to learn information contained either commonly in domains or domain-specific. Our work is unique. First, there is only one domain in our problem setting. Second, we use iterative optimization to encourage discrepancies between domains. Third, we have two empirical improvements (noise modality and cooperative optimization) that make our Consensus Networks outperform traditional classifiers.

3 Methods

3.1 Dataset

We use DementiaBank, the largest publicly available dataset for detecting cognitive impairments. It includes verbal descriptions (and associated transcripts) of the Cookie Theft picture description task from the Boston Diagnostic Aphasia Examination (Becker et al., 1994). The version we have access to contains 240 speech samples labeled Control (from 98 people), 234 with AD (from 148 people), and 43 with MCI (from 19 people)[3]. All participants were older than 44 years.

3.2 Linguistic Features

The dataset contains narrative speech descriptions and their transcriptions. We preprocess them by extracting 413 linguistic features for each speech sample. These linguistic features are proposed by and identified as the most indicative of cognitive impairments by various previous works, including Roark et al. (2007), Chae and Nenkova (2009), Roark et al. (2011), Fraser et al. (2015), and Hernández-Domínguez et al. (2018). After calculating these features, we use KNN imputation to replace the undefined values (resulting from divide-by-zero, for example), and then normalize the features by their z-scores. The following are brief descriptions of these features, grouped by their natural categories. More detailed descriptions are included in the Appendix.

There are 185 acoustic features (e.g., average pause time), 117 syntactic features (e.g., Yngve statistics (Yngve, 1960) of the parse tree, computed by the LexParser in CoreNLP (Manning et al., 2014)), and 31 semantic features (e.g., cosine similarity between pairs of utterances) Moreover, we use 80 part-of-speech features that relate to both syntax and semantics but are here primarily associated with the latter.

Modality Division After representing each sample with a 413-dimensional vector $\mathbf{x}$ consisting of all available linguistic features, we divide the vector into M partitions ('modalities') of approximately equal sizes $[\mathbf{x_1}, \mathbf{x_2}, ..., \mathbf{x_M}]$, according to the groups mentioned above. Unless mentioned otherwise (e.g., in the ablation study shuffling

---

[3] The version of DementiaBank dataset we acquired contains a slightly different number of samples from what some previous works used. In Control:AD, Fraser et al. (2015) used 233 Control and 240 AD samples; Yancheva and Rudzicz (2016) had 241 Control and 255 AD samples; Hernández-Domínguez et al. (2018) had 242 Control and 257 AD samples (with 10% control samples excluded from the evaluation). In Control:MCI, Santos et al. (2017) used all 43 transcriptions from MCI and 43 sampled from the Control group. With no clear descriptions of the sampling procedures, the constituents of the Control group might differ from our sample. In this paper, we run our models on the same tasks (i.e., Control:AD) and compare to the results of models used in the literature.

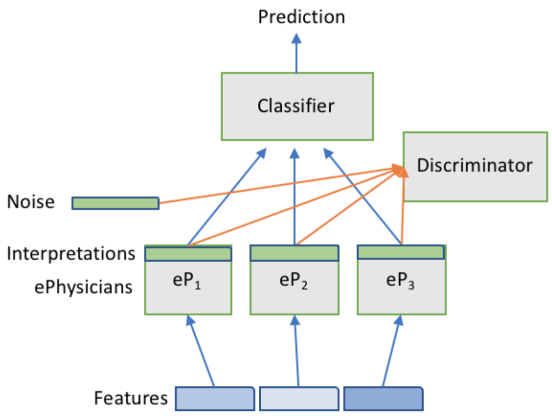

Figure 1: Overview of model structure when features (blue rectangles) are divided into three modalities (non-overlapping subsets). Each subset of features are passed into an "ePhysician" neural network whose outputs (green rectangles) are the representations. They are passed (one by one) into a "Discriminator" neural network and (after combined) into a "Classifier" network, respectively.

modalities), this is our default choice for assigning modalities.

3.3 Model

Figure 1 is an example of our model structure (with $M = 3$ modalities), and this section elaborates the inference procedure, the training algorithm, and our two improvements.

Inference With the extracted linguistic features divided into subsets by their modalities, each speech sample is described by $M = 3$ non-overlapping feature vectors $\mathbf{x} = [\mathbf{x_1}, ..., \mathbf{x_m}]$. These feature vectors are then passed into corresponding ePhysician networks, each outputting a vector $\mathbf{i_m}$, which is a distilled representation of the subject from a modal-specific perspective (e.g., the semantic). We also refer to it as the *interpretation vector* and use them interchangeably. Formally, the m^{th} ePhysician can be written as a function, $f_m(.)$ generating the representation:

$$\mathbf{i_m} = f_m(\mathbf{x_m})$$

To challenge the similarity of representations from different modalities, we let a discriminator neural network $f_D(.)$ take in each of the M representations and predict the likelihood of the originating modality m.

$$P(m = k \,|\, \mathbf{i}) = \frac{e^{f_D(\mathbf{i})_k}}{\sum_k e^{f_D(\mathbf{i})_k}}$$

where $k = 1, ..., M$.

To attempt a diagnosis, a classifier network $f_C(.)$ takes in the combination of M representations of each speech sample, and outputs a prediction probability for detection result y:

$$P(y = l \,|\, \mathbf{x}) = \frac{e^{f_C(\mathbf{i_{1..M}})_l}}{\sum_l e^{f_C(\mathbf{i_{1..M}})_l}}$$

where $l \in \{0, 1\}$ for two-class classification (i.e., 0 for healthy and 1 for dementia). The predicted class corresponds to those with the highest probability:

$$\hat{y} = \arg\max_l P(y = l|\mathbf{x})$$

Optimization The training procedure optimizes the adversarial objective, and the conventional classifier objective:

- The adversarial objective sets up the ePhysicians and the Discriminator to work in an adversarial manners. The ePhysicians try to produce indistinguishable representations, while the discriminator tries to tell them apart.

$$\min_D \max_P \mathcal{L_D} \text{ where}$$
$$\mathcal{L_D} = \mathbb{E}_\mathbf{x} \mathbb{E}_{m=1..M} \{-\text{log}P(\hat{m} = m|\mathbf{i_m})\} \tag{1}$$

- Make the classifier network as accurate as possible. This is done by minimizing the cross entropy classification loss:

$$\min_C \mathcal{L_C} \text{ where}$$
$$\mathcal{L_C} = \mathbb{E}_\mathbf{x} \{-\text{log}P(\hat{y} = y|\mathbf{i_{1..M}})\} \tag{2}$$

Overall, $\min_C \mathcal{L_C}$ and $\min_D \max_P \mathcal{L_D}$ set up a complex optimization problem. We use iterative optimization steps, similar to Goodfellow et al. (2014).

There are two tricks that we found to improve the performance of the models. Namely, the *noise modality* and the *cooperative optimization*. We explain them below.

Noise Modality For each participant session, we add a "noise modality representation" $\mathbf{i_0}$ drawn from a Gaussian distribution with the mean and variance identical to those of other representation vectors.

$$\mathbf{i_0} \sim \mathcal{N}(\mu_{\mathbf{i_{1..M}}}, \sigma^2_{\mathbf{i_{1..M}}})$$

This additional representation vector is passed into the discriminator, but not passed into the classifier. The first optimization goal (1) is therefore:

$$\min_D \max_P \mathcal{L}_{\mathcal{D}} \text{ where}$$
$$\mathcal{L}_{\mathcal{D}} = \mathbb{E}_{\mathbf{x}} \mathbb{E}_{m=0..M} \left\{ -\log P(\hat{m} = m | \mathbf{i_m}) \right\} \tag{3}$$

To some extent, the noise representation vector works like a regularization mechanism to refrain the discriminator from making decisions based on superficial statistics. We show in 4.1 that this addition empirically improves classifier performance.

Cooperative Optimization When optimizing the classifier, we find that allowing gradients to propagate back to the ePhysicians improves the model's overall performance. During optimization, the ePhysicians need to *cooperate* with the classifier (while adversarial to the discriminator). The second optimization goal (2) is therefore:

$$\min_{C,P} \mathcal{L}_{\mathcal{C}} \text{ where}$$
$$\mathcal{L}_{\mathcal{C}} = \mathbb{E}_{\mathbf{x}} \left\{ -\log P(\hat{y} = y | \mathbf{i_{1..M}}) \right\} \tag{4}$$

Implementation As a note of implementation, all ePhysicians, the classifier, and the discriminator networks are fully connected networks with Leaky ReLU activations (Nair and Hinton, 2010) and batch normalization (Ioffe and Szegedy, 2015). The hidden layer sizes are all 10 for all ePhysician networks, and there are no hidden layers for the discriminator or classifier networks. Although modalities might contain slightly different numbers of input dimensions, we do not scale the ePhysician sizes. This choice comes from the intuition that the ePhysicians should extract into the representation as similar information as possible. We use three Adam optimizers (Kingma and Ba, 2014), each corresponding to the minimization of ePhysician, Discriminator, and the Classifier, and optimize iteratively for no more than 100 steps. The optimization is stopped prior to step 100 if the classification loss $\mathcal{L}_{\mathcal{C}}$ converges (i.e., does not differ from the previous iteration by more than 1×10^{-4}) on training set. The train / validation / test set are divided randomly in 60/20/20 proportions.

Algorithm 1 The overall algorithm

```
Initialize the networks
for step := 1 to N do        ▷ N is a hyper-param
    for minibatch $\mathbf{x}$ in training data $\mathcal{X}$ do
        for modality m := 1 to M do
            $\mathbf{i_m} = I_m(\mathbf{x_m})$
        Sample the noise modality $\mathbf{i_0}$
        Calculate $\mathcal{L}_{\mathcal{D}}$ with $\mathbf{i_{0..M}}$
        Concatenate $\mathbf{i_{1..M}}$ and calculate $\mathcal{L}_{\mathcal{C}}$

            $\min_{D} \mathcal{L}_{\mathcal{D}}$
```

4 Experiments

We first show the effectiveness of our two improvements to the model. Next, we do two ablation studies on the arrangements of modalities. Then, we evaluate our model against several traditional supervised learning classifiers used by state-of-the-art works. To understand the model further, we also visualize the principal components of the representation vectors throughout several runs.

4.1 Noise Modality Improves Performance

We compare a CN model with a noise modality to one without (with other hyper parameters including hidden dimensions and learning rates identical).

Table 1 shows that in the AD:MCI classification task, the model with an additional noise modality is better than the one without ($p = 0.04$ on 2-tailed t-test with 18 DoF). Here is a possible explanation. Without adding a noise modality, the discriminators may simply look at the superficial statistics, like the mean and variances of the representations. This strategy tends to neglect the detailed aspects encoded in the representation vectors. Adding in the noise modality penalizes this strategy and trains better discriminators by forcing them to *study the details*.

In the following experiments, all models contain the additional noise modality.

4.2 Effectiveness of Cooperative Optimization

The second improvement, cooperative optimization, also significantly improves model perfor-

Model	Micro F1	Macro F1
Noise	**.7995 ± .0450**	**.7998 ± .0449**
No noise	.7572 ± .0461	.7577 ± .0456

Table 1: Comparison of models with and without representations in noise modality. The models containing a Gaussian noise modality outperform those without.

mance. We compare Consensus Network classifiers trained with cooperative optimization (i.e., $\min_{C,P_{1..M}} \mathcal{L}_\mathcal{C}$) to models with the same hyper-parameters but trained non-cooperatively (i.e., $\min_C \mathcal{L}_\mathcal{C}$). As shown in Table 2, the cooperative variant produces higher-score classifiers than the non-cooperative one ($p < 0.001$ on a 2-tailed t-test with 18 DoF). With the cooperative optimization setting, the ePhysicians are encouraged towards producing representations both indistinguishable (by the discriminator) and beneficial (for the classifier). Although the representations might agree less with each other, they could contain more *complementary* information, leading to better overall classifier performances.

In other experiments, all of our models use cooperative optimization.

Optimization	Micro F1	Macro F1
Non-coop	.6696 ± .0511	.6743 ± .0493
Cooperative	**.7995 ± .0450**	**.7998 ± .0449**

Table 2: Comparison of models optimized in cooperative and non-cooperative manner.

4.3 Effectiveness of Agreement Among Modalities

In this and the next experiment, we illustrate the effectiveness of our models on different configurations of modalities in an ablation study. We show that our models work well because of the effectiveness of the "consensus between modalities" scheme.

In this experiment, we compare our Consensus Network models (i.e., with agreements) with fully-connected neural network classifiers (i.e., without agreements) taking the same partial input features. The networks are all simple multiple layer perceptrons containing the same total number of neurons as the 'classifier pipeline' of our models (i.e., ePhysicians plus the classifier)[4] with batch normalization between hidden layers. A few observations could be made from Table 3:

1. Some features from particular modalities are more expressive than others. For example, acoustic features could be used for building better classifiers than those in the semantic ($p = .005$ for 2-tailed t-test with 18 DoF) or syntactic modality ($p < .001$ for 2-tailed t-test with 18 DoF). More specifically, the syntactic features themselves do not tell much. We think this is because the syntactic features are largely based on the contents of the speech, and remain similar across speakers. For example, almost none of the speakers asked questions, giving zero values in "occurrences" of corresponding syntactic patterns.

2. Our model is able to utilize multiple modalities better than MLP. For MLP classifiers, combining features from different modalities does not always give better models. The syntactic modality features confuse MLP and "drag down" the accuracy. However, our models built with the consensus framework are able to utilize the less informative features from additional modalities. In all scenarios using two modalities, our models achieve accuracies higher than neural networks trained on *any* of the two individual modalities.

3. Given the same combinations of features, letting neural networks produce representation in agreement *does* improve the accuracy in all four scenarios[5].

4.4 Dividing Features by Natural Modalities is Preferred

This is the second ablation study towards modality arrangement. We show that dividing features into subsets according to their natural modalities (i.e., the categories in which they are defined) is better than doing so randomly.

In this experiment, we train CNs on features grouped by either their natural modalities, or randomly divided. For natural groupings, we try to

---

[4] For example, for models taking in two modalities, if our model contain ePhysicians with one layer of 20 hidden neurons, the interpretation vector dimension 10, and classifier 5 neurons, then the benchmarking neural network contains three hidden layers with [20×2, 10×2, 5] neurons.

[5] $p = 3 \times 10^{-12}$ on syntactic+semantic features, $p = 0.044$ on acoustic + semantic, $p = 0.005$ on acoustic + syntactic, and $p = 0.046$ on all modalities. All 18 DoF one-tailed t-tests.

Models (Modality)	Accuracy
MLP (Acoustic)	.7519 ± .0245
MLP (Syntactic)	.5222 ± .0180
MLP (Semantic)	.6987 ± .0278
MLP (Syntactic + Semantic)	.5819 ± .0216
CN (Syntactic + Semantic)	.7257 ± .0344
MLP (Acoustic + Semantic)	.7002 ± .1128
CN (Acoustic + Semantic)	.7542 ± .0433
MLP (Acoustic + Syntactic)	.6776 ± .0952
CN (Acoustic + Syntactic)	.7574 ± .0361
MLP (All 3 modalities)	.7528 ± .0520
CN (All 3 modalities)	**.7995** ± **.0450**

Table 3: Performance comparison between Consensus Networks and fully-connected neural network classifiers having certain modality information.

let each group contain comparable number of features, resulting in the following settings:

- Two groups, natural: (a) acoustic + semantic, 216 features; (b) syntactic + PoS, 197 features.
- Three groups, natural: (a) acoustic, 185 features; (b) semantic and PoS, 111 features; and (c) syntactic, 117 features. This is the default configuration used in other experiments in this paper.

For random grouping, we divide the features into almost equal-sized 2/3/4 groups randomly. As shown in Table 4. The two natural modality division methods produce higher accuracies than those produced by any of the random modality division methods.

Modality division method	Accuracy
Three groups, random	.7408 ± .0340
Two groups, random	.7623 ± .0164
Four groups, random	.7666 ± .0141
Two groups, natural	.7769 ± .0449
Three groups, natural	**.7995** ± **.0450**

Table 4: Performance comparison between different modality division methods, sorted by accuracy.

4.5 Visualizing the Representations

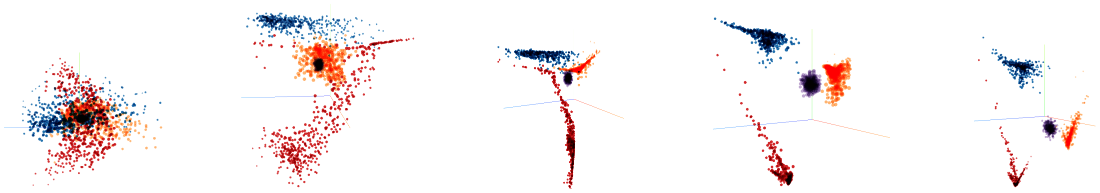
To further understand what happens inside consensus network models during training, we visualize the representation vectors with PCA. Figure 2 consists of the visualizations drawn from an arbitrary trial in training the model. Each representation vector is shown on the figure as a data point, with its color representing its originating modality (including the noise modality).

Several common themes could be observed:

1. *The clusters are symmetric*. Initially the configurations of representations largely depend on the initializations of the network parameters. Gradually the representations of the same modality tend to form clusters. Optimizing the ePhysicians towards both targets make they compress modalities into representations which are symmetrical in an *aggregate* manner.
2. *The agreements are simple*. The variances explained by the first a few principal components usually increase as the optimizations proceed. When distilling information relevant to detection, the agreement tend to become simple.
3. *The agreements are imperfect*. As shown in Figure 2, the modal representations do not overlap. Also, the discriminator loss is low (usually at 10^{-3} when training is done). This confirms that these representations are still easily distinguishable. This may because the modalities inherently have some *complementary* information, leading to the ePhysicians projecting the modalities differently.
4. *The representations are complex*. Their shapes do not resemble the noise representations (Gaussian) lying at the center of the three petals. This shows that the representations are not simply Gaussian.
5. *The accuracy increases*. The accuracy in validation set generally increases as the training proceeds. Note that the distributions of representation vectors are increasingly similar in shape but remains distinct in spatial allocations. This confirms our conjecture that the information about cognitive impairment resides in complicated details instead of superficial statistics, which neural networks could represent.

4.6 Evaluation Against Benchmarks

With the previous sets of experiments, we have a best working architecture. We now evaluate it against traditional classifiers, which are used by



(a) Step 5
$\mathcal{L}_{\mathcal{D}} = 1.34$
Val accr .74%
Variance 71.2%

(b) Step 10
$\mathcal{L}_{\mathcal{D}} = 1.32$
Val accr .76%
Variance 72.9%

(c) Step 20
$\mathcal{L}_{\mathcal{D}} = 1.17$
Val accr .77%
Variance 77.1%

(d) Step 30
$\mathcal{L}_{\mathcal{D}} = 0.89$
Val accr .79%
Variance 77.0%

(e) Step 40
$\mathcal{L}_{\mathcal{D}} = 0.64$
Val accr .79%
Variance 80.8%

Figure 2: Initially, the representations from the three modalities are mixed. As the training go on, the three modalities gradually form three symmetric "petals", while the (Gaussian) noise modality stays in the center. These petals do not overlap, as they contain complementary information when combined and passed into the classifier. Instead, their distributions become symmetric. (Best viewed in colours.)

the state-of-the-art papers (Hernández-Domínguez et al., 2018; Santos et al., 2017; Fraser et al., 2015) on our 413 features. Note that the results could be different from what they reported, because the feature sets are different.

We test several traditional supervised learning benchmark algorithms here: support vector machine (SVM), quadratic discriminant analysis (QDA), random forest (RF), and Gaussian process (GP). For completeness, multiple layer perceptrons (MLPs) containing all features as inputs are also mentioned in Table 5. On the binary classification task (healthy control vs. dementia), our model does better than them all.

Classifier	Micro F1	Macro F1
SVM	.4810 ± .0383	.6488 ± .0329
QDA	.5243 ± .0886	.5147 ± .0904
RF	.6184 ± .0400	.6202 ± .0422
GP	.6775 ± .0892	.6873 ± .0819
MLP	.7528 ± .0520	.7561 ± .0444
CN	**.7995 ± .0450**	**.7998 ± .0449**

Table 5: Comparison with different traditional classifiers in AD:Control classification task. In particular, our model has higher accuracy than the best traditional classifier, MLP.

5 Conclusion and Future Works

We introduce the consensus network framework, in which neural networks are encouraged to compress various modalities into indistinguishable representations ('interpretation vectors'). We show that consensus networks, with the noise modality and cooperative optimization, improve upon traditional neural network baselines given the same features. Specifically, with all 413 linguistic features, our models outperform fully-connected neural networks and other traditional classifiers used by state-of-the-art papers.

In the future, the "agreement among modalities" concept may be applied to design objective functions for training classifiers in various tasks, and from other data sets (for example, education and occupation "modalities" for the bank marketing prediction task). Furthermore, the mechanisms that represent linguistic features into symmetric spaces should be analyzed within the context of explainable AI.

A Appendices

Linguistic Features

Acoustic

- The fluency of speech. We quantify it with phonation rate, duration of pauses, and number of filled pauses (e.g., *"um"*) of various lengths.
- Following the convention of speech processing literatures (Zhou et al., 2016; Yancheva et al., 2015; Zhao et al., 2014), we compute Mel-scaled cepstral coefficients (MFCCs) containing the amount of energy in 12 different frequency intervals for each time frame of 40 milliseconds, as well as their first- and second-order derivatives. We calculate the mean, variance, kurtosis, and skewness of the MFCCs and include them as features.

Semantic and Lexical

- Lexical norms, including age-of-acquisition, familiarity, imageability, and frequency (Taler et al., 2009). These are averaged over the entire transcript and specific PoS categories, respectively.
- Lexical richness, including moving-average type-token ratio over different window sizes

(Covington and McFall, 2010), Brunet's index, and Honoré's statistics (Guinn and Habash, 2012).

- Cosine similarity statistics (minimum, maximum, average, etc.) between pairs of utterances (represented as sparse vectors based on lemmatized words)
- Average word length, counts of total words, not-in-dictionary words, and fillers. The dictionary we use contains around 98,000 entries, including common words, plural forms of countable nouns, possessive forms of subjective nouns, different tenses of verbs, etc.

Syntactic

- Composition of languages. We describe it by several features, including the average proportion of context-free grammar (CFG) phrase types[6], the rates of these phrase types[7], and the average phrase type length[8] (Chae and Nenkova, 2009)
- The syntactic complexity of languages. We characterize it by the average heights of the context-free grammar (CFG) parse trees, across all utterances in each transcript. Each tree comes from an utterance parsed by a context free grammar parser (`LexParser` implemented in Stanford CoreNLP (Manning et al., 2014)). In addition, we compute the Yngve scores statistics of CFG parse trees (Yngve, 1960; Roark et al., 2007), where Yngve score is the degree of left-branching of each node in a parsed tree.
- Syntactic components. We describe them by including the number of occurrences of a set of 104 context-free production rules (e.g.,`S->VP`) in the CFG parse trees.

Part-of-speech

- The number of occurrences of part-of-speech (PoS) tags from Penn-treebank[9].
- The ratio of occurrences of several PoS tags, including noun-pronoun ratio.
- Number of occurrences of words in each of the five categories: subordinate (e.g: "because", "since", etc.), demonstratives (e.g: "this", "that"), function (e.g: words with PoS tag CC, DT, and IN), light verbs (e.g: "be", "have"), and inflected verbs (words with PoS tag VBD, VBG, VBN, and VBZ), borrowing the categorization method in Kortmann and Szmrecsanyi (2004)

---

[6] number of words in these types of phrases, divided by the total number of words in the transcript

[7] number of occurrences in a transcript, divided by the total number of words in the transcript

Abstract

Relation Extraction (RE) aims to label relations between groups of marked entities in raw text. Most current RE models learn context-aware representations of the target entities that are then used to establish relation between them. This works well for intra-sentence RE and we call them first-order relations. However, this methodology can sometimes fail to capture complex and long dependencies. To address this, we hypothesize that at times two target entities can be explicitly connected via a context token. We refer to such indirect relations as second-order relations and describe an efficient implementation for computing them. These second-order relation scores are then combined with first-order relation scores. Our empirical results show that the proposed method leads to state-of-the-art performance over two biomedical datasets.

1 Introduction

There are wide applications for Information Extraction in general (Jin et al., 2018) and Relation Extraction (RE) in particular, one reason why relation extraction continues to be an active area of research (Bach and Badaskar, 2007; Kambhatla, 2004; Kumar, 2017). Traditionally, a standard RE model would start with entity recognition and then pass the extracted entities as inputs to a separate relation extraction model, which meant that the errors in entity recognition were propagated to RE. This problem was addressed by end-to-end models (Miwa and Bansal, 2016; Zheng et al., 2017; Adel and Schütze, 2017; Bhatia et al., 2018) that jointly learn both NER and RE.

Generally, these models consist of an encoder followed by a relationship classification (RC) unit (Verga et al., 2018; Christopoulou et al., 2018; Su et al., 2018). The encoder provides context-aware vector representations for both target entities, which are then merged or concatenated before being passed to the relation classification unit, where a two layered neural network or multi-layered perceptron classifies the pair into different relation types.

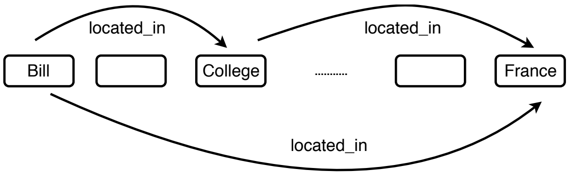

Figure 1: Pictorial representation of a second-order relation between two entities (*Bill* & *France*) connected by a context token (*College*).

Such RE models rely on the encoder to learn 'perfect' context-aware entity representations that can capture complex dependencies in the text. This works well for intra-sentence relation extraction i.e. the task of extracting relation from entities contained in a sentence (Christopoulou et al., 2018; Su et al., 2018). As these entities are closer together, the encoder can more easily establish connection based on the language used in the sentence. Additionally, these intra-sentence RE models can use linguistic/syntactical features for an improved performance e.g. shortest dependency path.

Unfortunately, success in intra-sentence RE has not been replicated for cross-sentence RE. As an example, a recent RE method called BRAN (Verga et al., 2018) proposed to use encoder of Transformer (Vaswani et al., 2017) for obtaining token representations and then used these representations for RE. However, our analysis revealed that it wrongly marks many cross-sentence relations as negative, especially when the two target entities were connected by a string of logic spanning over

Proceedings of NAACL-HLT 2019, pages 1442–1447
Minneapolis, Minnesota, June 2 - June 7, 2019.

multiple sentences. This showed that reliance on the encoder alone to learn these complex dependencies does not work well.

In this work we address this issue of over-reliance on the encoder. We propose a model based on the hypothesis that two target entities, whether intra-sentence or cross-sentence, could also be explicitly connected via a third context token (Figure 1). More specifically, we find a token in the text that is most related to both target entities, and compute the score for relation between the two target entities as the summation of their relation scores with this token. We refer to these relations as second-order relations. At the end, we combine these second-order scores with first-order scores derived from a traditional RE model, and achieve state-of-the-art performance over two biomedical datasets. To summarize the contribution of this work:

1. We propose using second-order relation scores for improved relation extraction.

2. We describe an efficient algorithm to obtain second-order relation scores.

2 Background

In this section we describe the encoder and relation classification unit of a SOTA RE model called BRAN (Verga et al., 2018). This model computes relation scores between two entities directly from their representations, therefore we refer to these as first-order relation scores.

2.1 Transformer Encoder

BRAN uses a variant of *Transformer* (Vaswani et al., 2017) encoder to generate token representations.

The encoder contains repeating blocks and each such block consists of two sublayers: multi-head self-attention layer followed by position-wise convolutional feedforward layer. There are residual connections and layer normalization (Ba et al., 2016) after each sublayer. The only difference from a standard transformer-encoder is the presence of a convolution layer of kernel width 5 between two consecutive convolution layers of kernels width 1 in the feedforward sublayer. It takes as input word embeddings that are added with positional embeddings (Gehring et al., 2017).

2.2 First-Order Relations

The relation classification unit takes as input token representations from the described encoder. These are then passed through two MLPs to generate head/tail representation e_i^{head}/e_i^{tail} for each token corresponding to whether it serves the first (head) or second (tail) position in the relation.

$$e_i^{head} = W_{head_2}(ReLU(W_{head_1} b_i)) \quad (1)$$

$$e_i^{tail} = W_{tail_2}(ReLU(W_{tail_1} b_i)) \quad (2)$$

where b_i is the representation of the i_{th} token generated by the encoder.

These are then combined with a bi-affine transformation operator to compute a $N \times R \times N$ tensor A of pairwise affinity scores for every token pair and all relation types, scoring all triplets of the form $(head, relation, tail)$:

$$A_{irj} = (e_i^{head} L) e_j^{tail}, \quad (3)$$

where L is a learned tensor of dimension $d \times R \times d$ to map pairs of tokens to scores over each of the R relation types and d is the dimension of head/tail representations. Going forward we will drop the subscript r for clarity.

The contributions from different mention pairs are then aggregated to give us **first-order** relation scores. This aggregation is done using $LogSumExp$, which is a smooth approximation of max that prevents sparse gradients:

$$\text{scores}^{(1)}(p^{head}, p^{tail}) = \log \sum_{\substack{i \in P^{head} \\ j \in P^{tail}}} \exp(A_{ij}), \quad (4)$$

where $P^{head}(P^{tail})$ contains mention indices for head (tail) entity.

3 Proposed Second-Order Relations

In this section we describe in detail our proposed method to obtain second-order relation scores.

We use the encoder described in Sec 2.1 for getting token representations. These token representations are then passed through two MLPs (as in previous section), which generate head/tail representations for each token corresponding to whether it serves the first or the second position in the relation. We used a separate set of these head/tail MLPs for second-order scores than the ones used for getting first-order scores. This was

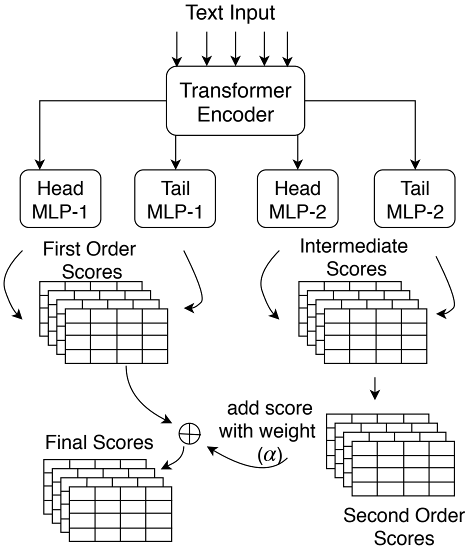

Figure 2: Schematic of the model architecture.

motivated by the need for representations focused on establishing relations with context tokens, as opposed to first-order relations (described in previous section) that attempt to directly connect two target entities.

The head and tail representations are then combined with a $d \times R \times d$ bilinear transformation tensor M to get a $N \times R \times N$ tensor B of intermediate pairwise scores.

$$B_{ij} = (e_i^{head} M) e_j^{tail} \tag{5}$$

After that we arbitrarily define the scores between tokens i and j when *conditioned* on a context token k as the sum of the scores of relations (i, k) and (k, j).

$$C(i, j|k) = B_{ik} + B_{kj} \tag{6}$$

These context-conditioned scores are computed for every triplet of the form (i, j, k).

Second-order relation scores are then derived by aggregating over all context tokens and mention pairs using $LogSumExp$.

$$\text{scores}^{(2)}(p^{head}, p^{tail}) = \log \sum_{\substack{k \\ i \in P^{head} \\ j \in P^{tail}}} \exp(C(i, j|k)) \tag{7}$$

Here $LogSumExp$ ensures that one specific mention pair connected via one specific context token is responsible for the relation. This is equivalent to max-pooling over all context tokens that could potentially connect the two target entities, which reduces over-fitting by removing contributions from noisy associations of the target entities with random tokens e.g. stopwords.

It is important to mention that a naive implementation of this would require $O(N^3)$ space to store context-conditioned scores between all pairs of token i.e. $C(i, j|k)$. To address this, we describe an efficient method in Section 3.1 that avoids explicitly storing these.

At the end, the final score for relation between two entities is given as a weighted sum of first (eq. 4) and second (eq. 7) order scores.

$$\begin{aligned} \text{scores}(p^{head}, p^{tail}) = {} & \text{scores}^{(1)}(p^{head}, p^{tail}) \\ & + \alpha * \text{scores}^{(2)}(p^{head}, p^{tail}) \end{aligned} \tag{8}$$

where α is a hyper-parameter denoting the weight of second-order relation scores.

Entity Recognition. We do entity recognition alongside relation extraction, as the transfer of knowledge between the two tasks has been shown to improve relation extraction performance (Verga et al., 2018; Miwa and Bansal, 2016). For this we feed encoder output b_i to a linear classifier W_{er} that predicts scores for each entity type.

$$d_i = W_{er}(b_i) \tag{9}$$

3.1 Efficient Implementation

The problem lies in storing score for every intermediate relation of the form $C(i, j|k)$, as that would require space of the order $O(N^3)$. Here we describe a space-time efficient method to compute final second-order relation scores.

The intermediate scores (eq. 5) are a tensor of dimension $b \times N \times R \times N$ comprising of pairwise scores for b batches. We create two tensors out of these intermediate scores, namely T_1 and T_2. T_1 computes the exponential of indices $(\{b, i \in P^{head}, j \in \mathcal{C}, R\})$ corresponding to pairwise scores between head entity and all the context tokens ($\mathcal{C}$ i.e., all the tokens except the two target entities), and sets other indices to 0. Similarly, T_2 computes exponential of indices $(\{b, i \in P^{tail}, j \in \mathcal{C}, R\})$ corresponding to pairwise scores between tail entity and context tokens, setting all other indices to 0. To get the context conditioned scores one needs to compute the batch product of

Data	Model	Pr	Re	F1
DCN	BRAN	0.614	0.850	0.712
	+ SOR	**0.643**	**0.879**	**0.734**
i2b2	HDLA	0.378	**0.422**	0.388
	BRAN	0.396	0.403	0.395
	+ SOR	**0.424**	0.419	**0.407**
CDR	BRAN	0.552	0.701	0.618
	+ SOR	0.552	0.701	0.618

Table 1: The performance of proposed model using second-order relations. BRAN is the model used in (Verga et al., 2018) and +SOR is our proposed model with second-order relations. Results for HDLA are quoted from Chikka and Karlapalem (2018). Results on CDR are identical for both BRAN and our proposed model as α was set to 0 after tuning over the dev set at which point our model is the same as BRAN. All the metrics are macro in nature.

R two dimensional slices of size $N \times N$ from T_1 and T_2 along the dimension of context, but this would be sequential in R. Instead we can permute T_1 and T_2 to $b \times R \times N \times N$ followed by reshaping to $bR \times N \times N$ and perform a batch matrix multiplication along the context dimension to get $bR \times N \times N$. Afterwards, we can sum along the last two dimensions to get a tensor of size bR. Finally, we can take the log succeeded by reshaping to $b \times R$ to obtain second-order scores.

4 Experimentation

4.1 Datasets

We have used three datasets in this work, i2b2 2010 challenge (Uzuner et al., 2011) dataset, a de-identified clinical notes dataset and a chemical-disease relations dataset known as BioCreative V (CDR) (Li et al., 2016; Wei et al., 2016).

First is a publicly available subset of the dataset used for the i2b2 2010 challenge. It consists of documents describing relations between different diseases and treatments. Out of the 426 documents available publicly, 10% are used each for both dev and test and the rest for training. There are 3244/409 relations in train/test set and 6 predefined relations types including one negative relation e.g. TrCP (**Tr**eatment Causes **Pr**oblem), TrIP (Tr Improves Pr), TrWP (Tr Worsens Pr). We have used the exact same dataset as Chikka *et al.* (Chikka and Karlapalem, 2018).

Second is a dataset of 4200 de-identified clinical notes (DCN), with vocabulary size of 50K. It contains approximately 170K relations in the train set and 50K each in dev/test set. There are 7 predefined relation types including one negative relation type. These are mostly between medication name and other entities e.g. "*paracetamol* ***every*** *day*","*aspirin* ***with_dosage*** *100mg*". The frequency of different relations in this dataset is fairly balanced.

Third is a widely used and publicly available dataset called CDR (Li et al., 2016; Wei et al., 2016). It was derived from Comparative Toxicogenomics Database (CTD) and contains documents describing the effect of chemicals (drugs) on diseases. There are only two relation types between any two target entities i.e. positive/negative and these relations are annotated at the document level. It consists of 1500 documents that are divided equally between train/dev/test sets. There are 1038/1012/1066 positive and 4280/4136/4270 negative relations in train/dev/test sets respectively. We performed the same preprocessing as done in BRAN (Verga et al., 2018).

4.2 Experimental Settings

We jointly solve for NER and RE tasks using cross-entropy loss. During training we alternate between mini-batches derived from each task. We fix the learn rate to 0.0005 and clip gradient for both tasks at 5.0. For training, we used adams optimizer with $\beta = (\beta_1, \beta_2) = (0.1, 0.9)$. We tune over the weight of second-order relations denoted by α to get $\alpha = 0.2$ for DCN/i2b2 and $\alpha = 0.0$ for CDR dataset.

Our final network had two encoder layers, with 8 attention heads in each multi-head attention sublayer and 256 filters for convolution layers in position-wise feedforward sublayer. We used dropout with probability 0.3 after: embedding layer, head/tail MLPs, output of each encoder sublayer. We also used a word dropout with probability 0.15 before the embedding layer.

4.3 Results

To show the benefits of using second-order relations we compared our model's performance to BRAN. The two models are different in the weighted addition of second-order relation scores. We tune over this weight parameter on the dev set and observed an improvement in MacroF1 score from 0.712 to 0.734 over DCN data and from 0.395 to 0.407 over i2b2 data. For further comparison a recently published model called HDLA (Chikka and Karlapalem, 2018) reported a macro-

F1 score of 0.388 on the same i2b2 dataset. It should be mentioned that HDLA used syntactic parsers for feature extraction but we do not use any such external tools.

In the case of CDR dataset we obtained $\alpha = 0$ after tuning, which means that the proposed model converged to BRAN and the results were identical for the two models. These results are summarized in Table 1.

4.4 Ablation Study

We experimented with different ablations of BRAN and noticed an improvement in results for DCN dataset upon removing multi-head self-attention layer. Also, our qualitative analysis showed that relations between distant entities were often wrongly marked negative. We attribute these errors to the token representations generated by the encoder. To this effect, our experiments showed that incorporating relative position (Shaw et al., 2018) information in the encoder to improve token representations does not lead to superior RE. Separately, we observed that the proposed method improved results when using a standard CNN encoder as well.

5 Conclusions and Future Work

We proposed a method that uses second-order relation scores to capture long dependencies for improved RE. These relations are derived by explicitly connecting two target entities via a context token. These second-order relations (SORs) are then combined with traditional relation extraction models, leading to state-of-the-art performance over two biomedical datasets. We also describe an efficient implementation for obtaining these SORs.

Despite restricting ourselves to SORs, it should be noted that the proposed method can be generalized to third and fourth order relations. We conjecture that these may serve well for cross-sentence relation extraction in long pieces of texts. Also, we only considered one relation type between each entity and bridge token but it is possible, and very likely that two different relation types may lead to a third relation type. We will explore both these aspects in future work.
