Message from the General Chair

Welcome to Minneapolis! NAACL 2019 promises to further build our growing and increasingly diverse community through substantive presentations, new diversity and inclusion initiatives, and a culturally-rich social event!

Christy Doran, Thamar Solorio, and Ted Pedersen, our 2019 Program Co-Chairs have gracefully managed the largest number of submissions at any NAACL to date – with submissions in 2019 almost doubling from the previous year. They demonstrated unrelenting dedication throughout the conference planning process to ensure preparation of a balanced program with thoughtfully-crafted and fair reviewing processes, on-time notifications, and a final careful selection of papers from a wide range of topics of interest represented in the main conference program. They also introduced a number of innovations in processes, including submission of abstracts before final submissions with the intention of getting a head start on the reviewing process and securing sufficient reviewers by topic; video lightning talks for posters to promote greater attendance and a preview of poster content; and, five categories of Best Papers: 1) Best Long Paper, 2) Best Short Paper, 3) Best Theme, 4) Best Resource, and 5) Best Explainable, to highlight a range of community values. The PCs introduced a conference theme this year that reflects a concern around ethics in our research community. Specifically, the theme examines the tension between data privacy and model bias in NLP. Our three invited talks, Arvind Narayanan, Rada Mihalcea, and Kieran Snyder will all present keynotes related to the conference theme.

In 2019, back by popular demand, there is an Industry Track, co-chaired by Rohit Kumar, Anastassia Loukina, and Michelle Morales. It will address practical issues in real-world deployment of Natural Language Processing and Speech Processing technologies that describe key lessons learned and new challenges posed by real-world implementations. There was an increase in the number of industry track submissions from 2018 (when the track was started) which suggests a continued interest in this track. A highlight this year is a Careers in NLP panel taking into consideration our more junior community members and their mentors.

As our international community grows, we can expect increasing diversity. Consistent with an awareness about diversity in the Natural Language Processing and Computational Linguistics community, at NAACL HLT 2019, we have introduced the Diversity and Inclusion (D&I) committee, co-chaired by Jason Eisner and Nathalie Schluter, and the Remote Presentation (RP) committee, co-chaired by Abhinav Misra and Meg Mitchell. The D&I committee was intended to support community concerns including, more diverse attendance through feasible childcare support efforts, community building through mentoring and social networking through the conference app, and comfort of all attendees through pronoun choice on badges and gender-neutral bathrooms. The RP committee responded to a concern to provide all members of our community with greater access to conferences, especially with regard to U.S. visa issues given the current political constraints. It is our hope that these new initiatives enrich the conference experience by further promoting greater access, and in turn, community-building.

On behalf of the Natural Language Processing and Computational Linguistics community, I would like to thank all of the organizers for their dedication, creativity, and lively communication that lead to a successful program and set of events: Christy Doran, Thamar Solorio and Ted Pedersen (program chairs); Rohit Kumar, Anastassia Loukina, and Michelle Morales (industrial track chairs); Nitin Madnani (website and app chair); Smaranda Muresan, Swapna Somasundaran, and Elena Volodina (workshop co-chairs); Anoop Sarkar and Michael Strube (tutorial co-chairs); Waleed Ammar, Annie Louis, and Nasrin Mostafazahdeh, (demo co-chairs); Jason Eisner and Nathalie Schulter (Diversity and Inclusion Co-Chairs) Stephanie Lukin and Alla Roskovskaya (publication co-chairs); Steve DeNeefe (handbook chair); Laura Burdick, Sudipta Kar, and Farah Nadeem (student co-chairs) along with Greg Durrett and Na-Rae-Han (Faculty Advisors) for the student research workshop; Lu Wang (student volunteer coordinator); Jason Baldridge and Alexis Palmer (the Americas International Sponsorship Team). Chris Callison-Burch and Tonya Custis (local sponsorships co-chairs); Yuval Pinter and Rachael Tatman (publicity and social media chairs); Abhinav Misra and Meg Mitchell (Remote Presentation co-chairs); Spencer Whitehead (video chair). Many thanks to Rich Gerber at SoftConf for on-going and rapid support. Many thanks to Julia Hockenmaier and the NAACL Executive Board for their on-going consultation, and Barbara Di Eugenio, Marti Hearst and David Yarowsky in their roles as ACL Conference Officer, ACL President, and ACL Treasurer, respectively. We also thank the Organizers of ACL 2019 and EMNLP 2019 for support in coordinating the programs, workshops and tutorials. We have twenty workshops plus the student research workshop. As we do every year, we owe many, many thanks to Priscilla Rasmussen for her guidance and moral support in addition to the mind-boggling task list associated with large-scale event planning, including managing exhibitors and our large sponsors. Thanks to Priscilla's efforts we have a great social event planned at the Minneapolis Institute of Art. In the spirit of community diversity, the museum offers internationally-themed galleries, and the food will reflect the themes.

We are immensely grateful to our sponsors for their generous contributions to NAACL 2019. Diamond sponsors are Amazon, ASAPP, Bloomberg Engineering, Facebook, and Google. Platinum sponsors are Capital One, DeepMind Google, Thomson Reuters, and Two Sigma. Our Gold sponsors are ByteDance and Megagon. Silver sponsors are Cisco, Duolingo, eBay, Grammarly, Microsoft Research, and SAP. Bronze sponsors are Clinc, ETS, Raytheon BBN Technology, and USC Viterbi School of Engineering/Information Sciences Institute. Additionally, Google is supporting our Diversity & Inclusion initiative and Grammarly also made an in-kind donation of Grammarly codes to help with proofreading. And, many of these same sponsors also generously support some of the workshops that make such a great finale to our conference. We are also pleased to welcome many companies who will participate in the Recruitment Lunch. There are many more people who through their hard work and dedication have contributed to make this conference a success: the area chairs and reviewers, tutorial presenters, workshop organizers, those who participated in D&I efforts, including student mentorship and the ACL Office staff. Many thanks to all of the presenters and conference attendees for your participation.

NAACL HLT 2019, General Chair
Jill Burstein, Educational Testing Service

Message from the Program Chairs

Welcome to Minneapolis and NAACL-HLT 2019! This conference is the largest by submission and acceptance volume of any NAACL to date, and it was through the fantastic hard work of the organizing committees, 94 Area Chairs, and 1321 reviewers that we were able to put together such a strong and varied program from a large pool of submissions. Similar to what other PCs have done in the past, we distributed a wide call for volunteers to recruit the Area Chairs and Reviewers–we seeded the areas with volunteers who responded, and then Area Chairs filled out the remainder of their respective committees. Our goal was to ensure greater diversity by including in each area some participants who may not have been previously involved, and therefore would not have been invited if the committees were built from lists of previous reviewers.

This year we followed a two-stage submission process, in which abstracts were due one week before full papers. Our goal was to get a head start on assigning papers to areas, and recruiting additional area chairs where submissions exceeded our predicted volume. Relative to the projected numbers from NAACL-HLT 2018, several areas received a higher-than-predicted number of submissions: Biomedical/Clinical, Dialogue and Vision. Text Mining ended up with the overall largest number of submissions. We used a hybrid reviewing form, combining elements of the EMNLP 2018, NAACL-HLT 2018 and ACL 2018, with a 6-point overall rating scale so there was no “easy out” mid-point, distinct sections of summary, strengths and weaknesses to make easy to scan and compare relevant sections, and the minimum length feature of START enabled to elicit more consistently substantive content for the authors.

Authors were permitted to switch format (long/short) when they submitted the full papers, so the total in the chart below uses 2271 as the total number of submissions, discounting the 103 that never submitted a full paper in the second phase. Seventy nine papers were desk-rejected due to anonymity, formatting, or dual-submission violations; 456 papers withdrawn prior to acceptance decisions being sent, although some were withdrawn part way through the review process; and an additional 11 papers were withdrawn after acceptance notifications had been sent. Keeping the acceptance rate consistent with past years meant we needed 5 parallel tracks to fit more papers into 3 days–as the conference grows, decisions will have to be made about continuing to add more tracks, adding more days to the main conference, or lowering the acceptance rate. The overall technical program consists of 423 main conference papers, plus 9 TACL papers, 23 SRW papers, 28 Industry papers, and 24 demos. The TACL and SRW papers are integrated into the program, and are marked SRW or TACL accordingly.

Acceptance break-down:

	Long	**Short**	**Total**	**TACL**
Reviewed	1067	666	1733	
Accepted as talk	140	72	212	4
Accepted as poster	141	70	211	5
Total Accepted	281 (26.3%)	142 (21.3%)	423 (24.4%)	9

A select group of Area Chairs was identified to make the Best Paper decisions, with independent teams assigned to select Best Long and Short Paper, Best Thematic Paper, Best Explainable NLP and Best Resource paper. The candidate papers were nominated by reviewers and/or Area Chairs.

It really takes a lot of volunteers' hard work to organize a NAACL conference. Our hearty thanks go out to:

- Jill Burstein, our fearless leader and General Conference Chair
- Priscilla Rasmussen, who knows everything and keeps the machine running
- Rich Gerber and his team at Softconf for having illuminated the secret corners of START and added several new features for us
- Recent past chairs–Amanda Stent, Heng Ji, Julia Hockenmaier, Emily Bender, Leon Derczynski, Iryna Gurevych and Yusuke Miyao–for answering piles of questions and generously sharing their documentation and resources
- All of the NAACL Organizing Committees
- The 43 session chairs (Alessandro Moschitti, Ani Nenkova, Anna Rumshisky, Bridget McInnes, Byron C. Wallace, Chenhao Tan, Daisuke Kawahara, Diyi Yang, Eduardo Blanco, Ekaterina Shutova, Emily Prud'hommeaux, Fei Liu, Gerard de Melo, Grzegorz Kondrak, Heng Ji, Ion Androutsopoulos, Kai-Wei Chang, Kevin Gimpel, Matt Gardner, Michael J. Paul, Mo Yu, Preslav Nakov, Roi Reichart, Ryan Cotterell, Saif Mohammad, Samuel Bowman, Sara Rosenthal, Serguei Pakhomov, Steven Bethard, Sujith Ravi, T. J. Hazen, Timothy Miller, Valia Kordoni, Vincent Ng, Wei Xu, William Yang Wang, Xiaodan Zhu, Yang Liu, Zornitsa Kozareva, Ellen Riloff, Colin Cherry, Joel Tetreault and Marine Carpuat)
- The special projects team: John Henderson for help detecting duplicate submissions and building us a clustering model to help with session creation, Sudipta Kar for additional help in detecting duplicate submissions, Cash de Leon and Jalen Tran for their help in putting together the slides for the poster highlights, Mahsa Shafaei for helping us screen volunteers, and Ted Pedersen for help getting this whole effort off the ground.

NAACL-HLT 2019 Program Co-Chairs
Christy Doran, Interactions, USA
Thamar Solorio, University of Houston, USA

Organizing Committee:

General Chair
Jill Burstein, ETS

Program Co-Chairs
Christy Doran, Interactions
Thamar Solorio, University of Houston

Industry Track Co-chairs
Rohit Kumar
Anastassia Loukina, Educational Testing Service, USA
Michelle Morales, IBM, USA

Workshop Co-Chairs
Smaranda Muresan, Columbia University, USA
Swapna Somasundaran, Educational Testing Service, USA
Elena Volodina, University of Gothenburg, Sweden

Tutorial Co-Chairs
Anoop Sarkar, Simon Fraser University, Canada
Michael Strube, Heidelberg Institute for Theoretical Studies, Germany

System Demonstration Co-Chairs
Waleed Ammar, Allen Institute for AI, USA
Annie Louis, University of Edinburgh, Scotland
Nasrin Mostafazadeh, Elemental Cognition, USA

Publication Co-Chairs
Stephanie Lukin, U.S. Army Research Laboratory
Alla Roskovskaya, City University of New York, USA

Keynote Speaker: Rada Mihalcea, University of Michigan

When the Computers Spot the Lie (and People Don't)

Abstract: Whether we like it or not, deception occurs everyday and everywhere: thousands of trials take place daily around the world; little white lies: "I'm busy that day!" even if your calendar is blank; news "with a twist" (a.k.a. fake news) meant to attract the readers attention or influence people in their future undertakings; misinformation in health social media posts; portrayed identities, on dating sites and elsewhere. Can a computer automatically detect deception in written accounts or in video recordings? In this talk, I will overview a decade of research in building linguistic and multimodal resources and algorithms for deception detection, targeting deceptive statements, trial videos, fake news, identity deception, and health misinformation. I will also show how these algorithms can provide insights into what makes a good lie - and thus teach us how we can spot a liar. As it turns out, computers can be trained to identify lies in many different contexts, and they can often do it better than humans do.

Bio: Rada Mihalcea is a Professor of Computer Science and Engineering at the University of Michigan and the Director of the Michigan Artificial Intelligence Lab. Her research interests are in lexical semantics, multilingual NLP, and computational social sciences. She serves or has served on the editorial boards of the Journals of Computational Linguistics, Language Resources and Evaluations, Natural Language Engineering, Journal of Artificial Intelligence Research, IEEE Transactions on Affective Computing, and Transactions of the Association for Computational Linguistics. She was a program co-chair for EMNLP 2009 and ACL 2011, and a general chair for NAACL 2015 and *SEM 2019. She currently serves as the ACL Vice-President Elect. She is the recipient of an NSF CAREER award (2008) and a Presidential Early Career Award for Scientists and Engineers awarded by President Obama (2009). In 2013, she was made an honorary citizen of her hometown of Cluj-Napoca, Romania.

Keynote Speaker: Kieran Snyder, Textio

Leaving the Lab: Building NLP Applications that Real People can Use

Abstract: There is a chasm between an NLP technology that works well in the research lab and something that works for applications that real people use. Research conditions are often theoretical or idealized. The first time they contribute to industry projects, many theoretical researchers are surprised to discover how much goes into building outside the lab, and how hard it is to build data products for real people ethically and transparently. This talk explores my NLP journey in three stages: working as an academic NLP researcher, learning to be a practical creator of NLP products in industry, and becoming the founding CEO of an NLP business. While each role has used my background in computational linguistics in essential ways, every step has also required me to learn and unlearn new things along the way. The further I have gone in my industry career, the more critical it has become to define and work within a well-established set of principles for data ethics. This talk is for academic researchers considering industry careers or collaborations, for people in industry who started out in academia, and for anyone on either side of the divide who wants to make NLP products that real people can use.

Bio: Kieran Snyder is the CEO and Co-Founder of Textio, the augmented writing platform. For anything you write, Textio tells you ahead of time who's going to respond based on the language you've used. Textio's augmented writing engine is designed to attach to any large text corpus with outcomes to find the patterns that work. Prior to founding Textio, Kieran held product leadership roles at Microsoft and Amazon. Kieran has a PhD in linguistics from the University of Pennsylvania. Her work has appeared in Fortune, Re/code, Slate, and the Washington Post.

Keynote Speaker: Arvind Narayanan, Princeton

Data as a Mirror of Society: Lessons from the Emerging Science of Fairness in Machine Learning

Abstract: Language corpora reflect human society, including cultural stereotypes, prejudices, and historical patterns. By default, statistical language models will absorb these stereotypes. As a result, NLP systems for word analogy generation, toxicity detection, and many other tasks have been found to reflect racial and gender biases. Based on this observation, I will discuss two emerging research directions. First, a deeper understanding of human culture can help identify possible harmful stereotypes in algorithmic systems. The second research direction is the converse of the first: if data is a mirror of society, machine learning can be used as a magnifying lens to study human culture.

Bio: Arvind Narayanan is an Associate Professor of Computer Science at Princeton. His research has shown how state-of-the-art word embeddings reflect racial, gender, and other cultural stereotypes. He leads the Princeton Web Transparency and Accountability Project to uncover how companies collect and use our personal information. His doctoral research showed the fundamental limits of de-identification, for which he received the Privacy Enhancing Technologies Award. Narayanan also co-created a Massive Open Online Course as well as a textbook on Bitcoin and cryptocurrency technologies.

Table of Contents

Conference Program

Sunday, June 2, 2019

18:00–20:00 *Welcome Reception (Nicollet Grand Ballroom)*

Monday, June 3, 2019

9:00–9:30 *Land Acknowledgments, Opening Remarks and Janyce Wiebe and Richard Kittredge Remembrances* (Nicollet Grand Ballroom)

Session 1

9:30–10:30 *Keynote 1: Arvind Narayanan "Data as a Mirror of Society: Lessons from the Emerging Science of Fairness in Machine Learning"* (Nicollet Grand Ballroom)

10:30–11:00 *Coffee Break*

11:00–12:30 ***Oral Sessions (long papers) and Posters (long and short papers)***

Session 1A: Psycholinguistics & Cognitive Modelling

Room: Nicollet B+C, Chair: **Serguei Pakhomov**

11:00–11:18 *Entity Recognition at First Sight: Improving NER with Eye Movement Information*
Nora Hollenstein and Ce Zhang

11:18–11:36 *The emergence of number and syntax units in LSTM language models*
Yair Lakretz, Germán Kruszewski, Théo Desbordes, Dieuwke Hupkes, Stanislas Dehaene and Marco Baroni

11:36–11:54 *Neural Self-Training through Spaced Repetition*
Hadi Amiri

11:54–12:12 *Neural language models as psycholinguistic subjects: Representations of syntactic state*
Richard Futrell, Ethan Wilcox, Takashi Morita, Peng Qian, Miguel Ballesteros and Roger Levy

12:12–12:30 *Understanding language-elicited EEG data by predicting it from a fine-tuned language model*
Dan Schwartz and Tom Mitchell

Monday, June 3, 2019 (continued)

Session 1B: Speech
Room: Nicollet A, Chair: **Yang Liu**

11:00–11:18 *Pre-training on high-resource speech recognition improves low-resource speech-to-text translation*
Sameer Bansal, Herman Kamper, Karen Livescu, Adam Lopez and Sharon Goldwater

11:18–11:36 *Measuring the perceptual availability of phonological features during language acquisition using unsupervised binary stochastic autoencoders*
Cory Shain and Micha Elsner

11:36–11:54 *Giving Attention to the Unexpected: Using Prosody Innovations in Disfluency Detection*
Vicky Zayats and Mari Ostendorf

11:54–12:12 *Massively Multilingual Adversarial Speech Recognition*
Oliver Adams, Matthew Wiesner, Shinji Watanabe and David Yarowsky

12:12–12:30 *Lost in Interpretation: Predicting Untranslated Terminology in Simultaneous Interpretation*
Nikolai Vogler, Craig Stewart and Graham Neubig

Session 1C: Generation
Room: Northstar Ballroom A, Chair: **Wei Xu**

11:00–11:18 *AudioCaps: Generating Captions for Audios in The Wild*
Chris Dongjoo Kim, Byeongchang Kim, Hyunmin Lee and Gunhee Kim

11:18–11:36 *"President Vows to Cut <Taxes> Hair": Dataset and Analysis of Creative Text Editing for Humorous Headlines*
Nabil Hossain, John Krumm and Michael Gamon

11:36–11:54 *Answer-based Adversarial Training for Generating Clarification Questions*
Sudha Rao and Hal Daumé III

11:54–12:12 *Improving Grammatical Error Correction via Pre-Training a Copy-Augmented Architecture with Unlabeled Data*
Wei Zhao, Liang Wang, Kewei Shen, Ruoyu Jia and Jingming Liu

12:12–12:30 *Topic-Guided Variational Auto-Encoder for Text Generation*
Wenlin Wang, Zhe Gan, Hongteng Xu, Ruiyi Zhang, Guoyin Wang, Dinghan Shen, Changyou Chen and Lawrence Carin

Session 1D: Tagging, Chunking, Syntax & Parsing
Room: Greenway, Chair: **Roi Reichart**

11:00–11:18 *Implementation of a Chomsky-Schützenberger n-best parser for weighted multiple context-free grammars*
Thomas Ruprecht and Tobias Denkinger

11:18–11:36 *Phylogenic Multi-Lingual Dependency Parsing*
Mathieu Dehouck and Pascal Denis

11:36–11:54 *Discontinuous Constituency Parsing with a Stack-Free Transition System and a Dynamic Oracle*
Maximin Coavoux and Shay B. Cohen

11:54–12:12 *How Bad are PoS Tagger in Cross-Corpora Settings? Evaluating Annotation Divergence in the UD Project.*
Guillaume Wisniewski and François Yvon

12:12–12:30 *CCG Parsing Algorithm with Incremental Tree Rotation*
Miloš Stanojević and Mark Steedman

Session 1E: Theory & Formalisms
Room: Nicollet D, Chair: **Ryan Cotterell**

11:00–11:18 *Cyclical Annealing Schedule: A Simple Approach to Mitigate KL Vanishing*
Hao Fu, Chunyuan Li, Xiaodong Liu, Jianfeng Gao, Asli Celikyilmaz and Lawrence Carin

11:18–11:36 *Recurrent models and lower bounds for projective syntactic decoding*
Natalie Schluter

11:36–11:54 *Evaluating Composition Models for Verb Phrase Elliptical Sentence Embeddings*
Gijs Wijnholds and Mehrnoosh Sadrzadeh

11:54–12:12 *Neural Finite-State Transducers: Beyond Rational Relations*
Chu-Cheng Lin, Hao Zhu, Matthew R. Gormley and Jason Eisner

12:12–12:30 *Riemannian Normalizing Flow on Variational Wasserstein Autoencoder for Text Modeling*
Prince Zizhuang Wang and William Yang Wang

Session 1F: Question Answering, Sentiment, Machine Translation, Resources & Evaluation (Posters)

Room: Hyatt Exhibit Hall

Question Answering

A Study of Incorrect Paraphrases in Crowdsourced User Utterances
Mohammad-Ali Yaghoub-Zadeh-Fard, Boualem Benatallah, Moshe Chai Barukh and Shayan Zamanirad

ComQA: A Community-sourced Dataset for Complex Factoid Question Answering with Paraphrase Clusters
Abdalghani Abujabal, Rishiraj Saha Roy, Mohamed Yahya and Gerhard Weikum

FreebaseQA: A New Factoid QA Data Set Matching Trivia-Style Question-Answer Pairs with Freebase
Kelvin Jiang, Dekun Wu and Hui Jiang

Simple Question Answering with Subgraph Ranking and Joint-Scoring
Wenbo Zhao, Tagyoung Chung, Anuj Goyal and Angeliki Metallinou

Learning to Attend On Essential Terms: An Enhanced Retriever-Reader Model for Open-domain Question Answering
Jianmo Ni, Chenguang Zhu, Weizhu Chen and Julian McAuley

UHop: An Unrestricted-Hop Relation Extraction Framework for Knowledge-Based Question Answering
Zi-Yuan Chen, Chih-Hung Chang, Yi-Pei Chen, Jijnasa Nayak and Lun-Wei Ku

BAG: Bi-directional Attention Entity Graph Convolutional Network for Multi-hop Reasoning Question Answering
Yu Cao, Meng Fang and Dacheng Tao

[SRW] *Is It Dish Washer Safe? Automatically Answering "Yes-No" Questions Using Customer Reviews*
Daria Dzendzik, Carl Vogel and Jennifer Foster

Sentiment

Vector of Locally-Aggregated Word Embeddings (VLAWE): A Novel Document-level Representation
Radu Tudor Ionescu and Andrei Butnaru

Multi-task Learning for Multi-modal Emotion Recognition and Sentiment Analysis
Md Shad Akhtar, Dushyant Chauhan, Deepanway Ghosal, Soujanya Poria, Asif Ekbal and Pushpak Bhattacharyya

Utilizing BERT for Aspect-Based Sentiment Analysis via Constructing Auxiliary Sentence
Chi Sun, Luyao Huang and Xipeng Qiu

A Variational Approach to Weakly Supervised Document-Level Multi-Aspect Sentiment Classification
Ziqian Zeng, Wenxuan Zhou, Xin Liu and Yangqiu Song

HiGRU: Hierarchical Gated Recurrent Units for Utterance-Level Emotion Recognition
Wenxiang Jiao, Haiqin Yang, Irwin King and Michael R. Lyu

Learning Interpretable Negation Rules via Weak Supervision at Document Level: A Reinforcement Learning Approach
Nicolas Pröllochs, Stefan Feuerriegel and Dirk Neumann

Simplified Neural Unsupervised Domain Adaptation
Timothy Miller

Learning Bilingual Sentiment-Specific Word Embeddings without Cross-lingual Supervision
Yanlin Feng and Xiaojun Wan

Machine Translation
ReWE: Regressing Word Embeddings for Regularization of Neural Machine Translation Systems
Inigo Jauregi Unanue, Ehsan Zare Borzeshi, Nazanin Esmaili and Massimo Piccardi

Lost in Machine Translation: A Method to Reduce Meaning Loss
Reuben Cohn-Gordon and Noah Goodman

Bi-Directional Differentiable Input Reconstruction for Low-Resource Neural Machine Translation
Xing Niu, Weijia Xu and Marine Carpuat

Code-Switching for Enhancing NMT with Pre-Specified Translation
Kai Song, Yue Zhang, Heng Yu, Weihua Luo, Kun Wang and Min Zhang

Aligning Vector-spaces with Noisy Supervised Lexicon
Noa Yehezkel Lubin, Jacob Goldberger and Yoav Goldberg

Understanding and Improving Hidden Representations for Neural Machine Translation
Guanlin Li, Lemao Liu, Xintong Li, Conghui Zhu, Tiejun Zhao and Shuming Shi

Monday, June 3, 2019 (continued)

Resources & Evaluation

Content Differences in Syntactic and Semantic Representation
Daniel Hershcovich, Omri Abend and Ari Rappoport

Attentive Mimicking: Better Word Embeddings by Attending to Informative Contexts
Timo Schick and Hinrich Schütze

Evaluating Style Transfer for Text
Remi Mir, Bjarke Felbo, Nick Obradovich and Iyad Rahwan

Big BiRD: A Large, Fine-Grained, Bigram Relatedness Dataset for Examining Semantic Composition
Shima Asaadi, Saif Mohammad and Svetlana Kiritchenko

Outlier Detection for Improved Data Quality and Diversity in Dialog Systems
Stefan Larson, Anish Mahendran, Andrew Lee, Jonathan K. Kummerfeld, Parker Hill, Michael A. Laurenzano, Johann Hauswald, Lingjia Tang and Jason Mars

Asking the Right Question: Inferring Advice-Seeking Intentions from Personal Narratives
Liye Fu, Jonathan P. Chang and Cristian Danescu-Niculescu-Mizil

Seeing Things from a Different Angle:Discovering Diverse Perspectives about Claims
Sihao Chen, Daniel Khashabi, Wenpeng Yin, Chris Callison-Burch and Dan Roth

12:30–13:00 *Grab your lunch break*

13:00–14:30 *Careers in NLP Panel (Nicollet Grand Ballroom)*

14:30–15:00 *Coffee Break*

15:00–16:30 ***Oral sessions (short papers), Posters (long and short papers) & Demos***

Session 2A: Dialogue & Discourse
Room: Northstar A, Chair: **Ellen Riloff**

15:00–15:15 *IMHO Fine-Tuning Improves Claim Detection*
Tuhin Chakrabarty, Christopher Hidey and Kathy McKeown

15:15–15:30 *Joint Multiple Intent Detection and Slot Labeling for Goal-Oriented Dialog*
Rashmi Gangadharaiah and Balakrishnan Narayanaswamy

15:30–15:45 *CITE: A Corpus of Image-Text Discourse Relations*
Malihe Alikhani, Sreyasi Nag Chowdhury, Gerard de Melo and Matthew Stone

15:45–16:00 *Improving Dialogue State Tracking by Discerning the Relevant Context*
Sanuj Sharma, Prafulla Kumar Choubey and Ruihong Huang

16:00–16:15 *CLEVR-Dialog: A Diagnostic Dataset for Multi-Round Reasoning in Visual Dialog*
Satwik Kottur, José M. F. Moura, Devi Parikh, Dhruv Batra and Marcus Rohrbach

16:15–16:30 *Learning Outside the Box: Discourse-level Features Improve Metaphor Identification*
Jesse Mu, Helen Yannakoudakis and Ekaterina Shutova

Session 2B: Ethics, Bias & Fairness

Room: Nicollet B+C, Chair: **Preslav Nakov**

15:00–15:15 *Detection of Abusive Language: the Problem of Biased Datasets*
Michael Wiegand, Josef Ruppenhofer and Thomas Kleinbauer

15:15–15:30 *Lipstick on a Pig: Debiasing Methods Cover up Systematic Gender Biases in Word Embeddings But do not Remove Them*
Hila Gonen and Yoav Goldberg

15:30–15:45 *Black is to Criminal as Caucasian is to Police: Detecting and Removing Multiclass Bias in Word Embeddings*
Thomas Manzini, Lim Yao Chong, Alan W. Black and Yulia Tsvetkov

15:45–16:00 *On Measuring Social Biases in Sentence Encoders*
Chandler May, Alex Wang, Shikha Bordia, Samuel R. Bowman and Rachel Rudinger

16:00–16:15 *Gender Bias in Contextualized Word Embeddings*
Jieyu Zhao, Tianlu Wang, Mark Yatskar, Ryan Cotterell, Vicente Ordonez and Kai-Wei Chang

16:15–16:30 [SRW] *Identifying and Reducing Gender Bias in Word-Level Language Models Status*
Shikha Bordia and Samuel R. Bowman

Session 2C: Style & Sentiment
Room: Nicollet D, Chair: **Diyi Yang**

15:00–15:15 *Combining Sentiment Lexica with a Multi-View Variational Autoencoder*
Alexander Miserlis Hoyle, Lawrence Wolf-Sonkin, Hanna Wallach, Ryan Cotterell and Isabelle Augenstein

15:15–15:30 *Enhancing Opinion Role Labeling with Semantic-Aware Word Representations from Semantic Role Labeling*
Meishan Zhang, Peili Liang and Guohong Fu

15:30–15:45 *Frowning Frodo, Wincing Leia, and a Seriously Great Friendship: Learning to Classify Emotional Relationships of Fictional Characters*
Evgeny Kim and Roman Klinger

15:45–16:00 *Generalizing Unmasking for Short Texts*
Janek Bevendorff, Benno Stein, Matthias Hagen and Martin Potthast

16:00–16:15 *Adversarial Training for Satire Detection: Controlling for Confounding Variables*
Robert McHardy, Heike Adel and Roman Klinger

16:15–16:30 [SRW] *Emotion impacts Speech Recognition Performance*
Rushab Munot and Ani Nenkova

Session 2D: Summarization & Information Retrieval

Room: Nicollet A, Chair: **Michael J. Paul**

15:00–15:15 *Keyphrase Generation: A Text Summarization Struggle*
Erion Çano and Ondřej Bojar

15:15–15:30 *SEQˆ3: Differentiable Sequence-to-Sequence-to-Sequence Autoencoder for Unsupervised Abstractive Sentence Compression*
Christos Baziotis, Ion Androutsopoulos, Ioannis Konstas and Alexandros Potamianos

15:30–15:45 *Crowdsourcing Lightweight Pyramids for Manual Summary Evaluation*
Ori Shapira, David Gabay, Yang Gao, Hadar Ronen, Ramakanth Pasunuru, Mohit Bansal, Yael Amsterdamer and Ido Dagan

15:45–16:00 *Serial Recall Effects in Neural Language Modeling*
Hassan Hajipoor, Hadi Amiri, Maseud Rahgozar and Farhad Oroumchian

16:00–16:15 *Fast Concept Mention Grouping for Concept Map-based Multi-Document Summarization*
Tobias Falke and Iryna Gurevych

16:15–16:30 [SRW] *The Strength of the Weakest Supervision: Topic Classification Using Class Labels*
Jiatong Li, Kai Zheng, Hua Xu, Qiaozhu Mei and Yue Wang

Session 2E: Tagging, Chunking, Syntax & Parsing

Room: Greenway, Chairs: **Joel Tetreault**

15:00–15:15 *Syntax-aware Neural Semantic Role Labeling with Supertags*
Jungo Kasai, Dan Friedman, Robert Frank, Dragomir Radev and Owen Rambow

15:15–15:30 *Left-to-Right Dependency Parsing with Pointer Networks*
Daniel Fernández-González and Carlos Gómez-Rodríguez

15:30–15:45 *Viable Dependency Parsing as Sequence Labeling*
Michalina Strzyz, David Vilares and Carlos Gómez-Rodríguez

15:45–16:00 *Pooled Contextualized Embeddings for Named Entity Recognition*
Alan Akbik, Tanja Bergmann and Roland Vollgraf

16:00–16:15 *Better Modeling of Incomplete Annotations for Named Entity Recognition*
Zhanming Jie, Pengjun Xie, Wei Lu, Ruixue Ding and Linlin Li

16:16–16:30 [SRW] *Handling Noisy Labels for Robustly Learning from Self-Training Data for Low-Resource Sequence Labeling*
Debjit Paul, Mittul Singh, Michael A. Hedderich and Dietrich Klakow

Session 2F: Information Extraction, Generation & Semantics (Posters & Demos)
Room: Hyatt Exhibit Hall

Information Extraction
Event Detection without Triggers
Shulin Liu, Yang Li, Feng Zhang, Tao Yang and Xinpeng Zhou

Sub-event detection from twitter streams as a sequence labeling problem
Giannis Bekoulis, Johannes Deleu, Thomas Demeester and Chris Develder

GraphIE: A Graph-Based Framework for Information Extraction
Yujie Qian, Enrico Santus, Zhijing Jin, Jiang Guo and Regina Barzilay

OpenKI: Integrating Open Information Extraction and Knowledge Bases with Relation Inference
Dongxu Zhang, Subhabrata Mukherjee, Colin Lockard, Luna Dong and Andrew McCallum

Imposing Label-Relational Inductive Bias for Extremely Fine-Grained Entity Typing
Wenhan Xiong, Jiawei Wu, Deren Lei, Mo Yu, Shiyu Chang, Xiaoxiao Guo and William Yang Wang

Improving Event Coreference Resolution by Learning Argument Compatibility from Unlabeled Data
Yin Jou Huang, Jing Lu, Sadao Kurohashi and Vincent Ng

Sentence Embedding Alignment for Lifelong Relation Extraction
Hong Wang, Wenhan Xiong, Mo Yu, Xiaoxiao Guo, Shiyu Chang and William Yang Wang

Description-Based Zero-shot Fine-Grained Entity Typing
Rasha Obeidat, Xiaoli Fern, Hamed Shahbazi and Prasad Tadepalli

[SRW] *Opinion Mining with Deep Contextualized Embeddings*
Wen-Bin Han and Noriko Kando

[SRW] *A Bag-of-concepts Model Improves Relation Extraction in a Narrow Knowledge Domain with Limited Data*
Jiyu Chen, Karin Verspoor and Zenan Zhai

Generation
Adversarial Decomposition of Text Representation
Alexey Romanov, Anna Rumshisky, Anna Rogers and David Donahue

PoMo: Generating Entity-Specific Post-Modifiers in Context
Jun Seok Kang, Robert Logan, Zewei Chu, Yang Chen, Dheeru Dua, Kevin Gimpel, Sameer Singh and Niranjan Balasubramanian

Improved Lexically Constrained Decoding for Translation and Monolingual Rewriting
J. Edward Hu, Huda Khayrallah, Ryan Culkin, Patrick Xia, Tongfei Chen, Matt Post and Benjamin Van Durme

Courteously Yours: Inducing courteous behavior in Customer Care responses using Reinforced Pointer Generator Network
Hitesh Golchha, Mauajama Firdaus, Asif Ekbal and Pushpak Bhattacharyya

How to Avoid Sentences Spelling Boring? Towards a Neural Approach to Unsupervised Metaphor Generation
Zhiwei Yu and Xiaojun Wan

[SRW] *Generating Text through Adversarial Training Using Skip-Thought Vectors*
Afroz Ahamad

[SRW] *A Partially Rule-Based Approach to AMR Generation*
Emma Manning

Semantics

Incorporating Context and External Knowledge for Pronoun Coreference Resolution
Hongming Zhang, Yan Song and Yangqiu Song

Unsupervised Deep Structured Semantic Models for Commonsense Reasoning
Shuohang Wang, Sheng Zhang, Yelong Shen, Xiaodong Liu, Jingjing Liu, Jianfeng Gao and Jing Jiang

Recovering dropped pronouns in Chinese conversations via modeling their referents
Jingxuan Yang, Jianzhuo Tong, Si Li, Sheng Gao, Jun Guo and Nianwen Xue

The problem with probabilistic DAG automata for semantic graphs
Ieva Vasiljeva, Sorcha Gilroy and Adam Lopez

A Systematic Study of Leveraging Subword Information for Learning Word Representations
Yi Zhu, Ivan Vulić and Anna Korhonen

Better Word Embeddings by Disentangling Contextual n-Gram Information
Prakhar Gupta, Matteo Pagliardini and Martin Jaggi

Integration of Knowledge Graph Embedding Into Topic Modeling with Hierarchical Dirichlet Process
Dingcheng Li, Siamak Zamani, Jingyuan Zhang and Ping Li

Correlation Coefficients and Semantic Textual Similarity
Vitalii Zhelezniak, Aleksandar Savkov, April Shen and Nils Hammerla

Generating Token-Level Explanations for Natural Language Inference
James Thorne, Andreas Vlachos, Christos Christodoulopoulos and Arpit Mittal

Strong Baselines for Complex Word Identification across Multiple Languages
Pierre Finnimore, Elisabeth Fritzsch, Daniel King, Alison Sneyd, Aneeq Ur Rehman, Fernando Alva-Manchego and Andreas Vlachos

[SRW] *Computational Investigations of Pragmatic Effects in Natural Language*
Jad Kabbara

16:30–17:00 *Coffee Break*

17:00–18:30 ***Oral sessions (long papers) and Posters (long and short papers)***

Session 3A: Information Extraction & Retrieval
Room: Nicollet A, Chair: **Gerard de Melo**

17:00–17:18 *Adaptive Convolution for Multi-Relational Learning*
Xiaotian Jiang, Quan Wang and Bin Wang

17:18–17:36 *Graph Pattern Entity Ranking Model for Knowledge Graph Completion*
Takuma Ebisu and Ryutaro Ichise

17:36–17:54 *Adversarial Training for Weakly Supervised Event Detection*
Xiaozhi Wang, Xu Han, Zhiyuan Liu, Maosong Sun and Peng Li

17:54–18:12 *A Submodular Feature-Aware Framework for Label Subset Selection in Extreme Classification Problems*
Elham J. Barezi, Ian D. Wood, Pascale Fung and Hamid R. Rabiee

18:12–18:30 *Relation Extraction with Temporal Reasoning Based on Memory Augmented Distant Supervision*
Jianhao Yan, Lin He, Ruqin Huang, Jian Li and Ying Liu

Session 3B: Semantics
Room: Nicollet D, Chair: **Kevin Gimpel**

17:00–17:18 *Integrating Semantic Knowledge to Tackle Zero-shot Text Classification*
Jingqing Zhang, Piyawat Lertvittayakumjorn and Yike Guo

17:18–17:36 *WordNode2Vec: Graph-based Embedding of Words*
Procheta Sen, Debasis Ganguly and Gareth Jones

17:36–17:54 *Cross-topic distributional semantic representations via unsupervised mappings*
Eleftheria Briakou, Nikos Athanasiou and Alexandros Potamianos

17:54–18:12 *What just happened? Evaluating retrofitted distributional word vectors*
Dmetri Hayes

18:12–18:30 *Linguistic Knowledge and Transferability of Contextual Representations*
Nelson F. Liu, Matt Gardner, Yonatan Belinkov, Matthew E. Peters and Noah A. Smith

Session 3C: Parsing & Modelling
Room: Greenway, Chair: **Kai-Wei Chang**

17:00–17:18 *Mutual Information Maximization for Simple and Accurate Part-Of-Speech Induction*
Karl Stratos

17:18–17:36 *Unsupervised Recurrent Neural Network Grammars*
Yoon Kim, Alexander Rush, Lei Yu, Adhiguna Kuncoro, Chris Dyer and Gábor Melis

17:36–17:54 *Cooperative Learning of Disjoint Syntax and Semantics*
Serhii Havrylov, Germán Kruszewski and Armand Joulin

17:54–18:12 *Unsupervised Latent Tree Induction with Deep Inside-Outside Recursive Auto-Encoders*
Andrew Drozdov, Patrick Verga, Mohit Yadav, Mohit Iyyer and Andrew McCallum

18:12–18:30 *Knowledge-Augmented Language Model and Its Application to Unsupervised Named-Entity Recognition*
Angli Liu, Jingfei Du and Veselin Stoyanov

Session 3D: Machine Translation
Room: Nicollet B+C, Chair: **Marine Carpuat**

17:00–17:18 *Syntax-Enhanced Neural Machine Translation with Syntax-Aware Word Representations*
Meishan Zhang, Zhenghua Li, Guohong Fu and Min Zhang

17:18–17:36 *Competence-based Curriculum Learning for Neural Machine Translation*
Emmanouil Antonios Platanios, Otilia Stretcu, Graham Neubig, Barnabas Poczos and Tom Mitchell

17:36–17:54 *Extract and Edit: An Alternative to Back-Translation for Unsupervised Neural Machine Translation*
Jiawei Wu, Xin Wang and William Yang Wang

17:54–18:12 *Consistency by Agreement in Zero-Shot Neural Machine Translation*
Maruan Al-Shedivat and Ankur Parikh

18:12–18:30 *Modeling Recurrence for Transformer*
Jie Hao, Xing Wang, Baosong Yang, Longyue Wang, Jinfeng Zhang and Zhaopeng Tu

Session 3E: Dialogue
Room: Northstar, Chair: **Sujith Ravi**

17:00–17:18 *Rethinking Action Spaces for Reinforcement Learning in End-to-end Dialog Agents with Latent Variable Models*
Tiancheng Zhao, Kaige Xie and Maxine Eskenazi

17:18–17:36 *Skeleton-to-Response: Dialogue Generation Guided by Retrieval Memory*
Deng Cai, Yan Wang, Wei Bi, Zhaopeng Tu, Xiaojiang Liu, Wai Lam and Shuming Shi

17:36–17:54 *Jointly Optimizing Diversity and Relevance in Neural Response Generation*
Xiang Gao, Sungjin Lee, Yizhe Zhang, Chris Brockett, Michel Galley, Jianfeng Gao and Bill Dolan

17:54–18:12 *Disentangling Language and Knowledge in Task-Oriented Dialogs*
Dinesh Raghu, Nikhil Gupta and Mausam

18:12–18:30 [TACL] *DREAM: A Challenge Dataset and Models for Dialogue-Based Reading Comprehension*
Kai Sun, Dian Yu, Jianshu Chen, Dong Yu, Yejin Choi and Claire Cardie

Session 3F: Applications, Social Media, Biomedical NLP & Clinical Text Processing (Posters)
NLP Applications

Tensorized Self-Attention: Efficiently Modeling Pairwise and Global Dependencies Together
Tao Shen, Tianyi Zhou, Guodong Long, Jing Jiang and Chengqi Zhang

WiC: the Word-in-Context Dataset for Evaluating Context-Sensitive Meaning Representations
Mohammad Taher Pilehvar and Jose Camacho-Collados

Does My Rebuttal Matter? Insights from a Major NLP Conference
Yang Gao, Steffen Eger, Ilia Kuznetsov, Iryna Gurevych and Yusuke Miyao

Casting Light on Invisible Cities: Computationally Engaging with Literary Criticism
Shufan Wang and Mohit Iyyer

PAWS: Paraphrase Adversaries from Word Scrambling
Yuan Zhang, Jason Baldridge and Luheng He

Cross-Corpora Evaluation and Analysis of Grammatical Error Correction Models — Is Single-Corpus Evaluation Enough?
Masato Mita, Tomoya Mizumoto, Masahiro Kaneko, Ryo Nagata and Kentaro Inui

Star-Transformer
Qipeng Guo, Xipeng Qiu, Pengfei Liu, Yunfan Shao, Xiangyang Xue and Zheng Zhang

[SRW] *SEDTWik: Segmentation-based Event Detection from Tweets Using Wikipedia*
Keval Morabia, Neti Lalita Bhanu Murthy, Aruna Malapati and Surender Samant

Social Media
Adaptation of Hierarchical Structured Models for Speech Act Recognition in Asynchronous Conversation
Tasnim Mohiuddin, Thanh-Tung Nguyen and Shafiq Joty

From legal to technical concept: Towards an automated classification of German political Twitter postings as criminal offenses
Frederike Zufall, Tobias Horsmann and Torsten Zesch

Joint Multi-Label Attention Networks for Social Text Annotation
Hang Dong, Wei Wang, Kaizhu Huang and Frans Coenen

Multi-Channel Convolutional Neural Network for Twitter Emotion and Sentiment Recognition
Jumayel Islam, Robert E. Mercer and Lu Xiao

Detecting Cybersecurity Events from Noisy Short Text
Semih Yagcioglu, Mehmet saygin Seyfioglu, Begum Citamak, Batuhan Bardak, Seren Guldamlasioglu, Azmi Yuksel and Emin Islam Tatli

White-to-Black: Efficient Distillation of Black-Box Adversarial Attacks
Yotam Gil, Yoav Chai, Or Gorodissky and Jonathan Berant

Analyzing the Perceived Severity of Cybersecurity Threats Reported on Social Media
Shi Zong, Alan Ritter, Graham Mueller and Evan Wright

Fake News Detection using Deep Markov Random Fields
Duc Minh Nguyen, Tien Huu Do, Robert Calderbank and Nikos Deligiannis

Issue Framing in Online Discussion Fora
Mareike Hartmann, Tallulah Jansen, Isabelle Augenstein and Anders Søgaard

Vector of Locally Aggregated Embeddings for Text Representation
Hadi Amiri and Mitra Mohtarami

Predicting the Type and Target of Offensive Posts in Social Media
Marcos Zampieri, Shervin Malmasi, Preslav Nakov, Sara Rosenthal, Noura Farra and Ritesh Kumar

Biomedical NLP & Clinical Text Processing
Biomedical Event Extraction based on Knowledge-driven Tree-LSTM
Diya Li, Lifu Huang, Heng Ji and Jiawei Han

Detecting cognitive impairments by agreeing on interpretations of linguistic features
Zining Zhu, Jekaterina Novikova and Frank Rudzicz

Relation Extraction using Explicit Context Conditioning
Gaurav Singh and Parminder Bhatia

Conversation Model Fine-Tuning for Classifying Client Utterances in Counseling Dialogues
Sungjoon Park, Donghyun Kim and Alice Oh

Using Similarity Measures to Select Pretraining Data for NER
Xiang Dai, Sarvnaz Karimi, Ben Hachey and Cecile Paris

Predicting Annotation Difficulty to Improve Task Routing and Model Performance for Biomedical Information Extraction
Yinfei Yang, Oshin Agarwal, Chris Tar, Byron C. Wallace and Ani Nenkova

Detecting Depression in Social Media using Fine-Grained Emotions
Mario Ezra Aragon, Adrian Pastor Lopez Monroy, Luis Carlos Gonzalez Gurrola and Manuel Montes-y-Gomez

Tuesday, June 4, 2019

[SRW] *Kickstarting NLP for the Whole-person Function Domain with Representation Learning and Data Analysis*
Denis Newman-Griffis

A Silver Standard Corpus of Human Phenotype-Gene Relations
Diana Sousa, Andre Lamurias and Francisco M Couto

9:00–10:30 ***Oral sessions (long papers) and Posters (long and short papers)***

Session 4A: Phonology & Morphology
Room: Nicollet A, Chair: **Greg Kondrak**

9:00–9:18 *Improving Lemmatization of Non-Standard Languages with Joint Learning*
Enrique Manjavacas, Ákos Kádár and Mike Kestemont

9:18–9:36 *One Size Does Not Fit All: Comparing NMT Representations of Different Granularities*
Nadir Durrani, Fahim Dalvi, Hassan Sajjad, Yonatan Belinkov and Preslav Nakov

9:36–9:54 *A Simple Joint Model for Improved Contextual Neural Lemmatization*
Chaitanya Malaviya, Shijie Wu and Ryan Cotterell

9:54–10:12 *A Probabilistic Generative Model of Linguistic Typology*
Johannes Bjerva, Yova Kementchedjhieva, Ryan Cotterell and Isabelle Augenstein

10:12–10:30 *Quantifying the morphosyntactic content of Brown Clusters*
Manuel Ciosici, Leon Derczynski and Ira Assent

Session 4B: Multilingual NLP
Room: Nicollet D, Chair: **Ekaterina Shutova**

9:00–9:18 *Analyzing Bayesian Crosslingual Transfer in Topic Models*
Shudong Hao and Michael J. Paul

9:18–9:36 *Recursive Subtree Composition in LSTM-Based Dependency Parsing*
Miryam de Lhoneux, Miguel Ballesteros and Joakim Nivre

9:36–9:54 *Cross-lingual CCG Induction*
Kilian Evang

9:54–10:12 *Density Matching for Bilingual Word Embedding*
Chunting Zhou, Xuezhe Ma, Di Wang and Graham Neubig

10:12–10:30 *Cross-Lingual Alignment of Contextual Word Embeddings, with Applications to Zero-shot Dependency Parsing*
Tal Schuster, Ori Ram, Regina Barzilay and Amir Globerson

Tuesday, June 4, 2019 (continued)

Session 4C: Social Media
Room: Nicollet B+C, Chair: **Xiaodan Zhu**

9:00–9:18 *Early Rumour Detection*
Kaimin Zhou, Chang Shu, Binyang Li and Jey Han Lau

9:18–9:36 *Microblog Hashtag Generation via Encoding Conversation Contexts*
Yue Wang, Jing Li, Irwin King, Michael R. Lyu and Shuming Shi

9:36–9:54 *Text Processing Like Humans Do: Visually Attacking and Shielding NLP Systems*
Steffen Eger, Gözde Gül Şahin, Andreas Rücklé, Ji-Ung Lee, Claudia Schulz, Mohsen Mesgar, Krishnkant Swarnkar, Edwin Simpson and Iryna Gurevych

9:54–10:12 *Something's Brewing! Early Prediction of Controversy-causing Posts from Discussion Features*
Jack Hessel and Lillian Lee

10:12–10:30 *No Permanent Friends or Enemies: Tracking Relationships between Nations from News*
Xiaochuang Han, Eunsol Choi and Chenhao Tan

Session 4D: Generation
Room: Northstar A, Chair: Ion Androutsopoulos

9:00–9:18 *Improving Human Text Comprehension through Semi-Markov CRF-based Neural Section Title Generation*
Sebastian Gehrmann, Steven Layne and Franck Dernoncourt

9:18–9:36 *Unifying Human and Statistical Evaluation for Natural Language Generation*
Tatsunori Hashimoto, Hugh Zhang and Percy Liang

9:36–9:54 *What makes a good conversation? How controllable attributes affect human judgments*
Abigail See, Stephen Roller, Douwe Kiela and Jason Weston

9:54–10:12 *An Empirical Investigation of Global and Local Normalization for Recurrent Neural Sequence Models Using a Continuous Relaxation to Beam Search*
Kartik Goyal, Chris Dyer and Taylor Berg-Kirkpatrick

10:12–10:30 *Pun Generation with Surprise*
He He, Nanyun Peng and Percy Liang

Session 4E: Industry Session: Real World Challenges
Room: Greenway

Session 4F: Discourse, Information Retrieval, Machine Translation, Vision & Robotics (Posters)

Discourse
Single Document Summarization as Tree Induction
Yang Liu, Ivan Titov and Mirella Lapata

Fixed That for You: Generating Contrastive Claims with Semantic Edits
Christopher Hidey and Kathy McKeown

Box of Lies: Multimodal Deception Detection in Dialogues
Felix Soldner, Verónica Pérez-Rosas and Rada Mihalcea

A Crowdsourced Corpus of Multiple Judgments and Disagreement on Anaphoric Interpretation
Massimo Poesio, Jon Chamberlain, Silviu Paun, Juntao Yu, Alexandra Uma and Udo Kruschwitz

A Streamlined Method for Sourcing Discourse-level Argumentation Annotations from the Crowd
Tristan Miller, Maria Sukhareva and Iryna Gurevych

Unsupervised Dialog Structure Learning
Weiyan Shi, Tiancheng Zhao and Zhou Yu

Modeling Document-level Causal Structures for Event Causal Relation Identification
Lei Gao, Prafulla Kumar Choubey and Ruihong Huang

[TACL] *Planning, Inference, and Pragmatics in Sequential Language Games*
Fereshte Khani, Noah Goodman and Percy Liang

Information Retrieval
Hierarchical User and Item Representation with Three-Tier Attention for Recommendation
Chuhan Wu, Fangzhao Wu, Junxin Liu and Yongfeng Huang

Text Similarity Estimation Based on Word Embeddings and Matrix Norms for Targeted Marketing
Tim vor der Brück and Marc Pouly

Glocal: Incorporating Global Information in Local Convolution for Keyphrase Extraction
Animesh Prasad and Min-Yen Kan

A Study of Latent Structured Prediction Approaches to Passage Reranking
Iryna Haponchyk and Alessandro Moschitti

Combining Distant and Direct Supervision for Neural Relation Extraction
Iz Beltagy, Kyle Lo and Waleed Ammar

Tweet Stance Detection Using an Attention based Neural Ensemble Model
Umme Aymun Siddiqua, Abu Nowshed Chy and Masaki Aono

Machine Translation
Word Embedding-Based Automatic MT Evaluation Metric using Word Position Information
Hiroshi Echizen'ya, Kenji Araki and Eduard Hovy

Learning to Stop in Structured Prediction for Neural Machine Translation
Mingbo Ma, Renjie Zheng and Liang Huang

Learning Unsupervised Multilingual Word Embeddings with Incremental Multilingual Hubs
Geert Heyman, Bregt Verreet, Ivan Vulić and Marie-Francine Moens

Curriculum Learning for Domain Adaptation in Neural Machine Translation
Xuan Zhang, Pamela Shapiro, Gaurav Kumar, Paul McNamee, Marine Carpuat and Kevin Duh

Improving Robustness of Machine Translation with Synthetic Noise
Vaibhav Vaibhav, Sumeet Singh, Craig Stewart and Graham Neubig

Non-Parametric Adaptation for Neural Machine Translation
Ankur Bapna and Orhan Firat

Online Distilling from Checkpoints for Neural Machine Translation
Hao-Ran Wei, Shujian Huang, Ran Wang, Xin-Yu Dai and Jiajun Chen

Vision & Robotics

Value-based Search in Execution Space for Mapping Instructions to Programs
Dor Muhlgay, Jonathan Herzig and Jonathan Berant

VQD: Visual Query Detection In Natural Scenes
Manoj Acharya, Karan Jariwala and Christopher Kanan

Improving Natural Language Interaction with Robots Using Advice
Nikhil Mehta and Dan Goldwasser

Generating Knowledge Graph Paths from Textual Definitions using Sequence-to-Sequence Models
Victor Prokhorov, Mohammad Taher Pilehvar and Nigel Collier

Shifting the Baseline: Single Modality Performance on Visual Navigation & QA
Jesse Thomason, Daniel Gordon and Yonatan Bisk

ExCL: Extractive Clip Localization Using Natural Language Descriptions
Soham Ghosh, Anuva Agarwal, Zarana Parekh and Alexander Hauptmann

10:30–11:00 *Coffee Break*

11:00–12:30 ***Oral Sessions (short papers), Posters (long and short papers) & Demos***

Session 5A: Multilingual NLP
Room: Nicollet D, Chair: **Valia Kordoni**

11:00–11:15 *Detecting dementia in Mandarin Chinese using transfer learning from a parallel corpus*
Bai Li, Yi-Te Hsu and Frank Rudzicz

11:15–11:30 *Cross-lingual Visual Verb Sense Disambiguation*
Spandana Gella, Desmond Elliott and Frank Keller

11:30–11:45 *Subword-Level Language Identification for Intra-Word Code-Switching*
Manuel Mager, Özlem Çetinoğlu and Katharina Kann

11:45–12:00 *MuST-C: a Multilingual Speech Translation Corpus*
Mattia A. Di Gangi, Roldano Cattoni, Luisa Bentivogli, Matteo Negri and Marco Turchi

12:00–12:15 *Contextualization of Morphological Inflection*
Ekaterina Vylomova, Ryan Cotterell, Trevor Cohn, Timothy Baldwin and Jason Eisner

12:15–12:30 *A Robust Abstractive System for Cross-Lingual Summarization*
Jessica Ouyang, Boya Song and Kathy McKeown

Session 5B: Machine Translation

Room: Nicollet B+C, Chair: **Daisuke Kawahara**

11:00–11:15 *Improving Neural Machine Translation with Neural Syntactic Distance*
Chunpeng Ma, Akihiro Tamura, Masao Utiyama, Eiichiro Sumita and Tiejun Zhao

11:15–11:30 *Measuring Immediate Adaptation Performance for Neural Machine Translation*
Patrick Simianer, Joern Wuebker and John DeNero

11:30–11:45 *Differentiable Sampling with Flexible Reference Word Order for Neural Machine Translation*
Weijia Xu, Xing Niu and Marine Carpuat

11:45–12:00 *Reinforcement Learning based Curriculum Optimization for Neural Machine Translation*
Gaurav Kumar, George Foster, Colin Cherry and Maxim Krikun

12:00–12:15 *Overcoming Catastrophic Forgetting During Domain Adaptation of Neural Machine Translation*
Brian Thompson, Jeremy Gwinnup, Huda Khayrallah, Kevin Duh and Philipp Koehn

12:15–12:30 [SRW] *Multimodal Machine Translation with Embedding Prediction*
Tosho Hirasawa, Hayahide Yamagishi, Yukio Matsumura and Mamoru Komachi

Session 5C: Social Media
Room: Greenway, Chair: **Chenhao Tan**

11:00–11:15 *Short-Term Meaning Shift: A Distributional Exploration*
Marco Del Tredici, Raquel Fernández and Gemma Boleda

11:15–11:30 *Detecting Derogatory Compounds – An Unsupervised Approach*
Michael Wiegand, Maximilian Wolf and Josef Ruppenhofer

11:30–11:45 *Personalized Neural Embeddings for Collaborative Filtering with Text*
Guangneng Hu

11:45–12:00 *An Embarrassingly Simple Approach for Transfer Learning from Pretrained Language Models*
Alexandra Chronopoulou, Christos Baziotis and Alexandros Potamianos

12:00–12:15 *Incorporating Emoji Descriptions Improves Tweet Classification*
Abhishek Singh, Eduardo Blanco and Wei Jin

12:15–12:30 *Modeling Personal Biases in Language Use by Inducing Personalized Word Embeddings*
Daisuke Oba, Naoki Yoshinaga, Shoetsu Sato, Satoshi Akasaki and Masashi Toyoda

Session 5D: Text Analysis
Room: Northstar A, Chair: **Saif Mohammad**

11:00–11:15 *Multi-Task Ordinal Regression for Jointly Predicting the Trustworthiness and the Leading Political Ideology of News Media*
Ramy Baly, Georgi Karadzhov, Abdelrhman Saleh, James Glass and Preslav Nakov

11:15–11:30 *Joint Detection and Location of English Puns*
Yanyan Zou and Wei Lu

11:30–11:45 *Harry Potter and the Action Prediction Challenge from Natural Language*
David Vilares and Carlos Gómez-Rodríguez

11:45–12:00 *Argument Mining for Understanding Peer Reviews*
Xinyu Hua, Mitko Nikolov, Nikhil Badugu and Lu Wang

12:00–12:15 *An annotated dataset of literary entities*
David Bamman, Sejal Popat and Sheng Shen

12:15–12:30 *Abusive Language Detection with Graph Convolutional Networks*
Pushkar Mishra, Marco Del Tredici, Helen Yannakoudakis and Ekaterina Shutova

Session 5E: Semantics
Room: Nicollet A, Chair: **Samuel Bowman**

11:00–11:15 *On the Importance of Distinguishing Word Meaning Representations: A Case Study on Reverse Dictionary Mapping*
Mohammad Taher Pilehvar

11:15–11:30 *Factorising AMR generation through syntax*
Kris Cao and Stephen Clark

11:30–11:45 *A Crowdsourced Frame Disambiguation Corpus with Ambiguity*
Anca Dumitrache, Lora Aroyo and Chris Welty

11:45–12:00 *Inoculation by Fine-Tuning: A Method for Analyzing Challenge Datasets*
Nelson F. Liu, Roy Schwartz and Noah A. Smith

12:00–12:15 [SRW] *Word Polysemy Aware Document Vector Estimation*
Vivek Gupta, Ankit Saw, Harshit Gupta, Pegah Nokhiz and Partha Talukdar

12:15–12:30 [SRW] *EQUATE: A Benchmark Evaluation Framework for Quantitative Reasoning in Natural Language Inference*
Abhilasha Ravichander, Aakanksha Naik, Carolyn Rose and Eduard Hovy

Session 5F: Information Retrieval, Question Answering, Generation & Syntax (Posters & Demos)

Information Retrieval
A Capsule Network-based Embedding Model for Knowledge Graph Completion and Search Personalization
Dai Quoc Nguyen, Thanh Vu, Tu Dinh Nguyen, Dat Quoc Nguyen and Dinh Phung

Partial Or Complete, That's The Question
Qiang Ning, Hangfeng He, Chuchu Fan and Dan Roth

Sequential Attention with Keyword Mask Model for Community-based Question Answering
Jianxin Yang, Wenge Rong, Libin Shi and Zhang Xiong

Simple Attention-Based Representation Learning for Ranking Short Social Media Posts
Peng Shi, Jinfeng Rao and Jimmy Lin

AttentiveChecker: A Bi-Directional Attention Flow Mechanism for Fact Verification
Santosh Tokala, Vishal G, Avirup Saha and Niloy Ganguly

Practical, Efficient, and Customizable Active Learning for Named Entity Recognition in the Digital Humanities
Alexander Erdmann, David Joseph Wrisley, Benjamin Allen, Christopher Brown, Sophie Cohen-Bodénès, Micha Elsner, Yukun Feng, Brian Joseph, Béatrice Joyeux-Prunel and Marie-Catherine de Marneffe

Doc2hash: Learning Discrete Latent variables for Documents Retrieval
Yifei Zhang and Hao Zhu

Generation

Evaluating Text GANs as Language Models
Guy Tevet, Gavriel Habib, Vered Shwartz and Jonathan Berant

Latent Code and Text-based Generative Adversarial Networks for Soft-text Generation
Md Akmal Haidar, Mehdi Rezagholizadeh, Alan Do Omri and Ahmad Rashid

Neural Text Generation from Rich Semantic Representations
Valerie Hajdik, Jan Buys, Michael Wayne Goodman and Emily M. Bender

Step-by-Step: Separating Planning from Realization in Neural Data-to-Text Generation
Amit Moryossef, Yoav Goldberg and Ido Dagan

Evaluating Rewards for Question Generation Models
Tom Hosking and Sebastian Riedel

Text Generation from Knowledge Graphs with Graph Transformers
Rik Koncel-Kedziorski, Dhanush Bekal, Yi Luan, Mirella Lapata and Hannaneh Hajishirzi

Question Answering

Open Information Extraction from Question-Answer Pairs
Nikita Bhutani, Yoshihiko Suhara, Wang-Chiew Tan, Alon Halevy and H. V. Jagadish

Question Answering by Reasoning Across Documents with Graph Convolutional Networks
Nicola De Cao, Wilker Aziz and Ivan Titov

A Qualitative Comparison of CoQA, SQuAD 2.0 and QuAC
Mark Yatskar

BERT Post-Training for Review Reading Comprehension and Aspect-based Sentiment Analysis
Hu Xu, Bing Liu, Lei Shu and Philip Yu

Old is Gold: Linguistic Driven Approach for Entity and Relation Linking of Short Text
Ahmad Sakor, Isaiah Onando Mulang', Kuldeep Singh, Saeedeh Shekarpour, Maria Esther Vidal, Jens Lehmann and Sören Auer

Be Consistent! Improving Procedural Text Comprehension using Label Consistency
Xinya Du, Bhavana Dalvi, Niket Tandon, Antoine Bosselut, Wen-tau Yih, Peter Clark and Claire Cardie

MathQA: Towards Interpretable Math Word Problem Solving with Operation-Based Formalisms
Aida Amini, Saadia Gabriel, Shanchuan Lin, Rik Koncel-Kedziorski, Yejin Choi and Hannaneh Hajishirzi

DROP: A Reading Comprehension Benchmark Requiring Discrete Reasoning Over Paragraphs
Dheeru Dua, Yizhong Wang, Pradeep Dasigi, Gabriel Stanovsky, Sameer Singh and Matt Gardner

Syntax
An Encoding Strategy Based Word-Character LSTM for Chinese NER
Wei Liu, Tongge Xu, Qinghua Xu, Jiayu Song and Yueran Zu

Highly Effective Arabic Diacritization using Sequence to Sequence Modeling
Hamdy Mubarak, Ahmed Abdelali, Hassan Sajjad, Younes Samih and Kareem Darwish

SC-LSTM: Learning Task-Specific Representations in Multi-Task Learning for Sequence Labeling
Peng Lu, Ting Bai and Philippe Langlais

Learning to Denoise Distantly-Labeled Data for Entity Typing
Yasumasa Onoe and Greg Durrett

A Simple and Robust Approach to Detecting Subject-Verb Agreement Errors
Simon Flachs, Ophélie Lacroix, Marek Rei, Helen Yannakoudakis and Anders Søgaard

A Grounded Unsupervised Universal Part-of-Speech Tagger for Low-Resource Languages
Ronald Cardenas, Ying Lin, Heng Ji and Jonathan May

On Difficulties of Cross-Lingual Transfer with Order Differences: A Case Study on Dependency Parsing
Wasi Ahmad, Zhisong Zhang, Xuezhe Ma, Eduard Hovy, Kai-Wei Chang and Nanyun Peng

A Multi-Task Approach for Disentangling Syntax and Semantics in Sentence Representations
Mingda Chen, Qingming Tang, Sam Wiseman and Kevin Gimpel

12:30–14:00 *Lunch Break*

14:00–15:00 *Keynote 2: Rada Mihalcea "When the Computers Spot the Lie (and People Don't)" (Nicollet Grand Ballroom)*

15:00–15:30 *Coffee Break*

15:30–17:00 ***Oral sessions (long papers), Posters (long and short papers) & Demos***

Session 6A: Sentiment Analysis
Room: Northstar A, Chair: **Sara Rosenthal**

15:30–15:48 *Self-Discriminative Learning for Unsupervised Document Embedding*
Hong-You Chen, Chin-Hua Hu, Leila Wehbe and Shou-de Lin

15:48–16:06 *Adaptive Convolution for Text Classification*
Byung-Ju Choi, Jun-Hyung Park and SangKeun Lee

16:06–16:24 *Zero-Shot Cross-Lingual Opinion Target Extraction*
Soufian Jebbara and Philipp Cimiano

16:24–16:42 *Adversarial Category Alignment Network for Cross-domain Sentiment Classification*
Xiaoye Qu, Zhikang Zou, Yu Cheng, Yang Yang and Pan Zhou

16:42–17:00 *Target-oriented Opinion Words Extraction with Target-fused Neural Sequence Labeling*
Zhifang Fan, Zhen Wu, Xin-Yu Dai, Shujian Huang and Jiajun Chen

Session 6B: Summarization

Room: Greenway, Chair: **Ani Nenkova**

15:30–15:48 *Abstractive Summarization of Reddit Posts with Multi-level Memory Networks*
Byeongchang Kim, Hyunwoo Kim and Gunhee Kim

15:48–16:06 *Automatic learner summary assessment for reading comprehension*
Menglin Xia, Ekaterina Kochmar and Ted Briscoe

16:06–16:24 *Data-efficient Neural Text Compression with Interactive Learning*
Avinesh P.V.S and Christian M. Meyer

16:24–16:42 *Text Generation with Exemplar-based Adaptive Decoding*
Hao Peng, Ankur Parikh, Manaal Faruqui, Bhuwan Dhingra and Dipanjan Das

16:42–17:00 *Guiding Extractive Summarization with Question-Answering Rewards*
Kristjan Arumae and Fei Liu

Session 6C: Vision & Robotics

Room: Nicollet A, Chair: **William Yang Wang**

15:30–15:48 *Beyond task success: A closer look at jointly learning to see, ask, and GuessWhat*
Ravi Shekhar, Aashish Venkatesh, Tim Baumgärtner, Elia Bruni, Barbara Plank, Raffaella Bernardi and Raquel Fernández

15:48–16:06 *The World in My Mind: Visual Dialog with Adversarial Multi-modal Feature Encoding*
Yiqun Yao, Jiaming Xu and Bo Xu

16:06–16:24 *Strong and Simple Baselines for Multimodal Utterance Embeddings*
Paul Pu Liang, Yao Chong Lim, Yao-Hung Hubert Tsai, Ruslan Salakhutdinov and Louis-Philippe Morency

16:24–16:42 *Learning to Navigate Unseen Environments: Back Translation with Environmental Dropout*
Hao Tan, Licheng Yu and Mohit Bansal

16:42–17:00 *Towards Content Transfer through Grounded Text Generation*
Shrimai Prabhumoye, Chris Quirk and Michel Galley

Session 6D: Question Answering
Room: Nicollet B+C, Chair: **Eduardo Blanco**

15:30–15:48 *Improving Machine Reading Comprehension with General Reading Strategies*
Kai Sun, Dian Yu, Dong Yu and Claire Cardie

15:48–16:06 *Multi-task Learning with Sample Re-weighting for Machine Reading Comprehension*
Yichong Xu, Xiaodong Liu, Yelong Shen, Jingjing Liu and Jianfeng Gao

16:06–16:24 *Semantically-Aligned Equation Generation for Solving and Reasoning Math Word Problems*
Ting-Rui Chiang and Yun-Nung Chen

16:24–16:42 *Iterative Search for Weakly Supervised Semantic Parsing*
Pradeep Dasigi, Matt Gardner, Shikhar Murty, Luke Zettlemoyer and Eduard Hovy

16:42–17:00 *Alignment over Heterogeneous Embeddings for Question Answering*
Vikas Yadav, Steven Bethard and Mihai Surdeanu

Session 6E: Industry Session: Deployed Systems
Room: Nicollet D

Session 6F: Phonology, Speech and Text Mining (Posters & Demos)

Phonology
Bridging the Gap: Attending to Discontinuity in Identification of Multiword Expressions
Omid Rohanian, Shiva Taslimipoor, Samaneh Kouchaki, Le An Ha and Ruslan Mitkov

Incorporating Word Attention into Character-Based Word Segmentation
Shohei Higashiyama, Masao Utiyama, Eiichiro Sumita, Masao Ideuchi, Yoshiaki Oida, Yohei Sakamoto and Isaac Okada

VCWE: Visual Character-Enhanced Word Embeddings
Chi Sun, Xipeng Qiu and Xuanjing Huang

Subword Encoding in Lattice LSTM for Chinese Word Segmentation
Jie Yang, Yue Zhang and Shuailong Liang

Improving Cross-Domain Chinese Word Segmentation with Word Embeddings
Yuxiao Ye, Weikang Li, Yue Zhang, Likun Qiu and Jian Sun

Neural Semi-Markov Conditional Random Fields for Robust Character-Based Part-of-Speech Tagging
Apostolos Kemos, Heike Adel and Hinrich Schütze

Shrinking Japanese Morphological Analyzers With Neural Networks and Semi-supervised Learning
Arseny Tolmachev, Daisuke Kawahara and Sadao Kurohashi

[TACL] *Grammar Error Correction in Morphologically-Rich Languages: The Case of Russian*
Alla Rozovskaya and Dan Roth

[SRW] *Deep Learning and Sociophonetics: Automatic Coding of Rhoticity Using Neural Networks*
Sarah Gupta and Anthony DiPadova

[SRW] *Learn Languages First and Then Convert: towards Effective Simplified to Traditional Chinese Conversion*
Pranav A, S.F. Hui, I-Tsun Cheng, Ishaan Batra and Chiu Yik Hei

Speech
Neural Constituency Parsing of Speech Transcripts
Paria Jamshid Lou, Yufei Wang and Mark Johnson

Acoustic-to-Word Models with Conversational Context Information
Suyoun Kim and Florian Metze

A Dynamic Speaker Model for Conversational Interactions
Hao Cheng, Hao Fang and Mari Ostendorf

Fluent Translations from Disfluent Speech in End-to-End Speech Translation
Elizabeth Salesky, Matthias Sperber and Alexander Waibel

[SRW] *Data Augmentation by Data Noising for Open-vocabulary Slots in Spoken Language Understanding*
Hwa-Yeon Kim, Yoon-Hyung Roh and Young-Kil Kim

[SRW] *Expectation and Locality Effects in the Prediction of Disfluent Fillers and Repairs in English Speech*
Samvit Dammalapati, Rajakrishnan Rajkumar and Sumeet Agarwal

Text Mining

Relation Classification Using Segment-Level Attention-based CNN and Dependency-based RNN
Van-Hien Tran, Van-Thuy Phi, Hiroyuki Shindo and Yuji Matsumoto

Document-Level Event Factuality Identification via Adversarial Neural Network
Zhong Qian, Peifeng Li, Qiaoming Zhu and Guodong Zhou

Distant Supervision Relation Extraction with Intra-Bag and Inter-Bag Attentions
Zhi-Xiu Ye and Zhen-Hua Ling

Ranking-Based Autoencoder for Extreme Multi-label Classification
Bingyu Wang, Li Chen, Wei Sun, Kechen Qin, Kefeng Li and Hui Zhou

Posterior-regularized REINFORCE for Instance Selection in Distant Supervision
Qi Zhang, Siliang Tang, Xiang Ren, Fei Wu, Shiliang Pu and Yueting Zhuang

Scalable Collapsed Inference for High-Dimensional Topic Models
Rashidul Islam and James Foulds

An Integrated Approach for Keyphrase Generation via Exploring the Power of Retrieval and Extraction
Wang Chen, Hou Pong Chan, Piji Li, Lidong Bing and Irwin King

Predicting Malware Attributes from Cybersecurity Texts
Arpita Roy, Youngja Park and Shimei Pan

Improving Distantly-supervised Entity Typing with Compact Latent Space Clustering
Bo Chen, Xiaotao Gu, Yufeng Hu, Siliang Tang, Guoping Hu, Yueting Zhuang and Xiang Ren

Modelling Instance-Level Annotator Reliability for Natural Language Labelling Tasks
Maolin Li, Arvid Fahlström Myrman, Tingting Mu and Sophia Ananiadou

Review-Driven Multi-Label Music Style Classification by Exploiting Style Correlations
Guangxiang Zhao, Jingjing Xu, Qi Zeng, Xuancheng Ren and Xu Sun

Fact Discovery from Knowledge Base via Facet Decomposition
Zihao Fu, Yankai Lin, Zhiyuan Liu and Wai Lam

A Richer-but-Smarter Shortest Dependency Path with Attentive Augmentation for Relation Extraction
Duy-Cat Can, Hoang-Quynh Le, Quang-Thuy Ha and Nigel Collier

Wednesday, June 5, 2019

9:00–10:00 *Keynote 3: Kieran Snyder "Leaving the Lab: Building NLP Applications that Real People can Use" (Nicollet Grand Ballroom)*

10:00–10:30 *Coffee Break*

10:30–12:00 ***Oral sessions (long papers) and Posters (long and short papers)***

Session 7A: Question Answering
Room: Greenway, Chair: **Alessandro Moschitti**

10:30–10:48 *Bidirectional Attentive Memory Networks for Question Answering over Knowledge Bases*
Yu Chen, Lingfei Wu and Mohammed J Zaki

10:48–11:06 *BoolQ: Exploring the Surprising Difficulty of Natural Yes/No Questions*
Christopher Clark, Kenton Lee, Ming-Wei Chang, Tom Kwiatkowski, Michael Collins and Kristina Toutanova

11:06–11:24 *Enhancing Key-Value Memory Neural Networks for Knowledge Based Question Answering*
Kun Xu, Yuxuan Lai, Yansong Feng and Zhiguo Wang

11:24–11:42 *Repurposing Entailment for Multi-Hop Question Answering Tasks*
Harsh Trivedi, Heeyoung Kwon, Tushar Khot, Ashish Sabharwal and Niranjan Balasubramanian

11:42–12:00 [TACL] *CoQA: A Conversational Question Answering Challenge*
Siva Reddy, Danqi Chen and Christopher D. Manning

Session 7B: Ethics, Bias & Fairness
Room: Nicollet A, Chair: **Emily Prud'hommeaux**

10:30–10:48 [TACL] *Mind the GAP: A Balanced Corpus of Gendered Ambiguous Pronouns*
Kellie Webster, Marta Recasens, Vera Axelrod and Jason Baldridge

10:48–11:06 *GenderQuant: Quantifying Mention-Level Genderedness*
Ananya, Nitya Parthasarthi and Sameer Singh

Wednesday, June 5, 2019 (continued)

11:06–11:24 *Analyzing Polarization in Social Media: Method and Application to Tweets on 21 Mass Shootings*
Dorottya Demszky, Nikhil Garg, Rob Voigt, James Zou, Jesse Shapiro, Matthew Gentzkow and Dan Jurafsky

11:24–11:42 *Learning to Decipher Hate Symbols*
Jing Qian, Mai ElSherief, Elizabeth Belding and William Yang Wang

11:42–12:00 [TACL] *Data Statements for Natural Language Processing: Toward Mitigating System Bias and Enabling Better Science*
Emily M. Bender and Batya Friedman

Session 7C: Information Extraction
Room: Nicollet D, Chair: **Heng Ji**

10:30–10:48 *Long-tail Relation Extraction via Knowledge Graph Embeddings and Graph Convolution Networks*
Ningyu Zhang, Shumin Deng, Zhanlin Sun, Guanying Wang, Xi Chen, Wei Zhang and Huajun Chen

10:48–11:06 *GAN Driven Semi-distant Supervision for Relation Extraction*
Pengshuai Li, Xinsong Zhang, Weijia Jia and Hai Zhao

11:06–11:24 *A general framework for information extraction using dynamic span graphs*
Yi Luan, Dave Wadden, Luheng He, Amy Shah, Mari Ostendorf and Hannaneh Hajishirzi

11:24–11:42 *OpenCeres: When Open Information Extraction Meets the Semi-Structured Web*
Colin Lockard, Prashant Shiralkar and Xin Luna Dong

11:42–12:00 *Structured Minimally Supervised Learning for Neural Relation Extraction*
Fan Bai and Alan Ritter

Session 7D: Machine Translation
Room: Northstar A, Chair: **Colin Cherry**

10:30–10:48 *Neural Machine Translation of Text from Non-Native Speakers*
Antonios Anastasopoulos, Alison Lui, Toan Q. Nguyen and David Chiang

10:48–11:06 *Improving Domain Adaptation Translation with Domain Invariant and Specific Information*
Shuhao Gu, Yang Feng and Qun Liu

Wednesday, June 5, 2019 (continued)

11:06–11:24 *Selective Attention for Context-aware Neural Machine Translation*
Sameen Maruf, André F. T. Martins and Gholamreza Haffari

11:24–11:42 *On Evaluation of Adversarial Perturbations for Sequence-to-Sequence Models*
Paul Michel, Xian Li, Graham Neubig and Juan Pino

11:42–12:00 *Accelerated Reinforcement Learning for Sentence Generation by Vocabulary Prediction*
Kazuma Hashimoto and Yoshimasa Tsuruoka

Session 7E: Text Analysis
Room: Nicollet B+C, Chair: **Steven Bethard**

10:30–10:48 *Mitigating Uncertainty in Document Classification*
Xuchao Zhang, Fanglan Chen, ChangTien Lu and Naren Ramakrishnan

10:48–11:06 *Complexity-Weighted Loss and Diverse Reranking for Sentence Simplification*
Reno Kriz, Joao Sedoc, Marianna Apidianaki, Carolina Zheng, Gaurav Kumar, Eleni Miltsakaki and Chris Callison-Burch

11:06–11:24 *Predicting Helpful Posts in Open-Ended Discussion Forums: A Neural Architecture*
Kishaloy Halder, Min-Yen Kan and Kazunari Sugiyama

11:24–11:42 *Text Classification with Few Examples using Controlled Generalization*
Abhijit Mahabal, Jason Baldridge, Burcu Karagol Ayan, Vincent Perot and Dan Roth

11:42–12:00 *Reinforcement Learning Based Text Style Transfer without Parallel Training Corpus*
Hongyu Gong, Suma Bhat, Lingfei Wu, JinJun Xiong and Wen-mei Hwu

Session 7F: Machine Learning, Tagging, Chunking, Syntax & Parsing (Posters)

Machine Learning

Adapting RNN Sequence Prediction Model to Multi-label Set Prediction
Kechen Qin, Cheng Li, Virgil Pavlu and Javed Aslam

Customizing Grapheme-to-Phoneme System for Non-Trivial Transcription Problems in Bangla Language
Sudipta Saha Shubha, Nafis Sadeq, Shafayat Ahmed, Md. Nahidul Islam, Muhammad Abdullah Adnan, Md. Yasin Ali Khan and Mohammad Zuberul Islam

Connecting Language and Knowledge with Heterogeneous Representations for Neural Relation Extraction
Peng Xu and Denilson Barbosa

Segmentation-free compositional n-gram embedding
Geewook Kim, Kazuki Fukui and Hidetoshi Shimodaira

Exploiting Noisy Data in Distant Supervision Relation Classification
Kaijia Yang, Liang He, Xin-Yu Dai, Shujian Huang and Jiajun Chen

Misspelling Oblivious Word Embeddings
Aleksandra Piktus, Necati Bora Edizel, Piotr Bojanowski, Edouard Grave, Rui Ferreira and Fabrizio Silvestri

Learning Relational Representations by Analogy using Hierarchical Siamese Networks
Gaetano Rossiello, Alfio Gliozzo, Robert Farrell, Nicolas Fauceglia and Michael Glass

An Effective Label Noise Model for DNN Text Classification
Ishan Jindal, Daniel Pressel, Brian Lester and Matthew Nokleby

Understanding Learning Dynamics Of Language Models with SVCCA
Naomi Saphra and Adam Lopez

Using Large Corpus N-gram Statistics to Improve Recurrent Neural Language Models
Yiben Yang, Ji-Ping Wang and Doug Downey

Continual Learning for Sentence Representations Using Conceptors
Tianlin Liu, Lyle Ungar and Joao Sedoc

Relation Discovery with Out-of-Relation Knowledge Base as Supervision
Yan Liang, Xin Liu, Jianwen Zhang and Yangqiu Song

Corpora Generation for Grammatical Error Correction
Jared Lichtarge, Chris Alberti, Shankar Kumar, Noam Shazeer, Niki Parmar and Simon Tong

Structural Supervision Improves Learning of Non-Local Grammatical Dependencies
Ethan Wilcox, Peng Qian, Richard Futrell, Miguel Ballesteros and Roger Levy

Benchmarking Approximate Inference Methods for Neural Structured Prediction
Lifu Tu and Kevin Gimpel

Evaluating and Enhancing the Robustness of Dialogue Systems: A Case Study on a Negotiation Agent
Minhao Cheng, Wei Wei and Cho-Jui Hsieh

Investigating Robustness and Interpretability of Link Prediction via Adversarial Modifications
Pouya Pezeshkpour, Yifan Tian and Sameer Singh

Analysis Methods in Neural Language Processing: A Survey
Yonatan Belinkov and James Glass

[TACL] *Attentive Convolution: Equipping CNNs with RNN-style Attention Mechanisms*
Wenpeng Yin and Hinrich Schütze

[TACL] *Rotational Unit of Memory: A Novel Representation Unit for RNNs with Scalable Applications*
Rumen Dangovski, Li Jing, Preslav Nakov, Mićo Tatalović and Marin Soljačić

Transferable Neural Projection Representations
Chinnadhurai Sankar, Sujith Ravi and Zornitsa Kozareva

[SRW] *Gating Mechanisms for Combining Character and Word-level Word Representations: an Empirical Study*
Jorge Balazs and Yutaka Matsuo

Tagging, Chunking, Syntax & Parsing
Semantic Role Labeling with Associated Memory Network
Chaoyu Guan, Yuhao Cheng and Hai Zhao

Better, Faster, Stronger Sequence Tagging Constituent Parsers
David Vilares, Mostafa Abdou and Anders Søgaard

CAN-NER: Convolutional Attention Network for Chinese Named Entity Recognition
Yuying Zhu and Guoxin Wang

Decomposed Local Models for Coordinate Structure Parsing
Hiroki Teranishi, Hiroyuki Shindo and Yuji Matsumoto

Multi-Task Learning for Japanese Predicate Argument Structure Analysis
Hikaru Omori and Mamoru Komachi

Domain adaptation for part-of-speech tagging of noisy user-generated text
Luisa März, Dietrich Trautmann and Benjamin Roth

Neural Chinese Address Parsing
Hao Li, Wei Lu, Pengjun Xie and Linlin Li

[SRW] *A Pregroup Representation of Word Order Alternation Using Hindi Syntax*
Alok Debnath and Manish Shrivastava

12:00–12:30 *Grab your lunch break*

12:30–13:30 *NAACL Business Meeting* (Nicollet B+C)

13:30–15:00 ***Oral Sessions (long papers) and Posters (long and short papers)***

Session 8A: Discourse
Room: Northstar A, Chair: **Vincent Ng**

13:30–13:48 *Learning Hierarchical Discourse-level Structure for Fake News Detection*
Hamid Karimi and Jiliang Tang

13:48–14:06 *DiscoFuse: A Large-Scale Dataset for Discourse-Based Sentence Fusion*
Mor Geva, Eric Malmi, Idan Szpektor and Jonathan Berant

14:06–14:24 *Linguistically-Informed Specificity and Semantic Plausibility for Dialogue Generation*
Wei-Jen Ko, Greg Durrett and Junyi Jessy Li

14:24–14:42 *Learning to Describe Unknown Phrases with Local and Global Contexts*
Shonosuke Ishiwatari, Hiroaki Hayashi, Naoki Yoshinaga, Graham Neubig, Shoetsu Sato, Masashi Toyoda and Masaru Kitsuregawa

14:42–15:00 *Mining Discourse Markers for Unsupervised Sentence Representation Learning*
Damien Sileo, Tim Van de Cruys, Camille Pradel and Philippe Muller

Session 8B: Machine Learning
Room: Nicollet B+C, Chair: **Anna Rumshisky**

13:30–13:48 *How Large a Vocabulary Does Text Classification Need? A Variational Approach to Vocabulary Selection*
Wenhu Chen, Yu Su, Yilin Shen, Zhiyu Chen, Xifeng Yan and William Yang Wang

13:48–14:06 *Subword-based Compact Reconstruction of Word Embeddings*
Shota Sasaki, Jun Suzuki and Kentaro Inui

14:06–14:24 *Bayesian Learning for Neural Dependency Parsing*
Ehsan Shareghi, Yingzhen Li, Yi Zhu, Roi Reichart and Anna Korhonen

14:24–14:42 *AutoSeM: Automatic Task Selection and Mixing in Multi-Task Learning*
Han Guo, Ramakanth Pasunuru and Mohit Bansal

14:42–15:00 *Studying the Inductive Biases of RNNs with Synthetic Variations of Natural Languages*
Shauli Ravfogel, Yoav Goldberg and Tal Linzen

Session 8C: Applications
Room: Nicollet A, Chair: **T. J. Hazen**

13:30–13:48 *Attention is not Explanation*
Sarthak Jain and Byron C. Wallace

13:48–14:06 *Playing Text-Adventure Games with Graph-Based Deep Reinforcement Learning*
Prithviraj Ammanabrolu and Mark Riedl

14:06–14:24 *Information Aggregation for Multi-Head Attention with Routing-by-Agreement*
Jian Li, Baosong Yang, Zi-Yi Dou, Xing Wang, Michael R. Lyu and Zhaopeng Tu

14:24–14:42 *Context Dependent Semantic Parsing over Temporally Structured Data*
Charles Chen and Razvan Bunescu

14:42–15:00 *Structural Scaffolds for Citation Intent Classification in Scientific Publications*
Arman Cohan, Waleed Ammar, Madeleine van Zuylen and Field Cady

Session 8D: Semantics

Room: Greenway, Chair: **Matt Gardner**

13:30–13:48 *pair2vec: Compositional Word-Pair Embeddings for Cross-Sentence Inference*
Mandar Joshi, Eunsol Choi, Omer Levy, Daniel Weld and Luke Zettlemoyer

13:48–14:06 *Submodular Optimization-based Diverse Paraphrasing and its Effectiveness in Data Augmentation*
Ashutosh Kumar, Satwik Bhattamishra, Manik Bhandari and Partha Talukdar

14:06–14:24 *Let's Make Your Request More Persuasive: Modeling Persuasive Strategies via Semi-Supervised Neural Nets on Crowdfunding Platforms*
Diyi Yang, Jiaao Chen, Zichao Yang, Dan Jurafsky and Eduard Hovy

14:24–14:42 *Recursive Routing Networks: Learning to Compose Modules for Language Understanding*
Ignacio Cases, Clemens Rosenbaum, Matthew Riemer, Atticus Geiger, Tim Klinger, Alex Tamkin, Olivia Li, Sandhini Agarwal, Joshua D. Greene, Dan Jurafsky, Christopher Potts and Lauri Karttunen

14:42–15:00 *Structural Neural Encoders for AMR-to-text Generation*
Marco Damonte and Shay B. Cohen

Session 8E: Biomedical NLP & Clinical Text Processing

Room: Nicollet D, Chair: **Timothy Miller**

13:30–13:48 *Multilingual prediction of Alzheimer's disease through domain adaptation and concept-based language modelling*
Kathleen C. Fraser, Nicklas Linz, Bai Li, Kristina Lundholm Fors, Frank Rudzicz, Alexandra Konig, Jan Alexandersson, Philippe Robert and Dimitrios Kokkinakis

13:48–14:06 *Ranking and Selecting Multi-Hop Knowledge Paths to Better Predict Human Needs*
Debjit Paul and Anette Frank

14:06–14:24 *NLP Whack-A-Mole: Challenges in Cross-Domain Temporal Expression Extraction*
Amy Olex, Luke Maffey and Bridget McInnes

14:24–14:42 *Document-Level N-ary Relation Extraction with Multiscale Representation Learning*
Robin Jia, Cliff Wong and Hoifung Poon

14:42–15:00 *Inferring Which Medical Treatments Work from Reports of Clinical Trials*
Eric Lehman, Jay DeYoung, Regina Barzilay and Byron C. Wallace

Session 8F: Dialogue, Multilingual NLP & Summarization (Posters)

Dialogue

Decay-Function-Free Time-Aware Attention to Context and Speaker Indicator for Spoken Language Understanding
Jonggu Kim and Jong-Hyeok Lee

Dialogue Act Classification with Context-Aware Self-Attention
Vipul Raheja and Joel Tetreault

Affect-Driven Dialog Generation
Pierre Colombo, Wojciech Witon, Ashutosh Modi, James Kennedy and Mubbasir Kapadia

Multi-Level Memory for Task Oriented Dialogs
Revanth Gangi Reddy, Danish Contractor, Dinesh Raghu and Sachindra Joshi

Topic Spotting using Hierarchical Networks with Self Attention
Pooja Chitkara, Ashutosh Modi, Pravalika Avvaru, Sepehr Janghorbani and Mubbasir Kapadia

Top-Down Structurally-Constrained Neural Response Generation with Lexicalized Probabilistic Context-Free Grammar
Wenchao Du and Alan W. Black

What do Entity-Centric Models Learn? Insights from Entity Linking in Multi-Party Dialogue
Laura Aina, Carina Silberer, Ionut-Teodor Sorodoc, Matthijs Westera and Gemma Boleda

Continuous Learning for Large-scale Personalized Domain Classification
Han Li, Jihwan Lee, Sidharth Mudgal, Ruhi Sarikaya and Young-Bum Kim

Multilingual NLP

Cross-lingual Transfer Learning for Multilingual Task Oriented Dialog
Sebastian Schuster, Sonal Gupta, Rushin Shah and Mike Lewis

Evaluating Coherence in Dialogue Systems using Entailment
Nouha Dziri, Ehsan Kamalloo, Kory Mathewson and Osmar Zaiane

On Knowledge distillation from complex networks for response prediction
Siddhartha Arora, Mitesh M. Khapra and Harish G. Ramaswamy

Cross-lingual Multi-Level Adversarial Transfer to Enhance Low-Resource Name Tagging
Lifu Huang, Heng Ji and Jonathan May

Unsupervised Extraction of Partial Translations for Neural Machine Translation
Benjamin Marie and Atsushi Fujita

Low-Resource Syntactic Transfer with Unsupervised Source Reordering
Mohammad Sadegh Rasooli and Michael Collins

Revisiting Adversarial Autoencoder for Unsupervised Word Translation with Cycle Consistency and Improved Training
Tasnim Mohiuddin and Shafiq Joty

Addressing word-order Divergence in Multilingual Neural Machine Translation for extremely Low Resource Languages
Rudra Murthy, Anoop Kunchukuttan and Pushpak Bhattacharyya

Massively Multilingual Neural Machine Translation
Roee Aharoni, Melvin Johnson and Orhan Firat

A Large-Scale Comparison of Historical Text Normalization Systems
Marcel Bollmann

Combining Discourse Markers and Cross-lingual Embeddings for Synonym–Antonym Classification
Michael Roth and Shyam Upadhyay

Context-Aware Cross-Lingual Mapping
Hanan Aldarmaki and Mona Diab

Polyglot Contextual Representations Improve Crosslingual Transfer
Phoebe Mulcaire, Jungo Kasai and Noah A. Smith

Typological Features for Multilingual Delexicalised Dependency Parsing
Manon Scholivet, Franck Dary, Alexis Nasr, Benoit Favre and Carlos Ramisch

Wednesday, June 5, 2019 (continued)

Summarization

Recommendations for Datasets for Source Code Summarization
Alexander LeClair and Collin McMillan

Question Answering as an Automatic Evaluation Metric for News Article Summarization
Matan Eyal, Tal Baumel and Michael Elhadad

Understanding the Behaviour of Neural Abstractive Summarizers using Contrastive Examples
Krtin Kumar and Jackie Chi Kit Cheung

Jointly Extracting and Compressing Documents with Summary State Representations
Afonso Mendes, Shashi Narayan, Sebastião Miranda, Zita Marinho, André F. T. Martins and Shay B. Cohen

News Article Teaser Tweets and How to Generate Them
Sanjeev Kumar Karn, Mark Buckley, Ulli Waltinger and Hinrich Schütze

Cross-referencing Using Fine-grained Topic Modeling
Jeffrey Lund, Piper Armstrong, Wilson Fearn, Stephen Cowley, Emily Hales and Kevin Seppi

Conversation Initiation by Diverse News Contents Introduction
Satoshi Akasaki and Nobuhiro Kaji

Positional Encoding to Control Output Sequence Length
Sho Takase and Naoaki Okazaki

15:00–15:30 *Coffee Break*

15:30–16:30 ***Oral Sessions (short papers) and Posters (Industry track)***

Session 9A: Question Answering
Room: Greenway, Chair: **Mo Yu**

15:30–15:45 *The Lower The Simpler: Simplifying Hierarchical Recurrent Models*
Chao Wang and Hui Jiang

15:45–16:00 *Using Natural Language Relations between Answer Choices for Machine Comprehension*
Rajkumar Pujari and Dan Goldwasser

16:00–16:15 *Saliency Learning: Teaching the Model Where to Pay Attention*
Reza Ghaeini, Xiaoli Fern, Hamed Shahbazi and Prasad Tadepalli

16:15–16:30 *Understanding Dataset Design Choices for Multi-hop Reasoning*
Jifan Chen and Greg Durrett

Session 9B: Applications
Room: Nicollet A, Chair: **Zornitsa Kozareva**

15:30–15:45 *Neural Grammatical Error Correction with Finite State Transducers*
Felix Stahlberg, Christopher Bryant and Bill Byrne

15:45–16:00 *Convolutional Self-Attention Networks*
Baosong Yang, Longyue Wang, Derek F. Wong, Lidia S. Chao and Zhaopeng Tu

16:00–16:15 *Rethinking Complex Neural Network Architectures for Document Classification*
Ashutosh Adhikari, Achyudh Ram, Raphael Tang and Jimmy Lin

16:15–16:30 [SRW] *Speak Up, Fight Back! Detection of Social Media Disclosures of Sexual Harassment*
Arijit Ghosh Chowdhury, Ramit Sawhney, Puneet Mathur, Debanjan Mahata and Rajiv Ratn Shah

Session 9C: Generation
Room: Northstar A, Chair: **Fei Liu**

15:30–15:45 *Pre-trained language model representations for language generation*
Sergey Edunov, Alexei Baevski and Michael Auli

15:45–16:00 *Pragmatically Informative Text Generation*
Sheng Shen, Daniel Fried, Jacob Andreas and Dan Klein

16:00–16:15 *Stochastic Wasserstein Autoencoder for Probabilistic Sentence Generation*
Hareesh Bahuleyan, Lili Mou, Hao Zhou and Olga Vechtomova

16:15–16:30 *Benchmarking Hierarchical Script Knowledge*
Yonatan Bisk, Jan Buys, Karl Pichotta and Yejin Choi

Session 9D: Cognitive Modeling & Psycholinguistics
Room: Nicollet D, Chair: **Bridget McInnes**

15:30–15:45 [SRW] *SNAP-BATNET: Cascading Author Profiling and Social Network Graphs for Suicide Ideation Detection on Social Media*
Rohan Mishra, Pradyumn Prakhar Sinha, Ramit Sawhney, Debanjan Mahata, Puneet Mathur and Rajiv Ratn Shah

15:45–16:00 *A large-scale study of the effects of word frequency and predictability in naturalistic reading*
Cory Shain

16:00–16:15 *Augmenting word2vec with latent Dirichlet allocation within a clinical application*
Akshay Budhkar and Frank Rudzicz

16:15–16:30 *On the Idiosyncrasies of the Mandarin Chinese Classifier System*
Shijia Liu, Hongyuan Mei, Adina Williams and Ryan Cotterell

Session 9E: Machine Learning
Room: Nicollet B+C, Chair: **Byron C. Wallace**

15:30–15:45 *Joint Learning of Pre-Trained and Random Units for Domain Adaptation in Part-of-Speech Tagging*
Sara Meftah, Youssef Tamaazousti, Nasredine Semmar, Hassane Essafi and Fatiha Sadat

15:45–16:00 *Show Some Love to Your n-grams: A Bit of Progress and Stronger n-gram Language Modeling Baselines*
Ehsan Shareghi, Daniela Gerz, Ivan Vulić and Anna Korhonen

16:00–16:15 *Training Data Augmentation for Context-Sensitive Neural Lemmatizer Using Inflection Tables and Raw Text*
Toms Bergmanis and Sharon Goldwater

16:15–16:30 *A Structural Probe for Finding Syntax in Word Representations*

Abstract

Previous research shows that eye-tracking data contains information about the lexical and syntactic properties of text, which can be used to improve natural language processing models. In this work, we leverage eye movement features from three corpora with recorded gaze information to augment a state-of-the-art neural model for named entity recognition (NER) with gaze embeddings. These corpora were manually annotated with named entity labels. Moreover, we show how gaze features, generalized on word type level, eliminate the need for recorded eye-tracking data at test time. The gaze-augmented models for NER using token-level and type-level features outperform the baselines. We present the benefits of eye-tracking features by evaluating the NER models on both individual datasets as well as in cross-domain settings.

1 Introduction

The field of natural language processing includes studies of tasks of different granularity and depths of semantics: from lower level tasks such as tokenization and part-of-speech tagging up to higher level tasks of information extraction such as named entity recognition, relation extraction, and semantic role labeling (Collobert et al., 2011). As NLP systems become increasingly prevalent in society, how to take advantage of information passively collected from human readers, e.g. eye movement signals, is becoming more interesting to researchers. Previous research in this area has shown promising results: Eye-tracking data has been used to improve tasks such as part-of-speech tagging (Barrett et al., 2016), sentiment analysis (Mishra et al., 2017), prediction of multiword expressions (Rohanian et al., 2017), and word embedding evaluation (Søgaard, 2016).

However, most of these studies focus on either relatively lower-level tasks (e.g. part-of-speech tagging and multiword expressions) or relatively global properties in the text (e.g. sentiment analysis). In this paper, we test a hypothesis on a different level: *Can eye movement signals also help improve higher-level semantic tasks such as extracting information from text?*

The answer to this question is not obvious. On one hand, the quality improvement attributed to eye movement signals on lower-level tasks implies that such signals do contain linguistic information. On the other hand, it is not clear whether these signals can also provide significant improvement for tasks dealing with higher-level semantics. Moreover, even if eye movement patterns contain signals related to higher-level tasks, as implied by a recent psycholinguistic study (Tokunaga et al., 2017), noisy as these signals are, it is not straightforward whether they would help, if not hurt, the quality of the models.

In this paper, we provide the first study of the impact of gaze features to automatic named entity recognition from text. We test the hypothesis that eye-tracking data is beneficial for entity recognition in a state-of-the-art neural named entity tagger augmented with embedding layers of gaze features. Our contributions in the current work can be summarized as follows:

1. First, we manually annotate three eye-tracking corpora with named entity labels to train a neural NER system with gaze features. This collection of corpora facilitates future research in related topics. The annotations are publicly available.

2. Beyond that, we present a neural architecture for NER, which in addition to textual information, incorporates embedding layers to encode eye movement information.

3. Finally, we show how gaze features generalized to word types eliminate the need for recorded eye-tracking data at test time. This

Proceedings of NAACL-HLT 2019, pages 1–10
Minneapolis, Minnesota, June 2 - June 7, 2019.

makes the use of eye-tracking data in NLP applications more feasible since recorded eye-tracking data for each token in context is not required anymore at prediction time. Moreover, type-aggregated features appear to be particularly useful for cross-domain systems.

Our hypotheses are evaluated not only on the available eye-tracking corpora, but also on an external benchmark dataset, for which gaze information does not exist.

2 Related Work

The benefits of eye movement data for machine learning have been assessed in various domains, including NLP and computer vision. Eye-trackers provide millisecond-accurate records on where humans look when they are reading, and they are becoming cheaper and more easily available by the day (San Agustin et al., 2009; Sewell and Komogortsev, 2010). Although eye-tracking data is still being recorded in controlled experiment environments, this will likely change in the near future. Recent approaches have shown substantial improvements in recording gaze data while reading by using cameras of mobile devices (Gómez-Poveda and Gaudioso, 2016; Papoutsaki et al., 2016). Hence, eye-tracking data will probably be more accessible and available in much larger volumes in due time, which will facilitate the creation of sizable datasets enormously.

Tokunaga et al. (2017) recently analyzed eye-tracking signals during the annotation of named entities to find effective features for NER. Their work proves that humans take into account a broad context to identify named entities, including predicate-argument structure. This further strengthens our intuition to use eye movement information to improve existing NER systems. And going even a step further, it opens the possibility for real-time entity annotation based on the reader's eye movements.

The benefit of eye movement data is backed up by extensive psycholinguistic studies. For example, when humans read a text they do not focus on every single word. The number of fixations and the fixation duration on a word depends on a number of linguistic factors (Clifton et al., 2007; Demberg and Keller, 2008). First, readers are more likely to fixate on open-class words that are not predictable from context (Rayner, 1998). Reading patterns are a reliable indicator of syntactical categories (Barrett and Søgaard, 2015a). Second, word frequency and word familiarity influence how long readers look at a word. The frequency effect was first noted by Rayner (1977) and has been reported in various studies since, e.g. Just and Carpenter (1980) and Cop et al. (2017). Moreover, although two words may have the same frequency value, they may differ in familiarity (especially for infrequent words). Effects of word familiarity on fixation time have also been demonstrated in a number of recent studies (Juhasz and Rayner, 2003; Williams and Morris, 2004). Additionally, the positive effect of fixation information in various NLP tasks has recently been shown by Barrett et al. (2018), where an attention mechanism is trained on fixation duration.

State-of-the-art NER Non-linear neural networks with distributed word representations as input have become increasingly successful for any sequence labeling task in NLP (Huang et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016). The same applies to named entity recognition: State-of-the-art systems are combinations of neural networks such as LSTMs or CNNs and conditional random fields (CRFs) (Strauss et al., 2016). Lample et al. (2016) developed such a neural architecture for NER, which we employ in this work and enhance with eye movement features. Their model successfully combines word-level and character-level embeddings, which we augment with embedding layers for eye-tracking features.

3 Eye-tracking corpora

For our experiments, we resort to three eye-tracking data resources: the *Dundee corpus* (Kennedy et al., 2003), the *GECO corpus* (Cop et al., 2017) and the *ZuCo corpus* (Hollenstein et al., 2018). For the purpose of information extraction, it is important that the readers process longer fragments of text, i.e. complete sentences instead of single words, which is the case in all three datasets.

Table 1 shows an overview of the domain and size of these datasets. In total, they comprise 142,441 tokens with gaze information. Table 1 also shows the differences in mean fixation times between the datasets (i.e. fixation duration (the average duration of a single fixation on a word in

milliseconds) and gaze duration (the average duration of all fixations on a word)).

Dundee Corpus The gaze data of the Dundee corpus (Kennedy et al., 2003) was recorded with a *Dr. Bouis Oculometer Eyetracker*. The English section of this corpus comprises 58,598 tokens in 2,367 sentences. It contains eye movement information of ten native English speakers as they read the same 20 newspaper articles from *The Independent*. The text was presented to the readers on a screen five lines at a time. This data has been widely used in psycholinguistic research to analyze the reading behavior of subjects while reading sentences in context under relatively naturalistic conditions.

GECO Corpus The Ghent Eye-Tracking Corpus (Cop et al., 2017) is a more recent dataset, which was created for the analysis of eye movements of monolingual and bilingual subjects during reading. The data was recorded with an *EyeLink 1000* system. The text was presented one paragraph at a time. The subjects read the entire novel *The Mysterious Affair at Styles* by Agatha Christie (1920) containing 68,606 tokens in 5,424 sentences. We use only the monolingual data recorded from the 14 native English speakers for this work to maintain consistency across corpora.

ZuCo Corpus The Zurich Cognitive Language Processing Corpus (Hollenstein et al., 2018) is a combined eye-tracking and EEG dataset. The gaze data was also recorded with an *EyeLink 1000* system. The full corpus contains 1,100 English sentences read by 12 adult native speakers. The sentences were presented at the same position on the screen one at a time. For the present work, we only use the eye movement data of the first two reading tasks of this corpus (700 sentences, 15,237 tokens), since these tasks encouraged natural reading. The reading material included sentences from movie reviews from the Stanford Sentiment Treebank (Socher et al., 2013) and the Wikipedia dataset by Culotta et al. (2006).

For the purposes of this work, all datasets were manually annotated with named entity labels for three categories: PERSON, ORGANIZATION and LOCATION. The annotations are available at `https://github.com/DS3Lab/ner-at-first-sight`.

The datasets were annotated by two NLP experts. The IOB tagging scheme was used for the labeling. We followed the ACE Annotation Guidelines (Linguistic Data Consortium, 2005). All conflicts in labelling were resolved by adjudication between both annotators. An inter-

Table 3: Gaze features extracted from the Dundee, GECO and ZuCo corpora.

annotator reliability analysis on 10,000 tokens (511 sentences) sampled from all three datasets yielded an agreement of 83.5% on the entity labels ($\kappa = 0.68$).

Table 2 shows the number of annotated entities in each dataset. The distribution of entities between the corpora is highly unbalanced: Dundee and ZuCo, the datasets containing more heterogeneous texts and thus, have a higher ratio of unique entity occurrences, versus GECO, a homogeneous corpus consisting of a single novel, where the named entities are very repetitive.

4 Eye-tracking features

The gaze data of all three corpora was recorded for multiple readers by conducting experiments in a controlled environment using specialized equipment. It is important to consider that, while we extract the same features for all corpora, there are certainly practical aspects that differ across the datasets. The following factors are expected to influence reading: experiment procedures; text presentation; recording hardware, software and quality; sampling rates; initial calibration and filtering, as well as *human factors* such as head movements and lack of attention. Therefore, separate normalization for each dataset should better preserve the signal within each corpus and for the same reason the type-aggregation was computed on the normalized feature values. This is especially relevant for the type-aggregated features and the cross-corpus experiments described below.

In order to add gaze information to the neural network, we have selected as many features as available from those present in all three corpora. Previous research shows benefits in combining multiple eye-tracking features of different stages of the human reading process (Barrett et al., 2016; Tokunaga et al., 2017).

The features extracted follow closely on Barrett et al. (2016). As described above, psycholinguistic research has shown how fixation duration and probability differ between word classes and syntactic comprehension processes. Thus, the features focus on representing these nuances as broadly as possible, covering the complete reading time of a word at different stages. Table 3 shows the eye movement features incorporated into the experiments. We split the 17 features into 4 distinct groups (analogous to Barrett et al. (2016)), which define the different stages of the reading process:

1. *BASIC* eye-tracking features capture characteristics on word-level, e.g. the number of all

fixations on a word or the probability that a word will be fixated (namely, the number of subjects who fixated the word divided by the total number of subjects).

2. *EARLY* gaze measures capture lexical access and early syntactic processing and are based on the first time a word is fixated.

3. *LATE* measures reflect the late syntactic processing and general disambiguation. These features are significant for words which were fixated more than once.

4. *CONTEXT* features capture the gaze measures of the surrounding tokens. These features consider the fixation probability and duration up to two tokens to the left and right of the current token. Additionally, regressions starting at the current word are also considered to be meaningful for the syntactic processing of full sentences.

The eye movement measurements were averaged over all native-speaking readers of each dataset to obtain more robust estimates. The small size of eye-tracking datasets often limits the potential for training data-intensive algorithms and causes overfitting in benchmark evaluation (Xu et al., 2015). It also leads to sparse samples of gaze measurements. Hence, given the limited number of observations available, we normalize the data by splitting the feature values into quantiles to avoid sparsity issues. The best results were achieved with 24 bins. This normalization is conducted separately for each corpus.

Moreover, special care had to be taken regarding tokenization, since the recorded eye-tracking data considers only whitespace separation. For example, the string *John's* would constitute a single token for eye-tracking feature extraction, but would be split into *John* and *'s* for NER, with the former token holding the label PERSON and the latter no label at all. Our strategy to address this issue was to assign the same values of the gaze features of the originating token to split tokens.

4.1 Type aggregation

Barrett and Søgaard (2015b) showed that type-level aggregation of gaze features results in larger improvements for part-of-speech tagging. Following their line of work, we also conducted experiments with type aggregation for NER. This implies that the eye-tracking feature values were averaged for each word type over all occurrences in the training data. For instance, the sum of the features of all n occurrences of the token "island" are averaged over the number of occurrences n. As a result, for each corpus as well as for the aggregated corpora, a lexicon of lower-cased word types with their averaged eye-tracking feature values was compiled. Thus, as input for the network, either the type-level aggregates for each individual corpus can be used or the values from the combined lexicon, which increases the number of word types with known gaze feature values.

The goal of type aggregation is twofold. First, it eliminates the requirement of eye-tracking features when applying the models at test time, since the larger the lexicon, the more tokens in the unseen data receive type-aggregated eye-tracking feature values. For those tokens not in the lexicon, we assign a placeholder for unknown feature values. Second, type-aggregated features can be used on any dataset and show that improvements can be achieved with aggregated gaze data without requiring large quantities of recorded data.

5 Model

The experiments in this work were executed using an enhanced version of the system presented by Lample et al. (2016). This hybrid approach is based on bidirectional LSTMs and conditional random fields and relies mainly on two sources of information: character-level and word-level representations.

For the experiments, the originally proposed values for all parameters were maintained. Specifically, the bidirectional LSTMs for character-based embeddings are trained on the corpus at hand with dimensions set to 25. The lookup table tor the word embeddings was initialized with the pre-trained GloVe vectors of 100 dimensions (Pennington et al., 2014). The model uses a single layer for the forward and backward LSTMs. All models were trained with a dropout rate at 0.5. Moreover, all digits were replaced with zeros.

The original model[1] was modified to include the gaze features as additional embedding layers to the network. The character-level representation, i.e. the output of a bidirectional LSTM, is concatenated with the word-level representation from

---

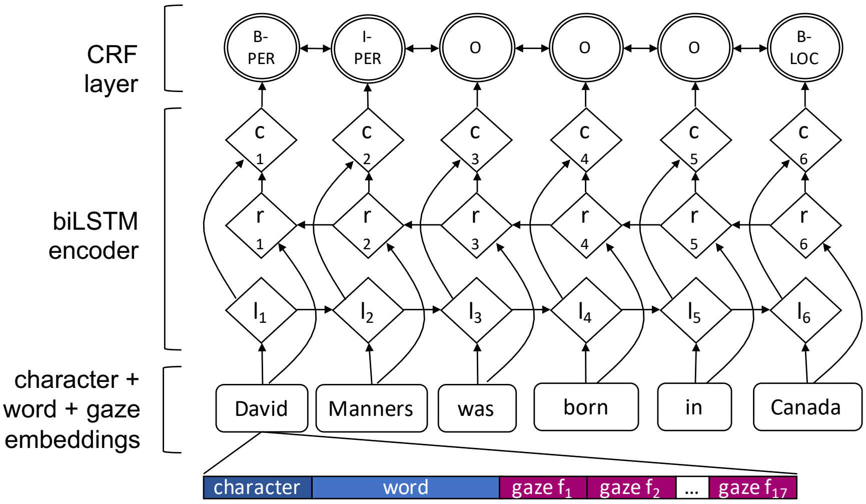

Figure 1: Main architecture of the network. Character and word embeddings concatenated with gaze features are given to a bidirectional LSTM. l_i represents the word *i* and its left context, r_i represents the word *i* and its right context. Concatenating these two vectors yields a representation of the word *i* in its context, c_i.

a word lookup table. In the augmented model with eye-tracking information, the embedding for each discrete gaze feature is also concatenated to the input. The dimension of the gaze feature embeddings is equal to the number of quantiles. This architecture is shown in Figure 1. Word length and word frequency are known to correlate and interact with gaze features (Tomanek et al., 2010), which is why we selected a base model that allows us to combine the eye-tracking features with word- and character-level information.

6 Results

Our main finding is that our models enhanced with gaze features consistently outperform the baseline. As our baseline, we trained and evaluated the original models with the neural architecture and parameters proposed by Lample et al. (2016) on the GECO, Dundee, and ZuCo corpora and compared it to the models that were enriched with eye-tracking measures. The best improvements on F_1-score over the baseline models are significant under one-sided t-tests ($p<0.05$).

All models were trained with 10-fold cross validation (80% training set, 10% development set, 10% test set) and early stopping was performed after 20 epochs of no improvement on the development set to reduce training time.

First, the performance on the individual datasets is tested, together with the performance of one combined dataset consisting of all three corpora (consisting of 142,441 tokens). In addition, we evaluate the effects of the type-aggregated features using individual type lexicons for each datasets, and combining the three type lexicons of each corpus. Finally, we experiment with cross-corpus scenarios to evaluate the potential of eye-tracking features in NER for domain adaptation. Both settings were also tested on an external corpus without eye-tracking features, namely the CoNLL-2003 dataset (Sang and De Meulder, 2003).

6.1 Individual dataset evaluation

First, we analyzed how augmenting the named entity recognition system with eye-tracking features affects the results on the individual datasets. Table 4 shows the improvements achieved by adding all 17 gaze features to the neural architecture, and training models on all three corpora, and on the combined dataset containing *all* sentences from the Dundee, GECO and ZuCo corpora. Noticeably, adding token-level gaze features improves the results on all datasets individually *and* combined, even on the GECO corpus, which yields a high baseline due to the homogeneity of the contained named entities (see Table 2).

Furthermore, Table 4 also presents the results of the NER models making use of the type-aggregated features instead of token-level gaze features. There are two different experiments for these type-level features: Using the features of the word types occurring in the corpus only, or using the aggregated features of all word types in the three corpora (as describe above). As can be seen, the performance of the different gaze fea-

	P	R	F
Dundee			
baseline	79.29	78.56	78.86
with gaze	79.55	79.27	79.35
type individual	**81.05**	**79.37**	**80.17***

All			
baseline	86.92	86.58	86.72
with gaze	88.72	89.39	89.03*
type combined	**89.04**	**89.52**	**89.26***

Table 4: Precision (P), recall (R) and F_1-score (F) for all models trained on individual datasets (best results in bold; * indicates statistically significant improvements on F_1-score). *With gaze* are models trained on the original eye-tracking features on token-level, *type individual* are the models trained on type-aggregated gaze features of this corpus only, while *type combined* are the models trained with type-aggregated features computed on all datasets.

ture levels varies between datasets, but both the original token-level features as well as the individual and combined type-level features achieve improvements over the baselines of all datasets.

To sum up, the largest improvement with eye-tracking features is achieved when combining all corpora into one larger dataset, where an additional 4% is gained in F_1-score by using type-aggregated features. Evidently, a larger mixed-domain dataset benefits from the type aggregation, while the original token-level gaze features achieve the best results on the individual datasets. Moreover, the additional gain when training on all datasets is due to the higher signal-to-noise ratio of type-aggregated features from multiple datasets.

Evaluation on CoNLL-2003 Going on step further, we evaluate the type-aggregated gaze features on an external corpus with no eye movement information available. The CoNLL-2003 corpus (Sang and De Meulder, 2003) has been widely used as a benchmark dataset for NER in different shared tasks. The English part of this corpus consists of Reuters news stories and contains 302,811 tokens in 22,137 sentences. We use this dataset as an additional corpus without gaze information. Only the type-aggregated features (based on the combined eye-tracking corpora) are added to each word. Merely 76% of the tokens in the CoNLL-2003 corpus also appear in the eye-tracking corpora described above and thus receive type-aggregated feature values. The rest of the tokens without aggregated gaze information available receive a placeholder for the unknown feature values.

CoNLL-2003	**P**	**R**	**F**
baseline	93.89	94.16	94.03
type combined	**94.38**	**94.32**	**94.35***

Table 5: Precision (P), recall (R) and F_1-score (F) for using type-aggregated gaze features on the CoNLL-2003 dataset (* marks statistically significant improvement).

Note that to avoid overfitting we do not train on the official train/test split of the CoNLL-2003 dataset, but perform 10-fold cross validation. Applying the same experiment setting, we train the augmented NER model with gaze features on the CoNLL-2003 data and compare it to a baseline model without any eye-tracking features. We achieve a minor, but nonetheless significant improvement (shown in Table 5), which strongly supports the generalizability effect of the type-aggregated features on unseen data.

6.2 Cross-dataset evaluation

In a second evaluation scenario, we test the potential of eye-tracking features for NER across corpora. The goal is to leverage eye-tracking features for domain adaptation. To show the robustness of our approach across domains, we train the models with token-level and type-level features on 100% of corpus A and a development set of 20% of corpus B and test on the remaining 80% of the corpus B, alternating only the development and the test set for each fold.

Table 6 shows the results of this cross-corpus evaluation. The impact of the eye-tracking features varies between the different combinations of datasets. However, the inclusion of eye-tracking features improves the results for all combinations, except for the models trained on the ZuCo corpus

Table 6: Cross-corpus results: Precision (P), recall (R) and F_1-score (F) for all models trained on one dataset and tested on another (rows = training dataset; columns = test dataset; best results in bold; * indicates statistically significant improvements). The baseline models are trained without eye-tracking features, *token* models on the original eye-tracking features, and *type* are the models trained with type-aggregated features computed on all datasets.

and tested on the GECO corpus. Presumably, this is due to the combination of the small training data size of the ZuCo corpus and the homogeneity of the named entities in the GECO corpus.

CoNLL-2003	**P**	**R**	**F**
baseline	72.80	56.97	63.92
type combined	**74.56**	**60.20**	**66.61***

Table 7: Precision (P), recall (R) and F_1-score (F) for using type-aggregated gaze features trained on all three eye-tracking datasets and tested on the CoNLL-2003 dataset (* marks statistically significant improvement).

Evaluation on CoNLL-2003 Analogous to the individual dataset evaluation, we also test the potential of eye-tracking features in a cross-dataset scenario on an external benchmark dataset. Again, we use the CoNLL-2003 corpus for this purpose. We train a model on the Dundee, GECO *and* ZuCo corpora using type-aggregated eye-tracking features and test this model on the ConLL-2003 data. Table 7 shows that compared to a baseline without gaze features, the results improve by 3% F_1-score. These results underpin our hypothesis of the possibility of generalizing eye-tracking features on word type level, such that no recorded gaze data is required at test time.

7 Discussion

The models evaluated in the previous section show that eye-tracking data contain valuable semantic information that can be leveraged effectively by NER systems. While the individual datasets are still limited in size, the largest improvement is observed in the models making use of *all* the available data.

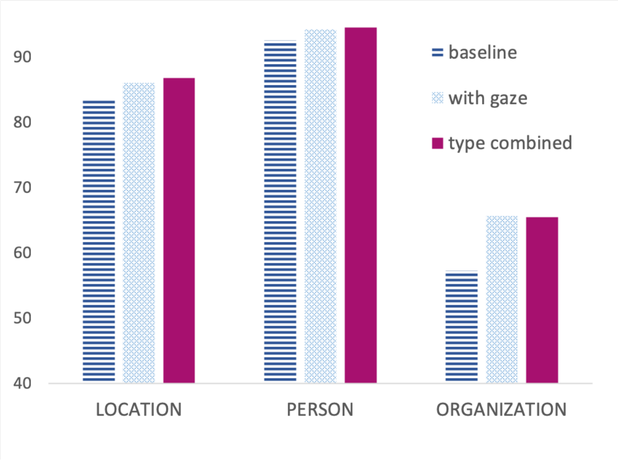

Figure 2: Results per class for the models trained on all gaze datasets combined.

At a closer look, the model leveraging gaze data yield a considerably higher increase in recall when comparing to the baselines. In addition, a class-wise analysis shows that the entity type benefiting the most from the gaze features over all models is ORGANIZATION, which is the most difficult class to predict. Figure 2 illustrates this with the results per class of the models trained on all three gaze corpora jointly.

In the individual dataset evaluation setting, the combined type-level feature aggregation from all datasets does not yield the best results, since each sentence in these corpora already has accurate eye-tracking features on toke-level. Thus, it is understandable that in this scenario the original gaze features and the gaze features aggregated only on the individual datasets result in better models. However, when evaluating the NER models in a cross-corpus scenario, the type-aggregated features lead to significant improvements.

Type aggregation evidently reduces the fine-grained nuances contained in eye-tracking information and eliminates the possibility of disambiguation between homographic tokens. Nevertheless, this type of disambiguation is not crucial for named entities, which mainly consist of proper nouns and the same entities tend to appear in the same context. Especially noteworthy is the gain in the models tested on the CoNLL-2003 benchmark corpus, which shows that aggregated eye-tracking features from other datasets can be applied to any unseen sentence and show improvements, even though more than 20% of the tokens have unknown gaze feature values. While the high number of unknown values is certainly a limitation of our approach, it shows at once the possibility of not requiring original gaze features at prediction time. Thus, the trained NER models can be applied robustly on unseen data.

8 Conclusion

We presented the first study of augmenting a NER system with eye-tracking information. Our results highlight the benefits of leveraging cognitive cues such as eye movements to improve entity recognition models. The manually annotated named entity labels for the three eye-tracking corpora are freely available. We augmented a neural NER architecture with gaze features. Experiments were performed using a wide range of features relevant to the human reading process and the results show significant improvements over the baseline for all corpora individually.

In addition, the type-aggregated gaze features are effective in cross-domain settings, even on an external benchmark corpus. The results of these type-aggregated features are a step towards leveraging eye-tracking data for information extraction at training time, without requiring real-time recorded eye-tracking data at prediction time.

Abstract

Recent work has shown that LSTMs trained on a generic language modeling objective capture syntax-sensitive generalizations such as long-distance number agreement. We have however no mechanistic understanding of how they accomplish this remarkable feat. Some have conjectured it depends on heuristics that do not truly take hierarchical structure into account. We present here a detailed study of the inner mechanics of number tracking in LSTMs at the single neuron level. We discover that long-distance number information is largely managed by two "number units". Importantly, the behaviour of these units is partially controlled by other units independently shown to track syntactic structure. We conclude that LSTMs are, to some extent, implementing genuinely syntactic processing mechanisms, paving the way to a more general understanding of grammatical encoding in LSTMs.

1 Introduction

In the last years, recurrent neural networks (RNNs), and particularly long-short-term-memory (LSTM) architectures (Hochreiter and Schmidhuber, 1997), have been successfully applied to a variety of NLP tasks. This has spurred interest in whether these generic sequence-processing devices are discovering genuine structural properties of language in their training data, or whether their success can be explained by opportunistic surface-pattern-based heuristics.

Until now, this debate has mostly relied on "behavioural" evidence: The LSTM had been treated as a black box, and its capacities had been indirectly inferred by its performance on linguistic tasks. In this study, we took a complementary approach inspired by neuroscience: We thoroughly investigated the inner dynamics of an LSTM language model performing a number agreement task, striving to achieve a mechanistic understanding of how it accomplishes it. We found that the LSTM had specialized two "grandmother" cells (Bowers, 2009) to carry number features from the subject to the verb across the intervening material.[1] Interestingly, the LSTM also

---

[1] In the neuroscientific literature, "grandmother" cells are (sets of) neurons coding for specific information, e.g., about your grandmother, in a non-distributed manner.

Proceedings of NAACL-HLT 2019, pages 11–20
Minneapolis, Minnesota, June 2 - June 7, 2019.

possesses a more distributed mechanism to predict number when subject and verb are close, with the grandmother number cells only playing a crucial role in more difficult long-distance cases. Crucially, we independently identified a set of cells tracking syntactic structure, and found that one of them encodes the presence of an embedded phrase separating the main subject-verb dependency, and has strong efferent connections to the long-distance number cells, suggesting that the network relies on genuine syntactic information to regulate agreement-feature percolation.

Our analysis thus provides direct evidence for the claim that LSTMs trained on unannotated corpus data, despite lacking significant linguistic priors, learn to perform structure-dependent linguistic operations. In turn, this suggests that raw linguistic input and generic memory mechanisms, such as those implemented in LSTMs, may suffice to trigger the induction of non-trivial grammatical rules.

2 Related Work

Starting with the seminal work of Linzen et al. (2016), a long-distance number agreement task has emerged as a standard way to probe the syntactic capabilities of neural language models. In the number agreement task, a model is asked to predict the verb in a sentence where the subject and main verb are separated by one or more intervening nouns ("the **boy** near the *cars* **greets**...") and evaluated based on how often it predicts the right verb form.

Following mixed initial results by Linzen and colleagues and Bernardy and Lappin (2017), Gulordava et al. (2018) and Kuncoro et al. (2018b) have robustly established that LSTM language models achieve near-human performance on the agreement task. While Gulordava and colleagues provided some evidence that the LSTMs are relying on genuine syntactic generalizations, Kuncoro et al. (2018a) and Linzen and Leonard (2018) suggested that the LSTM achievements can, at least in part, be accounted by superficial heuristics (e.g., "percolate the number of the first noun in a sentence"). Other recent work has extended syntax probing to other phenomena such as negative polarity items and island constraints (Chowdhury and Zamparelli, 2018; Jumelet and Hupkes, 2018; Marvin and Linzen, 2018; Wilcox et al., 2018).

While Linzen et al. (2016) presented intriguing qualitative data showing cells that track grammatical number in a network directly trained on the agreement task, most of the following work focused on testing the network output behaviour, rather than on understanding how the latter follows from the inner representations of the network. Another research line studied linguistic processing in neural networks through 'diagnostic classifiers', that is, classifiers trained to predict a certain property from network activations (e.g., Gelderloos and Chrupała, 2016; Adi et al., 2017; Alain and Bengio, 2017; Hupkes et al., 2018). This approach may give insight into which information is encoded by the network in different layers or at different time points, but it only provides indirect evidence about the specific mechanics of linguistic processing in the network.

Other studies are closer to our approach in that they attempt to attribute function to specific network cells, often by means of visualization (Karpathy et al., 2016; Li et al., 2016; Tang et al., 2017). Radford et al. (2017), for example, detected a "sentiment" grandmother cell in a language-model-trained network. Kementchedjhieva and Lopez (2018) recently found a character-level RNN to track morpheme boundaries in a single cell. We are however not aware of others studies systematically characterizing the processing of a linguistic phenomenon at the level of RNN cell dynamics, as is the attempt in the study hereby presented.

3 Setup

Language Model We study the pretrained LSTM language model made available by Gulordava et al. (2018). This model is composed of a 650-dimensional embedding layer, two 650-dimensional hidden layers, and an output layer with vocabulary size 50,000. The model was trained on Wikipedia data, without fine-tuning for number agreement, and obtained perplexity close to state of the art in the experiments of Gulordava et al.[2]

Number-Agreement Tasks We complement analysis of the naturalistic, corpus-derived number-agreement test set of Linzen et al. (2016), in the version made available by Gulordava et al. (2018), with synthetically generated data-sets.

---

[2] Key findings reported below were also replicated with the same model trained with different initialization seeds and variations with different hyper-parameters.

Simple	the **boy** **greets** the guy
Adv	the **boy** probably **greets** the guy
2Adv	the **boy** most probably **greets** the guy
CoAdv	the **boy** openly and deliberately **greets** the guy
NamePP	the **boy** near Pat **greets** the guy
NounPP	the **boy** near the car **greets** the guy
NounPPAdv	the **boy** near the car kindly **greets** the guy

Table 1: NA tasks illustrated by representative singular sentences.

Each synthetic number-agreement task (NA-task) instantiates a fixed syntactic structure with varied lexical material, in order to probe subject-verb number agreement in controlled and increasingly challenging setups.[3] The different structures are illustrated in Table 1, where all forms are in the singular. Distinct sentences were randomly generated by selecting words from pools of 20 subject/object nouns, 15 verbs, 10 adverbs, 5 prepositions, 10 proper nouns and 10 location nouns. The items were selected so that their combination would not lead to semantic anomalies. For each NA-task, we generated singular and plural versions of each sentence. We refer to each such version as a *condition*. For NA-tasks that have other nouns occurring between subject and main verb, we also systematically vary their number, resulting in two *congruent* and two *incongruent* conditions. For example, the NounPP sentence in the table illustrates the congruent SS (singular-singular) condition and the corresponding sentence in the incongruent PS (plural-singular) condition is: "the *boys* near the *car greet* the guy". For all NA-tasks, each condition consisted of 600 sentences

Syntactic Depth Data-Set We probed the implicit syntax-parsing abilities of the model by testing whether its representations predict the syntactic depth of the words they process. Following Nelson et al. (2017), this was operationalized as predicting the number of open syntactic nodes at each word, given the canonical syntactic parse of a sentence. We generated a data-set of sentences with unambiguous but varied syntactic structures and annotated them with the number of open nodes at each word. For example: "Ten$_1$ really$_2$ ecstatic$_3$ cousins$_3$ of$_4$ four$_5$ teachers$_6$ are$_2$ quickly$_3$ laughing$_4$", where indexes show the corresponding number of open nodes. Since syntactic depth is naturally correlated with the position of a word in a sentence, we used a data-point sampling strategy to de-correlate these factors. For each length between 2 and 25 words, we randomly generated 300 sentences. From this set, we randomly picked examples uniformly covering all possible position-depth combinations within the 7-12 position and 3-8 depth ranges. The final data-set contains 4,033 positions from 1,303 sentences.[4]

4 Experiments

To successfully perform the NA-task, the LSTM should: (1) encode and store the grammatical number of the subject; and (2) track the main subject-verb syntactic dependency. The latter information is important for identifying the time period during which subject number should be stored, output and then updated by the network. This section describes the 'neural circuit' that encodes and processes this information in the LSTM.

4.1 Long-Range Number Units

We first tested the performance of the LSTM on the Linzen's data and on the NA-tasks in Table 1. Following Linzen et al. (2016) and later work, we computed the likelihood that the LSTM assigns to the main verb of each sentence given the preceding context and compared it to the likelihood it assigns to the wrong verb inflection. Accuracy in a given condition was measured as the proportion of sentences in this condition for which the model assigned a higher likelihood to the correct verb form than to the wrong one.

Network performance is reported in Table 2 (right column – 'Full'). We first note that our results on the Linzen NA-task confirm those reported in Gulordava et al. (2018). For the other NA-tasks, results show that some tasks and conditions are more difficult than others. For example, performance on the Simple (0-distance) NA-task is better than that on the Co-Adv NA-task, which in turn is better than that of the nounPP tasks. Second, as expected, incongruent conditions (the number-mismatch conditions of namePP, nounPP and nounPPAdv) reduce network performance.

---

[3] We exclude, for the time being, agreement across a relative clause, as it comes with the further complication of accounting for the extra agreement process taking place inside the relative clause.

[4] All our data-sets are available at: `https://github.com/FAIRNS/Number_and_syntax_units_in_LSTM_LMs`.

NA task	**C**	**Ablated**		**Full**

Table 2: Ablation-experiments results: Percentage accuracy in all NA-tasks. Full: non-ablated model, C: condition, S: singular, P: plural. Pink (dark lines in B&W printing): plural subject, Light blue: singular subject. Performance reduction less than 10% is denoted by '-'.

Third, for long-range dependencies, reliably encoding singular subject across an interfering noun is more difficult than a plural subject: for both nounPP and nounPPAdv, PS is easier than SP. A possible explanation for this finding is that in English the plural form is almost always more frequent than the singular one, as the latter only marks third person singular, whereas the former is identical to the infinitive and other forms. Thus, if the network reverts to unigram probabilities, it will tend to prefer the plural.

Looking for Number Units Through Ablation Number information may be stored in the network in either a local, sparse, or a distributed way, depending on the fraction of active units that carry it. We hypothesized that if the network uses a local or sparse coding, meaning that there's a small set of units that encode number information, then ablating these units would lead to a drastic decrease in performance in the NA-tasks. To test this, we ablated each unit of the network, one at a time, by fixing its activation to zero, and tested on the NA-tasks.

Two units were found to have exceptional effect on network performance (Table 2, 776 and 988 columns).[5] Ablating them reduced network performance by more than 10% across various conditions, and, importantly, they were the only units whose ablation consistently brought network performance to around chance level in the more difficult incongruent conditions of the namePP, nounPP and nounPPAdv tasks.

Moreover, the ablation effect depended on the grammatical number of the subject: ablating 776 significantly reduced network performance only if the subject was plural (P, PS or PP conditions) and 988 only if the subject was singular (S, SP or SS conditions). In what follows, we will therefore refer to these units as the 'plural' and 'singular' units, respectively, or long-range (LR) number units when referring to both. Finally, we note that although the Linzen NA-task contained mixed stimuli from many types of conditions, the plural unit was found to have a substantial effect on average on network performance. The singular unit didn't show a similar effect in this case, which highlights the importance of using carefully crafted stimuli, as in the nounPP and nounPPAdv tasks, for understanding network dynamics. Taken together, these results suggest a highly local coding scheme of grammatical number when processing long-range dependencies.

Visualizing Gate and Cell-State Dynamics To understand the functioning of the number units, we now look into their gate and state dynamics during sentence processing. We focus on the nounPP NA-task, which is the simplest NA-task that includes a long-range dependency with an interfering noun, in both SP and PS conditions.

Recall the standard LSTM memory update and output rules (Hochreiter and Schmidhuber, 1997):

$$C_t = f_t \circ C_{t-1} + i_t \circ \widetilde{C}_t \qquad (1)$$

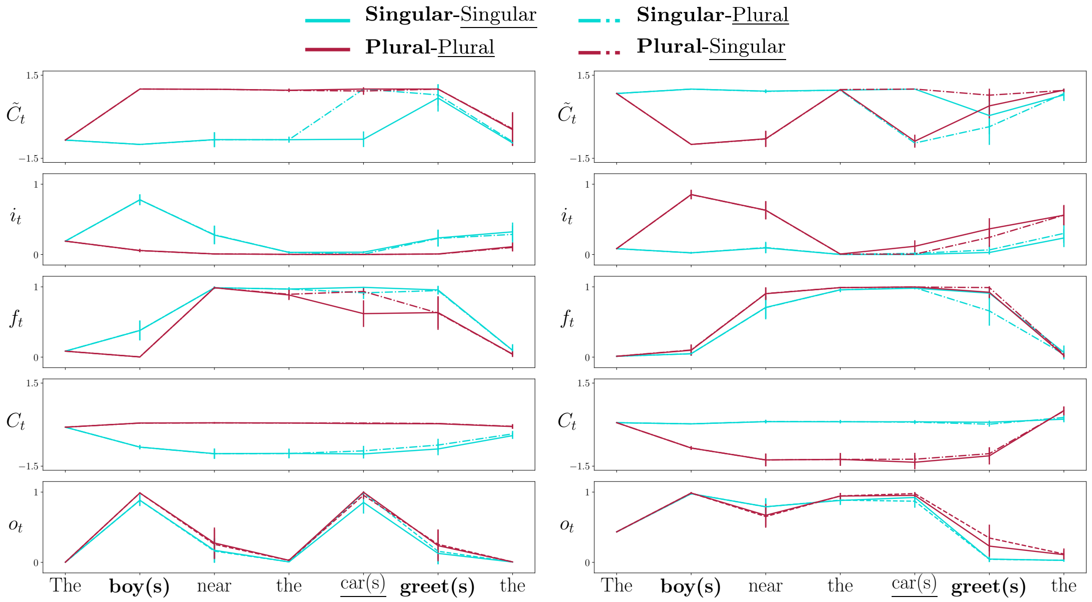
$$h_t = o_t \circ \tanh(C_t), \qquad (2)$$

where $f_t, i_t, o_t \in (0,1)$ are gating scalars computed by the network, and $\widetilde{C}_t \in (-1,1)$ is an update candidate for cell value.

Consider now how a number unit may reliably encode and store subject number across interfering nouns. Figure 1c exemplifies this for a singular

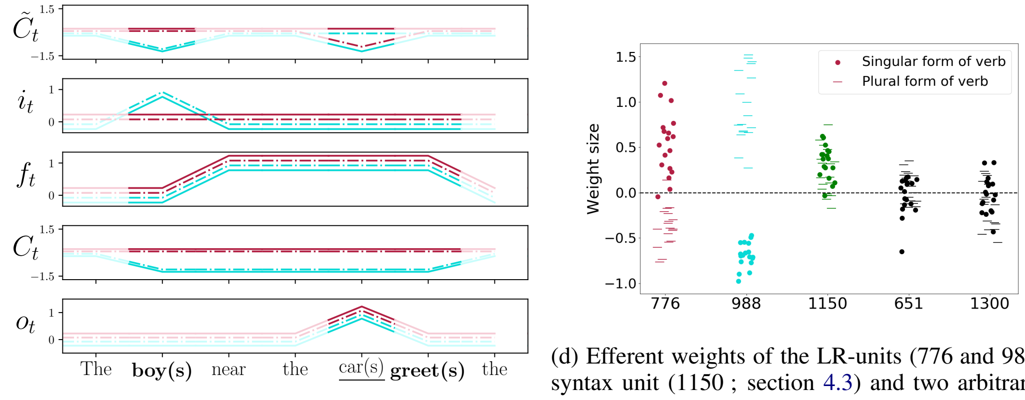
---

[5] Units 1-650 belong to the first layer, 651-1300 to the second. All units detected by our analyses come from the latter.



(a) 988 (singular)

(b) 776 (plural)



(c) Prediction (singular)

(d) Efferent weights of the LR-units (776 and 988), the syntax unit (1150 ; section 4.3) and two arbitrary units (651 and 1300).

Figure 1: (a) to (c) – Cell and gate activations during processing of sentences with a prepositional phrase between subject and verb. Values in (a) and (b) are averaged across all condition sentences, with error bars showing standard deviations. (d) – Efferent weights of specific units at the output layer to singular and plural verb forms.

unit, showing the desired gate and cell dynamics. The four conditions are represented with separated curves - pink for plural subject, light blue for singular, and dashed lines for incongruent conditions. Gate and cell activity at time points unrelated to solving the NA-task are masked with white, as we do not make precise predictions for them.

The update rule of the LSTM cell has two terms (Eq. 1).[6] In the first, $f_t \circ C_{t-1}$, the forget gate controls whether to keep the previous cell content ($f_t = 1$: perfect remembering) or forget it ($f_t = 0$: complete forgetting). In the second, $i_t \circ \tilde{C}_t$, the input gate controls whether the information currently presented to the network, as encoded by $\tilde{C}_t$, should be written onto the cell ($i_t = 1$: full access) or not ($i_t = 0$). The singular unit can thus use these gates to reliably store number information across long-range dependencies. Specifically, the unit can (enumeration follows the same order as the panels in Figure 1c): (1) encode subject number via $\tilde{C}_{t_{subject}}$ with different values for singular and plural; (2) open the input gate *only* when a singular subject is presented ($i_{t_{subject}} = 1$ in light-blue curves *only*) and protect it from interfering nouns ($i_t = 0, t_{subject} < t < t_{verb}$); (3) at the same time, clear the cell from previously stored information ($f_{t_{subject}} = 0$) and then

---

[6] We abuse notation here, using the symbols denoting whole layers in equations (1) and (2) to denote the components of single cells.

store subject number across the entire dependency ($f_t = 1, t_{subject} < t < t_{verb}$); (4) this will result in stable encoding of subject number in the cell C_t throughout the dependency; (5) finally, output subject number at the right moment, when predicting the verb form ($o_{t_{verb}-1} = 1$) (Eq. 2).

Figures 1a and 1b present the actual gate and cell dynamics of the singular and plural units. Both units follow the general solution for reliable number storage described above. Note that for $\tilde{C}_t$ and i_t, and as a result also for C_t, the plural unit 'mirrors' the singular unit with respect to subject number (pink curves of PP and PS vs. Light blue curves of SS and SP). This is in accordance with the results of the ablation experiments, which showed that ablating these units had an effect that depended on the grammatical number of the subject (Table 2). This provides complementary support for the identification of these units as 'singular' and 'plural'.

A single divergence between the solution depicted in Figure 1c and the actual dynamics of the number units is that input gate activity is smaller, but not zero, at the time step immediately following the subject. One speculative explanation is that this might be useful to process compound nouns. In these cases, subject number information is stored with the second noun, whereas in the case of simple nouns there is no 'risk' of encountering an interfering noun immediately after the subject, making the delay in closing the gate safe.

The singular and plural units had emerged at the second layer of the network. This seems appropriate since number information needs to be directly projected to the output layer for correct verb-form prediction. Moreover, number-unit output should be projected differently to singular and plural verb forms in the output layer, only increasing activity in output units representing the suitable form. For example, for the singular unit, since singular subjects are encoded with a negative value ($C_{t_{verb}-1} < -1$ in figure 1a), the more negative its efferent weights to singular verb forms in the output layer, the higher the probabilities of these verb forms would be. Figure 1d shows the efferent weights of the LR-number units to all verbs in our data-sets. We found that, indeed, the efferent weights to the singular and plural verb forms are segregated from each other, with weight signs that correspond to the negative encoding of subject number used by both singular and plural units.

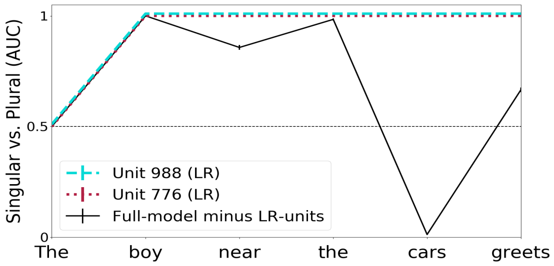


Figure 2: Generalization across time of subject-number prediction. Error bars represent standard deviations across cross-validation splits.

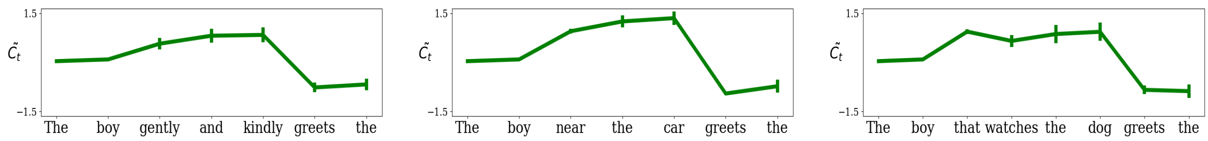
Two other arbitrary units, 651 and 1300 , and the syntax unit 1150 to be described below (Section 4.3) do not have segregated efferent weights to verb forms, as expected.

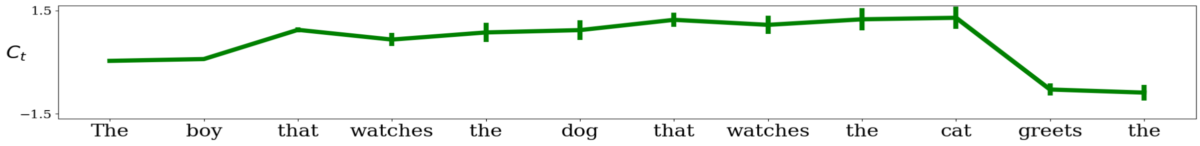
4.2 Short-Range Number Information

Performance on the easier NA-tasks (Simple, Adv, 2Adv) was not impaired by single-unit ablations. This suggests that number may be encoded also elsewhere in the network, perhaps via a more distributed code. To verify this, we tested whether subject number can be decoded from the whole pattern of activities in the network (excluding the two LR-number units) and whether this decoding is stable across time (see Giulianelli et al., 2018, for similar observations and related methods). We expected this distributed activity to track number in a small time window after the subject, but, unlike the LR-number units, to be affected by incongruent intervening nouns.

We trained a linear model to predict the grammatical number of the subject from network activity in response to the presentation of the subject, and tested its prediction on test sets from all time points (King and Dehaene, 2014), in incongruent conditions only of the nounPP task. We used Area under of Curve (AUC) to evaluate model performance. Figure 2 shows decoding across time of subject number from cell activity of each number unit separately and from cell activity of the entire network without these two units ('Full model minus LR-units'). Results show that number information can be efficiently decoded from other units in the network, and that this information can be carried for several time steps (relatively high AUC up to the second determiner). However, the way in which these units encode number is sensitive to the last encountered noun, with AUC decreasing



(a) 2Adv (b) nounPP (c) subject relative



(d) Two embeddings with subject relatives

Figure 3: Cell activity of syntax unit 1150 while processing various syntactic structures. Values averaged across all stimuli in an NA-task, with error bars representing standard deviations. Relative clause NA-task stimuli were specifically generated for this visualization.

to zero around the second noun (‘cars’), whereas test performance of the models trained on cell activity of the LR-number units is consistently high. This confirms that number prediction is supported both by the LR-number units, and by distributed activation patterns of other short-range (SR) number units. The latter, however, are not syntax-sensitive, and simply encode the number of the last noun encountered.

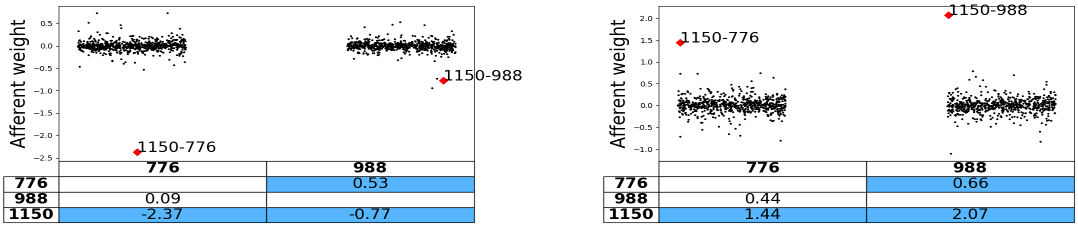
A full description of the SR-number units is beyond our scope. However, we note that 10 SR-number units in the second layer of the network were identified, which had efferent weights with a similar segregated structure as that of the LR units (Figure 1d). These units were indeed sensitive to the last encountered noun: subject number could be decoded from single-unit cell activity during its presentation (AUC$>$ 0.9), but activity ‘swaps’ once an interfering noun appears (i.e., AUC decreases to zero in a generalization-across-time analysis). Finally, to validate the role of SR-number units in encoding number for easier NA-tasks, we ablated both SR and LR number units (12 in total) or SR units only (10 in total) and evaluated network performance on these NA-tasks. Both experiments resulted in a significant reduction in task performance compared to 1,000 random equi-size ablations ($p < 0.01$ in all ‘easier’ tasks).

Intriguingly, we observed qualitatively that LR units are almost always making the right prediction, even when the network predicts the wrong number. The wrong outcome, in such cases, might be due to interference from the syntax-insensitive SR units. We leave the study of LR-SR unit interplay to future work.

4.3 Syntax Units

We saw how the input and forget gates of the LR-number units control the flow of subject-number information. It remains unclear, however, how the dynamics of these gates are controlled by the network. We hypothesized that other units in the network may encode information about the syntactic structure of the sentence, and thus about the subject-verb dependency. These units could then control and coordinate the opening and closing of the input and forget gates of the number units.

To identify such ’syntax’ units, we tested from which units syntactic information can be efficiently decoded. We used depth of the syntactic tree as a proxy for syntactic structure (Nelson et al., 2017) and trained an L2-regularized regression model to predict syntactic tree-depth from the hidden-state activity of all units. In all experiments, we used the data presented in Section 3 above and performed a nested 5-fold cross-validation procedure. Word frequency, which was added as a covariate to the model, had a negligible effect on the results. Syntactic tree-depth was found to be efficiently decodable from network activity ($R^2_{test-set} = 0.85 \pm 0.009$; covariate-corrected). A small subset of ‘syntax’ units had relatively high weights in the regression model (mean weight = 7.6×10^{-4}, SD=7.86×10^{-2}; cutoff for outlier weights was set to three SDs). Since the interpretation of the regression weights may depend on possible correlations among the features, we also tested the causal effect of these units on NA-task performance. Ablating the syntax units together resulted in significant performance reduction in NA-tasks that have an interfering noun: Linzen NA-task: $p = 0.024$, nounPPAdv-



(a) Input gate

(b) Forget gate

Figure 4: Connectivity among the syntax unit 1150 and LR-number units 776 and 988 . Projecting units are on the table rows. Blue background highlights outlier values ($|z - score| > 3$). Weights from the syntax unit are marked with large diamond markers and are explicitly labeled in the plots.

SP: $p = 0.011$, nounPPAdv-PS: $p = 0.034$, nounPP-SP: $p < 0.001$ and marginally significant in nounPP-PS: $p = 0.052$ (compared to 1000 random ablations of subsets of units of the same size).

To gain further insight regarding the functioning of the syntax units, we next visualized their gate and cell dynamics during sentence processing. We found that cell activity of unit 1150 , which also had one of the highest weights in the regression model, was remarkably structured. The activity of this unit increases across the entire subject-verb dependency and drops abruptly right after. Figures 3a and 3b show cell activity of this unit during the processing of stimuli from the 2Adv and nounPP tasks. We found the same dynamics in cases where another verb occurs between subject and main verb, as in subject relatives (Figure 3c), and in exceptionally long-distance dependencies with two interfering nouns and verbs (Figure 3d). Taken together, these results suggest that unit 1150 consistently encodes subject-verb dependencies in a syntax-sensitive manner. Other syntax units did not show an easily interpretable dynamics and had no clear interactions with the number units in the analysis discussed next. This suggests that they perform different syntactic, or possibly other, functions.

4.4 Syntax-Number Units Connections

We finally look at the connections that were learned by the LSTM between syntax unit 1150 , which appears to be more closely involved in tracking subject-verb agreement, and the LR number units, as well as at the connections between the LR-number units themselves. For each unit pair, there are 4 connection types, one for each component of the target cell (to the 3 gates and to the update candidate). We focus on input and forget gates, as they control the flow and storage of number information.

Figures 4a and 4b show the distributions of all afferent recurrent weights to the input and forget gates of the LR-number units, scaled by the maximal activity h_t of the pre-synaptic units during the nounPP task (this scaling evaluates the *effective* input to the units and did not change the conclusions described below). We found that the weights from the syntax unit to the forget gate of both 776 and 988 are exceptionally high in the positive direction compared to all other afferent connections in the network ($z - score = 8.1, 11.2$, respectively) and those to their input gates exceptionally negative ($z - score = -16.2, -7.2$). Since the cell activity of syntax unit 1150 is positive across the entire subject-verb dependency (e.g., Figure 3d), the connectivity from the syntax unit drives the number unit forget gates towards one ($W^f_{776,1150}h^{1150} \gg 0$ and $W^f_{988,1150}h^{1150} \gg 0$; $t_{subject} < t < t_{verb}$) and their input gates towards zero ($W^i_{776,1150}h^{1150} \ll 0$ and $W^i_{988,1150}h^{1150} \ll 0$). Looking at the right-hand-side of Eq. (1), this means that the first term becomes dominant and the second vanishes, suggesting that, across the entire dependency, the syntax unit conveys a 'remember flag' to the number units. Similarly, when the activity of the syntax unit becomes negative at the end of the dependency, it conveys an 'update flag'.

Last, we note that the reciprocal connectivity between the two LR-number units is always positive, to both input and forget gates (with $|z - score| > 3$ for the 776 -to-988 direction). Since their activity is negative throughout the subject-verb dependency (Figures 1a and 1b), this means that they are *mutually inhibiting*, thus steering towards an unequivocal signal about the grammatical number of the subject to the output layer.

5 Summary and Discussion

We provided the first detailed description of the underlying mechanism by which an LSTM language-model performs long-distance number agreement. Strikingly, simply training an LSTM on a language-model objective on raw corpus data brought about single units carrying exceptionally specific linguistic information. Three of these units were found to form a highly interactive local network, which makes up the central part of a 'neural' circuit performing long-distance number agreement.

One of these units encodes and stores grammatical number information when the main subject of a sentence is singular, and it successfully carries this information across long-range dependencies. Another unit similarly encodes plurality. These number units show that a highly local encoding of linguistic features can emerge in LSTMs during language-model training, as was previously suggested by theoretical studies of artificial neural networks (e.g., Bowers, 2009) and in neuroscience (e.g., Kutter et al., 2018).

Our analysis also identified units whose activity correlates with syntactic complexity. These units, as a whole, affect performance on the agreement tasks. We further found that one of them encodes the main subject-verb dependency across various syntactic constructions. Moreover, the highest afferent weights to the forget and input gates of both LR-number units were from this unit. A natural interpretation is that this unit propagates syntax-based remember and update flags that control when the number units store and release information.

Finally, number is also redundantly encoded in a more distributed way, but the latter mechanism is unable to carry information across embedded syntactic structures. The computational burden of tracking number information thus gave rise to two types of units in the network, encoding similar information with distinct properties and dynamics.

The relationship we uncovered and characterized between syntax and number units suggests that agreement in an LSTM language-model cannot be entirely explained away by superficial heuristics, and the networks have, to some extent, learned to build and exploit structure-based syntactic representations, akin to those conjectured to support human-sentence processing.

In future work, we intend to explore how the encoding pattern we found varies across network architectures and hyperparameters, as well as across languages and domains. We also would like to investigate the timecourse of emergence of the found behaviour over training time.

More generally, we hope that our study will inspire more analyses of the inner dynamics of LSTMs and other sequence-processing networks, complementing the currently popular "black-box probing" approach. Besides bringing about a mechanistic understanding of language processing in artificial models, this could inform work on human-sentence processing. Indeed, our study yields particular testable predictions on brain dynamics, given that the computational burden of long-distance agreement remains the same for artificial and biological neural network, despite implementation differences and different data sizes required for language acquisition. We conjecture a similar distinction between SR and LR units to be found in the human brain, as well as an interaction between syntax-processing and feature-carrying units such as the LR units, and plan to test these in future work.

Neural Self-Training through Spaced Repetition

Abstract

Self-training is a semi-supervised learning approach for utilizing unlabeled data to create better learners. The efficacy of self-training algorithms depends on their data sampling techniques. The majority of current sampling techniques are based on predetermined policies which may not effectively explore the data space or improve model generalizability. In this work, we tackle the above challenges by introducing a new data sampling technique based on *spaced repetition* that dynamically samples informative and diverse unlabeled instances with respect to individual learner and instance characteristics. The proposed model is specifically effective in the context of neural models which can suffer from overfitting and high-variance gradients when trained with small amount of labeled data. Our model outperforms current semi-supervised learning approaches developed for neural networks on publicly-available datasets.

1 Introduction

It is often expensive or time-consuming to obtain labeled data for Natural Language Processing tasks. In addition, manually-labeled datasets may not contain enough samples for downstream data analysis or novelty detection (Wang and Hebert, 2016). To tackle these issues, semi-supervised learning (Zhu, 2006; Chapelle et al., 2009) has become an important topic when one has access to small amount of labeled data and large amount of unlabeled data.

Self-training is a type of semi-supervised learning in which a downstream learner (e.g. a classifier) is first trained with labeled data, then the trained model is applied to unlabeled data to generate more labeled instances. A select sample of these instances together with their *pseudo* (predicted) labels are added to the labeled data and the learner is re-trained using the new labeled dataset. This process repeats until there is no more unlabeled data left or no improvement is observed in model performance on validation data (Zhu, 2006; Zhu and Goldberg, 2009).

Conventional self-training methods often rely on prediction confidence of their learners to sample unlabeled data. Typically the most confident unlabeled instances are selected (HEARST, 1991; Yarowsky, 1995; Riloff and Jones, 1999; Zhou et al., 2012). This strategy often causes only those unlabeled instances that match well with the current model being selected during self-training, therefore, the model may fail to best generalize to complete sample space (Zhang and Rudnicky, 2006; Wu et al., 2018). Ideally, a self-training algorithm should explore the space thoroughly for better generalization and higher performance. Recently Wu et al. (2018) developed an effective data sampling technique for "co-training" (Blum and Mitchell, 1998) methods which require two distinct views of data. Although effective, this model can't be readily applied to some text datasets due to the two distinct view requirement.

In the context of neural networks, *pretraining* is an effective semi-supervised approach in which layers of a network are first pretrained by learning to reconstruct their inputs, and then network parameters are optimized by supervised fine-tuning on a target task (Hinton and Salakhutdinov, 2006; Bengio et al., 2007; Erhan et al., 2010). While pretraining has been effective in neural language modeling and document classification (Dai and Le, 2015; Miyato et al., 2016), it has an inherent limitation: the *same* neural model or parts thereof must be used in both pretraining and fine-tuning steps. This poses a major limitation on the design choices as some pretraining tasks may need to exploit several data types (e.g., speech and text), or might require deeper network architectures.

Proceedings of NAACL-HLT 2019, pages 21–31
Minneapolis, Minnesota, June 2 - June 7, 2019.

The above challenges and intuitions inspire our work on developing a novel approach for neural self-training. The core part of our approach is a data sampling policy which is inspired by findings in cognitive psychology about spaced repetition (Dempster, 1989; Cepeda et al., 2006; Averell and Heathcote, 2011); the phenomenon in which a learner (often a human) can learn efficiently and effectively by accurately scheduling reviews of learning materials. In contrast to previous self-training approaches, our spaced repetition-based data sampling policy is not predetermined, explores the entire data space, and dynamically selects unlabeled instances with respect to the "strength" of a downstream learner on a target task, and "easiness" of unlabeled instances. In addition, our model relaxes the "same model" constraint of pretraining-based approaches by naturally decoupling pretraining and fine-tuning models through spaced repetition.

The contributions of this paper are (a): we propose an effective formulation of spaced repetition for self-training methods; to the best of our knowledge, this is the first work that investigates spaced repetition for semi-supervised learning, (b): our approach dynamically samples data, is not limited to predetermined sampling strategies, and naturally decouples pretraining and fine-tuning models, and (c): it outperforms current state-of-the-art baselines on large-scale datasets.

Our best model outperforms standard and current state-of-the-art semi-supervised learning methods by 6.5 and 4.1 points improvement in macro-F1 on sentiment classification task, and 3.6 and 2.2 points on churn classification task. Further analyses show that the performance gain is due to our model's ability in sampling *diverse* and *informative* unlabeled instances (those that are different from training data and can improve model generalizability).

2 Method

Conventional self-training methods employ the following steps to utilize unlabeled data for semi-supervised learning: (1) train a learner, e.g. a classifier, using labeled data, (2) iteratively select unlabeled instances based on a data sampling technique, and add the sampled instances (together with their predicted *pseudo* labels) to the labeled data, and (3) iteratively update the learner using the new labeled dataset.

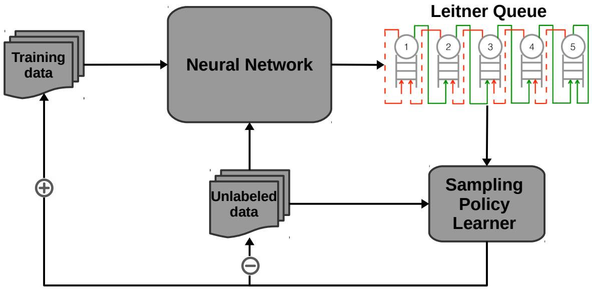

Figure 1: Neural Self-training Framework: at every self-training episode, the network uses current labeled data to iteratively optimize its parameters against a target task, and dynamically explores unlabeled data space through spaced repetition (specifically Leitner queue) to inform a data sampler that selects unlabeled data for the next self-training episode. Dashed/Red and solid/green arrows in Leitner queue indicate instance movements among queues.

The core difference between self-training algorithms is in the second step: data sampling policy. In this paper, we develop a new data sampling technique based on "spaced repetition" which dynamically explores the data space and takes into account instance and learner characteristics (such as easiness of instances or learner strength on target task) to sample unlabeled data for effective self-training.

Figure 1 illustrates our proposed neural self-training framework. We assume the downstream learner is a neural network that, at every self-training episode, (a): takes *current* labeled and unlabeled data as input, (b): uses labeled data to iteratively optimize its parameters with respect to a target task, and (c): dynamically explores unlabeled data space through spaced repetition to inform a data sampler that selects unlabeled data for the next self-training episode.

2.1 Spaced Repetition

Spaced repetition (Dempster, 1989; Cepeda et al., 2006; Averell and Heathcote, 2011) was presented in psychology and forms the building block of many educational devices, including flashcards, in which small pieces of information are repeatedly presented to a learner on a schedule determined by a spaced repetition algorithm. Such algorithms show that humans and machines can better learn by scheduling reviews of materials so that more time is spent on difficult concepts and less time on easier ones (Dempster, 1989; Novikoff et al., 2012; Amiri et al., 2017).

In this paper, we focus on a specific spaced repetition framework called Leitner system (Leitner, 1974). Suppose we have n queues $\{q_0, \ldots, q_{n-1}\}$. In general, Leitner system initially places all instances in the first queue, q_0. During training, if an instance from q_i is correctly classified by the learner, it will be "promoted" to q_{i+1} (solid/green arrows in Figure 1), otherwise it will be "demoted" to the previous queue, q_{i-1} (dashed/red arrows in Figure 1). Therefore, as the learner trains through time, higher queues will accumulate instances that are easier for the learner, while lower queues will accumulate harder instances.

To use Leitner system for neural self-training, we assume our learner is a neural network, place all *unlabeled* instances in the first queue of Leitner system (line 2 in Algorithm 1), and gradually populate them to other queues while training the network. Our Leitner system uses iteration-specific network predictions on unlabeled instances and current pseudo labels of these instances to move them between queues (see line 4-5 in Algorithm 1); pseudo labels can be obtained through posterior predictions generated by any trained downstream learner (see Section 2.2). Instances with similar class predictions and pseudo labels will be promoted to their next queues, and those with opposite predictions and labels will be demoted to lower queues. We note that, errors (e.g. inaccurate pseudo labels or network predictions) can inversely affect instance movements among queues. However, our sampling technique (see below) alleviates this issue because such misleading instances, if sampled, can't improve the generalizability of downstream learners. Details of our Leitner system is shown in Table 1.

Algorithm 1. Leitner system

```
Input:
  $\mathbf{L}, \mathbf{U}, \mathbf{V}$ : labeled, unlabeled, and validation data
  $\mathbf{y}$ : pseudo labels for $\mathbf{U}$
  $k$ : number of training epochs
  $n$ : number of queues
Output:
  $Q$: Leitner queue populated with $\mathbf{U}$

1  $Q = [q_0, q_1, \ldots, q_{n-1}]$
2  $q_0 = [\mathbf{U}], q_i = []$ for $i \in [1, n-1]$
3  for $epoch = 1$ to $k$:
4    $model = \texttt{epoch\_train}(\mathbf{L}, \mathbf{V})$
5    $promos, demos = \texttt{eval}(Q, \mathbf{y}, model)$
6    $Q = \texttt{schedule}(Q, promos, demos)$
7  end for
8  return Q
```

Table 1: Leitner system for neural self-training. All *unlabeled* instances are initially placed in the first queue and then populated to other queues depending on their easiness and learner (network) performance. `epoch_train(.)` uses training data to train the network for a single epoch and returns a trained model, `eval(.)` applies the current model on unlabeled instances in all queues and, based on given pseudo labels (treated as gold labels), returns lists of correctly and incorrectly classified instances, $promos$ and $demos$ respectively, and `schedule(.)` moves $promos$ and $demos$ instances to their next and previous queues respectively, and returns the updated queue.

2.2 Self-Training with Leitner Queues

We formulate the data sampling process as a decision-making problem where, at every self-training episode, the decision is to select a subset of unlabeled instances for self-training using information from Leitner queues. A simple, yet effective, approach to utilize such information is a greedy one in which instances of the queue that most improves the performance of the current model on validation data will be selected. We refer to this queue as *designated* queue:

Algorithm 2 shows details of our self-training approach. At every episode, we use current labeled data to train a task-specific neural network (line 2). Here, we weight the loss function using class size to deal with imbalanced data, and weight pseudo-labeled instances (as a function of episodes) to alleviate the effect of potentially wrong pseudo labels while training the network. We then use the trained network to generate pseudo labels for current unlabeled instances (line 3). These instances are then populated in Leitner queues as described before (line 4). Given the populated Leitner queues, the sample for current self-training episode is then created using instances of the designated queue, the queue that most improves the performance of the current network on validation data (lines 5-8). Instances of the designated queue will be removed from unlabeled data and added to labeled data with their pseudo labels treated as gold labels (lines 9-10).

We note that finding designated queues (lines 5-8 in Algorithm 2) imposes computational complexity on our model. However, in practice, we observe that designated queues are almost always among middle or higher queues in Leitner system, i.e. $q_i, \forall i \in [\lfloor n/2 \rfloor, n-1]$ where n in the number of queues. This can help accelerating the search

Algorithm 2. Neural Self-training

```
Input:
  $\mathbf{L}, \mathbf{U}, \mathbf{V}$ : labeled, unlabeled, and validation data
  $K$ : number of self-training episodes
Output:
  $M$: classification model

for $episode = 1$ to $K$:
  $M_L = \texttt{train}(\mathbf{L}, \mathbf{V})$
  $\mathbf{y} = \texttt{label}(M_L, \mathbf{U})$
  $Q = \texttt{Leitner\_system}(\mathbf{L}, \mathbf{U}, \mathbf{V}, \mathbf{y})$ \\Alg. 1
  for $q$ in $Q$:
    $M_q = \texttt{train}(\mathbf{L} + [q, \mathbf{y}[q]], \mathbf{V})$
  end for
  $M, q_{desig} = \texttt{get\_best}(M_Q, M_L)$
  $\mathbf{L} = \mathbf{L} + [q_{desig}, \mathbf{y}[q_{desig}]]$
  $\mathbf{U} = \mathbf{U} - q_{desig}$
end for
return $M$
```

Table 2: Proposed neural self-training framework. `train`(.) uses current labeled data to train the network and returns a trained model, `label`(.) generates pseudo labels for unlabeled instances using the trained model, `Leitner_system`(.) populates current unlabeled instances in Leitner queue, and `get_best`(.) compares performance of given models on validation data and returns the best model in conjunction with the queue that leads to the best performance, if any. Instances of the designated queue will be removed from unlabeled data and added to labeled data with their pseudo labels treated as gold labels.

process. In addition, learning a data sampling policy from movement patterns of instances among queues may help alleviating/eliminating the need for such an iterative search; see Section 4.4.

Finally, at test time, we apply the resulting self-trained network to test data and use the result for model comparison.

3 Experiments

We compare different self-training approaches in two settings where learners (neural networks) have low or high performance on original labeled data. This consideration helps investigating sensitivity of different self-training algorithms to the initial performance of learners.

3.1 Datasets and Evaluation Metric

As datasets, we use movie reviews from IMDb and short microblog posts from Twitter. These datasets and their corresponding tasks are described below and their statistics are provided in Table 3. In terms of preprocessing, we change all texts to lowercase, and remove stop words, user names, and URLs from texts in these datasets:

	Train	**Val.**	**Test**	**Unlabeled**
IMDb	5×1K	5×1K	5×48K	50K
Churn	5×1K	5×1K	5×3K	100K

Table 3: Statistics of dataset used in experiments.

IMDb: The IMDb dataset was developed by Maas et al. (2011)[1] for sentiment classification where systems should classify the polarity of a given movie review as positive or negative. The dataset contains 50K labeled movie reviews. For the purpose of our experiments, we randomly sample 1K, 1K, and 48K instances from this data (with balanced distribution over classes) and treat them as labeled (training), validation, and test data respectively. We create five such datasets for robustness against different seeding or data partitions. This dataset also provides 50K unlabeled reviews.

Churn: This dataset contains more than 5K tweets about three telecommunication brands and was developed by Amiri and Daumé III (2015)[2] for the task of *churn* prediction[3] where systems should predict if a twitter post indicates user intention about leaving a brand - classifying tweets as *churny* or *non-churny* with respect to brands. We replace all target brand names with the keyword BRAND and other non-target brands with BRAND-OTHER for the purpose of our experiments. Similar to IMDb, we create five datasets for experiments. We also crawl an additional 100K tweets about the target brands and treat them as unlabeled data.

We evaluate models in terms of macro-F1 score, i.e. the mean of F1-scores across classes.

3.2 Downstream Learner and Settings

As downstream neural networks (referred to as base classifiers), we consider current state-of-the-art deep averaging networks (DANs) (Shen et al., 2018; Iyyer et al., 2015; Joulin et al., 2017; Arora et al., 2017) for IMDb, and a basic CNN model for Churn dataset with parameters set from the work presented in (Gridach et al., 2017) except for pretrained embeddings. In terms of DANs, we use `FastText` (Joulin et al., 2017) for its high per-

---

[1] `http://ai.stanford.edu/~amaas/data/sentiment/`

[2] `https://scholar.harvard.edu/hadi/chData`

[3] Churn is a term relevant to customer retention in marketing discourse; examples of churny tweets are "my days with BRAND are numbered," "debating if I should stay with BRAND," and "leaving BRAND in two days."

formance and simplicity. `FastText` is a feedforward neural network that consists of an embedding layer that maps vocabulary indices to embeddings, an averaging layer that averages word embeddings of inputs, and several hidden layers (we use two layers of size 256) followed by a prediction layer with `sigmoid` activation.

We use 300-dimensional word embeddings provided by Google's `word2vec` toolkit (Mikolov et al., 2013). In Algorithm 1, we set the number of training epochs to $k = 32$, and stop training when F1 performance on validation data stops improving with patience of three continuous iterations, i.e. after three continuous epochs with no improvement, training will be stopped. In addition, we set the number of training episodes to $K = 20$ and stop training when this number of episodes is reached or there is no unlabeled data left for sampling; the latter case is often the reason for stopping in our self-training method. In addition, we experiment with different number of Leitner queues chosen from $n = \{3, 5, 7, 9, 11\}$.

3.3 Baselines

We consider the following baselines:

- **Standard self-training**: This approach iteratively trains a network on current labeled data and applies it to current unlabeled data; it uses a prediction confidence threshold to sample unlabeled instances (Zhu, 2006). We set the best confidence threshold from {.80,.85,.90,.95} using validation data.
- **Autoencoder self-training** (Dai and Le, 2015): This approach first pretrains a network using unlabeled data (through a layer-wise training approach to optimally reconstruct the inputs), and then fine-tunes it using labeled data with respect to the target task.
- **Adversarial self-training** (Miyato et al., 2016): This model utilizes pretraining as described above, but also applies adversarial perturbations to word embeddings for more effective learning (perturbation is applied to embeddings instead of word inputs because words or their one-hot vectors do not admit infinitesimal perturbation; the network is trained to be robust to the worst perturbation).
- **Knowledge Transfer self-training** (Noroozi et al., 2018): This model uses a clustering approach (e.g. k-means) to create clusters of unlabeled instances that have similar representations, where representations are derived from standard pretraining as described above. The model then pretrains a network by learning to *classify* unlabeled instances to their corresponding clusters. The resulting pretrained network is then fine-tuned with respect to the target task using labeled data (with slight modification at prediction layer which makes the network suitable for target task). We set the best number of clusters from $\{10, 20, \ldots, 100\}$ based on model performance on validation data.

	IMDb	**Churn**
Base Classifier	73.02	65.77
SST (Standard ST)	74.43	65.77
PST (Pretraining ST)	76.36	67.27
AST (Adversarial ST)	76.09	67.70
KST (Knowledge Transfer ST)	77.11	67.06
LST (Leitner ST)	**78.27***	**69.90***

Table 4: Macro-F1 performance of models across datasets; Note that Standard ST (SST) samples only 1.4K and 0 instances from IMDb and Churn datasets respectively; sampling more data decreases SST's performance down to 66.94 and 57.04 perhaps due to ineffective exploring of data space. Our model achieves its best performance on IMDb and Churn datasets with $n = 5$ and $n = 7$ Leitner queues respectively.

3.4 Model Performance

Table 4 reports Macro-F1 performance of different models; we report average performance across five random test sets for each task (see Section 3.1 and Table 3). The performance of base classifiers in supervised settings, where the networks are only trained on original labeled datasets, is reasonably high on IMDb (73.02) and low on Churn (65.77). Standard ST (SST) improves performance on IMDb but not on Churn dataset. SST achieves its best performance (on validation data) in the first few episodes when, on average, 1.4K and 0 instances are sampled for IMDb and Churn datasets respectively. Beyond that, the performance considerably decreases down to 66.94 (IMDb) and 57.04 (Churn) respectively. This is perhaps due to imbalanced class size in Churn dataset, failure of SST to explore the data space, or classification mistakes that reinforce each other. Several previous works also observed no improvement with SST (Gollapalli et al., 2013; Zhu and Goldberg, 2009; Zhang and Rudnicky, 2006); but some successful applications have been reported (Wu et al., 2018; Zhou et al., 2012; Riloff and Jones, 1999; Yarowsky, 1995; HEARST, 1991).

The result also show that pretraining and adversarial-based training, PST and AST in Table 4 respectively, improve the performance of base classifiers by 3.34 and 3.37 points in macro-F1 on IMDb, and by 1.5 and 1.93 points on Churn dataset. In addition, since PST and AST show comparable performance, we conjecture that when original labeled data has a small size, adversarial-based self-training do not considerably improve pretraining. But, considerable improvement can be achieved with larger amount of labeled data, see (Miyato et al., 2016) for detailed comparison on pretraining and adversarial-based training. The results also show that knowledge transfer (KST) outperforms PST and AST on IMDb - indicating that good initial labels derived through clustering information could help semi-supervised learning, even with small amount of seed labeled data.

Table 4 also shows the result of our model, Leitner ST (LST). The best performance of LST is obtained using $n = 5$ and $n = 7$ queues for IMDb and Churn datasets respectively. Considering these queue lengths, our model outperforms base classifiers by 5.25 and 4.13 points in Macro-F1 on IMDb and Churn datasets respectively; similar to PST and AST, our model results in a greater gain when the learner has higher initial performance. It also improves the best self-training baseline, KST for IMDb and AST for Churn, by 1.16 and 2.2 points in macro-F1 on IMDb and Churn datasets respectively where both differences are significant (average ρ-values based on t-test are .004 and .015 respectively).

4 Model Introspection

We investigate several questions about our model to shed light on its improved performance. One partial explanation is that by differentiating instances and augmenting the informative ones, we are creating a more powerful model that better explores the space of unlabeled data. In this section, we elaborate on the behavior of our model by conducting finer-grained analysis at queue-level and investigating the following questions in the context of challenges of semi-supervised learning. Due to space limit, we mainly report results on IMDb and discuss corresponding behaviors on Churn dataset in the text.

4.1 Queue-level Performance

We analyze queue level performance to understand how instances of different queues contribute in creating better models during the self-training process. For this experiment, we train networks using our Leitner self-training framework as normal (where, at every iteration, only instances of the designated queue are added to training data), and report the average macro-F1 performance of the network–on validation data–if it is trained with instances of each queue. Concretely, we report average macro-F1 performance of models learned at line 6 of Algorithm 2 (see M_qs in Table 2).

Figures 2(a) and 2(b) show the results on IMDb and Churn datasets for $n = 5$ and $n = 7$ queues respectively. Note that the last queue for Churn dataset, q_6, has never been reached by any instance. This is perhaps because of the difficulty of this task[4] and low initial performance of the network on Churn dataset. q_2 on IMDb and q_4 on Churn dataset result in the best average performance across training episodes, both queues are close to the middle. In addition, the result show that the highest queues (q_4 for IMDb and q_5 for Churn) are often not the best queues. This result can justify the lower performance of Standard ST (SST) as instances in these queues are the easiest (and perhaps most confident ones) for the network; we further analyze these queues in Section 4.2.[5]

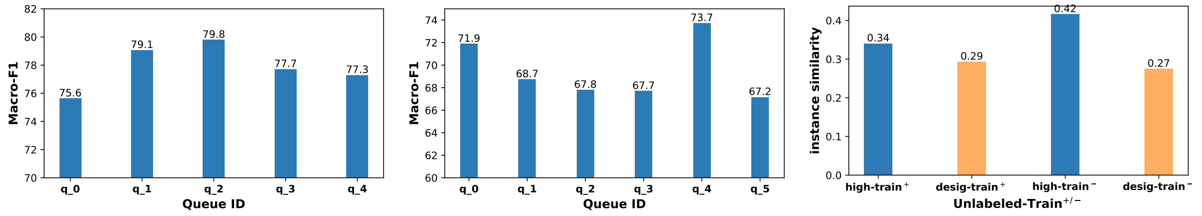
4.2 What's the Issue with Highest Queues?

As we discussed before, instances in the highest queues, although easy to learn for the classifier, are not informative and do not contribute to training an improved model; therefore, highest queues are often not selected by our model. To understand the reason, we try to quantify how well instances of these queues *match* with training data. For this purpose, we compute `cosine` similarity between representations of training instances (see below) and those in the highest and designated queues

---

[4] Churn prediction is a target-dependent task, largely affected by negation and function words, e.g. compare "*switching from*" and "*switching to*," and language complexity, e.g. the tweets "*hate that I may end up leaving BRAND cause they have the best service*" is a positive yet churny tweet.

[5] Note that the performance on lower queues (e.g. q_1 for IMDb and q_0 for Churn) are higher than expected. This is because, at the end of each iteration, instances of designated (best-performing) queues–but not lower queues–are added to training data; instances of designated queues help creating better and more robust models which still perform well even if instances of lower queues are added.



(a) Queue level performance (IMDb) (b) Queue level performance (Churn) (c) Highest vs. designated queue (IMDb)

Figure 2: (a) and (b): Average macro-F1 performance computed over individual queues using validation dataset across training episodes (average performance of M_qs at line 6 of Algorithm 2). (a): Performance on IMDb with optimal queue length of $n = 5$, and (b): performance on Churn with optimal queue length of $n = 7$: note that none of unlabeled instances has made it to the last queue. (c): Comparison of highest and designated queues in terms of instance similarity to training data; `high_train` indicates similarity between (representations of) instances in the highest queue and training instances, and `desig_train` shows the corresponding values for instances in the designated queue. $+$ and $-$ signs indicate positive and negative pseudo/gold labels for unlabeled/training instances.

during self-training as follows:

$$\frac{1}{K}\sum_{e=1}^{K}\texttt{cosine}(\mathbf{T}^e, \mathbf{Q}^e)$$

where $\mathbf{T}^e \in \mathbb{R}^{m^e \times d}$ and $\mathbf{Q}^e \in \mathbb{R}^{p^e \times d}$ indicate representations of training instances and those of a given target queue respectively (where d indicates the dimension of representations, and m^e and p^e indicate number of instances in training data and target queue at episode e respectively), and `cosine(.,.)` computes L2-normalized dot product of its input matrices. To obtain the above representations for instances, we compute the output of the last hidden layer (the layer below prediction layer) of the *trained* network at each episode. These outputs can be considered as feature representations for inputs. For finer-grained comparison, we compute similarities with respect to positive and negative classes.

As the results in Figure 2(c) show, instances in the highest queue match well with current training data (and hence the current model), and, therefore, are less informative. On the other hand, instances in the designated queues show considerably smaller similarity with training instances in both positive and negative classes, and, therefore, do not match well with training data. These instances are more informative, and help the network to better explore the space of unlabeled data and optimize for the target task.

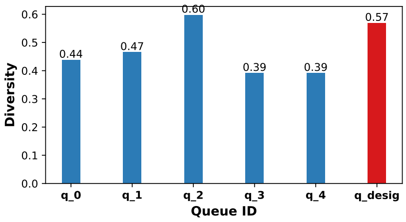


Figure 3: The amount of diversity that instances of each queue introduce if added to training data (on IMDb).

4.3 Does Diversity Matter?

We analyze different queues to measure the extent of diversity that each queue introduces to training data during our normal self-training process where, at every iteration, only instances of the designated queue are added to training data. Specifically, we compute the extent of diversity that each given queue introduces as follows:

$$\frac{1}{K}\sum_{e=1}^{K} 1 - \texttt{cosine}(\mathbf{T}^e, \texttt{concat}(\mathbf{T}^e, \mathbf{Q}^e))$$

where, as before, $\mathbf{T}^e$ and $\mathbf{Q}^e$ indicate the representations of training and queue instances at episode e respectively, and `concat(.,.)` is a function that creates a new dataset by vertically concatenating $\mathbf{T}^e$ and $\mathbf{Q}^e$.

Figure 3 shows the results. On IMDb, q_2 and designated queues show greater diversity to training data compared to other queues. We note that q_0 carries a greater diversity than q_3 and q_4, but, as we observed in Figure 2, instances of q_0 do not improve performance of the model, perhaps due to their difficulty or wrong pseudo labels. We observe similar behavior in case of Churn dataset where q_4 introduces the highest diversity. From this analysis, we conclude that Leitner self-training enables sampling diverse sets of instances that contributes to training an improved model.

	Leitner ST				
	$n = 3$	$n = 5$	$n = 7$	$n = 9$	$n = 11$
IMDb	76.83	76.77	78.03	75.34	**80.71**
Churn	65.74	64.87	67.06	**68.56**	65.80

Table 5: Macro-F1 performance of diverse queues across datasets. Compare these results with those obtained by designated queues in Table 4.

4.3.1 Diverse Queue

Given the above results on diversity, we investigate whether greater diversity can further improve the performance of our model. For this analysis, we create a considerably more "diverse" queue at every self-training episode and treat it as the designated queue. We create the diverse queue by sampling instances with *high* prediction confidence from *all* queues. In particular, at every episode, we rank instances of each queue based on their prediction confidence and create a diverse queue by combining top $r\%$ instances of each queue, where r indicates the rate of adding new instances and set to $r = 10\%$. We note that a smaller rate is better for adding instances because it allows the model to gradually consume unlabeled instances with high prediction confidence.

Table 5 shows the effect of diverse queues on the performance of our model on both IMDb and Churn datasets. The results show that diverse queues improve the performance of our Leitner self-training model from 78.27 (reported in Table 4) to 80.71 on IMDb, i.e. 2.44 points improvement in macro-F1. However, the corresponding performance on Churn dataset decreases from 69.90 to 68.56, i.e. 1.34 points decrease in macro-F1. The inverse effect of diverse queues in case of Churn dataset is because diverse queues suffer from the issue of considerable class imbalance more than designated queues. This is because highly confident instances which accumulate in higher queues are often negative instances in case of Churn prediction. Although we tackle this issue by weighting the loss function during training, diverse positive instances which are different from their training counterparts are still needed for performance improvement.

4.4 Do We Need Better Sampling Policies?

We investigate the challenges associated with our data sampling policy by conducting finer-grained analysis on instance movement patterns among queues. To illustrate, assume that we have a Leitner queue of size $n = 3$ and the following movement patterns for four individual instances that ultimately home in on q_0 (recall that correct prediction promotes an instance to a higher queue, while wrong prediction demotes it to a lower queue):

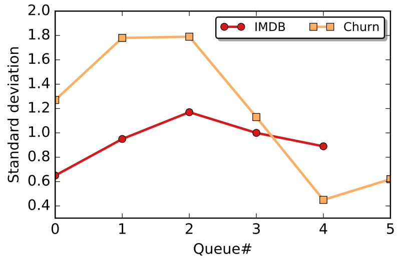

Figure 4: Deviation in instance movements for each queue (in terms of average standard deviation over all training episodes). At every episode, we keep track of instance movements among queues and measure movement variation among instances that ultimately home in on the same queue.

$q_0 \rightarrow q_0 \rightarrow q_0 \rightarrow q_0 \rightarrow q_0$: always in q_0
$q_0 \rightarrow q_1 \rightarrow q_0 \rightarrow q_0 \rightarrow q_0$: mainly in q_0
$q_0 \rightarrow q_1 \rightarrow q_0 \rightarrow q_1 \rightarrow q_0$: partially in q_0
$q_0 \rightarrow q_1 \rightarrow q_2 \rightarrow q_1 \rightarrow q_0$: partially in q_0 & q_1.

Although all these instances ultimately home in on the same queue, they may have different contributions to the training of a model because there is a considerable difference in the ability of the downstream network in learning their labels. Therefore, if there is a large deviation among movement patterns of instances of the same queue, better data sampling policies could be developed, perhaps through finer-grained queue-level sampling.

For this analyses, we keep track of instance movements among queues and measure standard deviation among movement patterns of instances of the same queue at every self-training episode, and report the average of these deviations.

Figure 4 shows the results. On both datasets, there is considerably greater deviation in movements for middle queues than lower/higher queues. This is meaningful because Leitner system (and other spaced repetition schedulers) are expected to keep easy and hard instances at higher and lower queues respectively. Since such instances mainly stay at lower or higher queues, we observe smaller deviation in their movements. On the other hand, the corresponding values for middle queues indicate that movements in these queues are spread out over a larger range of queues. From these results, we conjecture that a data sampling policy that conducts finer-grained analysis at queue-level (e.g. by taking into account queue movement patterns) could create better data samples. Verifying this hypothesis will be the subject for future work.

5 Related Work

Semi-supervised learning (Zhu, 2006; Chapelle et al., 2009) is a type of machine learning where one has access to a small amount of labeled data and a large amount of unlabeled data. Self-training is a type of semi-supervised learning to boost the performance of downstream learners (e.g. classifiers) through data sampling from unlabeled data. Most data sampling policies rely on prediction confidence of the downstream learner for sampling unlabeled data (Zhu and Goldberg, 2009). Self-training has been successfully applied to various tasks and domains including word sense disambiguation (HEARST, 1991; Yarowsky, 1995), information extraction (Riloff and Jones, 1999), and object recognition (Zhou et al., 2012).

In addition, co-training (Blum and Mitchell, 1998; Zhang and Rudnicky, 2006; Wu et al., 2018) is another type of semi-supervised learning. It assumes that each instance can be described using two *distinct* feature sets that provide different and complementary information about the instance. Ideally, the two views should be conditionally independent, i.e., the two feature sets of each instance are conditionally independent given the class, and each view should be sufficient, i.e., the class of an instance can be accurately predicted from each view alone. Co-training first learns separate downstream learners for each view using a small set of labeled data. The most confident predictions of each learner on the unlabeled data are then used to iteratively construct additional labeled training data. Recently Wu et al. (2018) developed an effective model based on reinforcement learning (specifically, a joint formulation of a Q-learning agent and two co-training classifiers) to learn data sampling policies and utilize unlabeled data space in the context of co-training methods.

Effective semi-supervised learning algorithms based on pretraining techniques (Hinton and Salakhutdinov, 2006; Bengio et al., 2007; Erhan et al., 2010) have been developed for text classification, deep belief networks (Hinton and Salakhutdinov, 2006), and stacked autoencoders (Vincent et al., 2010; Bengio et al., 2007). In particular, Dai and Le (2015) developed an autoencoder for the later supervised learning process. Miyato et al. (2016) applied perturbations to word embeddings and used pretraining technique and adversarial training for effective semi-supervised learning. These models although effective have not been well studied in the context of semi-supervised learning where models may have low initial performance or limited amount of labeled data. In addition, pretraining is limited by the same architecture requirement in both pretraining and fine-tuning steps.

In this work, we extend previous work in self-training by developing a new and effective data sampling policy based on spaced repetition (Dempster, 1989; Cepeda et al., 2006; Averell and Heathcote, 2011) which addresses some of the above challenges. In particular, our model's data sampling policy is not predetermined, it explores the entire data space and dynamically selects unlabeled instances with respect to the strength of a learner on a target task and easiness of unlabeled instances, and it relaxes the same model constraint of pretraining-based approaches by decoupling pretraining and fine-tuning steps.

6 Conclusion and Future Work

We propose a novel method based on spaced repetition to self-train neural networks using small amount of labeled and large amount of unlabeled data. Our model can select high-quality unlabeled data samples for self-training and outperforms current state-of-the-art semi-supervised baselines on two text classification problems. We analyze our model from various perspectives to explain its improvement gain with respect to challenges of semi-supervised learning. There are several venues for future work including (a): finer-grained data sampling at queue level, (b): extending our model to other machine learning algorithms that employ iterative training, such as boosting approaches, and (c): applying this model to areas where neural networks have not been investigated, e.g. due to limited availability of labeled data.

Abstract

We investigate the extent to which the behavior of neural network language models reflects incremental representations of syntactic state. To do so, we employ experimental methodologies which were originally developed in the field of psycholinguistics to study syntactic representation in the human mind. We examine neural network model behavior on sets of artificial sentences containing a variety of syntactically complex structures. These sentences not only test whether the networks have a representation of syntactic state, they also reveal the specific lexical cues that networks use to update these states. We test four models: two publicly available LSTM sequence models of English (Jozefowicz et al., 2016; Gulordava et al., 2018) trained on large datasets; an RNN Grammar (Dyer et al., 2016) trained on a small, parsed dataset; and an LSTM trained on the same small corpus as the RNNG. We find evidence for basic syntactic state representations in all models, but only the models trained on large datasets are sensitive to subtle lexical cues signalling changes in syntactic state.

1 Introduction

It is now standard practice in NLP to derive sentence representations using neural sequence models of various kinds (Elman, 1990; Sutskever et al., 2014; Goldberg, 2017; Peters et al., 2018; Devlin et al., 2018). However, we do not yet have a firm understanding of the precise content of these representations, which poses problems for interpretability, accountability, and controllability of NLP systems. More specifically, the success of neural sequence models has raised the question of whether and how these networks learn robust syntactic generalizations about natural language, which would enable robust performance even on data that differs from the peculiarities of the training set.

Here we build upon recent work studying neural language models using experimental techniques that were originally developed in the field of psycholinguistics to study language processing in the human mind. The basic idea is to examine language models' behavior on targeted sentences chosen to probe particular aspects of the learned representations. This approach was introduced by Linzen et al. (2016), followed more recently by others (Bernardy and Lappin, 2017; Enguehard et al., 2017; Gulordava et al., 2018), who used an agreement prediction task (Bock and Miller, 1991) to study whether RNNs learn a hierarchical morphosyntactic dependency: for example, that *The key to the cabinets...* can grammatically continue with *was* but not with *were*. This dependency turns out to be learnable from a language modeling objective (Gulordava et al., 2018). Subsequent work has extended this approach to other grammatical phenomena, with positive results for filler–gap dependencies (Chowdhury and Zamparelli, 2018; Wilcox et al., 2018) and negative results for anaphoric dependencies (Marvin and Linzen, 2018).

In this work, we consider syntactic representations of a different kind. Previous studies have focused on relationships of **dependency**: one word licenses another word, which is tested by asking whether a language model favors one (grammatically licensed) form over another in a particular context. Here we focus instead on whether neural language models show evidence for incremental **syntactic state** representations: whether behavior of neural language models reflects the kind of generalizations that would be captured using a stack-based incremental parse state in a symbolic grammar-based model. For example, during the underlined portion of Example (1), an incremental language model should represent and maintain the knowledge that it is currently inside a subordinate clause, implying (among other things) that a full main clause must follow.

Proceedings of NAACL-HLT 2019, pages 32–42
Minneapolis, Minnesota, June 2 - June 7, 2019.

(1) As the doctor studied the textbook, the nurse walked into the office.

In this work, we use a targeted evaluation approach (Marvin and Linzen, 2018) to elicit evidence for syntactic state representations from language models. That is, we examine language model behavior on artificially constructed sentences designed to expose behavior that is crucially dependent on syntactic state representations. In particular, we study complex subordinate clauses and garden path effects (based on main-verb/reduced-relative ambiguities and NP/Z ambiguities). We ask three general questions: (1) Is there basic evidence for the representation of syntactic state? (2) What textual cues does a neural language model use to infer changes to syntactic state? (3) Do the networks maintain knowledge about syntactic state over long spans of complex text, or do the syntactic state representations degrade?

Among neural language models, we study both generic sequence models (LSTMs), which have no explicit representation of syntactic structure, and an RNN Grammar (RNNG) (Dyer et al., 2016), which explicitly calculates Penn Treebank-style context-free syntactic representations as part of the process of assigning probabilities to words. This comparison allows us to evaluate the extent to which explicit representation of syntactic structure makes models more or less sensitive to syntactic state. RNNGs have been found to outperform LSTMs not only in overall test-set perplexity (Dyer et al., 2016), but also in modeling long-distance number agreement in Kuncoro et al. (2018) for certain model configurations; our work extends this comparison to a variety of syntactic state phenomena.

2 General methods

We investigate neural language model behavior primarily by studying the **surprisal**, or log inverse probability, that a language model assigns to each word in a sentence:

$$S(x_i) = -\log_2 p(x_i|h_{i-1}),$$

where x_i is the current word or character, h_{i-1} is the model's hidden state before consuming x_i, the probability is calculated from the network's softmax activation, and the logarithm is taken in base 2, so that surprisal is measured in bits. Surprisal is equivalent to the pointwise contribution to the language modeling loss function due to a word.

In psycholinguistics, the common practice is to study reaction times per word (for example, reading time as measured by an eyetracker), as a measure of the word-by-word difficulty of online language processing. These reading times are often taken to reflect the extent to which humans expect certain words in context, and may be generally proportional to surprisal given the comprehender's probabilistic language model (Hale, 2001; Levy, 2008; Smith and Levy, 2013; Futrell and Levy, 2017). In this study, we take language model surprisal as the analogue of human reading time, using it to probe the neural networks' expectations about what words will follow in certain contexts. There is a long tradition linking RNN performance to human language processing (Elman, 1990; Christiansen and Chater, 1999; MacDonald and Christiansen, 2002) and grammaticality judgments (Lau et al., 2017), and RNN surprisals are a strong predictor of human reading times (Frank and Bod, 2011; Goodkind and Bicknell, 2018). RNNGs have also been used as models of human online language processing (Hale et al., 2018).

2.1 Experimental methodology

In each experiment presented below, we design a set of sentences such that the word-by-word surprisal values will show evidence for syntactic state representations. The idea is that certain words will be surprising to a language model only if the model has a representation of a certain syntactic state going into the word. We analyze word-by-word surprisal profiles for these sentences using regression analysis. Except where otherwise noted, all statistics are derived from linear mixed-effects models (Baayen et al., 2008) with sum-coded fixed-effect predictors and maximal random slope structure (Barr et al., 2013). This method lets us factor out by-item variation in surprisal and focus on the contrasts between conditions.

2.2 Models tested

We study the behavior of four models of English: two LSTMs trained on large data, an an RNNG and an LSTM trained on matched, smaller data (the Penn Treebank). The models are summarized in Table 1. All models are trained on a language modeling objective.

Our first LTSM is the model presented in Jozefowicz et al. (2016) as "BIG LSTM+CNN Inputs", which we call "JRNN", which was trained on the One Billion Word Benchmark (Chelba et al., 2013) with two hidden layers of 8196 units each

Model	Architecture	Training data	Data size (tokens)	Reference
JRNN	LSTM	One Billion Word	~ 800 million	Jozefowicz et al. (2016)
GRNN	LSTM	Wikipedia	~ 90 million	Gulordava et al. (2018)
RNNG	RNN Grammar	Penn Treebank	~ 1 million	Dyer et al. (2016)
TinyLSTM	LSTM	Penn Treebank	~ 1 million	—

Table 1: Models tested, by architecture, training data, and training data size.

and CNN character embeddings as input. The second large LSTM is the model described in the supplementary materials of Gulordava et al. (2018), which we call “GRNN”, trained on 90 million tokens of English Wikipedia with two hidden layers of 650 hidden units each.

Our RNNG is trained on syntactically labeled Penn Treebank data (Marcus et al., 1993), using 256-dimensional word embeddings for the input layer and 256-dimensional hidden layers, and dropout probability 0.3. Next-word predictions are obtained through hierarchical softmax with 140 clusters, obtained with the greedy agglomerative clustering algorithm of Brown et al. (1992). We estimate word surprisals using word-synchronous beam search (Stern et al., 2017; Hale et al., 2018): at each word w_i a beam of incremental parses is filled, the summed forward probabilities (Stolcke, 1995) of all candidates on the beam is taken as a lower bound on the prefix probability: $P_{\min}(w_{1\ldots i})$, and the surprisal of the i-th word in the sentence is estimated as $\log \frac{P_{\min}(w_{1\ldots i})}{P_{\min}(w_{1\ldots i-1})}$. Our action beam is size 100, and our word beam is size 10. Finally, to disentangle effects of training set from model architecture, we use an LSTM trained on string data from the Penn Treebank training set, which we call TinyLSTM. For TinyLSTM we use 256-dimensional word-embedding inputs and hidden layers and dropout probability 0.3, just as with the RNNG.

3 Subordinate clauses

We begin by studying subordinate clauses, a key example of a construction requiring stack-like representation of syntactic state. In such constructions, as shown in Example (1), a **subordinator** such as “as” or “when” serves as a cue that the following clause is a subordinate clause, meaning that it must be followed by some main (matrix) clause. In an incremental language model, this knowledge must be maintained and carried forward while processing the words inside subordinate clause. A grammar-based symbolic language model (e.g., Stolcke, 1995; Manning and Carpenter, 2000) would maintain this knowledge by keeping track of syntactic rules representing the incomplete subordinate clause and the upcoming main clause in a stack data structure. Psycholinguistic research has clearly demonstrated that humans maintain representations of this kind in syntactic processing (Staub and Clifton, 2006; Lau et al., 2006; Levy et al., 2012). Here we ask whether the string completion probabilities produced by neural language models show evidence of the same knowledge.

We can detect the knowledge of syntactic state in this case by examining whether the network licenses and requires a matrix clause following the subordinate clause. These expectations can be detected by examining surprisal differences between sentences of the form in Example (2):

(2) a. As the doctor studied the textbook, the nurse walked into the office. [SUBordinator, MATRIX]
b. *As the doctor studied the textbook. [SUB, NO-MATRIX]
c. ?The doctor studied the textbook, the nurse walked into the office. [NO-SUBordinator, MATRIX]
d. The doctor studied the textbook. [NO-SUB, NO-MATRIX]

If the network *licenses* a matrix clause following the subordinate clause—and maintains knowledge of that licensing relationship throughout the clause, from the subordinator to the comma—then this should be manifested as lower surprisal at the matrix clause in (2-a) as compared to (2-c). We call this the **matrix licensing effect**: the surprisal of the condition [SUB, MATRIX] minus [NOSUB, MATRIX], which will be negative if there is a licensing effect. If the network *requires* a following matrix clause, then this will be manifested as higher surprisal at the matrix clause for (2-b) compared with (2-d). We call this the **no-matrix penalty effect**: the surprisal of [SUB,NOMATRIX] minus [NOSUB, NOMATRIX], which will be positive if there is a penalty.

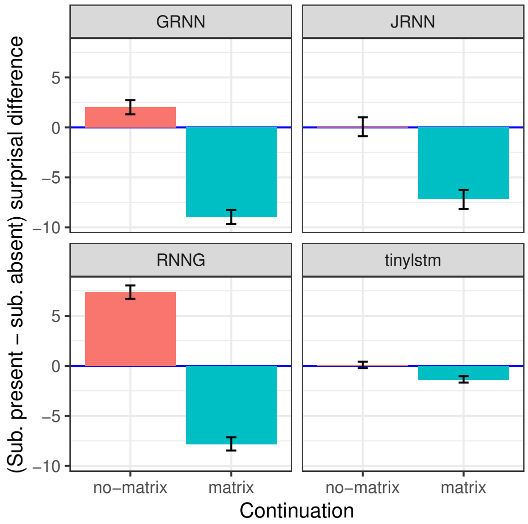

Figure 1: Effect of subordinator absence/presence on surprisal of continuations. Red: no-matrix penalty effect. Blue: matrix licensing effect. In this and all other figures, unless otherwise noted, **error bars** represent 95% confidence intervals of the *contrasts between conditions shown*, computed from the standard error of the by-item and by-condition mean surprisals after subtracting out the by-item means (Masson and Loftus, 2003).

We designed 23 experimental items on the pattern of (2) and calculated difference in the sum surprisal of the words in the matrix clause.[1] Figure 3 shows the matrix licensing effect (in blue) and the no-matrix penalty effect (in red), averaged across items. For all models, we see a facilitative matrix licensing effect ($p < .001$ for all models), smallest in TinyLSTM. However, we only find a significant no-matrix penalty for GRNN and the RNNG ($p < .001$ in both): the other models do not significantly penalize an ungrammatical continuation ($p = .9$ for JRNN; $p = .5$ for TinyLSTM). That is, JRNN and TinyLSTM give no indication that (2-b) is less probable than (2-c).

We found that all models at least partially represent the licensing relationship between a subordinate and matrix clause. However, in order to fully represent the syntactic requirements induced by a subordinator, it seems that a model needs either large amounts of data (as in GRNN) or explicit representation of syntax (as in the RNNG, as opposed to TinyLSTM).

3.1 Maintenance and degradation of syntactic state

The foregoing results show that neural language models use the presence of a subordinator as a cue to the onset of a subordinate clause, and that they maintain knowledge that they are in a subordinate clause throughout the intervening material up to the comma. Now we probe the ability of models to maintain this knowledge over long spans of complex intervening material. To do so, we use sentences on the template of (2) and add intervening material modifying the NPs in the subordinate clause. To both of these NPs (in subject and object position), we add modifiers of increasing syntactic complexity: PPs, subject-extracted relative clauses (SRCs), and object-extracted relative clauses (ORCs), as shown in Figure 2. We study the extent to which these modifiers weaken the language models' expectations about the upcoming matrix clause.

As a summary measure of the strength of language models' expectations about an upcoming matrix clause, we collapse the two measures of the previous section into one: the **matrix licensing interaction**, consisting of the difference between the no-matrix penalty effect and the matrix licensing effect (the two bars in Figure 1). A similar measure was used to detect filler–gap dependencies by Wilcox et al. (2018).

Figure 3 shows the strength of the matrix licensing interaction given sentences with various modifiers inserted. For the large LSTMs, GRNN exhibits a strong interaction when the intervening material is short and syntactically simple, and the interaction gets progressively weaker as the intervening material becomes progressively longer and more complex ($p < 0.001$ for subject postmodifiers and $p < 0.01$ object postmodifiers). The other models show less interpretable behavior.

Our results indicate that at least some large LSTMs, along with the RNNG, are capable of maintaining a representation of syntactic state over spans of complex intervening material. Quantified as a licensing interaction, this representation of syntactic state exhibits the most clearly understandable behavior in GRNN, which shows a graceful degradation of syntactic expectations as the complexity of intervening material increases. The representation is maintained most strongly in the RNNG, except for one particular construction (object-position SRCs).

---

[1] Note that it would not be sufficient to look at surprisal only at the punctuation token, because the comma could indicate the beginning of a conjoined NP.

4 Garden path effects

The major phenomenon that has been used to probe incremental syntactic representations in humans is **garden path effects**. Garden path effects arise from local ambiguities, where a context leads a comprehender to believe one parse is likely, but then a disambiguating word forces her to drastically revise her beliefs, resulting in high surprisal/reading time at the disambiguating word. In effect, the comprehender is "led down the garden path" by a locally likely but ultimately incorrect parse (Bever, 1970). Garden-pathing in LSTMs has recently been demonstrated by van Schijndel and Linzen (2018a,b) in the context of modeling human reading times.

Garden path effects allow us to detect representations of syntactic state because if a person or language model shows a garden path effect at a word, that means that the person or model had some belief about syntactic state which was disconfirmed by that word. In psycholinguistics, these effects have been used to study the question of what information determines people's beliefs about likely parses given locally ambiguous contexts: for example, whether factors such as world knowledge play a role (Ferreira and Clifton, 1986; Trueswell et al., 1994).

Here we study two major kinds of local ambiguities inducing garden path effects. For each ambiguity, we ask two main questions. First, whether the network shows the basic garden path effect, which would indicate that it had a syntactic state representation that made a disambiguating word surprising. Second, whether the network is sensitive to subtle lexical cues to syntactic structure which may modulate the size of the garden path effect: this question allows us to determine what information the network uses to determine the beginnings and endings of certain syntactic states.

4.1 NP/Z Ambiguity

The **NP/Z ambiguity**[2] refers to a local ambiguity in sentences of the form given in Example (3).

(3)a. When the dog scratched the vet with his new assistant **took off** the muzzle. [TRANSITIVE, NOCOMMA]
b. When the dog scratched, the vet with his new assistant **took off** the muzzle. [TRANSITIVE, COMMA]
c. When the dog struggled the vet with his new assistant **took off** the muzzle. [INTRANSITIVE, NOCOMMA]
d. When the dog struggled, the vet with his new assistant **took off** the muzzle. [INTRANSITIVE, COMMA]

When a comprehender reads the underlined phrase "the vet with his new assistant" in (3-a), she may at first believe that this phrase is the direct object of the verb "scratched" inside the subordinate clause. However, upon reaching the verb "took off", she realizes that the underlined phrase was not in fact an object of the verb "scratched", rather it was the subject of a new clause, and the subordinate clause in fact ended after the verb "scratched". The key region of the sentence where the garden path disambiguation happens—called the **disambiguator**—is the phrase "took off", marked in bold.

While a garden path should obtain in (3-a), no such garden path should exist for (3-b), because a comma clearly demarcates the end of the subordinate clause. Therefore a basic garden path effect would be indicated by the difference in surprisal at the disambiguator for (3-a) minus (3-b). Furthermore, if a comprehender is sensitive to the relationship between verb argument structure and clause boundaries, then there should be no garden path in (3-c), because the verb "struggled" is INTRANSITIVE: it cannot take an object in English, so an incremental parser should never be misled into believing that "the vet..." is its object. This lexical information about syntactic structure is subtle enough that there has been controversy about whether even humans are sensitive to it in online processing (Staub, 2007).

4.1.1 NP/Z Garden Path Effect

We tested whether neural language models would show the basic garden path effect and if this ef-

---

[2] For Noun Phrase/Zero ambiguity. At first the embedded verb appears to take an NP object, but later it turns out that it was a zero (null) object.

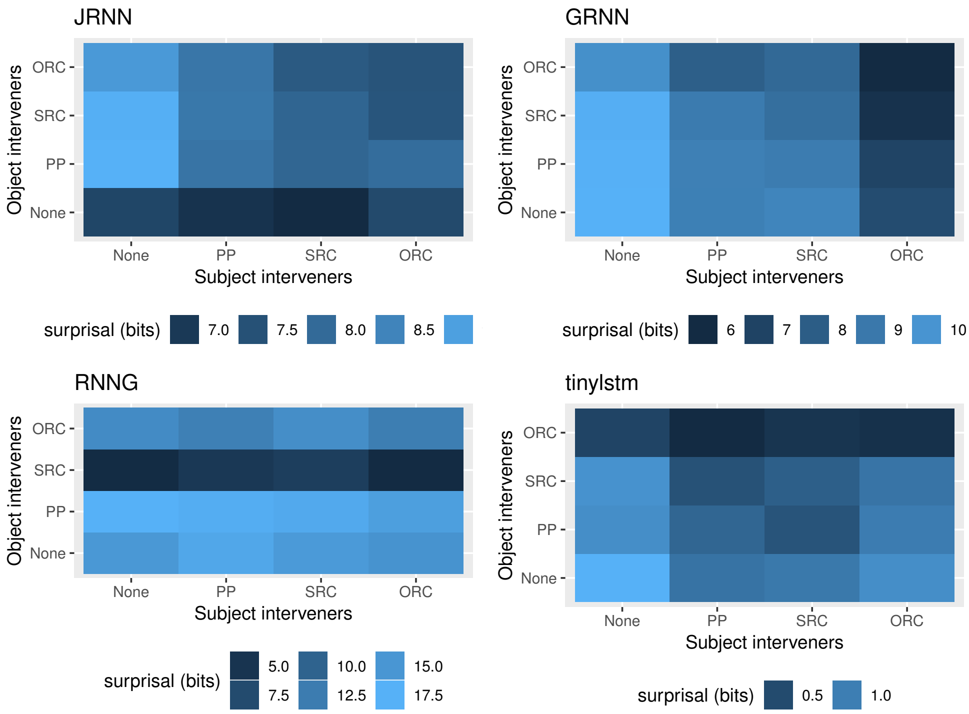

Figure 3: Size of matrix clause licensing interaction (see text) given various intervening elements in the subordinate clause. Note that the heatmaps are on different scales across models.

fect would be modulated by verb transitivity. We constructed 32 items based of the same structure as (3), based on materials from Staub (2007), manipulating the transitivity of the embedded verb ("scratched" vs. "struggled"), and the presence of a disambiguating comma at the end of the subordinate clause. An NP/Z garden path effect would show up as increased surprisal at the main verb "took off" in the absence of a comma. If the networks use the transitivity of the embedded verb as a cue to clause structure, and maintain that information over the span of six words between the embedded verb and the main verb, then there should be a garden path effect for the transitive verb, but not for the intransitive verb. More generally we would expect a *stronger* garden path given the transitive verb than given the intransitive verb.

Figure 4 shows the mean surprisals at the disambiguator for all four models, for both transitive and intransitive embedded verbs. The overall per-region surprisals, averaged over words in each region, are shown in Figure 5. We see that a garden path effect exists in all models (though very small in TinyLSTM): all models show significantly higher surprisal at the main verb when the disambiguating comma is absent ($p < .001$ for all models). However, only the large LSTMs appear to be sensitive to the transitivity of the embedded verb, showing a smaller garden path effect for intransitive verbs. Statistically, there is a significant interaction of comma presence and verb transitivity only in GRNN and JRNN (GRNN: $p < .01$; JRNN: $p < .001$; RNNG: $p = .3$, TinyLSTM: $p = .3$).

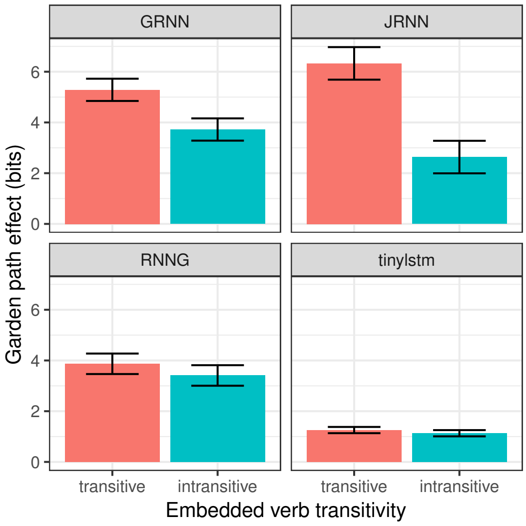

Figure 4: Average garden path effect (surprisal at disambiguator in NO-COMMA condition minus COMMA condition) by model and embedded verb transitivity.

All models show NP/Z garden path effects, indicating that they are sensitive to some cues indicat-

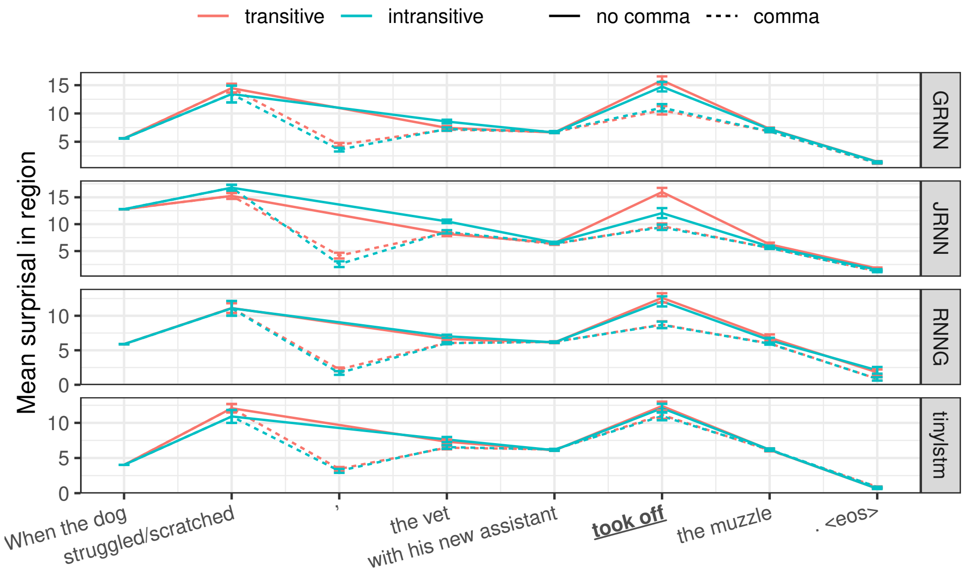

Figure 5: Region-by-region surprisal values for NP/Z garden path materials. Surprisal values are averaged across items and across words in regions. The critical region where the garden path effect is visible is the verb "took off".

ing end-of-clause boundaries. However, only the large LSTMs appear to use verb argument structure information as a cue to these boundaries. The results suggest that very large amounts of data may be necessary for current neural models to discover such fine-grained dependencies between syntactic properties of verbs and sentence structure.

4.1.2 Maintenance and degradation of state

We can probe the maintenance and degradation of syntactic state information by manipulating the length of the intervening material between the onset of the local ambiguity and the disambiguator in examples such as (3). The question is whether the networks maintain the knowledge, while processing the intervening material, that the intervening noun phrase is probably the object of the embedded verb inside a subordinate clause, or whether they gradually lose track of this information. To study this question we used materials on the pattern of (4): these materials manipulate the length of the intervening material (underlined) while holding constant the distance between the subordinator ("As") and the disambiguator (**grew**).

(4)a. As the author studying Babylon in ancient times wrote the book **grew**. [SHORT, NO-COMMA]

b. As the author studying Babylon in ancient times wrote, the book **grew**. [SHORT, COMMA]

c. As the author wrote the book describing Babylon in ancient times **grew**. [LONG, NO-COMMA]

d. As the author wrote, the book describing Babylon in ancient times **grew**. [LONG, COMMA]

If neural language models show degradation of syntactic state, then the garden path effect (measured as the difference in surprisal between the COMMA and NO-COMMA conditions at the disambiguator) will be smaller for the LONG conditions. We tested 32 sentences of the form in (4), based on materials from Tabor and Hutchins (2004). The garden path effect sizes are shown in Figure 6.

We find a significant garden effect in all models in the SHORT condition ($p < .001$ in JRNN and GRNN; $p < .01$ in the RNNG and $p = .03$ in TinyLSTM). In the long condition, we find the garden path effect in all models except TinyLSTM: ($p < .001$ in JRNN; $p < .01$ in GRNN; $p = .02$ in the RNNG; and $p = .2$ in TinyLSTM). The crucial interaction between length and comma presence (indicating that syntactic state degrades) is significant in GRNN ($p < .01$) and TinyLSTM ($p < .001$) but not JRNN ($p = .7$) nor the RNNG ($p = .6$). The pattern is reminiscent of the results on degradation of state information about subordinate clauses in Section 3, where GRNN and TinyLSTM showed the clearest evidence of degradation.

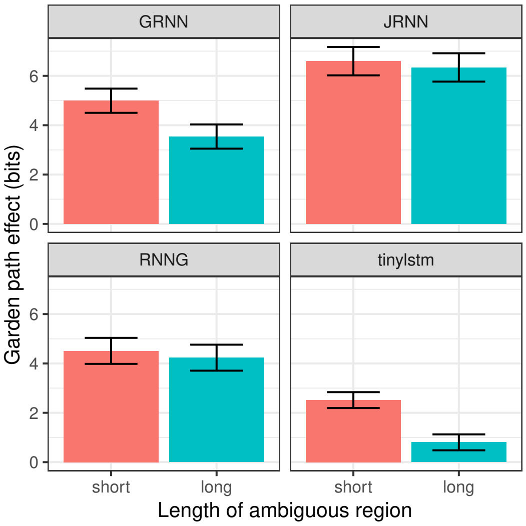

Figure 6: Average garden path effect by model and length of ambiguous region.

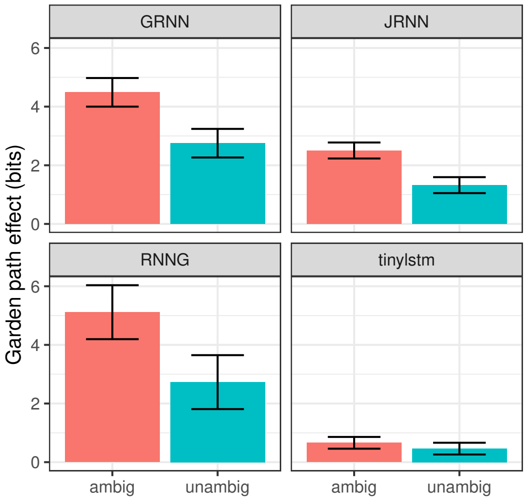

Figure 7: Garden path effect size for MV/RR ambiguity by model and verb-form ambiguity.

Note that the pattern found here is the opposite of the pattern of human reading times. Humans appear to show "digging-in" effects: the longer the span of time between the introduction of a local ambiguity and its resolution, the larger the garden path effect (Tabor and Hutchins, 2004; Levy et al., 2009).

4.2 Main Verb/Reduced Relative Ambiguity

Next we turn to garden path effects induced by the classic **Main Verb/Reduced Relative (MV/RR) ambiguity**, in which a word is locally ambiguous between being the main verb of a sentence or introducing a **reduced relative clause** (reduced RC: a relative clause with no explicit complementizer, headed by a passive-participle verb). That ambiguity can be maintained over a long stretch of material:

(5)a. The woman brought the sandwich from the kitchen **tripped** on the carpet. [REDUCED, AMBIGuous]
b. The woman who was brought the sandwich from the kitchen **tripped** on the carpet. [UNREDUCED, AMBIG]
c. The woman given the sandwich from the kitchen **tripped** on the carpet. [REDUCED, UNAMBIGuous]
d. The woman who was given the sandwich from the kitchen **tripped** on the carpet. [UNREDUCED, UNAMBIG]

In Example (5-a), the verb "brought" is initially analyzed as a main verb phrase, but upon reaching the verb "tripped"—the disambiguator in this case—the reader must re-analyze it as an RC. The garden path should be eliminated in sentences such as (5-b), the UNREDUCED condition, where the words "who was" clarify that the verb "brought" is part of an RC, rather than the main verb of the sentence. Therefore we quantify the garden path effect as the surprisal at the disambiguator for the REDUCED minus UNREDUCED conditions.

There is another possible cue that the initial verb is the head of an RC: the morphological form of the verb. In examples such as (5-c), the the verb "given" is unambiguously in its past-participle form, indicating that it cannot be the main verb of the sentence. If a language model is sensitive to morphological cues to syntactic structure, then it should either not show a garden path effect in this UNAMBIGuous condition, or it should show a reduced garden path effect.

We constructed 29 experimental items following the template of (5). Figure 7 shows the garden path effect sizes by model and verb-form ambiguity. All networks show the basic garden path effect ($p < .001$ in JRNN, GRNN, and RNNG; $p < 0.01$ in TinyLSTM). However, the garden path effect in TinyLSTM is much smaller than the other models: RC reduction causes an additional .3 bits of surprisal at the disambiguating verb, as compared to 2.8 bits in the RNNG, 1.9 in JRNN, and 3.6 in GRNN (TinyLSTM's garden path effect is significantly smaller than each other model at $p < 0.001$).

If the network is using the morphological form

Phenomenon	GRNN	JRNN	RNNG	TinyLSTM
Subordination	✓✓	✓✗	✓✓	✓✗
NP/Z Garden Path	✓✓	✓✓	✓✗	✓✗
MV/RR Garden Path	✓✓	✓✓	✓✓	✓✗

Table 2: Summary of results by model and phenomenon. The first check mark indicates basic evidence of syntactic state representation. The second check mark indicates the ability to capture more fine-grained phenomena: for subordination, the no-matrix penalty effect; for the NP/Z garden path, the effect of verb transitivity; and for the MV/RR garden path, the effect of verb morphology.

of the verb as a cue to syntactic structure, then it should show the garden path effect more strongly in the AMBIG condition than the UNAMBIG condition. The large language models and the RNNG do show this pattern: at the critical main-clause verb, surprisal is superadditively highest in the reduced ambiguous condition (the dotted blue line; a positive interaction between the reduced and ambiguous conditions is significant in the three models at $p < 0.001$). However, TinyLSTM does not show evidence for superadditive surprisal for the ambiguous verbform and the reduced RC ($p = .45$).

The three large LSTMs and the RNNG replicate the key human-like garden-path disambiguation effect due to to ambiguity in verb form. But strikingly, even when the participial verbform is unambiguous, there is still a significant garden path effect in all models ($p < 0.01$ in all models except TinyLSTM, where $p = .08$). Apparently, these networks treat an unambiguous passive-participial verb as only a *noisy cue* to the presence of an RC.

5 General Discussion and Conclusion

In all models studied, we found clear evidence of basic incremental state syntactic representation. However, models varied in how well they fully captured the effects of such state and the potentially subtle lexical cues indicating the beginnings and endings of such states: only the large LSTMs could sometimes reliably infer clause boundaries from verb argument structure (Section 4.1) and morphological verb-form (Section 4.2), and only GRNN and the RNNG fully captured the proper behavior of subordinate clauses. The results are summarized in Table 2. We suggest that representation of course-grained syntactic structure requires either syntactic supervision or large data, while exploiting fine-grained lexical cues to structure requires large data.

More generally, we believe that the psycholinguistic methodology employed in this paper provides a valuable lens on the internal representations of black-box systems, and can form the basis for more systematic tests of the linguistic competence of NLP systems. We make all experimental items, results, and analysis scripts available online at `github.com/langprocgroup/nn_syntactic_state`.

Abstract

Electroencephalography (EEG) recordings of brain activity taken while participants read or listen to language are widely used within the cognitive neuroscience and psycholinguistics communities as a tool to study language comprehension. Several time-locked stereotyped EEG responses to word-presentations – known collectively as event-related potentials (ERPs) – are thought to be markers for semantic or syntactic processes that take place during comprehension. However, the characterization of each individual ERP in terms of what features of a stream of language trigger the response remains controversial. Improving this characterization would make ERPs a more useful tool for studying language comprehension. We take a step towards better understanding the ERPs by fine-tuning a language model to predict them. This new approach to analysis shows for the first time that all of the ERPs are predictable from embeddings of a stream of language. Prior work has only found two of the ERPs to be predictable. In addition to this analysis, we examine which ERPs benefit from sharing parameters during joint training. We find that two pairs of ERPs previously identified in the literature as being related to each other benefit from joint training, while several other pairs of ERPs that benefit from joint training are suggestive of potential relationships. Extensions of this analysis that further examine what kinds of information in the model embeddings relate to each ERP have the potential to elucidate the processes involved in human language comprehension.

1 Introduction

The cognitive processes involved in human language comprehension are complex and only partially identified. According to the dual-stream model of speech comprehension (Hickok and Poeppel, 2007), sound waves are first converted to phoneme-like features and further processed by a ventral stream that maps those features onto words and semantic structures, and a dorsal stream that (among other things) supports audio-short term memory. The mapping of words onto meaning is thought to be subserved by widely distributed regions of the brain that specialize in particular modalities — for example visual aspects of the

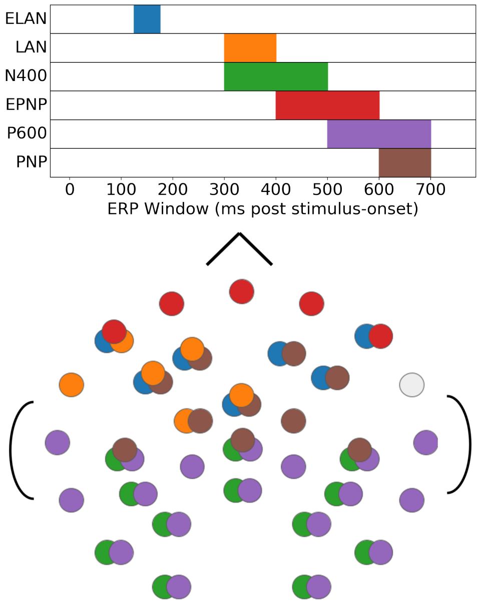

Figure 1: The electrodes from which each event-related potential was recorded in the data from Frank et al. (2015) (after figure 3 in (Frank et al., 2015)). The bottom portion of the figure shows a top-down schematic of the electrode locations with the nose facing towards the top of the page. Each ERP is the mean potential from all of the indicated electrodes during a specific time-window, creating a single scalar value per ERP per word. Overlapping circles indicate multiple ERPs recorded from the same electrode. The ELAN is measured from 125-175ms after stimulus onset, the LAN from 300-400ms, the N400 from 300ms-500ms, the EPNP from 400-600ms, the P600 from 500-700ms, and the PNP from 600-700ms.

Proceedings of NAACL-HLT 2019, pages 43–57

word *banana* reside in the occipital lobe of the brain and are activated when the word *banana* is heard (Kemmerer, 2014) — and the different representation modalities are thought to be integrated into a single coherent latent representation in the anterior temporal lobe (Ralph et al., 2010). While this part of meaning representation in human language comprehension is somewhat understood, much less is known about how the meanings of words are integrated together to form the meaning of sentences and discourses. One tool researchers use to study the integration of meaning across words is electroencephelography (EEG), which measures the electrical activity of large numbers of neurons acting in concert. EEG has the temporal resolution necessary to study the processes involved in meaning integration, and certain stereotyped electrical responses to word presentations, known as event-related potentials (ERPs), have been identified with some of the processes thought to contribute to comprehension.

In this work, we consider six ERP components that have been associated in the cognitive neuroscience and psycholinguistics literature with language processing and which we analyze in the data from Frank et al. (2015) (see Figure 1 for spatial and temporal definitions of these ERP components). Three of these — the N400, EPNP, and PNP responses — are primarily considered markers for semantic processing, while the other three — the P600, ELAN, and LAN responses — are primarily considered markers for syntactic processing. However, the neat division of the ERP responses into either semantic or syntactic categories is controversial. The N400 response has been very well studied (for an overview see (Kutas and Federmeier, 2011)) and it is well established that it is associated with semantic complexity, but the features of language that trigger the other ERP responses we consider here are poorly understood. We propose to use a neural network pretrained as a language model to probe what features of language drive these ERP responses, and in turn to probe what features of language mediate the cognitive processes that underlie human language comprehension, and especially the integration of meaning across words.

2 Background

While a full discussion of each ERP component and the features of language thought to trigger each are beyond the scope of this document (for reviews see e.g. Frank et al. (2015), Kemmerer (2014), Kutas and Federmeier (2011), Kuperberg et al. (2003), and Van Petten and Luka (2012)), we introduce some basic features of ERP components to help in the discussion later. ERP components are electrical potential responses measured with respect to a baseline that are triggered by an event (in our case the presentation of a new word to a participant in an experiment). The name of each ERP component reflects whether the potential is positive or negative relative to the baseline. The N400 is so-named because it is **N**egative relative to a baseline (the baseline is typically recorded just before a word is presented at an electrode that is not affected by the ERP response) and because it peaks in magnitude at about **400**ms after a word is presented to a participant in an experiment. The P600 is **P**ositive relative to a baseline and peaks around **600**ms after a word is presented to a participant (though its overall duration is much longer and less specific in time than the N400). The post-N400 positivity is so-named because it is part of a biphasic response; it is a positivity that occurs after the negativity associated with the N400. The early post-N400 positivity (EPNP) is also part of a biphasic response, but the positivity has an eariler onset than the standard PNP. Finally, the LAN and ELAN are the left-anterior negativity and early left-anterior negativity respectively. These are named for their timing, spatial distribution on the scalp, and direction of difference from the baseline. It is important to note that ERP components can potentially cancel and mask each other, and that it is difficult to precisely localize the neural activity that causes the changes in electrical potential at the electrodes where those changes are measured.

3 Related Work

This work is most closely related to the paper from which we get the ERP data: Frank et al. (2015). In that work, the authors relate the surprisal of a word, i.e. the (negative log) probability of the word appearing in its context, to each of the ERP signals we consider here. The authors do not directly train a model to predict ERPs. Instead, models of the probability distribution of each word in context are used to compute a surprisal for each word, which is input into a mixed effects regression along with word frequency, word length, word position in the sentence, and sentence position in the experiment. The effect of the surprisal is assessed using a likelihood-ratio test. In Hale et al. (2018), the authors take an approach similar to Frank et al. (2015). The authors compare the explanatory power of surprisal (as computed by an LSTM or a Recurrent Neural Network Grammar (RNNG) language model) to a measure of syntactic complexity they call "distance" that counts the number of parser actions in the RNNG language model. The authors find that surprisal (as predicted by the RNNG) and distance are both significant factors in a mixed effects regression which predicts the P600, while the surprisal as computed by an LSTM is not. Unlike Frank et al. (2015) and Hale et al. (2018), we do not use a linking function (e.g. surprisal) to relate a language model to ERPs. We thus lose the interpretability provided by the linking function, but we are able to predict a significant proportion of the variance for all of the ERP components, where prior work could not. We interpret our results through characterization of the ERPs in terms of how they relate to each other and to eye-tracking data rather than through a linking function. The authors in Wehbe et al. (2014) also use a recurrent neural network to predict neural activity directly. In that work the authors predict magnetoencephalography (MEG) activity, a close cousin to EEG, recorded while participants read a chapter of *Harry Potter and the Sorcerers Stone* (Rowling, 1999). Their approach to characterization of processing at each MEG sensor location is to determine whether it is best predicted by the context vector of the recurrent network (prior to the current word being processed), the embedding of the current word, or the probability of the current word given the context. In future work we also intend to add these types of studies to the ERP predictions.

4 Method

Data. We use two sources of data for this analysis. The primary dataset we use is the ERP data collected and computed by Frank et al. (2015), and we also use behavioral data (eye-tracking data and self-paced reading times) from Frank et al. (2013) which were collected on the same set of 205 sentences. In brief, the sentences were selected from sources using British English with a criterion that they be understandable out of context. We use the ERP component values as computed by Frank et al. (2015) which have been high-pass filtered at 0.5 Hz to reduce correlation between ERP components and modulus transformed (John and Draper, 1980) to make the distribution of component values more normal. We do not use the 100ms pre-trial baseline which is made available by Frank et al. (2015) and which they use as a separate input to the mixed effects regression. For more information about the ERP datasets and data collection procedures we refer the reader to the original papers. For the behavioral data, we use self-paced reading times and four eye-tracking measures. Self-paced reading time is considered a signal of integration difficulty (i.e. as it becomes more difficult to integrate the meaning of the current word into the context, the amount of time a reader spends on the current word increases). The eye-tracking measures are intended to capture both early effects (effects modulated primarily by properties of the word independent of its context, such as word frequency and word length) and late effects (effects modulated by the context in which the word is found, i.e. comprehension difficulty) in word processing (Rayner and Pollatsek, 2006). In both cases, the eye-tracking measures provide a signal of overt visual attention, which is thought to strongly correlate with covert perceptual attention in normal reading (Rayner, 2009). We log-transform the self-paced reading time and the eye-tracking measures.

Model. To predict the ERP signals in the data, we start with a 3-layer bidirectional LSTM-based language model encoder using the architecture found in Merity et al. (2017) and pretrained on the WikiText-103 dataset (Merity et al., 2016) (we use the pretrained model from Howard and Ruder (2018)). The pretraining objective is to minimize the negative log-likelihood of the next word for the forward LSTM and the previous word for the reverse LSTM. The word-embeddings (input embeddings) in the encoder have 400 components, the hidden layer outputs have 1150 components each, and the context-embeddings output from the encoder have 400 components. The forward-encoder and backward-encoder are independently fine-tuned on the baby version of the British National Corpus (Consortium, 2005) to help with prediction of British English (both the ERP data and eye-tracking data use British English). During task training the two encoders' output embeddings are concatenated together and fed into a causal-convolution layer which combines each pair of adjacent timepoints into a single pair-embedding with 10 components. The causal-convolution (i.e. convolution which is left padded) ensures that the pair-embeddings are aligned so that the prediction targets correspond to the later word in the pair. In other words the pair can be thought of as representing the ‘current’ and ‘previous’ words together. A ReLU is applied to the pair-embedding before it, along with the word length and the log probability of the word, is fed into a linear output layer to predict each ERP and behavioral measure (see Figure 2). The convolution and linear layers are initialized using the default PyTorch (Paszke et al., 2017) initialization, i.e. the initialization proposed in He et al. (2015). The encoder portion of the model includes dropout as applied in Merity et al. (2017), but we use different dropout probabilities when we fit the neural and behavioral data (the dropout probability on the input embeddings was 0.05, 0.4 on the input to the LSTM, 0.4 on LSTM hidden layers, 0.5 on the output of the LSTM, and 0.5 on the recurrent weights). We did not find dropout in the decoder to be helpful. We use the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.95, \beta_2 = 0.999$ for training and we use mean squared error as the loss.

Procedure. We begin our training procedure by fine-tuning the forward- and backward-encoders independently on the baby version of the British National Corpus (Consortium, 2005). This corpus has British English that may help in modeling the University College London corpus, while not overlapping with it.

After the model fine-tuning, we estimate how well the model predicts each of the ERP signals and eye-tracking measures by training the model 100 times with different train/test splits and decoder parameter initializations. We use 10% of the data for testing and the remainder for training. The sentences in the ERP data are split at random. After we split the data, we compute the mean and standard deviation of each ERP signal (and each eye-tracking measure and the self-paced reading time) within participant on the training data. We use these values to standardize the training data within participant, and then average the data from all of the participants together. After we average, we again compute the mean and standard deviation to standardize the average. We follow a similar procedure for the test data, but we use the mean and standard deviation from the training data when standardizing. Note that we use the log of the behavior measures, and the log is taken before the data-standardization.

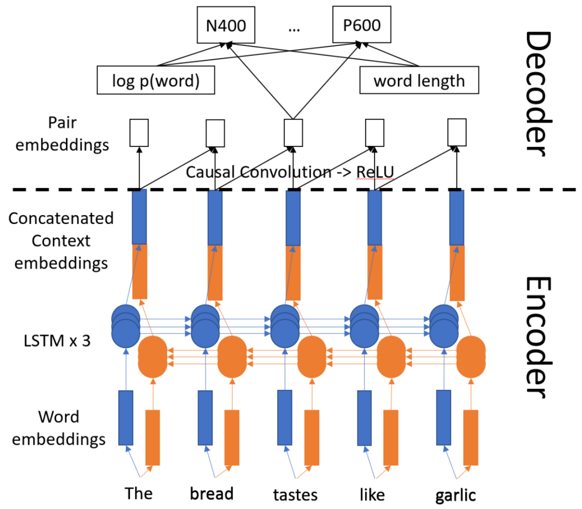

Figure 2: The model uses an encoder based on the architecture and regularization in Merity et al. (2017) and pretrained by Howard and Ruder (2018). Within this architecture 2 independent 3-layer LSTM models encode a sentence. The context-embeddings output from each encoder are then concatenated together to give a single representation to each word in the sentence. These concatenated context-embeddings are fed into a causal-convolution, which learns a function to combine each pair of context-representations into a pair-embedding. A rectified linear unit (ReLU) non-linearity is applied to the pair-embedding, after which independent linear layers map the pair-embedding along with the log-probability of a word and the word-length to a prediction of each ERP or behavioral signal.

In the loss function (and when we evaluate model performance) we only consider content words. We mark as a content word any word that is an adjective, adverb, auxiliary verb, noun, pronoun, proper noun, or verb (including to-be verbs). All other words are considered function words.

During the first 20 epochs of training, only the parameters of the decoder are modified. Following this, we train the model for an additional 15 epochs during which the parameters of the decoder and the final layer of the encoder (the final LSTM layer in both the forward and backward encoder) can be modified. We also experimented with additional training epochs and allowing all parameters of the model to be modified, but we found that this caused overfitting.

Comparing models trained with different loss functions. To better understand the relationship between ERP signals, and between ERP signals and behavioral data, we train the model with different loss functions that include mean squared error terms corresponding to various combinations of the ERP signals and behavioral data. For example, one of the training variations includes a mean squared error term for the P600 and a mean squared error term for the N400 in the loss, but does not use the other signals during training. In this variation, for a mini-batch of size B, where example b has T_b content tokens and the superscripts p and a denote the predicted and actual values for a measure respectively, the loss function can be written as:

$$\frac{1}{\sum_{b=1}^{B} T_b} \sum_{b=1}^{B} \sum_{t=1}^{T_b} (\mathrm{P600}_{b,t}^{p} - \mathrm{P600}_{b,t}^{a})^2 + (\mathrm{N400}_{b,t}^{p} - \mathrm{N400}_{b,t}^{a})^2 \tag{1}$$

For each of the training variations, we repeat the training procedure described above (but fine-tuning the language model on the British National Corpus is done only once). We use a consistent train/test split procedure, such that the split for the ith run of the 100 runs is the same across all training variations, but the split changes between run i and run j. This enables us to use paired statistical testing when we test for significance.

We test for whether the proportion of variance explained (computed as $1 - \frac{\text{MSE}}{\text{variance}}$ on the validation set) on each ERP and behavioral measure is significantly different from 0 using the single sample t-test controlled for false discovery rate using the Benjamini-Hochberg-Yekutieli procedure (Benjamini and Yekutieli, 2001) with a false discovery rate of 0.01.

To test whether the proportion of variance explained is different between different training variations (for example training with just the N400 signal included in the loss vs. training with both the N400 and the LAN included in the loss), we use a paired t-test. We then adjust for the false discovery rate again with a rate of 0.01.

5 Results

All ERP components are predictable. In the original study on this dataset, the investigators found that when surprisal was used as a linking function between the language model and the mixed effects regression, the only ERP for which the surprisal showed a significant effect in the regression was the N400 (Frank et al., 2015). In contrast, we find that when we directly predict the ERP signals we are able to predict a significant proportion of the variance for all of them (see Table 1).

Joint training benefits ERP component prediction. To explore the relationship between ERP components, we train $63 = \binom{6}{1} + \binom{6}{2} + \cdots + \binom{6}{6}$ different models using all of the possible combinations of which of the six ERP signals are included in the loss function during training. For each of the six ERP components, we look for the best performing models (see Table 1). The N400 is best predicted when the model is trained on that component independently, but every other ERP component prediction can be improved by including a second ERP component in the training. Thus multitask learning has a clear benefit when applied to the ERP data and some information is shared between ERP component predictions via the model parameters. We also note that it is not the case that training with more ERP components is always better, or that the signals which are most correlated benefit each other most (see Appendix A). The relationship between components clearly impacts whether the prediction of one ERP component benefits from the inclusion of others in model training. The results suggest that 8 pairs of ERP signals are related to each other: the LAN is paired with the P600, EPNP, and PNP, the ELAN with the N400, EPNP, PNP, and P600, and the EPNP is paired with the P600. We discuss these relationships in the Discussion section.

In an additional analysis, we modified our training procedure slightly to probe how jointly training on multiple ERP components compares to training individually on each ERP component. In this analysis we compare only training on each ERP component individually to training on all six ERP components together. We also train for a total of 60 epochs (rather than the 35 epochs used elsewhere). During the first 20 epochs we allow only the parameters of the decoder to be modified. During the next 20 epochs, we allow the parameters of the decoder and the final layer of the encoder (i.e. the final recurrent layer) to be modified. During the last 20 epochs, we allow all of the parameters of the model to be modified. The mean squared error for each of the ERP components from this anal-

Target	Additional	POVE	Target	Additional	POVE	Target	Additional	POVE
ELAN		0.20	LAN		0.30	N400		0.26

Table 1: Proportion of variance explained (POVE) for each of the ERP components (mean of 100 training runs). The second column in each cell shows which ERP components in addition to the target ERP component were included in training. All combinations of training signals were explored. Shown is the best combination for each ERP target as well as every combination which is (i) significantly different from training on the target component alone, (ii) not significantly different from the best training combination, and (iii) uses no more than the number of signals used by the best combination. The N400 is predicted best when only the N400 signal is included in training. All values are significantly different from 0. GROUP A refers to (PNP, ELAN, LAN, P600) and GROUP B refers to (EPNP, ELAN, LAN, P600).

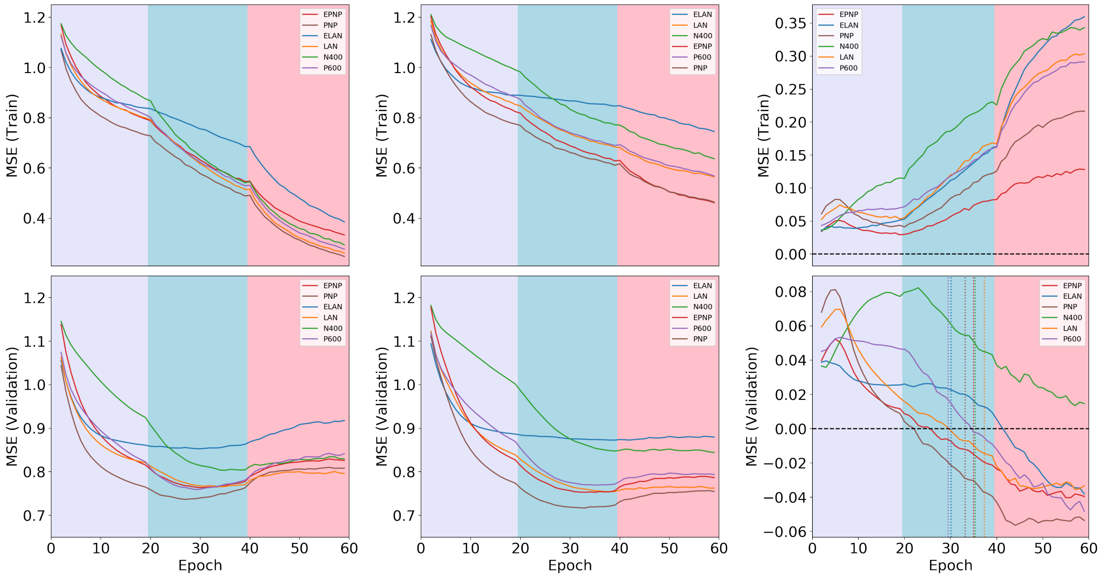
ysis is shown for each epoch in Figure 3. From the loss curves, we make a few observations. First, we see inflection points at epochs 20 and 40, when we allow more parameters of the model to be modified. The first inflection point indicates that allowing the recurrent layer to be modified benefits the prediction, while the second inflection point shows that overfitting becomes more severe if we allow all parameters of the model to be modified. We also see from these curves that part of the benefit of joint training is that it helps reduce overfitting – we see less of a climb in the validation loss after the minimum point in the joint training. Beyond this reduction in overfitting severity, we note that for some of the ERP components (the LAN, EPNP and PNP components) joint training actually gives a better overall minimum in prediction error.

Behavioral data benefits the prediction of ERP components. We are also interested in whether behavioral data can be used to improve ERP prediction since it should signal both the amount of overt attention required at various points in a sentence as well as integration difficulty. To study this question, we again train models using different combinations of training signals that include or do not include the behavioral data predictions in the loss function (see Table 2). We see that self-paced reading time indeed can improve prediction of a target ERP component relative to training on the target ERP component alone by about the same amount as the best combination of ERP components for all but the N400. Eye-tracking data can also improve the prediction accuracy of the ELAN, P600, and PNP components.

Insensitivity to choice of architecture. One potential concern about our results is the degree to which the relationships we see between ERP components and between ERP components and behavioral data is an artefact of our rather arbitrary choice of network architecture. We partially address this by running the same analysis using (i) only the forward direction of the encoder, and (ii) only the word-embeddings (the input embeddings) and not the context-embeddings (the output embeddings) of the encoder. The proportion of variance explained for each ERP component is lower using these variants of the analysis than using the bidirectional variant (see Appendix A), but qualitatively the relationships are similar. We leave further analysis of the sensitivity of our qualitative results to choice of architecture for future work.

6 Discussion

In this work we find that all six of the ERP components from Frank et al. (2015) can be predicted above chance by a model which has been pretrained using a language modeling objective and then directly trained to predict the components. This is in contrast to prior work which has successfully linked language models to the N400 (Frank et al., 2015) and P600 (Hale et al., 2018) but not the other ERP components. We also note that con-



(a) Independently trained (b) Jointly trained (c) Joint - Indep.

Figure 3: The mean squared error (MSE) for prediction of each of the ERP signals during each epoch of training (mean of 100 training runs). The first 2 epochs have been omitted for clarity. During the first 20 epochs (lavender background), only the decoder parameters are modified. During the next 20 epochs (light blue background), the parameters in the final layer of the encoder are also modified. During the last 20 epochs (pink background), all of the parameters are modified. Note that in this model architecture, information can be shared between ERP signals even when only the decoder is modified. The figure shows the MSE when separate models are trained for each ERP independently (a), the MSE when a single model is trained on all ERPs jointly (b), and the difference between these two scenarios (c). The top row in each column shows the MSE on the training data while the bottom row shows the MSE on the validation data. In the bottom row right, the dotted vertical lines indicate the epoch at which the minimum MSE is reached in the lower of the independent or joint training. The LAN, EPNP, and PNP all show modest benefits from joint training before overfitting sets in (the minimum value occurs in the joint training scenario), while all ERP signals other than the N400 show reduced overfitting in joint training.

Target	Additional	POVE	Target	Additional	POVE	Target	Additional	POVE
ELAN		0.20	LAN		0.30	N400		0.26
ELAN	+ ERP	**0.22**	LAN	+ ERP	**0.33**	N400	+ ERP	0.26
ELAN	+ READ	**0.22**	LAN	+ READ	**0.31**	N400	+ READ	0.27
ELAN	+ EYE	**0.22**	LAN	+ EYE	0.30	N400	+ EYE	0.25
EPNP		0.34	P600		0.27	PNP		0.33
EPNP	+ ERP	**0.36**	P600	+ ERP	**0.30**	PNP	+ ERP	**0.36**
EPNP	+ READ	**0.35**	P600	+ READ	**0.29**	PNP	+ READ	**0.34**
EPNP	+ EYE	0.34	P600	+ EYE	**0.29**	PNP	+ EYE	**0.34**

Table 2: Proportion of variance explained (POVE) for each of the ERP components (mean of 100 training runs). +ERP indicates the best combination of ERP training signals for the target ERP component, + READ indicates the inclusion of self-paced reading times, +EYE indicates the inclusion of eye-tracking data, and bold font indicates a significant difference from training on the target component alone.

trary to Hale et al. (2018), we find that an LSTM does contain information that can be used to predict EEG data, and in particular that it can predict the P600. We speculate that the analysis used in Hale et al. (2018) did not find reliable effects because the language models were related to the EEG data through functions chosen a priori (the surprisal, and the 'distance' metric). These functions, though interpretable, might be interpretable at the cost of losing much of the information in the representations learned by the network.

In addition, we show through our multitask learning analysis that information is shared between ERP components, and between ERP components and behavioral data. Although these relationships must be viewed with caution until they can be verified across multiple datasets and with more variation in neural network architectures, here we consider some potential reasons for our findings. The broad point we wish to make is that by better understanding which ERP components share information with each other and with behavioral data through the type of analysis we present here (multitask learning) or other means, we can better understand what drives each ERP component and in turn the processes involved in human language comprehension.

Relationship between ERPs. Our findings that the LAN and P600 are related, and that the ELAN and P600 are related are expected from both a theoretical perspective and from previous work examining the interactions of ERP components (Gunter et al., 1997; Hagoort et al., 2003a; Hahne and Friederici, 1999; Kutas et al., 2006; Palolahti et al., 2005). Since the ELAN and LAN have been theorized by some to mark word-category (i.e. part-of-speech) or morpho-syntactic (e.g. subject-verb number agreement) violations (Friederici, 2011; Hahne and Friederici, 2002; Hagoort et al., 2003b) and the P600 is considered a marker for syntactic effort (Coulson et al., 1998; Huettig, 2015; Kemmerer, 2014; Kuperberg, 2007; Kuperberg et al., 2003; Van Petten and Luka, 2012), these signals would naturally be related to each other.

The other relationships we find are more surprising. Some researchers have speculated that the LAN and ELAN are markers for working memory demands (King and Kutas, 1995; Kutas et al., 2006), and that indeed these might be part of sustained negativities that are frequently masked by the P600 (Kemmerer, 2014). If we take this view, then we would expect to find them in the presence of semantic and syntactic complexity, and this might explain why they seem to benefit from joint training with the other ERP component signals (and benefit prediction of other ERP signals with which they are trained). However, it is notable that predictions of the LAN and ELAN do not benefit each other in our analysis, and that the N400 (a marker for semantic complexity) is not benefited by the prediction of any other ERP component. This absence is by no means definitive, but it undermines the argument that all of these relationships can be explained by complexity and working memory demands alone.

The relative isolation of the N400 from other ERP components in our analysis is interesting. If the N400 is a marker for semantic memory retrieval (Kutas and Federmeier, 2011), then it might be expected to be somewhat isolated from the other components, which may involve syntactic processing or later integration effects.

Alternatively, the relationships we find in our analysis might be an artefact of the way the ERPs are operationalized in Frank et al. (2015). Several of the pairings we find overlap spatially and are near to each other in time, so the ERP components might spill over into each other. Further work is required to disambiguate between these possibilities.

Relationship between behavioral data and ERPs. It is reassuring to see that jointly training models to predict behavioral data along with a target ERP component benefits the prediction of the ERP component compared to training on the target ERP component alone. The benefit to prediction in this case cannot be explained as an artefact of how the ERP components are operationalized in the datasetes we use for analysis.

Self-paced reading times widely benefit ERP prediction, while eye-tracking data seems to have more limited benefit to just the ELAN, LAN, and PNP ERP components. It's difficult to know why this might be the case, but perhaps it is not a coincidence that these three ERP components also show up frequently in the pairs of components that benefit from joint training. If indeed the PNP marks semantic role irregularities (Van Petten and Luka, 2012) and the ELAN and LAN mark working memory or look-forward or look-back operations (Kutas et al., 2006), then its possible that eye-movements might be more related to these types of operations than to general semantic and syntactic complexities marked by other ERP components. Self-paced reading might better capture these generic difficulties. This explanation is highly speculative, and further work is required to determine whether the relationships between the ERP components and behavioral data are consistent across datasets, and if so, what the explanation is for these relationships.

Choice of bidirectional architecture. We emphasize that the neural network architecture we chose for these analyses was motivated primarily by its success on downstream NLP tasks, public availability of pre-trained models and code, and prior work studying how best to fine-tune the model (Howard and Ruder, 2018; Merity et al., 2017). We do not claim that this architecture reflects human processing. We experimented with a forward-only model variant of our analysis, and found that the bidirectional model predicts brain activity better than the forward-only version (see Appendix A). Although the bidirectional model has access to 'future' language input, it does not have access to future brain-activity, so the bidirectional model is not 'cheating' when it makes predictions. There are at least three possible explanations for why the bidirectional model performs better than the forward-only model. First, it is possible that when a human reads a sentence, he or she predicts the upcoming language input. Under this hypothesis, a model with access to the future language input can do a better job of predicting the current brain activity because the future language is reflected in that brain activity. Second, it is possible that a bidirectional model is simply able to produce better embeddings for each word in the input because it has more context than a forward-only model. For example, the bidirectional model might be (implicitly) better at anaphora resolution given more context. Under this hypothesis, the additional context given to the model partially compensates for its relative deficit of real-world knowledge compared to a human. Where a human can in many cases solve the anaphora resolution problem by using background knowledge and does not need to see the future language input, a model benefits from additional context. Finally, in our setup, the bidirectional model has more parameters than the forward-only model, and the additional degrees of freedom might give the model an advantage in predicting brain activity. Exploration of why the bidirectional model is better than the forward-only model is an interesting question, but it is left to future work. Additionally, as we noted earlier, the qualitative results of our analysis (e.g. how ERP components relate to each other) should be viewed with caution until they are replicated across multiple choices of architecture.

7 Conclusion

We have shown that ERP components can be predicted from neural networks pretrained as language models and fine-tuned to directly predict those components. To the best of our knowledge, prior work has not successfully used statistical models to predict all of these components. Furthermore, we have shown that multitask learning benefits the prediction of ERP components and can suggest how components relate to each other. At present, these joint-training benefit relationships are only suggestive, but if these relationships ultimately lead to insights about what drives each ERP component, then the components become more useful tools for studying human language comprehension. By using multitask learning as a method of characterization, we have found some expected relationships (LAN+P600 and ELAN+P600) and several more surprising relationships. We believe that this is exactly the kind of finding that makes multitask learning an interesting exploratory technique in this area. Additionally, we have shown that information can be shared between heterogeneous types of data (eye-tracking, self-paced reading, and ERP components) in the domain of human language processing prediction, and in particular between behavioral and neural data. Given the small datasets associated with human language processing, using heterogeneous data is a potentially major advantage of a multitask approach. In future work, we will further explore what information is encoded into the model representations when neural and behavioral data are used to train neural networks, and how these representations differ from the representations in a model trained on language alone.

A Appendix

Here we present a visualization (Figure 4) of the results presented in Table 1 of the main paper, and a visualization (Figure 5) of a more complete set of results from which the information in Table 2 of the main paper is drawn. We also show supplemental results for variants of our primary analysis on multitask learning with eye-tracking, self-paced reading time and ERP data. In the variants we modify the input representation to our decoder network to see whether the relationships between the behavioral data and neural activity appear to be consistent with different choices of encoder architectures. Additional (and more varied) choices or architectures are left to future work. The results in Table 3 reflect using only the forward-encoder (rather than the bi-LSTM) in the encoder network, while the results in Table 4 reflect using only the word embeddings (i.e. bypassing the LSTM entirely). While the results are clearly worse for each of these choices of architecture than for using a bi-LSTM encoder, the relationships between the behavioral data and the ERP signals is qualitatively similar. Finally, 5 shows the Pearson correlation coefficient between different measures. We note that the patterns of correlation are different than the patterns of which measures benefit from joint training with each other.

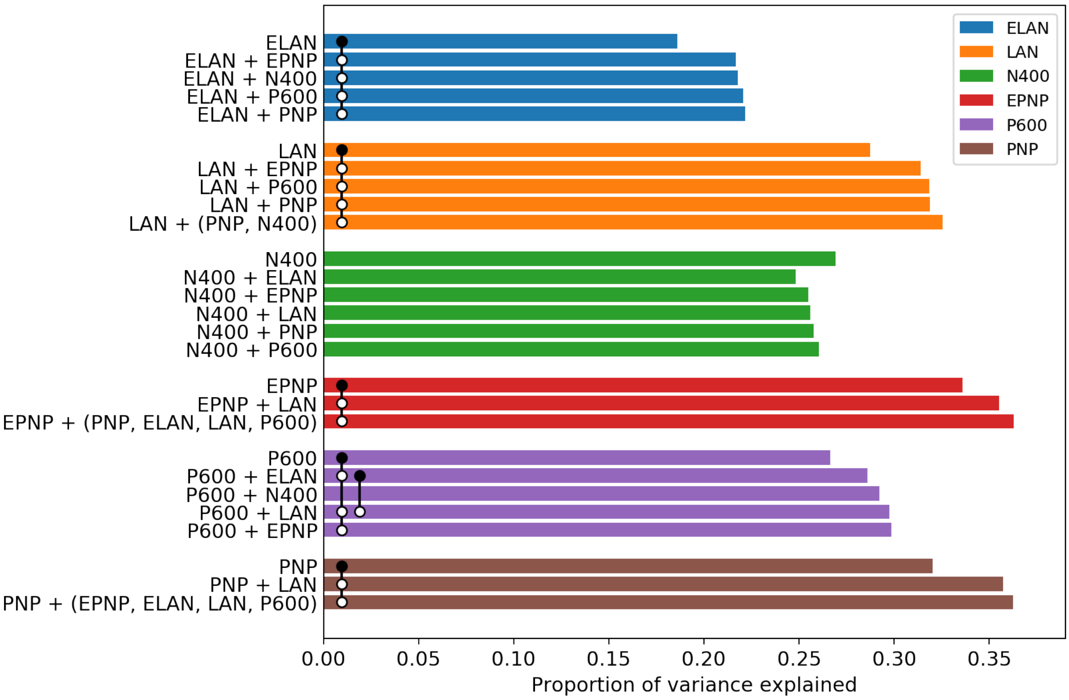

Figure 4: The proportion of variance explained for prediction of each of the ERP signals (mean of 100 training runs). The target ERP is indicated by color; each group of bars shows performance for a different target ERP. The top bar in each group shows the proportion of variance explained when the model is trained using only the target ERP. The bottom bar in each group shows the maximum proportion of variance explained over all combinations of training ERPs (or in the case of the N400, the second best). Also shown in each group are any training combinations that (i) used no more than the number of ERP signals used by the combination that achieved the maximum, and (ii) which were not significantly different from the maximum. Bars are statistically different from each other if a black dot on one bar is connected by a contiguous vertical line to a white dot on the other bar. The bars in the N400 group are not significantly different from each other. The N400 signal is best predicted when the model is trained on just that signal. In every other group, there is at least one ERP that, when combined with the target ERP during training, improves the prediction of the target ERP. The results suggest that these pairs are related: (LAN, P600), (LAN, EPNP), (LAN, PNP), (ELAN, N400), (ELAN, EPNP), (ELAN, PNP), (ELAN, P600), (EPNP, P600).

Target	Additional	POVE	Target	Additional	POVE	Target	Additional	POVE
ELAN		0.20	LAN		0.23	N400		0.20
ELAN	+ERP	**0.22**	LAN	+ ERP	**0.26**	N400	+ ERP	0.20
ELAN	+READ	**0.22**	LAN	+ READ	**0.25**	N400	+ READ	0.20
ELAN	+EYE	0.21	LAN	+ EYE	**0.24**	N400	+ EYE	0.18
EPNP		0.28	P600		0.24	PNP		0.28
EPNP	+ ERP	0.28	P600	+ ERP	**0.25**	PNP	+ ERP	**0.31**
EPNP	+ READ	**0.29**	P600	+ READ	**0.25**	PNP	+ READ	**0.30**
EPNP	+ EYE	0.29	P600	+ EYE	0.24	PNP	+ EYE	0.29

Table 3: Proportion of variance explained for each of the ERP components when using only the forward direction of the encoder (mean of 100 training runs). +ERP indicates the best combination of ERP training signals for the target ERP component, + READ indicates the inclusion of self-paced reading times, +EYE indicates the inclusion of eye-tracking data, and bold font indicates a significant difference from training on the target component alone.

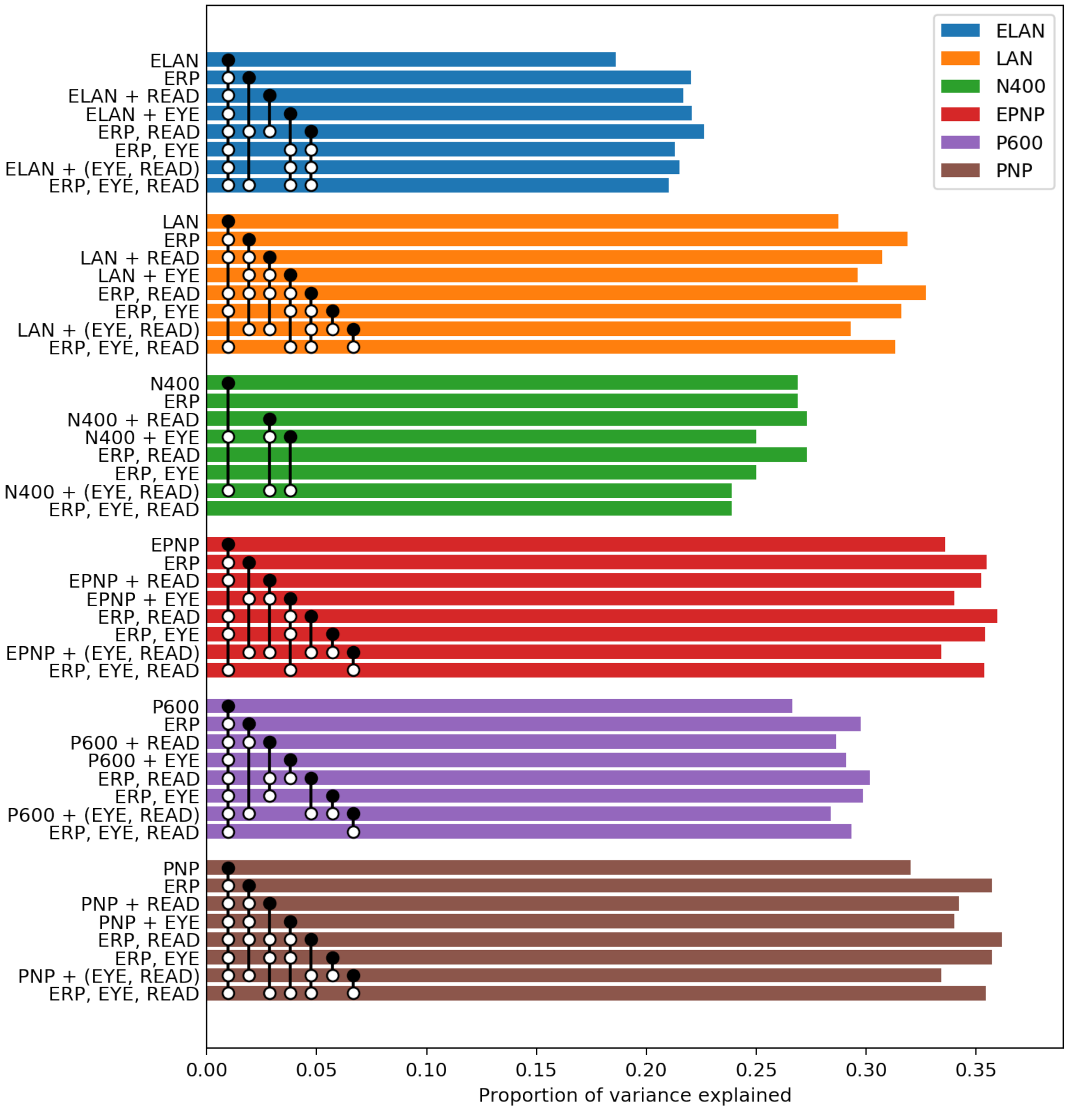

Figure 5: The proportion of variance explained for prediction of each of the ERP signals (mean of 100 training runs). The target ERP is indicated by color; each group of bars shows performance for a different target ERP. The top bar in each group shows the proportion of variance explained when the model is trained using only the target ERP. Moving down, the next bar in each group, labeled *ERP* shows the proportion of variance explained by the best combination of ERP signals for the target ERP. The other bars in each group moving from top to bottom show training variations that use behavioral data with either just the target ERP, or with the best combination of ERP signals. *READ* denotes self-paced reading data, and *EYE* denotes all four eye-tracking measures (in this analysis we use right-bounded pass time, gaze duration, go-past time, and first-fixation duration). Pairs of bars are significantly different from each other (paired t-test, false discovery rate ¡ 0.01) if a black dot on one bar is connected to a white dot on the other bar by a contiguous vertical line. Self-paced reading time benefits prediction of all target ERP components except the N400. In the case of the ELAN, LAN, and PNP, self-paced reading time also has marginal benefit compared to the best combination of ERP training signals. Eye-tracking data benefits prediction of the ELAN, P600, and PNP components.

Table 5: Raw Pearson's correlation coefficients (computed on content words after the standardization and participant-averaging) between each neural and behavioral measure and each other measure. FIX indicates first-fixation time, PASS indicates first-pass time, GO indicates go-past time, RIGHT indicates right-bounded reading time, and READ indicates self-paced reading. Many of the measures are highly correlated, but the pattern of correlations is different from the pattern of benefits that we find during joint-training. In particular we note that the N400 is correlated with the other ERP signals, and yet we do not see benefit in prediction of the N400 when jointly training a model to predict it and other signals.

Pre-training on High-Resource Speech Recognition Improves Low-Resource Speech-to-Text Translation

Abstract

We present a simple approach to improve direct speech-to-text translation (ST) when the source language is low-resource: we pre-train the model on a high-resource automatic speech recognition (ASR) task, and then fine-tune its parameters for ST. We demonstrate that our approach is effective by pre-training on 300 hours of English ASR data to improve Spanish-English ST from 10.8 to 20.2 BLEU when only 20 hours of Spanish-English ST training data are available. Through an ablation study, we find that the pre-trained encoder (acoustic model) accounts for most of the improvement, despite the fact that the shared language in these tasks is the target language text, not the source language audio. Applying this insight, we show that pre-training on ASR helps ST even when the ASR language differs from both source and target ST languages: pre-training on French ASR also improves Spanish-English ST. Finally, we show that the approach improves performance on a true low-resource task: pre-training on a combination of English ASR and French ASR improves Mboshi-French ST, where only 4 hours of data are available, from 3.5 to 7.1 BLEU.

1 Introduction

Speech-to-text Translation (ST) has many potential applications for low-resource languages: for example in language documentation, where the source language is often unwritten or endangered (Besacier et al., 2006; Martin et al., 2015; Adams et al., 2016a,b; Anastasopoulos and Chiang, 2017); or in crisis relief, where emergency workers might need to respond to calls or requests in a foreign language (Munro, 2010). Traditional ST is a pipeline of automatic speech recognition (ASR) and machine translation (MT), and thus requires transcribed source audio to train ASR and parallel text to train MT. These resources are often unavailable for low-resource languages, but for our potential applications, there may be some source language audio paired with target language text translations. In these scenarios, end-to-end ST is appealing.

Recently, Weiss et al. (2017) showed that end-to-end ST can be very effective, achieving an impressive BLEU score of 47.3 on Spanish-English ST. But this result required over 150 hours of translated audio for training, still a substantial resource requirement. By comparison, a similar system trained on only 20 hours of data for the same task achieved a BLEU score of 5.3 (Bansal et al., 2018). Other low-resource systems have similarly low accuracies (Anastasopoulos and Chiang, 2018; Bérard et al., 2018).

To improve end-to-end ST in low-resource settings, we can try to leverage other data resources. For example, if we have transcribed audio in the source language, we can use multi-task learning to improve ST (Anastasopoulos and Chiang, 2018; Weiss et al., 2017; Bérard et al., 2018). But source language transcriptions are unlikely to be available in our scenarios of interest.

Could we improve low-resource ST by leveraging data from a high-resource language? For ASR, training a single model on multiple languages can be effective for all of them (Toshniwal et al., 2018b; Deng et al., 2013). For MT, *transfer learning* (Thrun, 1995) has been very effective: pre-training a model for a high-resource language pair and transferring its parameters to a low-resource language pair when the target language is shared (Zoph et al., 2016; Johnson et al., 2017). Inspired by these successes, we show that low-resource ST can leverage transcribed audio in a high-resource target language, or even a different language altogether, simply by pre-training a model for the high-resource ASR task, and then transferring and fine-tuning some or all of the model's parameters for low-resource ST.

Proceedings of NAACL-HLT 2019, pages 58–68
Minneapolis, Minnesota, June 2 - June 7, 2019.

We first test our approach using Spanish as the source language and English as the target. After training an ASR system on 300 hours of English, fine-tuning on 20 hours of Spanish-English yields a BLEU score of 20.2, compared to only 10.8 for an ST model without ASR pre-training. Analyzing this result, we discover that the main benefit of pre-training arises from the transfer of the *encoder* parameters, which model the input acoustic signal. In fact, this effect is so strong that we also obtain improvements by pre-training on a language that differs from both the source and the target: pre-training on French and fine-tuning on Spanish-English. We hypothesize that pre-training the encoder parameters, even on a different language, allows the model to better learn about linguistically meaningful phonetic variation while normalizing over acoustic variability such as speaker and channel differences. We conclude that the acoustic-phonetic learning problem, rather than translation itself, is one of the main difficulties in low-resource ST. A final set of experiments confirm that ASR pre-training also helps on another language pair where the input is truly low-resource: Mboshi-French.

2 Method

For both ASR and ST, we use an encoder-decoder model with attention adapted from Weiss et al. (2017), Bérard et al. (2018) and Bansal et al. (2018), as shown in Figure 1. We use the same model architecture for all our models, allowing us to conveniently transfer parameters between them. We also constrain the hyper-parameter search to fit a model into a single Titan X GPU, allowing us to maximize available compute resources.

We use a pre-trained English ASR model to initialize training of Spanish-English ST models, and a pre-trained French ASR model to initialize training of Mboshi-French ST models. During ST training, all model parameters are updated. In these configurations, the decoder shares the same vocabulary across the ASR and ST tasks. This is practical for settings where the target text language is high-resource with ASR data available.

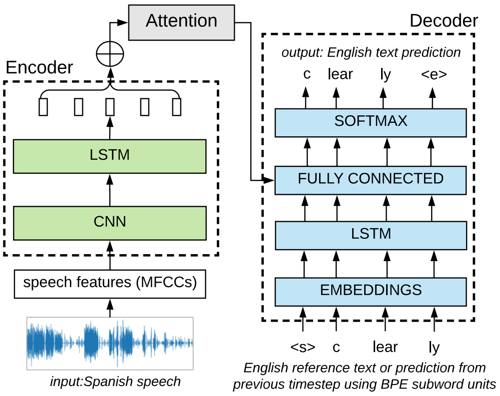

Figure 1: Encoder-decoder with attention model architecture for both ASR and ST. The encoder input is the Spanish speech utterance *claro*, translated as *clearly*, represented as BPE (subword) units.

In settings where both ST languages are low-resource, ASR data may only be available in a third language. To test whether transfer learning will help in this setting, we use a pre-trained French ASR model to train Spanish-English ST models; and English ASR for Mboshi-French models. In these cases, the ST languages are different from the ASR language, so we can only transfer the encoder parameters of the ASR model, since the dimensions of the decoder's output softmax layer are indexed by the vocabulary, which is not shared.[1] Sharing only the speech encoder parameters is much easier, since the speech input can be preprocessed in the same manner for all languages. This form of transfer learning is more flexible, as there are no constraints on the ASR language used.

3 Experimental Setup

3.1 Data sets

English ASR. We use the Switchboard Telephone speech corpus (Godfrey and Holliman, 1993), which consists of around 300 hours of English speech and transcripts, split into 260k utterances. The development set consists of 5 hours that we removed from the training set, split into 4k utterances.

French ASR. We use the French speech corpus from the GlobalPhone collection (Schultz, 2002), which consists of around 20 hours of high quality read speech and transcripts, split into 9k utterances. The development set consists of 2 hours, split into 800 utterances.

Spanish-English ST. We use the Fisher Spanish speech corpus (Graff et al., 2010), which consists of 160 hours of telephone speech in a variety of Spanish dialects, split into 140K utterances. To simulate low-resource conditions, we construct smaller train-

---

[1] Using a shared vocabulary of characters or subwords is an interesting direction for future work, but not explored here.

ing corpora consisting of 50, 20, 10, 5, or 2.5 hours of data, selected at random from the full training data. The development and test sets each consist of around 4.5 hours of speech, split into 4K utterances. We do not use the corresponding Spanish transcripts; our target text consists of English translations that were collected through crowdsourcing (Post et al., 2013, 2014).

Mboshi-French ST. Mboshi is a Bantu language spoken in the Republic of Congo, with around 160,000 speakers.[2] We use the Mboshi-French parallel corpus (Godard et al., 2018), which consists of around 4 hours of Mboshi speech, split into a training set of 5K utterances and a development set of 500 utterances. Since this corpus does not include a designated test set, we randomly sampled and removed 200 utterances from training to use as a development set, and use the designated development data as a test set.

3.2 Preprocessing

Speech. We convert raw speech input to 13-dimensional MFCCs using Kaldi (Povey et al., 2011).[3] We also perform speaker-level mean and variance normalization.

Text. The target text of the Spanish-English data set contains 1.5M word tokens and 17K word types. If we model text as sequences of words, our model cannot produce any of the unseen word types in the test data and is penalized for this, but it can be trained very quickly (Bansal et al., 2018). If we instead model text as sequences of characters as done by Weiss et al. (2017), we would have 7M tokens and 100 types, resulting in a model that is open-vocabulary, but very slow to train (Bansal et al., 2018). As an effective middle ground, we use byte pair encoding (BPE; Sennrich et al., 2016) to segment each word into subwords, each of which is a character or a high-frequency sequence of characters—we use 1000 of these high-frequency sequences. Since the set of subwords includes the full set of characters, the model is still open vocabulary; but it results in a text with only 1.9M tokens and just over 1K types, which can be trained almost as fast as the word-level model.

The vocabulary for BPE depends on the frequency of character sequences, so it must be computed with respect to a specific corpus. For English, we use the full 160-hour Spanish-English ST target training text. For French, we use the Mboshi-French ST target training text.

3.3 Model architecture for ASR and ST

Speech encoder. As shown schematically in Figure 1, MFCC feature vectors, extracted using a window size of 25 ms and a step size of 10ms, are fed into a stack of two CNN layers, with 128 and 512 filters with a filter width of 9 frames each. In each CNN layer we stride with a factor of 2 along time, apply a ReLU activation (Nair and Hinton, 2010), and apply batch normalization (Ioffe and Szegedy, 2015). The output of the CNN layers is fed into a three-layer bi-directional long short term memory network (LSTM; Hochreiter and Schmidhuber, 1997); each hidden layer has 512 dimensions.

Text decoder. At each time step, the decoder chooses the most probable token from the output of a softmax layer produced by a fully-connected layer, which in turn receives the current state of a recurrent layer computed from previous time steps and an attention vector computed over the input. Attention is computed using the *global attentional model* with *general* score function and *input-feeding*, as described in Luong et al. (2015). The predicted token is then fed into a 128-dimensional embedding layer followed by a three-layer LSTM to update the recurrent state; each hidden state has 256 dimensions. While training, we use the predicted token 20% of the time as input to the next decoder step and the training token for the remaining 80% of the time (Williams and Zipser, 1989). At test time we use beam decoding with a beam size of 5 and length normalization (Wu et al., 2016) with a weight of 0.6.

Training and implementation. Parameters for the CNN and RNN layers are initialized using the scheme from (He et al., 2015). For the embedding and fully-connected layers, we use Chainer's (Tokui et al., 2015) default initialition.

We regularize using dropout (Srivastava et al., 2014), with a ratio of 0.3 over the embedding and LSTM layers (Gal, 2016), and a weight decay rate of 0.0001. The parameters are optimized using Adam (Kingma and Ba, 2015), with a starting alpha of 0.001.

---

[2] `ethnologue.com/language/mdw`

[3] In preliminary experiments, we did not find much difference between between MFCCs and more raw spectral representations like Mel filterbank features.

Following some preliminary experimentation on our development set, we add Gaussian noise with standard deviation of 0.25 to the MFCC features during training, and drop frames with a probability of 0.10. After 20 epochs, we corrupt the true decoder labels by sampling a random output label with a probability of 0.3.

Our code is implemented in Chainer (Tokui et al., 2015) and is freely available.[4]

3.4 Evaluation

Metrics. We report BLEU (Papineni et al., 2002) for all our models.[5] In low-resource settings, BLEU scores tend to be low, difficult to interpret, and poorly correlated with model performance. This is because BLEU requires exact four-gram matches only, but low four-gram accuracy may obscure a high unigram accuracy and inexact translations that partially capture the semantics of an utterance, and these can still be very useful in situations like language documentation and crisis response. Therefore, we also report word-level unigram precision and recall, taking into account *stem*, *synonym*, and *paraphrase* matches. To compute these scores, we use METEOR (Lavie and Agarwal, 2007) with default settings for English and French.[6] For example, METEOR assigns "eat" a recall of 1 against reference "eat" and a recall of 0.8 against reference "feed", which it considers a synonym match.

Naive baselines. We also include evaluation scores for a naive baseline model that predicts the *K* most frequent words of the training set as a bag of words for each test utterance. We set *K* to be the value at which precision/recall are most similar, which is always between 5 and 20 words. This provides an empirical lower bound on precision and recall, since we would expect any usable model to outperform a system that does not even depend on the input utterance. We do not compute BLEU for these baselines, since they do not predict sequences, only bags of words.

4 ASR results

Using the experimental setup of Section 3, we pretrained ASR models in English and French, and report their word error rates (WER) on development data in Table 1.[7] We denote each ASR model by *L-Nh*, where *L* is a language code and *N* is the size of the training set in hours. For example, *en-300h* denotes an English ASR model trained on 300 hours of data.

	en-100h	**en-300h**	**fr-20h**
WER	35.4	27.3	29.6

Table 1: Word Error Rate (WER, in %) for the ASR models used as pretraining, computed on Switchboard *train-dev* for English and Globalphone dev for French.

Training ASR models for state-of-the-art performance requires substantial hyper-parameter tuning and long training times. Since our goal is simply to see whether pre-training is useful, we stopped pretraining our models after around 30 epochs (3 days) to focus on transfer experiments. As a consequence, our ASR results are far from state-of-the-art: current end-to-end Kaldi systems obtain 16% WER on Switchboard *train-dev*, and 22.7% WER on the French Globalphone dev set.[8] We believe that better ASR pre-training may produce better ST results, but we leave this for future work.

5 Spanish-English ST

In the following, we denote an ST model by *S-T-Nh*, where *S* and *T* are source and target language codes, and *N* is the size of the training set in hours. For example, *sp-en-20h* denotes a Spanish-English ST model trained using 20 hours of data. We use the code *mb* for Mboshi and *fr* for French.

5.1 Using English ASR to improve ST

Figure 2 shows the BLEU and unigram precision/recall scores on the development set for baseline Spanish-English ST models and those trained after initializing with the *en-300h* model. Corresponding results on the test set (Table 2) reveal very similar patterns. The remainder of our analysis is confined to the development set. The naive baseline, which predicts the 15 most frequent English words in the training set, achieves a precision/recall of around 20%, setting a performance lower bound.

Low-resource: 20-50 hours of ST training data. Our baseline ST models substantially improve over

$N =$	0	2.5	5	10	20	50
base	0	2.1	1.8	2.1	10.8	22.7
+asr	0.5	5.7	9.1	14.5	20.2	28.2

Table 2: BLEU scores for Spanish-English ST on the Fisher test set, using N hours of training data. base: no transfer learning. +asr: using model parameters from English ASR (en-300h).

Spanish	super caliente pero muy bonito
English	super hot but very nice
20h	you support it but it was very nice
20h+asr	you can get alright but it's very nice
50h	super expensive but very nice
50h+asr	super hot but it's very nice
Spanish	sí y usted hace mucho tiempo que que vive aquí
English	yes and have you been living here a long time
20h	yes i've been a long time what did you come here
20h+asr	yes and you have a long time that you live here
50h	yes you are a long time that you live here
50h+asr	yes and have you been here long

Table 3: Example translations on selected sentences from the Fisher development set, with stem-level n-gram matches to the reference sentence underlined. 20h and 50h are Spanish-English models without pretraining; 20h+asr and 50h+asr are pre-trained on 300 hours of English ASR.

previous results (Bansal et al., 2018) using the same train/test splits, primarily due to better regularization and modeling of subwords rather than words. Yet transfer learning still substantially improves over these strong baselines. For *sp-en-20h*, transfer learning improves dev set BLEU from 10.8 to 19.9, precision from 41% to 51%, and recall from 38% to 49%. For *sp-en-50h*, transfer learning improves BLEU from 23.3 to 27.8, precision from 54% to 58%, and recall from 51% to 56%.

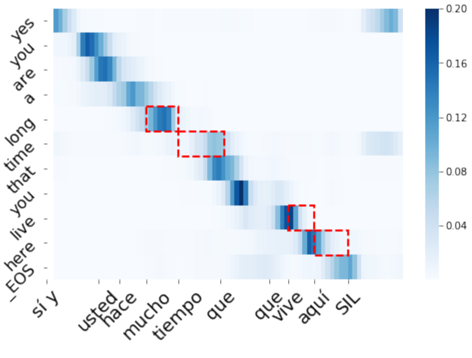
Very low-resource: 10 hours or less of ST training data. Figure 2 shows that without transfer learning, ST models trained on less than 10 hours of data struggle to learn, with precision/recall scores close to or below that of the naive baseline. But with transfer learning, we see gains in precision and recall of between 10 and 20 points.

We also see that with transfer learning, a model trained on only 5 hours of ST data achieves a BLEU of 9.1, nearly as good as the 10.8 of a model trained on 20 hours of ST data without transfer learning. In other words, fine-tuning an English ASR model—which is relatively easy to obtain—produces similar results to training an ST model on four times as much data, which may be difficult to obtain.

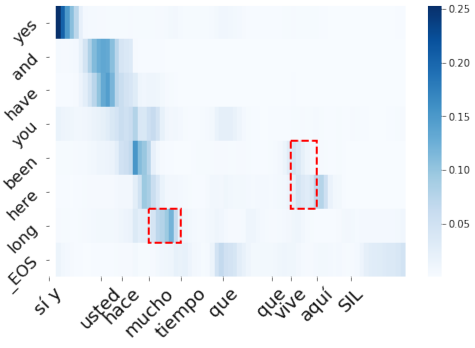
We even find that in the very low-resource setting of just 2.5 hours of ST data, with transfer learning the model achieves a precision/recall of around 30% and improves by more than 10 points over the naive baseline. In very low-resource scenarios with time constraints—such as in disaster relief—it is possible that even this level of performance may be useful, since it can be used to spot keywords in speech and can be trained in just three hours.

Sample translations. Table 3 shows example translations for models *sp-en-20h* and *sp-en-50h* with and without transfer learning using *en-300h*.

Figure 3 shows the attention weights for the last sample utterance in Table 3. For this utterance, the Spanish and English text have a different word order: *mucho tiempo* occurs in the middle of the speech utterance, and its translation, *long time*, is at the end of the English reference. Similarly, *vive aquí* occurs at the end of the speech utterance, while the translation, *living here*, is in the middle of the English reference. The baseline *sp-en-50h* model translates the words correctly but doesn't get



(a) **50h:baseline**



(b) **50h:asr**

Figure 3: Attention plots for the final example in Table 3, using 50h models with and without pre-training. The x-axis shows the reference Spanish word positions in the input; the y-axis shows the predicted English subwords. In the reference, *mucho tiempo* is translated to *long time*, and *vive aquí* to *living here*, but their order is reversed, and this is reflected in (b).

the English word order right. With transfer learning, the model produces a shorter but still accurate translation in the correct word order.

5.2 Analysis

To understand the source of these improvements, we carried out a set of ablation experiments. For most of these experiments, we focus on Spanish-English ST with 20 hours of training data, with and without transfer learning.

Transfer learning with selected parameters. In our first set of experiments, we transferred all parameters of the *en-300h* model, including the speech encoder CNN and LSTM; the text decoder embedding, LSTM and output layer parameters; and attention parameters. To see which set of parameters has the most impact, we train the *sp-en-20h* model by transferring only selected parameters from *en-300h*, and randomly initializing the rest.

The results (Figure 4) show that transferring all parameters is most effective, and that the speech encoder parameters account for most of the gains. We hypothesize that the encoder learns transferable low-level acoustic features that normalize across variability like speaker and channel differences to better capture meaningful phonetic differences, and that much of this learning is language-independent. This hypothesis is supported by other work showing the benefits of cross-lingual and multilingual training for speech technology in low-resource target languages (Carlin et al., 2011; Jansen et al., 2010; Deng et al., 2013; Vu et al., 2012; Thomas et al., 2012; Cui et al., 2015; Alumäe et al., 2016; Yuan et al., 2016; Renshaw et al., 2015; Hermann and Goldwater, 2018).

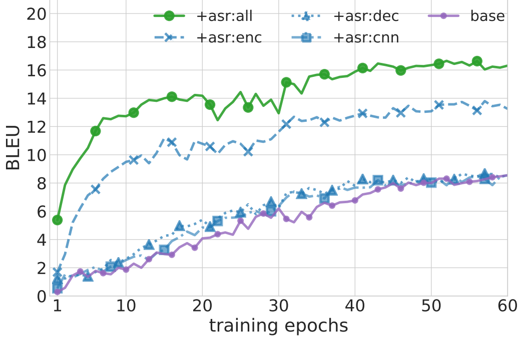


Figure 4: Fisher development set training curves (reported using BLEU) for *sp-en-20h* using selected parameters from *en-300h*: none (base); encoder CNN only (+asr:cnn); encoder CNN and LSTM only (+asr:enc); decoder only (+asr:dec); and all: encoder, attention, and decoder (+asr:all). These scores do not use beam search and are therefore lower than the best scores reported in Figure 2.

By contrast, transferring only decoder parameters does not improve accuracy. Since decoder parameters help when used in tandem with encoder parameters, we suspect that the dependency in parameter training order might explain this: the transferred decoder parameters have been trained to expect particular input representations from the encoder, so transferring only the decoder parameters without the encoder might not be useful.

Figure 4 also suggests that models make strong gains early on in the training when using transfer learning. The *sp-en-20h* model initialized with all model parameters (*+asr:all*) from *en-300h* reaches a higher BLEU score after just 5 epochs (2 hours) of training than the model without transfer learning trained for 60 epochs/20 hours. This again can be useful in disaster-recovery scenarios, where the

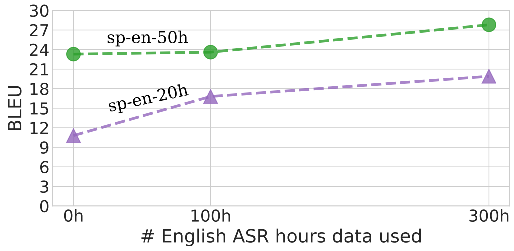

Figure 5: Spanish-to-English BLEU scores on Fisher dev set, with 0h (no transfer learning), 100h and 300h of English ASR data used.

time to deploy a working system must be minimized.

Amount of ASR data required. Figure 5 shows the impact of increasing the amount of English ASR data used on Spanish-English ST performance for two models: *sp-en-20h* and *sp-en-50h*.

For *sp-en-20h*, we see that using *en-100h* improves performance by almost 6 BLEU points. By using more English ASR training data (*en-300h*) model, the BLEU score increases by almost 9 points. However, for *sp-en-50h*, we only see improvements when using *en-300h*. This implies that transfer learning is most useful when only a few tens of hours of training data are available for ST. As the amount of ST training data increases, the benefits of transfer learning tail off, although it's possible that using even more monolingual data, or improving the training at the ASR step, could extend the benefits to larger ST data sets.

Impact of code-switching. We also tried using the *en-300h* ASR model without any fine-tuning to translate Spanish audio to English text. This model achieved a BLEU score of 1.1, with a precision of 15 and recall of 21. The non-zero BLEU score indicates that the model is matching *some* 4-grams in the reference. This seems to be due to code-switching in the Fisher-Spanish speech data set. Looking at the dev set utterances, we find several examples where the Spanish transcriptions match the English translations, indicating that the speaker switched into English. For example, there is an utterance whose Spanish transcription and English translation are both "right yeah", and this English expression is indeed present in the source audio. The English ASR model correctly translates this utterance, which is unsurprising since the phrase "right yeah" occurs nearly 500 times in Switchboard.

Overall, we find that in nearly 500 of the 4,000 development set utterances (14%), the Spanish transcription and English translations share more than half of their tokens, indicating likely code-switching. This suggests that transfer learning from English ASR models might help more than from other languages. To isolate this effect from transfer learning of language-independent speech features, we carried out a further experiment.

5.3 Using French ASR to improve Spanish-English ST

In this experiment, we pre-train using French ASR data for a Spanish-English translation task. Here, we can only transfer the speech encoder parameters, and there should be little if any benefit due to code-switching.

Because our French data set (20 hours) is much smaller than our English one (300 hours), for a fair comparison we used a 20 hour subset of the English data for pre-training in this experiment. For both the English and French models, we transferred only the encoder parameters.

Table 4 shows that both the English and French 20-hour pre-trained models improve performance on Spanish-English ST. The English model works slightly better, as would be predicted given our discussion of code-switching, but the French model is also useful, improving BLEU from 10.8 to 12.5. This result strengthens the claim that ASR pre-training on a completely distinct third language can help low-resource ST. Presumably benefits would be much greater if we used a larger ASR data set, as we did with English above.

In this experiment, the French pre-trained model used a French BPE output vocabulary, distinct from the English BPE vocabulary used in the ST system. In the future it would be interesting to try combining the French and English text to create a combined output vocabulary, which would allow transferring both the encoder and decoder parameters, and may be useful for translating names or cognates. More generally, it would also be possible to pre-train on multiple languages simultaneously using a shared BPE vocabulary. There is evidence that speech features trained on multiple languages transfer better than those trained on the same amount of data from a single language (Hermann and Goldwater, 2018), so multilingual pretraining for ST could improve results.

	baseline	**+fr-20h**	**+en-20h**
sp-en-20h	10.8	12.5	13.2

Table 4: Fisher dev set BLEU scores for *sp-en-20h*. baseline: model without transfer learning. Last two columns: Using encoder parameters from French ASR (+fr-20h), and English ASR (+en-20h).

model	**pretrain**	**BLEU**	**Pr.**	**Rec.**
fr-top-8w	–	0	23.5	22.2
fr-top-10w	–	0	20.6	24.5
en-300h	–	0	0.2	5.7
fr-20h	–	0	4.1	3.2
mb-fr-4h	–	3.5	18.6	19.4
	fr-20h	5.9	23.6	20.9
	en-300h	5.3	23.5	22.6
	en + fr	**7.1**	**26.7**	**23.1**

Table 5: Mboshi-to-French translation scores, with and without ASR pre-training. Pr. is the precision, and Rec. the recall score. fr-top-8w and fr-top-10w are *naive baselines* that, respectively, predict the 8 or 10 most frequent training words. For en + fr, we use encoder parameters from *en-300h* and attention+decoder parameters from *fr-20h*

6 Mboshi-French ST

Our final set of experiments test our transfer method on ST for the low-resource language Mboshi, where we have only 4 hours of ST training data: Mboshi speech input paired with French text output.

Table 5 shows the ST model scores for Mboshi-French with and without using transfer learning. The first two rows *fr-top-8w*, *fr-top-10w*, show precision and recall scores for the *naive baselines* where we predict the top 8 or 10 most frequent French words in the Mboshi-French training set. These show that a precision/recall in the low 20s is easy to achieve, although with no n-gram matches (0 BLEU). The pre-trained ASR models by themselves (next two lines) are much worse.

The baseline model trained only on ST data actually has lower precision/recall than the naive baseline, although its non-zero BLEU score indicates that it is able to correctly predict some n-grams. We see comparable precision/recall to the naive baseline with improvements in BLEU by transferring either French ASR parameters (both encoder and decoder, *fr-20h*) or English ASR parameters (encoder only, *en-300h*).

Finally, to achieve the benefits of both the larger training set size for the encoder and the matching language of the decoder, we tried transferring the encoding parameters from the *en-300h* model and the decoding parameters from the *fr-20h* model. This configuration (*en*+*fr*) gives us the best evaluation scores on all metrics, and highlights the flexibility of our framework. Nevertheless, the 4-hour scenario is clearly a very challenging one.

7 Conclusion

This paper introduced the idea of pre-training an end-to-end speech translation system involving a low-resource language using ASR training data from a higher-resource language. We showed that large gains are possible: for example, we achieved an improvement of 9 BLEU points for a Spanish-English ST model with 20 hours of parallel data and 300 hours of English ASR data. Moreover, the pre-trained model trains faster than the baseline, achieving higher BLEU in only a couple of hours, while the baseline trains for more than a day.

We also showed that these methods can be used effectively on a real low-resource language, Mboshi, with only 4 hours of parallel data. The very small size of the data set makes the task challenging, but by combining parameters from an English encoder and French decoder, we outperformed baseline models to obtain a BLEU score of 7.1 and precision/recall of about 25%. We believe ours is the first paper to report word-level BLEU scores on this data set.

Our analysis indicates that, other things being equal, transferring both encoder and decoder parameters works better than just transferring one or the other. However, transferring the encoder parameters is where most of the benefit comes from. Pre-training using a large ASR corpus from a mismatched language will therefore probably work better than using a smaller ASR corpus that matches the output language.

Our analysis suggests several avenues for further exploration. On the speech side, it might be even more effective to use multilingual training; or to replace the MFCC input features with pre-trained multilingual features, or features that are targeted to low-resource multispeaker settings (Kamper et al., 2015, 2017; Thomas et al., 2012; Cui et al., 2015; Yuan et al., 2016; Renshaw et al., 2015). On the language modeling side, simply transferring decoder parameters from an ASR model did not work; it might work better to use pre-trained decoder parameters from a language model, as proposed by Ramachandran et al. (2017), or *shallow fusion* (Gülçehre et al., 2015; Toshniwal et al., 2018a), which interpolates a pre-trained language model during beam search. In these methods, the decoder parameters are independent, and can therefore be used on their own. We plan to explore these strategies in future work.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable feedback. This work was supported in part by a James S McDonnell Foundation Scholar Award, a Google faculty research award, and NSF grant 1816627. We thank Ida Szubert and Clara Vania for helpful comments on previous drafts of this paper and Antonios Anastasopoulos for tips on experimental setup.

Measuring the Perceptual Availability of Phonological Features During Language Acquisition Using Unsupervised Binary Stochastic Autoencoders

Abstract

In this paper, we deploy binary stochastic neural autoencoder networks as models of infant language learning in two typologically unrelated languages (Xitsonga and English). We show that the drive to model auditory percepts leads to latent clusters that partially align with theory-driven phonemic categories. We further evaluate the degree to which theory-driven phonological features are encoded in the latent bit patterns, finding that some (e.g. [±approximant]), are well represented by the network in both languages, while others (e.g. [±spread glottis]) are less so. Together, these findings suggest that many reliable cues to phonemic structure are immediately available to infants from bottom-up perceptual characteristics alone, but that these cues must eventually be supplemented by top-down lexical and phonotactic information to achieve adult-like phone discrimination. Our results also suggest differences in degree of perceptual availability between features, yielding testable predictions as to which features might depend more or less heavily on top-down cues during child language acquisition.

1 Introduction

Distinctive features like [±voice] and [±sonorant] have been a core construct of phonological theory for many decades (Trubetskoy, 1939; Jakobson et al., 1951; Chomsky and Halle, 1968; Clements, 1985). They have been used in automatic speech recognition (Livescu and Glass, 2004), and psycholinguistic evidence suggests that they are cognitively available during language acquisition (Kuhl, 1980; White and Morgan, 2008). Nonetheless, distinctive features are not directly observed by humans; they are abstractions that must be inferred from dense perceptual information (sound waves) during language acquisition and comprehension, which raises questions about how they are learned and recognized. In adults, phonological comprehension is aided by top-down lexical and phonotactic (i.e. sound sequencing) constraints. For example, the classic *phonemic restoration effect* (Warren, 1970) shows that adults infer missing phonemes from context with such ease that they often fail to notice when acoustic cues to phone identity are erased. However, infants first learning their phonemic categories have not yet acquired reliable top-down lexical and phonotactic models and must rely more heavily on bottom-up perceptual information. To a learner faced with the immense challenge of discovering structure in dense perceptual input, do theory-driven phonological features “stand out” or are they swamped by noise? In this paper, we address this question using an unsupervised computational acquisition model.

Previous models of phonological category induction have emphasized the importance of top-down information (information about the contexts in which phonemes occur) (Peperkamp et al., 2006; Swingley, 2009; Feldman et al., 2009a, 2013a,b; Moreton and Pater, 2012a,b; Martin et al., 2013; Pater and Moreton, 2014; Frank et al., 2014; Doyle et al., 2014; Doyle and Levy, 2016). But to prevent the acquisition process from being circular, the learner cannot operate solely on top-down information — the acoustic signal must provide some evidence for the phonemic categories. We hypothesize that the same must be true for at least some phonological features (e.g. [±nasal], [±lateral]), but previous work on unsupervised speech processing has inferred phonological structure from spoken utterances using either (1) discrete transition-based architectures (Varadarajan et al., 2008; Jansen and Church, 2011; Lee and Glass, 2012), which do attempt to discover featurally-related natural classes, or (2) continuous deep neural (Kamper et al., 2015,

Proceedings of NAACL-HLT 2019, pages 69–85
Minneapolis, Minnesota, June 2 - June 7, 2019.

2017a; Renshaw et al., 2015) architectures, whose internal representations are difficult to interpret. Furthermore, these approaches do not separate the contributions of top-down sequential information from bottom-up acoustic properties of segments, making it difficult to assess the relative importance of these information sources throughout the acquisition process.

By contrast, our model attends exclusively to phone-internal acoustic patterns using a deep neural autoencoder with a discrete embedding space composed of binary stochastic neurons (BSNs) (Rosenblatt, 1958; Hinton, 2012; Bengio et al., 2013; Courbariaux et al., 2016). BSNs allow us to exploit (1) the interpretability of discrete representations, (2) the decomposability of phone segments into phonological features, and (3) and the power of deep neural function approximators to relate percepts and their representations. Since every token is labeled with a binary latent code, it is possible to evaluate the model's recovery not only of phonological categories but also of phonological features. Featural representations can encode distributional facts about which processes apply to which classes of sounds in ways that cross-cut the phonological space, rather than simply grouping each segment with a set of similar neighbors (LeCun et al., 2015). By focusing on the acoustic properties of sounds themselves rather than their sequencing in context, our model enables exploration of two questions about the data available to young learners whose training signal must primarily be extracted from bottom-up perceptual information: (1) to what extent can phoneme categories emerge from a drive to model auditory percepts, and (2) how perceptually available are theory-driven phonological features (that is, how easily can they be extracted directly from low-level acoustic percepts)?

Our results show (a) that phonemic categories emerge naturally but imperfectly from perceptual reconstruction and (b) that theory-driven features differ in their degree of perceptual availability. Together, these findings suggest that many reliable cues to phonemic structure are immediately available to infants from bottom-up perceptual characteristics alone, but that these cues may eventually need to be supplemented by top-down lexical and phonotactic information to achieve adult-like phone discrimination (Feldman et al., 2013a; Pater and Moreton, 2014). Our findings also suggest hypotheses as to precisely which kinds of phonological features are more or less perceptually available and therefore might depend more or less heavily on top-down cues for acquisition. Such differences might suggest relative timelines at which different features might be appropriated in support of phonemic, phonotactic, and lexical generalization, providing a rich set of testable hypotheses about child language acquisition.

2 Background and Related Work

2.1 Unsupervised Speech Processing

The present paper has a strong connection to recent work on unsupervised speech processing, especially the Zerospeech 2015 (Versteegh et al., 2015) and 2017 (Dunbar et al., 2017) shared tasks. Participating systems (Badino et al., 2015; Renshaw et al., 2015; Agenbag and Niesler, 2015; Chen et al., 2015; Baljekar et al., 2015; Räsänen et al., 2015; Lyzinski et al., 2015; Zeghidour et al., 2016; Heck et al., 2016; Srivastava and Shrivastava, 2016; Kamper et al., 2017b; Chen et al., 2017; Yuan et al., 2017; Heck et al., 2017; Shibata et al., 2017; Ansari et al., 2017a,b) perform unsupervised ABX discrimination and/or spoken term discovery on the basis of unlabeled speech alone. The design and evaluation of these and related systems (Kamper et al., 2015, 2017a; Elsner and Shain, 2017; Räsänen et al., 2018) are oriented toward word-level modeling. As such, our focus on the perceptual availability of phonological features is orthogonal to but complementary with this line of research. Since distinctive features are important for indexing lexical contrasts, especially between highly confusable words (e.g. onset voicing alone distinguishes *sap* and *zap* in English), studying the perceptual availability of distinctive features to an unsupervised learner may help improve the design and analysis of low-resource speech processing systems.

To our knowledge, the task most closely related to the current paper is unsupervised phone discovery. Some studies in this tradition segment speech into phone-like units without clustering them (Dusan and Rabiner, 2006; Qiao et al., 2008), while others cluster small subsets of pre-segmented sounds (usually vowels) using parametric models (mixture-of-Gaussians) (Vallabha et al., 2007; Feldman et al., 2013a; Antetomaso et al., 2017). Further work combines these tasks and extends the approach to cover the entire acoustic space (Lee and Glass, 2012). However, for a variety of reasons, the Lee and Glass (2012) model does not straightforwardly support evaluation of the perceptual availability of phonological features. First, they do not quantitatively evaluate the discovered phoneme clusters. Second, the model incorporates phonotactics through transition probabilities, making it difficult to disentangle the contributions of top-down and bottom-up information to the learning process. Third, the clustering model is not feature-based, but instead consists of atomic categories, each defining a distinct generative process for acoustics. This design is at odds with the widely held view in linguistic theory that phonemes are not inscrutable atoms of the phonological grammar, but instead labels for bundles of features that define natural classes (Clements, 1985). Our approach is therefore more appropriate to the question at hand.

2.2 Distinctive Features and Phonology Acquisition

There is a great deal of evidence that many phonological contrasts are perceptually available from a very early stage (Eimas et al., 1971; Moffitt, 1971; Trehub, 1973; Jusczyk and Derrah, 1987; Eimas et al., 1987). However, studies of infant phone discrimination typically use carefully-enunciated laboratory stimuli, which have been shown to be substantially easier to discriminate than phones in naturalistic utterances (Feldman et al., 2013a; Antetomaso et al., 2017). It is thus likely that inferring phone categories from acoustic evidence is a persistently challenging task, and studies have found language-specific tuning of the speech perception system from fetal stages (Moon et al., 2013) through the first year (Kuhl et al., 1992; Werker and Tees, 1984) and even all the way into the preteen years (Hazan and Barrett, 2000).

Experiments show that these contrasts are expressed, not simply as oppositions between particular categories, but as a featural system, even in early infancy. Evidence of featural effects has been found in the phone discrimination patterns of both adults (Chládková et al., 2015) and infants (Kuhl, 1980; Hillenbrand, 1985; White and Morgan, 2008). Studies have also shown that infants generalize new distinctions along featural dimensions (Maye et al., 2008b; Cristià et al., 2011). Given infants' early detection and use of some featural contrasts, we hypothesize that there is strong evidence in the acoustic signal for these distinctions, which may then bootstrap the acquisition of phonotactic and lexical patterns (Beckman and Edwards, 2000).

Experiments also suggest asymmetries in the perceptual availability of features. For example, a consonant-vowel distinction appears to be an important early foothold in phonology acquisition: vowel/consonant discrimination emerges early in infant speech processing (Dehaene-Lambertz and Dehaene, 1994), language-specificity in perception follows different timecourses for consonants (Werker and Tees, 1984) and vowels (Kuhl et al., 1992), and vowels and consonants play distinct roles in lexical access vs. rule discovery in children (Nazzi, 2005; Pons and Toro, 2010; Hochmann et al., 2011). Young infants have also been shown to be sensitive to voicing contrasts (Lasky et al., 1975; Aslin et al., 1981; Maye et al., 2008b). Features that distinguish consonant-like from vowel-like segments or voiced from unvoiced segments may thus be highly available to young learners. Infants struggle by comparison with other kinds of phone discrimination tasks, including certain stop-fricative contrasts (Polka et al., 2001) and certain place distinctions within nasal (Narayan et al., 2010) and sibilant (Nittrouer, 2001; Cristià et al., 2011) segments. Even adults struggle with fricative place discrimination from strictly acoustic cues (McGuire and Babel, 2012). Similar asymmetries emerge from our unsupervised learner, as shown in Section 4.2.

Our computational acquisition model complements this experimental research in several ways. First, its internal representations, unlike those of human infants, are open to detailed analysis, even when exposed to naturalistic language stimuli. Second, we can perform cross-linguistic comparisons using readily available corpora without requiring access to a pool of human subjects in each language community. Third, our model provides global and graded quantification of the perceptual availability of distinctive features in natural speech, permitting us to explore relationships between features in a way that is difficult to do through experiments on infants, which are generally constrained to same-different contrasts over a small set of manipulations.

2.3 Cognition and the BSN Autoencoder

The reconstruction objective used here is not merely a convenient supervision signal. There is reason to believe that people actively model their perceptual worlds (Mamassian et al., 2002; Feldman, 2012; Singer et al., 2018; Yan et al., 2018), and autoassociative structures have been found in several brain areas (Treves and Rolls, 1991; Rolls and Treves, 1998). There is also evidence that phonetic comprehension and production can be acquired symbiotically through a sensorimotor loop relating acoustic perception and articulator movements (Houde and Jordan, 1998; Fadiga et al., 2002; Watkins et al., 2003; Wilson et al., 2004; Pulvermüller et al., 2006; Kröger et al., 2009; Bolhuis et al., 2010; Kröger and Cao, 2015; Bekolay, 2016). Finally, evidence suggests that working memory limitations impose compression pressures on the perceptual system that favor sparse representations of dense acoustic percepts (Baddeley and Hitch, 1974) and may guide infant language acquisition (Baddeley et al., 1998; Elsner and Shain, 2017). It is thus reasonable to suppose that perceptual reconstruction — such as that implemented by an autoencoder architecture — is immediately available as a learning signal to infants who still lack reliable guidance from phonotactics or the lexicon.

Our use of BSNs follows the spirit of the earliest work on artificial neural networks (Rosenblatt, 1958). Rosenblatt's perceptron was designed to study learning and decision-making in the brain and therefore used binary neurons to model the discrete firing behavior of their biological counterparts. This tradition has been replaced in deep learning research with differentiable activation functions that support supervised learning through backpropagation of error but are less biologically plausible. Our work takes advantage of the development of effective estimators for the gradients of discrete neurons (Williams, 1992; Hinton, 2012; Bengio et al., 2013; Courbariaux et al., 2016; Chung et al., 2017) to wed these two traditions, exploiting BSNs to encode the learner's latent representation of auditory percepts and deep networks to map between percepts and their latent representations. In addition to the greater similarity of BSNs to biological neurons, the use of discrete featural representations is motivated by experimental evidence that human phone perception (including that of infants) is both featural (White and Morgan, 2008; Chládková et al., 2015) and categorical (Liberman et al., 1961; Eimas et al., 1987; Harnad, 2003; Feldman et al., 2009b).

Experiments reported here use an 8-bit binary segment encoding. Eight bits is the the lower bound on binary encodings that are sufficiently expressive to capture all segmental contrasts in any known language (Mielke, 2009). Although theory-driven taxonomies generally contain more than eight distinctive features, these taxonomies are known to be highly redundant (Cherry et al., 1953). For example, the phonological featurization of the Xitsonga segments analyzed in our experiments contains 26 theory-driven features (Hayes, 2011; Hall et al., 2016), yielding up to $2^{26} = 67108864$ distinct segment categories, far more than the number of known segment types in Xitsonga or even the number of training instances in our data. By entailment, any representation that can identify all segment types in a language can also identify all featural contrasts that discriminate those types, regardless of how the feature space is factored. For this reason, we consider a phonological feature to be represented if it can be detected by an arbitrary function of the latent bits (Section 4.2), without assuming that the true and discovered feature spaces will factor identically.

2.4 Supervised Acoustic Feature Learning

Our study shares an interest in phonological features with previous work in automatic speech recognition attempting to discover mappings between acoustics and hand-labeled featural representations (Liu, 1996; Bitar and Espy-Wilson, 1996; Frankel and King, 2001; Kirchhoff et al., 2002; Livescu and Glass, 2004; Mitra et al., 2011, *inter alia*). While these results provide evidence that such a mapping is indeed learnable in an oracle setting, they rely on a supervision signal (direct annotation of the target representations) to which children do not have access. Our unsupervised approach measures perceptual availability of features in a more realistic learning scenario.

3 Experimental Setup

3.1 Model

The simulated learner used in this study is a deep neural autoencoder with an 8-bit layer of BSNs as its principle information bottleneck, depicted in Figure 1. The model processes a given phone segment by encoding the segment's acoustic informa-

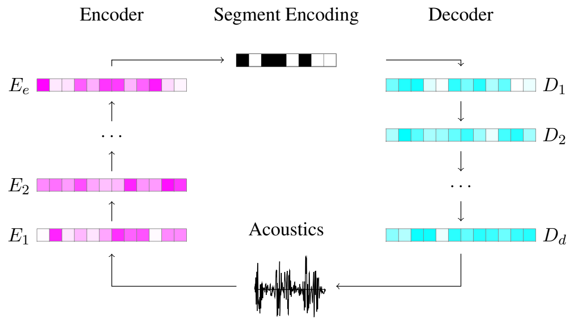

Figure 1: The binary stochastic neural autoencoder architecture with encoder layers $E_{1,\ldots,e}$ and decoder layers $D_{1,\ldots,d}$. For expository purposes, acoustics are represented as pressure waves. In reality, the system uses frames of Mel frequency cepstral coefficients.

tion into a bit pattern and then reconstructing the acoustic information from the encoded bit pattern. It is thus incentivized to use the latent bits in a systematic featural manner, encoding similar segments in similar ways.

The encoder and decoder are both deep feedfoward residual networks (He et al., 2016).[1] To enable feedforward autoencoding of sequential data, phone segments are clipped at 50 timesteps (500ms), providing complete coverage of over 99% of the phone segments in each corpus. Given F-dimensional input acoustic frames and a maximum input length of M timesteps, the weight matrix of each encoder layer is $\in \mathbb{R}^{FM \times FM}$ except the final layer ($\in \mathbb{R}^{FM \times 8}$). Given R-dimensional reconstructed acoustic frames and a maximum output length of N timesteps, the weight matrix of each decoder layer is $\in \mathbb{R}^{RN \times RN}$ except the first layer ($\in \mathbb{R}^{8 \times RN}$). Both the encoder and decoder contain initial and final dense transformation layers, with three residual layers in between. Each residual layer contains two dense layers. All internal layers use tanh activations and are batch-normalized with a decay rate of 0.9 (Ioffe and Szegedy, 2015).

Given that the capacity for *speaker adaptation* — short-term accommodation of idiosyncrasies in individuals' productions — has been shown for both adults (Clarke and Garrett, 2004; Maye et al., 2008a) and children (Kuhl, 1979; van Heugten and Johnson, 2014), we equip the models with a 16-dimensional speaker embedding, which is concatenated both to the acoustic input frames and to the latent bit vector.

Each BSN of the latent encoding is associated with a firing probability $\in [0, 1]$ parameterized by the encoder network. The neural activation can be discretized either deterministically or by sampling. The use of BSNs to encode segments is a problem for gradient-based optimization since it introduces a non-differentiable discrete decision into the network's latent structure. We overcome this problem by approximating missing gradients using the straight-through estimator (Hinton, 2012; Bengio et al., 2013; Courbariaux et al., 2016) with slope-annealing (Chung et al., 2017). Slope annealing multiplies the pre-activations a by a monotonically increasing function of the training iteration t, incrementally decreasing the bias of the straight-through estimator. We use the following annealing function:

$$a \leftarrow a(1 + 0.1t)$$

We discretize the latent dimensions using Bernoulli sampling during training and thresholding at 0.5 during evaluation.

The models are implemented in Tensorflow (Abadi et al., 2015) and optimized using Adam (Kingma and Ba, 2014) for 150 training epochs with a constant learning rate of 0.001. The source code is available at `https://github.com/coryshain/dnnseg`.

3.2 Data

We apply our model to the Xitsonga and English speech data from the Zerospeech 2015 shared task. The Xitsonga data are drawn from the NCHLT corpus (De Vries et al., 2014) and contain 2h29m07s of read speech from 24 speakers. The English data are drawn from the Buckeye Corpus (Pitt et al., 2005) and contain 4h59m05s of conversational speech from 12 speakers. While neither of these corpora represent child-directed speech, they both consist of fluently produced word tokens in context, rather than isolated productions as in many previous laboratory studies with infants (Eimas et al., 1971; Werker and Tees, 1984; Kuhl et al., 1992, *inter alia*). We pre-segment the audio files using time-aligned phone transcriptions pro-

---

[1] Feedforward networks are used both for computational reasons and because they dramatically outperformed recurrent networks in initial experiments, especially when RNN's were used for decoding. We hypothesize that this is due to the lack of direct access to the encoder timesteps, such as that permitted by sequence to sequence models with attention (Bahdanau et al., 2015). Attention is not viable for our goals because it defeats the purposes of an autoencoder by allowing the decoder to bypass the encoder's latent representation.

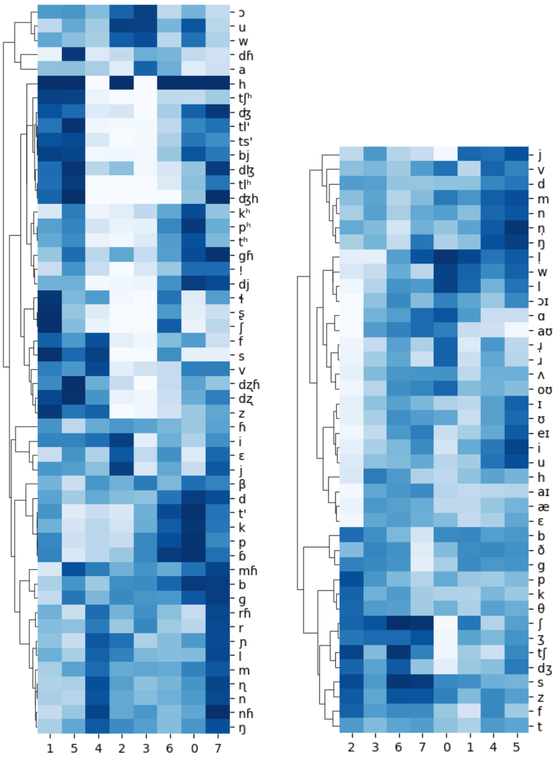
vided in the challenge repository. The gold segment labels are used in clustering evaluation metrics, but the unsupervised learner never has access to them. Data selection criteria and annotation procedures are are described in more detail in Versteegh et al. (2015).

Prior to fitting, we apply a standard spectral preprocessing pipeline from automatic speech recognition: raw acoustic signals are converted into 13-dimensional vectors of Mel frequency cepstral coefficients (MFCCs) (Mermelstein, 1976) with first and second order deltas, yielding 39-dimensional frames sequenced in time. Each frame covers 25ms of speech, and frames are spaced 10ms apart. The deltas are used by the encoder but stripped from the reconstruction targets. Following preceding work showing improved unsupervised clustering when segments are given fixed-dimensional acoustic representations, thus abstracting away from the variable temporal dilation in natural speech (Kamper et al., 2017a,b), we resample all reconstruction targets to a length of 25 frames.

This pipeline instantiates some standard assumptions about the perceptual representations underlying human speech processing. Alternative representations — for instance, articulatory representations (Liu, 1996; Frankel and King, 2001; Kirchhoff et al., 2002; Livescu and Glass, 2004) or other spectral transforms (Zwicker, 1961; Makhoul, 1975; Hermansky, 1990; Hermansky et al., 1991; Coifman and Wickerhauser, 1992; Shao et al., 2009) — have been proposed as alternatives to MFCCs. Our results concerning perceptual availability are of course tied to our input representation, since phenomena that are poorly distinguished by MFCCs have less effect on our autoencoder loss function. Nonetheless, MFCCs are known to produce high-quality supervised speech recognizers (Zheng et al., 2001; Hinton et al., 2012), and we therefore leave optimization of the representation of speech features to future work.

4 Results and Discussion

4.1 Phonemic Categories Partially Emerge from Modeling Auditory Percepts



(a) Xitsonga (b) English

Figure 2: Mean activation pattern by gold segment label from the BSN model with speaker embeddings, with darker color indexing higher average activation.

The first research question posed in the introduction was to what extent theory-driven phoneme categories emerge from a drive to model auditory percepts. We explore this question by evaluating the degree of correspondence between the autoencoder hidden states and the gold phone labels. Table 1 reports learning outcomes using the information theoretic measures *homogeneity* (H), *completeness* (C), and *V-measure* (V) for unsupervised cluster evaluation (Rosenberg and Hirschberg, 2007). All three metrics range over the interval $[0, 1]$, with 1 indexing perfect performance. As shown in the table, our model yields dramatically better clustering performance than a random baseline that uniformly draws cluster IDs from a pool of 256 categories: we obtain 2118% and 4500% relative V-measure improvements in Xitsonga and English, respectively. At the same time, clustering performance is far from perfect. This result indicates that perceptual modeling — an immediately-available learning signal in infant language acquisition — both (1) drives the learner a long way toward phoneme acquisition, and (2) is insufficient to fully identify phone categories in our learners. One likely explanation for the latter is evidence from cognitive science that phonotactic and lexical information (to which our learners do not have access) supplement perception as the acquisition process unfolds (Feldman et al., 2013a; Pater and Moreton, 2014).

The middle rows of Table 1 show ablation results from using non-discrete sigmoid neurons rather than BSNs in the encoding layer (*Sigmoid* vs. *BSN*)[2] and/or removing the speaker adaptation feature (i.e. removing speaker embeddings). As shown, the classification performance of our model benefits substantially from the use of BSN encodings with speaker adaptation, especially on Xitsonga. Note that the reconstruction losses of the sigmoid encoders are better than those of the BSN encoders despite their degraded classification performance. This is to be expected: sigmoid neurons have greater representational capacity than binary neurons, since they can encode information through continuous gradations. They are therefore more capable of memorizing idiosyncratic properties of the input and are less incentivized to discover generalizable latent classes. The ablation results thus suggest that speaker adaptation and categorical perception support the discovery of linguistically relevant abstractions.

4.2 Distinctive Features Differ in Perceptual Availability

The second research question posed in the introduction was to what extent distinctive features differ in perceptual availability. We explore this question in two ways.

First, we qualitatively assess the linguistic plausibility of the natural clustering in the latent bits. Figure 2 visualizes this clustering based on correlations between the average of the bit patterns across all instances of each gold phone type for both datasets. If the unsupervised classifier ignored phonological structure altogether, the plots would be roughly uniform in color, and if the unsupervised classifier perfectly identified phonemes, the plots would consist entirely of fully light or fully dark cells, with unique bit patterns associated with each phone type. As shown, the reality falls in between: while the visualized classifications are far from perfect, they nonetheless contain a great deal of structure and suggest the presence of rough natural classes in both languages, especially of affricates, nasals, sibilants, and approximants. Our learners also replicate infants' difficulty in discriminating some nasal and fricative place features (Polka et al., 2001; Nittrouer, 2001; Narayan et al., 2010), assigning highly similar representations to many subtypes of nasals and fricatives across places of articulation (see e.g. similar mean bit patterns of /n/ vs. /ŋ/ and /s/ vs. /ʃ/ in both languages).

Second, we quantitatively evaluate the degree to which theory-driven features like [±voice] are recoverable from the network's latent representations. To do so, we map gold phone labels into binary distinctive feature clusters from Hayes (2011) using Phonological CorpusTools (Hall et al., 2016). One possible form of analysis would be to search for individual correspondences between distinctive features and the model's latent dimensions. However, this is likely to underestimate the degree of feature learning because the deep decoder can learn arbitrary logics on the latent bit patterns, a necessary property for fitting complex non-linear mappings from latent features to acoustics. We instead evaluate distinctive feature discovery by fitting random forest classifiers that predict theory-driven features using the latent bit patterns as inputs. We can then use classifier performance to assess the degree to which a given distinctive feature can be recovered by a logical statement on the network's latent bits. The classifiers were fitted using 5-fold cross-validation in Scikit-learn (Pedregosa et al., 2011) with 100 estimators, balanced class weighting, and an entropy-based split criterion.

Results are given in Tables 2 and 3. As shown, (1) there are large differences in perceptual availability between features, and (2) relative avail-

---

[2] To obtain class labels from the sigmoid encoder, we rounded the activations. Rounding was only used for evaluation and had no impact on the fitting procedure.

Table 3: Perceptual availability by feature in English

ability of features is remarkably consistent between these unrelated languages, suggesting that the models are tapping into generalized perceptual patterns. The best-learned feature in both languages is [±voice], which is consistent with early evidence of voicing sensitivity in infants (see Section 2.2). Below this, the features [±sonorant], [±continuant], [±consonantal], [±approximant], and [±syllabic] are faithfully recovered in both languages. All of these features distinguish prototypical consonants from prototypical vowels but differ in their treatment of edge cases like nasals, liquids, and glides. Thus, similarly to the infant subjects discussed in Section 2.2, the model finds the consonant-vowel contrast to be highly available. Like human infants, our computational learner finds certain consonantal place and manner features relatively more difficult, although the features [±dorsal], [±coronal], [±strident] and [±delayed release] are also fairly well recovered in both languages. By contrast, both models poorly capture features like [±lateral], [±labiodental], [±distributed], [±nasal], [±constricted glottis], [±spread glottis], and [±implosive],[3] suggesting that these features are more difficult to discover bottom-up and may therefore be more dependent on phonotactic and lexical constraints for acquisition.[4] This finding aligns with the acquisition literature in suggesting that there may be substantial differences in perceptual availability between different place and manner features (see Section 2.2).

In addition to these cross-linguistic similarities, the models also reveal important differences between Xitsonga and English. For example, the two languages differ in the relative availability of features that distinguish vowels vs. features that distinguish consonants. In English, vowel features like [±front], [±high], and [±back] are substantially less well learned than consonant features like [±coronal], [±anterior], and [±delayed release], while the opposite holds in Xitsonga. We hypothesize that this is due to the fact that there are more vowels and fewer consonants in English than in Xitsonga: having fewer distinctions might reduce the degree of "crowding" in the articulatory space, increasing perceptual contrast between phone types (Liljencrants and Lindblom, 1972).

---

[3] Delayed release: affricates, constricted glottis: ejectives; spread glottis: glottal frication (e.g. aspirated stops).

[4] Note that we are not suggesting that e.g. [±spread glottis] cannot be detected in speech. Our claim is rather that acoustic cues to [±spread glottis] are less pronounced and/or less reliable than cues to e.g. [±voice] and therefore perhaps more difficult to exploit in early infancy, since our autoencoder model does not find them particularly useful for perceptual reconstruction.

Finally, note that the cluster maps in Figure 2 and the feature recovery data in Tables 2 and 3 provide complementary perspectives on the learned representations. For example, it may at first seem surprising that the feature [±nasal] is recovered relatively poorly in both languages, given that nasals are well clustered in Figure 2. This discrepancy indicates that nasal segments are represented similarly to each other but also similarly enough to other segments that they are not reliably differentiated as a class. Conversely, the voicing feature is well recovered in both languages despite the lack of a visible cluster of voiced segments. This indicates that voicing is reliably encoded in the latent bits, even if the representation as a whole is dominated by other kinds of information.

5 Conclusion

In this paper, we used binary stochastic neural autoencoders to explore the perceptual availability of (1) theory-driven phonemic categories and (2) theory-driven phonological features, based only on the acoustic properties of segments. We found that phonemic categories exert substantial influence on a learner driven to model its auditory percepts, but that additional information — especially phonotactic and lexical (Feldman et al., 2013a) — is likely necessary for full adult-like phone discrimination. We also found asymmetries in the perceptual availability of phonological features like [±voice] and [±nasal] and showed that these asymmetries reflect attested patterns of infant phone discrimination. Our model both replicates broad trends in the child acquisition literature (successful consonant-vowel and voicing discrimination, relatively less successful discrimination of various place and manner features) and sheds new light on potential relationships between auditory perception and language acquisition: the overall cline of perceptual availability revealed by the model in Tables 2 and 3 suggests a range of testable hypotheses about the role of perception in infant speech processing.

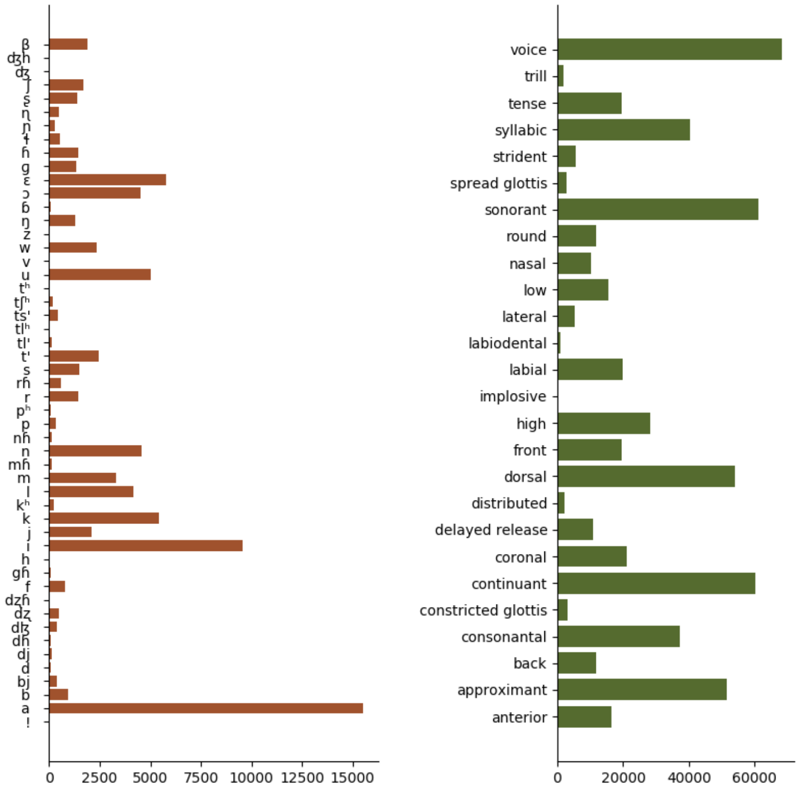
A Phonological feature definitions

We adopt the phonological feature definitions presented in Hayes (2011). For full exposition of the features and their motivations, we refer readers to the source. However, for convenience, we provide the following brief (and in some cases oversimplified) definitions based on Hayes (2011):

- **syllabic:** Vowels are [+syllabic], others are [-syllabic]
- **consonantal:** Vowels and glides are [-consonantal], others are [+consonantal]
- **approximant:** Vowels, liquids, and glides are [+approximant], others are [-approximant]

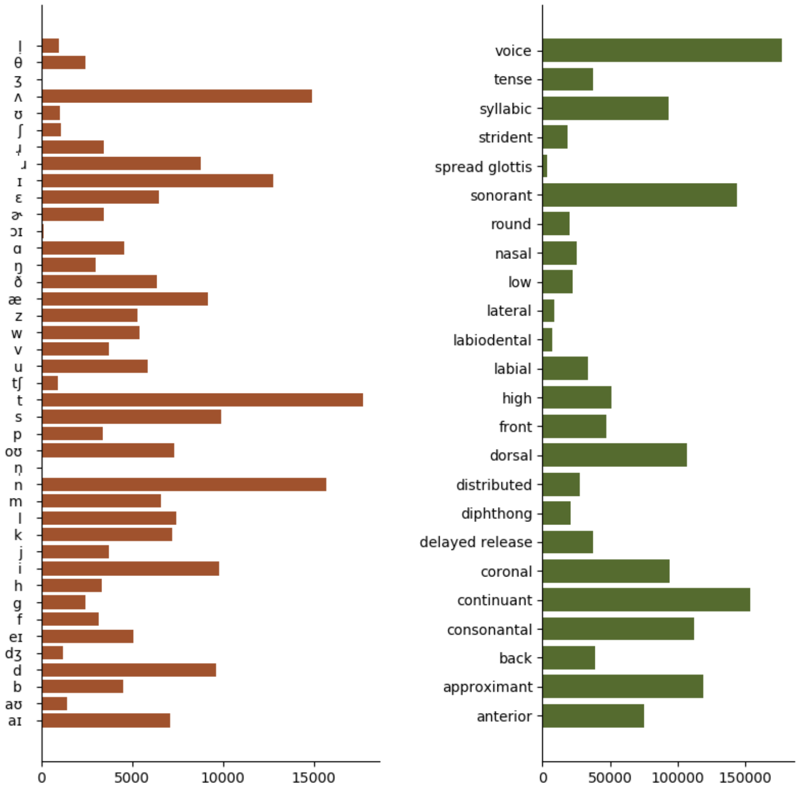


(a) Phonemes

(b) Features

Figure 3: Xitsonga phoneme and feature distributions.

- **sonorant:** Vowels, liquids, glides, and nasals are [+sonorant], others are [-sonorant]
- **continuant:** Stops and affricates are [-continuant], others are [+continuant]
- **delayed release:** Affricates and fricatives are [+delayed release], others are [-delayed release]
- **trill:** Trills are [+trill], others are [-trill]
- **front:** Front vowels and fronted velars are [+front], others are [-front]
- **back:** Back vowels and back velars are [+back], others are [-back]
- **high:** High vowels and velars are [+high], others are [-high]
- **low:** Low vowels and pharyngeals are [+low], others are [-low]
- **tense:** Tense vowels are [+tense], others are [-tense]
- **round:** Rounded vowels and rounded labial consonants are [+round], others are [-round]
- **nasal:** Nasal consonants and (contrastively) nasalized vowels are [+nasal], others are [-nasal]
- **labial:** Sounds articulated with the lips are [+labial], others are [-labial]
- **coronal:** Sounds articulated with the tongue blade/tip are [+coronal], others are [-coronal]
- **dorsal:** Sounds articulated with the tongue body are [+dorsal], others are [-dorsal]
- **anterior:** Coronals articulated at the alveolar ridge or forward are [+anterior], others are [-anterior]
- **distributed:** Coronals articulated with the tongue blade are [+distributed], others are [-distributed]
- **strident:** Sibilants (i.e. coronal fricatives and affricates) are [+strident], others are [-strident]
- **lateral:** Sounds with lateral oral closure (open at edges, like [l]) are [+lateral], others are [-lateral]
- **labiodental:** Sounds that are articulated by touching the lower lip to the upper teeth are [+labiodental], others are [-labiodental]



(a) Phonemes

(b) Features

Figure 4: English phoneme and feature distributions.

- **voice:** Voiced sounds are [+voice], others are [-voice]
- **spread glottis:** [h], [ɦ], and (contrastively) aspirated consonants are [+spread glottis], others are [-spread glottis]
- **constricted glottis:** Ejectives and glottal stops are [+constricted glottis], others are [-constricted glottis]
- **implosive:** Implosives are [+implosive], others are [-implosive]

B Xitsonga Phoneme Featurization

To the best of our knowledge, the gold Xitsonga phone transcriptions provided by the Zerospeech 2015 dataset use a non-standard pronunciation alphabet that is undocumented but isomorphic to the NCHLT transcription convention. In order to extract distinctive features for the Xitsonga phone labels, we hand-mapped the Zerospeech labels onto NCHLT labels by cross-referencing the Zerospeech phone sequences, the Zerospeech orthographic word sequences, and the NCHLT pronunciation dictionary, searching for systematic correspondences between Zerospeech and NCHLT transcription practices. Once the Zerospeech-to-NCHLT mapping was obtained, we used the International Phonetic Alphabet (IPA) phone labels provided by NCHLT to look up distinctive features in the Phonological CorpusTools (PCT) feature maps (Hall et al., 2016). Some IPA labels from NCHLT were not found in the PCT database, and for those we used the following featurization rules:

- **Consonants with palatal offglides:** We used the features associated with the non-offglide consonant and switched on the *approximant*, *dorsal*, *high*, *front*, and *tense* features.
- **Aspirated consonants:** We used the features associated with the non-aspirated consonant and switched on the *spread glottis* feature.
- **Ejective consonants:** We used the features associated with the non-ejective consonant and switched on the *constricted glottis* feature.
- **Voiceless alveolar lateral stops:** We used the features associated with voiceless alveolar lateral affricates and switched off the *de-*

layed release feature.

Our hand-made symbol correspondences and featurizations are distributed with this project's code repository.

C Phoneme and feature distributions

For reference, counts of phonemes and features by corpus are plotted in Figures 3 and 4. Note that the feature counts are generally larger because multiple features can be true of any one segment.

Giving Attention to the Unexpected: Using Prosody Innovations in Disfluency Detection

Vicky Zayats and Mari Ostendorf
Electrical Engineering Department
University of Washington
`[vzayats, ostendor]@uw.edu`

Abstract

Disfluencies in spontaneous speech are known to be associated with prosodic disruptions. However, most algorithms for disfluency detection use only word transcripts. Integrating prosodic cues has proved difficult because of the many sources of variability affecting the acoustic correlates. This paper introduces a new approach to extracting acoustic-prosodic cues using text-based distributional prediction of acoustic cues to derive vector z-score features (innovations). We explore both early and late fusion techniques for integrating text and prosody, showing gains over a high-accuracy text-only model.

1 Introduction

Speech disfluencies are frequent events in spontaneous speech. The rate of disfluencies varies with the speaker and context; one study observed disfluencies once in every 20 words, affecting up to one third of utterances (Shriberg, 1994). Disfluencies are important to account for, both because of the challenge that the disrupted grammatical flow poses for natural language processing of spoken transcripts and because of the information that they provide about the speaker.

Most work on disfluency detection builds on the framework that annotates a disfluency in terms of a reparandum followed by an interruption point (+), an optional interregnum ({ }), and then the repair, if any. A few simple examples are given below:

```
[ it's + {uh} it's] almost...
[ was it, + {I mean} , did you ] put...
[I just + I] enjoy working...
[By + ] it was attached to...
```

Based on the similarity/differences between the reparandum and the repair, disfluencies are often categorized into three types: repetition (the first example), rephrase (the next example), and restart (the last example).

The interruption point is associated with a disruption in the realization of a prosodic phrase, which could involve cutting words off or elongation associated with hesitation, followed by a prosodic reset at the start of the repair. There may also be emphasis in the repair to highlight the correction.

Researchers have been working on automatic disfluency detection for many years (Lickley, 1994; Shriberg et al., 1997; Charniak and Johnson, 2001; Johnson and Charniak, 2004; Lease et al., 2006; Qian and Liu, 2013; Zayats et al., 2016), motivated in part by early work on parsing speech that assumed reliable detection of the interruption point (Nakatani and Hirschberg, 1994; Shriberg and Stolcke, 1997; Liu et al., 2006). The first efforts to integrate prosody with word cues for disfluency detection (Baron et al., 2002; Snover et al., 2004) found gains from using prosody, but word cues played the primary role. In subsequent work (Qian and Liu, 2013; Honnibal and Johnson, 2014; Wang et al., 2017), more effective models of word transcripts have been the main source of performance gains. The success of recent neural network systems raises the question of what the role is for prosody in future work. In the next section, we hypothesize where prosody might help and look at the relative frequency of these cases and the performance of a high accuracy disfluency detection algorithm in these contexts.

With the premise that there is a potential for prosody to benefit disfluency detection, we then propose a new approach to extracting prosodic features. A major challenge for all efforts to incorporate prosodic cues in spoken language understanding is the substantial variability in the acoustic correlates of prosody. For example, duration cues are expected to be useful – disfluencies are often associated with duration lengthening related to hesitation. However, duration varies with

Proceedings of NAACL-HLT 2019, pages 86–95
Minneapolis, Minnesota, June 2 - June 7, 2019.

phonetic context, word function, prosodic phrase structure, speaking rate, etc. To account for some of this variability, various feature normalization techniques are used, but typically these account for only limited contexts, e.g. phonetic context for duration or speaker pitch range for fundamental frequency. In our work, we introduce a mechanism for normalization using the full sentence context. We train a sequential neural prediction model to estimate distributions of acoustic features for each word, given the word sequence of a sentence. Then, the actual observed acoustic feature is used to find the prediction error, normalized by the estimated variance. We refer to the resulting features as innovations, which can be thought of as a non-linear version of the innovations in a Kalman filter. The innovations will be large when the acoustic cues do not reflect the expected prosodic structure, such as during hesitations, disfluencies, and contrastive or emphatic stress. The idea is to provide prosodic cues that are less redundant with the textual cues. We assess the new prosodic features in experiments on disfluency detection using the Switchboard corpus, exploring both early and late fusion techniques to integrate innovations with text features. Our analysis shows that prosody does help with detecting some of the more difficult types of disfluencies.

This paper has three main contributions. First, our analysis of a high performance disfluency detection algorithm confirms hypotheses about contexts where text-only models have high error rates. Second, we introduce a novel representation of prosodic cues, i.e. the innovation vector resulting from predicting prosodic cues given the whole sentence context. Analyses of the innovation distributions show expected patterns of prosodic cues at interruption points. Finally, we demonstrate improved disfluency detection performance on Switchboard by integrating prosody and text-based features in a neural network architecture, while comparing early and late fusion approaches.

2 How Might Prosody Help?

Disfluency detection algorithms based on text alone rely on the fact that disfluencies often involve parallel syntactic structure in the reparandum and the repair, as illustrated in the previous examples. In these cases, pattern match provides a strong cue to the disfluency. In addition, ungrammatical function word sequences are frequently associated with disfluencies, and these are relatively easy for a text-based model to learn. In some cases, an interregnum word (or words) provides a word cue to the interruption point. In the Switchboard corpus, only 15% of interruption points are followed by an interregnum, but it can provide a good cue when present. Prosody mainly serves to help identify the interruption point. Thus, for these types of disfluencies, it makes sense that prosodic cues would not really be needed.

	Reparandum Length				**% in**
Type	**1-2**	**3-5**	**6-8**	**8+**	**type**
repetition	1894	419	12	1	46%
rephrase	794	585	66	–	28%
restart	196	14	–	–	4%
nested*	149	262	158	118	13%

Table 1: Total word counts associated with reparanda of different lengths and types of disfluencies. *Counts for nested disfluencies exclude repetition tokens.

	Reparandum Length				
Type	**1-2**	**3-5**	**6-8**	**8+**	**overall**
repetition	0.99	0.99	1	1	0.99
rephrase	0.75	0.66	0.44	–	0.70
restart	0.41	0	–	–	0.39
nested*	0.79	0.66	0.62	0.21	0.62

Table 2: Percent of reparandum tokens that were correctly predicted as disfluent. *Statistics for nested disfluencies exclude repetition tokens.

Because disfluencies with a parallel syntactic structure do represent a substantial fraction of disfluencies in spontaneous speech, text-based algorithms have been relatively effective. The best models achieve F-scores of 86-91%[1] (Lou and Johnson, 2017; Zayats and Ostendorf, 2018; Wang et al., 2017, 2018). We hypothesize that many er-

---

[1] It is difficult to directly compare published results, because there are different approaches to tokenization that have a non-trivial impact on performance but are not well documented in the literature. Those differences include handling of fragment words, turn boundaries, and tokenization. For example, some studies use fragment features explicitly, while others omit them because speech recognition systems often miss them. Turn boundaries that do not end with a slash unit pose an ambiguity during speaker overlap: cross-turn 'sentences' can either be combined into a longer sentence or separated based on the turn boundary, which impacts what can be detected. Lastly, there are differences in whether contractions and possessives are split into two tokens, and whether conversational terms such as "you know" are combined into a single token.

	Reparandum Length	
Type	**1-2**	**3-5**
content-content	0.61 (30%)	0.58 (52%)
content-function	0.77 (20%)	0.66 (17%)
function-function	0.83 (50%)	0.80 (32%)

Table 3: Relative frequency of rephrases correctly predicted as disfluent for disfluencies that contain a content word in both the reparandum and repair (content-content), either the reparandum or repair (content-function) or in neither. Percentages in parentheses show the fraction of tokens belong to each category.

rors are associated with contexts where we expect that prosodic cues are useful, specifically the five cases below, with examples from the development set.

Restarts: Some disfluencies have no repair; the speaker simply restarts the sentence with no obvious parallel phrase.

`[ it would be + ] I think it's clear...`
`well [the +] uh i think what changed...`

Long disfluencies: These include distant pattern match or substantial rephrasing.

`[there is + for people who don't want to do the military service it would be neat if there were]`
`[what they're basically trying to do + i don't know up here in massachusetts anyhow what they're basically trying to do]`

Complex (nested) disfluencies: Disfluencies can occur within other disfluencies.

`[really + [[i + i] + we were really]...`
`[[to + to try to] + for two people who don't really have a budget to] ]...`

Non-trivial rephrasing: Rephrasing does not always involve a simple "rough copy" of a repair.

`[can + still has the option of]...`
`to keep them [in + uh quiet ]...`

Fluent repetitions: Contexts with fluent repetitions often include expressing a strong stance.

`a long long time ago...`
`she has very very black and white...`

In order to confirm that there is potential for prosody to help in these contexts, we first categorize the disfluencies. To avoid hand-labeling of categories, we distinguished disfluencies based on surface forms (repetition, rephrase, restart) and length of the disfluency reparandum. Word counts for the different categories are given in Table 1.

Conditioning on the different contexts, we analyze errors in the development set made by the high accuracy text-based disfluency detection system that is the baseline for this study (Zayats and Ostendorf, 2018). For this model, trained on Switchboard, the performance is 87.4 F-score (P=93.3, R=82.2) on the development set and 87.5 (P=93.1, R=82.5) on the test set. For each class, we measured the disfluency detection recall (relative frequency of reparandum tokens that were predicted correctly), as well as the percentage of tokens associated with each class. The results in Table 2 confirm that error rates are higher for restarts, longer rephrasings, and complex disfluencies.

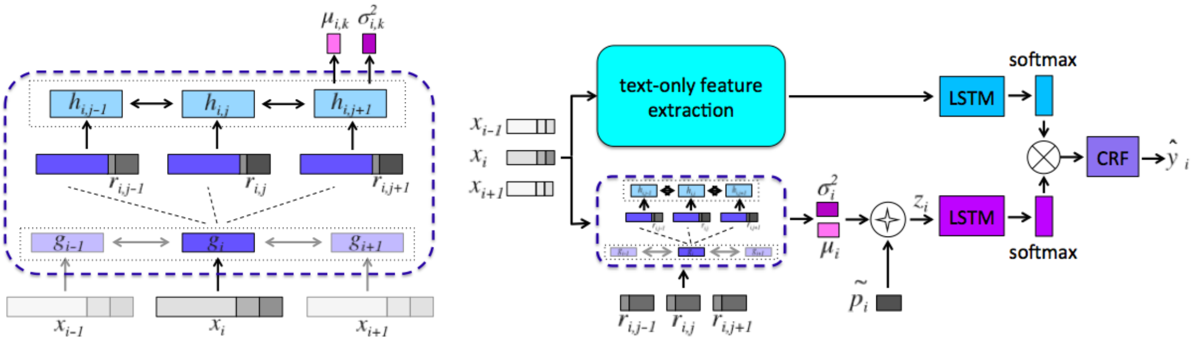
Rephrase disfluencies include both short lexical access errors, as well as non-trivial rewordings, which tend to be longer and involve content words. Table 3 breaks down performance for different lengths and word class to explore this difference. We found that rephrase disfluencies that contain content words are harder for the model to detect, compared to rephrases with function words only, and error increases for longer disfluencies.

Finally, the relative frequency of false positives in fluent repetitions is 0.35. Since fluent repetitions account for only 4% of all repetitions, the impact on overall performance is small.

The ultimate goal of a disfluency detection system is to perform well in domains other than Switchboard. Other datasets are likely to have different distributions of disfluencies, often with a higher frequency of those that are hard to detect, such as restarts and repairs (Zayats et al., 2014). In addition, due to the differences in vocabulary, disfluencies with content words are more likely to get misdetected if there is a domain mismatch. Thus, we hypothesize that prosody features can have a greater impact in a domain transfer scenario.

3 Method

Integrating prosodic cues has proved difficult because of the many sources of variability affecting the acoustic correlates, while systems that only use text achieve high performance. In this work, we propose a new approach that operates on differences in information found in text and prosody. In order to calculate such differences, we introduce innovation features, similar to the concept of innovations in Kalman filters. The key idea is to predict prosodic features based on text information, and then use the difference between the predicted and observed prosodic signal (innovations)



(a) Prosody prediction model

(b) Late fusion model

Figure 1: Prosody prediction (**left**) and late fusion (**right**) models. x_i is a contcatenation of token, POS and identity features embeddings at time i; r_i, j is a concatenation of stress and phone embeddings for phone j in token i; $\widetilde{p_i}$ is a vector of prosodic cues; g_i and h_i are hidden states of token level and phone level LSTMs, correspondingly.

as a new feature that is additionally used to predict disfluencies.

Let a prosody cue, p_i at time i be an observation associated with a sentence transcript containing n word tokens, $x_0 \dots x_n$. This observation can be modeled as a function of the sentence context $H(x_0 \dots x_n)$ perturbed with Gaussian noise $v_i \sim \mathcal{N}(0,\, \sigma_i^2)$:

$$p_i = H(x_0 \dots x_n) + v_i \qquad (1)$$

v_i can be viewed as a difference in information found between text and prosody. This difference can be measured using a z-score, which is a measure of how many standard deviations below or above the population mean an observation is. This framework can be viewed as a non-linear extension of a Kalman filter, where both H and σ_i^2 are parametrized using a neural network. Since disfluencies are irregularities in spoken language, they can be considered anomalies to fluent speech flow. A prosody flow that is unusual for a given word sequence, such as one that happens at interruption points, will likely have higher deviation from the predicted distribution. This anomaly in speech flow provides a strong signal when extracted using innovations, which is complementary to the text cues. In the next sections we give more details about the neural network architecture for text encoding, prosodic cues and innovation features, as well as an overview of the whole system.

3.1 Text Encoding for Prosody Prediction

We use both context around a word as well as subword information in text encoding for prosody prediction. Our text encoding consists of two bidirectional LSTMs: one on the token level and another on the phone level. First, we use pretrained word embeddings (Levy and Goldberg, 2014), part-of-speech tags embeddings, and identity features (whether the word is a filled pause, discourse marker, or incomplete) as inputs to a word-level bidirectional LSTM. Then, for each phone in a word we concatenate the phone embedding, its stress embedding, and the hidden state of the word-level LSTM for the corresponding token. The resulting phone feature vector is used as input to the second bidirectional LSTM. The last hidden state h_i of this second LSTM for token i summarizes the phone, stress and context information of that token, which we use to predict word-level prosodic cues. We use 3 categories of stress features in our experiments: primary, secondary and a non-stress phone.

3.2 Prosodic Cues

Our prosodic cues include:

Pause. Given a pause before a word, r_i, our pause cues are scaled as follows:

$$\widetilde{r_i} = \min(1, \ln(1 + r_i)) \qquad (2)$$

Pause information is extracted on a word-level using Mississippi State (MsState) time alignments (more details on data preprocessing in Section 4.1.) We use scaled real-valued pause information. Scaling pause lengths this way, including the threshold for pauses longer than 1 sec (which are rare), makes the pause distribution less skewed.

Word Duration. Similar to pause information, we extract word duration information using MsState time alignments. We do not need to do the standard word-based duration normalization, since the idea behind the innovation model is to normalize prosodic features using a richer context representation.

Fundamental frequency (F0) and Energy (E). Similar to Tran et al. (2018), we use three F0 features and three energy features. The three F0 features include normalized cross correlation function (NCCF), log-pitch weighted by probability of voicing (POV), and the estimated delta of log pitch. The three energy features include the log of total energy, the log of total energy from lower 20 mel-frequency bands and the log of total energy from higher 20 mel-frequency bands. The contour features are extracted from 25-ms frames with 10-ms hops using Kaldi (Povey et al., 2011). Our model is trained to predict the mean of these features across the frames in a word.

MFCCs. In addition to features used in Tran et al. (2018), we also use 13 mel-frequency cepstral coefficients, averaged at the word level, similar to F0 and energy features as described above.

3.3 Prosody Innovation Cues

Given a word-level text encoding h_i, for each token in a sentence we predict each of the k prosodic cues $\widetilde{p_i}^k$ listed above. We assume that the predicted prosody cues conditioned on text have a Gaussian distribution:

$$\begin{aligned}\widetilde{p_i}^k | h_i &\sim \mathcal{N}(\mu_{i,k}, \sigma^2_{i,k}) \\ \mu_{i,k} &= f(W_1^k h_i + b_1^k) \\ \sigma^2_{i,k} &= softplus(W_2^k h_i + b_2^k)\end{aligned} \tag{3}$$

W_1^k, b_1^k, W_2^k, b_2^k are learnable parameters; the activation function

$$softplus(x) = \log(1 + \exp(x))$$

ensures that the variance is always positive; f is an activation function, which is $softplus$ for pauses and durations, and $tanh$ for the rest of the prosodic cues. The objective function is a sum of the negative log-likelihood of prosodic cues $\widetilde{p_i}^k$ given text encoding. Then, given the predicted $\mu_{i,k}$, $\sigma^2_{i,k}$ and true values of prosodic cues $\widetilde{p_i}^k$, we calculate z-scores for each of the cues, which should have high absolute value for tokens with unusual prosodic behaviour:

$$z_i^k = \frac{\widetilde{p_i}^k - \mu_{i,k}}{\sigma_{i,k}} \tag{4}$$

The prosody prediction module is illustrated in Figure 1a.

These z-scores, or *innovations*, are used as additional features in our disfluency detection model. We train the prosody prediction model only on sentences that do not contain any disfluencies. Any unusual behaviours in disfluency regions, therefore, should have large innovation values predicted by our model.

3.4 Disfluency Detection System

Following (Zayats and Ostendorf, 2018), we use a bidirectional LSTM-CRF model as our disfluency detection framework. This framework uses a BIO tagging approach, where we predict whether each token is a part of a reparandum, repair or both. Following previous studies, the overall performance is measured in F-score of correctly predicted disfluencies in the reparandum. Previous work used textual features only. Here, we evaluate the importance of innovation cues with two types of multimodal fusion - early and late fusion. In early fusion, we concatenate innovations and/or prosody features with the rest of the textual features used in the framework at the input to LSTM layer. In late fusion, we create two separate models - one with only textual features and another with innovations and/or prosody features. Then we do a linear interpolation of the states of two models just before feeding the result to the CRF layer:

$$u_i^{shared} = \alpha u_i^{prosody} + (1 - \alpha) u_i^{text} \tag{5}$$

We tune the interpolation weight α and report the best in our experiments section. We train our model jointly, optimizing both prosodic cues prediction and disfluency detection. The schematic view of the late fusion system is presented in Figure 1b.

4 Experiments

In our experiments we evaluate the usefulness of innovation features, and compare it to baselines with text-only or raw prosodic cues. For each model configuration, we run 10 experiments with different random seeds. This alleviates the potential of making wrong conclusions due to "lucky/unlucky" random seeds. We report both the mean and best scores among the 10 runs.

4.1 Data Preprocessing

Switchboard (Godfrey et al., 1992) is a collection of telephone conversations between strangers,

	Model	**dev**		**test**		α
		mean	best	mean	best	
single	text	86.54	86.80	86.47	86.96	–
	raw	35.00	37.33	35.78	37.70	–
	innovations	80.86	81.51	80.28	82.15	–
early	text + raw	86.46	86.65	86.24	86.53	–
	text + innovations	86.53	86.77	86.54	87.00	–
	text + raw + innovations	86.35	86.69	86.55	86.44	–
late	text + raw	86.71	87.05	86.35	86.71	0.2
	text + innovations	**86.98**	**87.48**	**86.68**	**87.02**	0.5
	text + raw + innovations	86.95	87.30	86.60	86.87	0.5

Table 4: F1 scores on disfluency detection when using a single set of features (text-only, raw prosody features or innovation features), with early fusion and late fusion. “Raw” indicates the usage of original prosodic features (Section 3.2), while “innovations” indicate the usage of innovation features (Section 3.3).

but it ’s just you know leak leak leak everywhere
people should know that that ’s an option
and i think you do accomplish more after that
i mean [it was + it]
interesting thing [about gas is when + i mean about battery powered cars is]

Table 5: Examples of sentences where prosody innovations help. Words in red are correctly labeled when using prosody but not with text only. The first three show fluent phrases; the last two have disfluencies that are missed without prosody.

containing 1126 files hand-annotated with disfluencies. Because human transcribers are imperfect, the original transcripts contained errors. MsState researchers ran a clean-up project which hand-corrected the transcripts and word alignments (Deshmukh et al., 1998). In this work, we use the MsState version of the word alignments, which allows us to extract more reliable prosodic features. Since the corrected version of Switchboard does not contain updated disfluency annotations, we corrected the annotations using a semi-automated approach: we used a text-based disfluency detection algorithm to re-annotate tokens that were corrected by MsState, while keeping the rest of the original disfluency annotations. The result is referred to as a silver annotation. Most of the corrected tokens are repetitions and restarts. To assess the quality of the automatic mapping of disfluencies, we hand-annotated a subset (6.6k tokens, 453 sentences) of the test data and evaluated the performance of the silver annotation against the gold annotation, which has an F1 score of 90.1 (Prec 90.1, Rec 90.1). Comparing the performance estimates from gold and silver annotations on this subset, we find that the silver annotations give somewhat lower F1 scores (2-3% absolute), both due to lower precision and recall scores.

4.2 Results

Our experiments evaluate the use of innovations with two popular multimodal fusion approaches: early fusion and late fusion. Our baselines include models with text-only, prosody cues only (raw), and innovation features only as inputs. Since innovations require both text and raw prosodic cues, this baseline is multimodal. In addition, for the late fusion experiments, we show the optimal value of α, the interpolation weight from Equation 5. All experiment results are presented in Table 4.

We found that innovations are helpful in both early and late fusion frameworks, while late fusion performs better on average. The interpolation weight α for the late fusion experiments is high when innovations are used, which further indicates that innovation features are useful in overall prediction. Interestingly, innovation features alone perform surprisingly well. We also take a closer look at the importance of joint training of the disfluency detection system with prosody prediction. To do this, we pretrain the prosody pre-

i like to run [about + oh about] [two + two and a half] miles
the old-timers even the people who are technologists do n’t know how to operate
i do n’t know whether that ’s because they you know sort of give up hope
it must be really challenging to um try to juggle a job

Table 6: Examples of the sentences where prosody innovations hurt. Words in red are incorrectly labeled when using prosody but not with text only. The first shows a disfluency missed when using prosody; the other three are fluent regions with false detections.

diction part of the model first. Then, we train the full model with innovation inputs while freezing the part of the network responsible for predicting prosodic cues. The mean F-score of this disjointly trained model is 49.27% on the dev set, compared to 80.86% for the jointly trained model. This result suggests that training the system end-to-end in a multitask setup is very important.

5 Analysis

5.1 Error analysis

In order to better understand the impact of the prosody innovations, we perform an error analysis where we compare the predictions of two models: a late fusion model that uses both text and innovation features, and a baseline model that uses text only. All of the analysis is done on the dev set with the model that has the median performance out of 10 that were trained.

First, we extract all the sentences where the number of disfluency detection errors using the innovation model is lower than when using the text-only model (168 sentences). Examples of such sentences are presented in Table 5. By looking at the sentences where the model with innovations performs better, we see fluent repetitions and other ambiguous cases where audio is useful for correctly identifying disfluencies.

On the other hand, in Table 6, we have examples of sentences that have a higher number of errors when prosody is used (143 sentences). In the first example, the labeling of “two” as fluent by the model with prosody is arguably correct, with the repetition indicating a range rather than a correction. The next involves a parenthetical phrase, the start of which may be confused with an interruption point. In the last two cases, there is a prosodic disruption and an interegnum, but no correction.

In order to understand whether incorporating prosody through our model supports the hypotheses in Section 2, we compare the performance of two models for different categories of disfluencies. We found that using prosody innovations improves detection of: non-repetition disfluencies (from 68.2% to 73.7%), particularly for disfluencies with content words (65.2% to 71.0%); long repairs (64.0% to 72.7% and 40.0% to 64.6% for disfluencies with length of repair greater than 3 and 5 correspondingly); and restarts (from 36.0% to 37.4%). Prosodic innovations also help decrease the rate of false positives for fluent repetitions: the false positives rate decreased from 46.5% to 38.4%. However, the prosody model increases the false positives in other contexts, such as in the examples in Table 6.

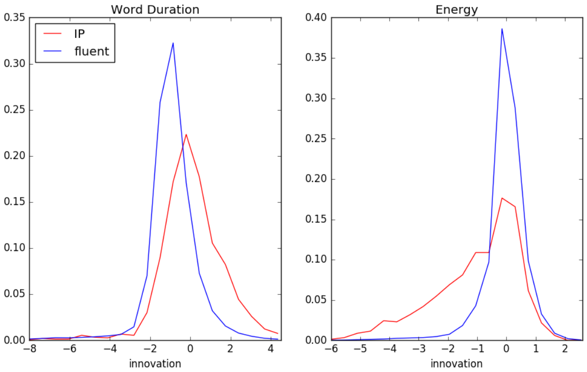


Figure 2: Histogram of innovations for word duration and energy features for words preceding an interruption point vs. fluent words.

5.2 Innovation Predictors

In order to understand what the model actually learns with respect to innovations, we look at innovation distributions for words preceding interruption points compared to fluent words. The histograms are presented in Figure 2. As expected, we see that words preceding interruption points have atypically longer duration and lower energy. The intonation features did not show substantial distribution differences, probably due to the overly simplistic word-level averaging strategy.

6 Related Work

Most work on disfluency detection falls into three main categories: sequence tagging, noisy-channel and parsing-based approaches. Sequence tagging approaches rely on BIO tagging with recurrent neural networks (Hough and Schlangen, 2015; Zayats et al., 2016; Wang et al., 2016; Zayats and Ostendorf, 2018; Lou et al., 2018). Noisy channel models operate on a relationship between the reparandum and repair for identifying disfluencies (Charniak and Johnson, 2001; Zwarts et al., 2010). Lou and Johnson (2017) used a neural language model to rerank sentences using the noisy channel model. Another line of work combined parsing and disfluency removal tasks (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Tran et al., 2018). Recently a transition-based neural model architecture was proposed for disfluency detection (Wang et al., 2017). The current state of the art in disfluency detection (Wang et al., 2018) uses a neural machine translation framework with a transformer architecture and additional simulated data. All of the models mentioned above rely heavily on pattern match features, hand-crafted or automatically extracted, that help to identify repetitions and disfluencies with parallel syntactic structure.

While prosodic features are useful for detecting interruption points (Nakatani and Hirschberg, 1994; Shriberg and Stolcke, 1997; Shriberg, 1999; Liu et al., 2006), recent methods on disfluency detection predominantly rely on lexical information exclusively. An exception is (Ferguson et al., 2015), which showed some gains using a simple concatenation of pause and word duration features. Similar to disfluency detection, parsing has seen little use of prosody in recent studies. However, Tran et al. (2018) recently demonstrated that that a neural model using pause, word and rhyme duration, f0 and energy helps in spoken language parsing, specifically in the regions that contain disfluencies.

Early fusion and late fusion are the two most popular types of modality fusion techniques. In recent years, more interesting modality fusion approaches were introduced, most of them where the fusion happens inside the model (Zadeh et al., 2017; Chen et al., 2017; Zadeh et al., 2018). Those methods usually require the model to learn interactions between modalities implicitly, by backpropagating the errors based on the main objective function with respect to the task. Other multimodal representation learning approaches learn a shared representation between multiple modalities (Andrew et al., 2013; Ryan Kiros, 2014; Xu et al., 2015; Suzuki et al., 2016), often targeting unsupervised translation from one modality to the other. In our work we use innovations as a novel representation learning approach, where our emphasis is on looking into complementary cues rather than similarity between multiple modalities.

7 Conclusions

In this paper, we introduce a novel approach to extracting acoustic-prosodic cues with the goal of improving disfluency detection, but also with the intention of impacting spoken language processing more generally. Our initial analysis of a text-only disfluency detection system shows that despite high performance of such models, there exists a big gap in the performance of text-based approaches for some types of disfluencies, such as restarts and non-trivial or long rephrases. Thus, prosody cues, which can be indicative of interruption points, have a potential to contribute towards detection of more difficult types of disfluencies. Since the acoustic-prosodic cues carry information related to multiple phenomena, it can be difficult to isolate the cues that are relevant to specific events, such as interruption points. In this work, we introduce a novel approach where we extract relevant acoustic-prosodic information using text-based distributional prediction of acoustic cues to derive vector z-score features, or innovations. The innovations point to irregularities in prosody flow that are not predicted by the text, helping to better isolate signals relevant to disfluency detection that are not simply redundant with textual cues. We explore both early and late fusion approaches to combine innovations with text-based features. Our experiments show that innovation features are better predictors of disfluencies compared to the original acoustic cues.

Our analysis of the errors and of the innovation features point to a limitation of the current work, which is in the modeling of F0 features. The current model obtains word-based F0 (and energy) features by simply averaging the values over the duration of the word, which loses any distinctions between rising and falling F0. By leveraging polynomial contour models, we expect to improve both intonation and energy features, which we hope will reduce some of the false detections associated with emphasis and unexpected fluent phrase boundaries.

An important next step is to test the system using ASR rather than hand transcripts. It is possible that errors in the transcripts could hurt the residual prediction, but if prosody is used to refine the recognition hypothesis, this could actually lead to improved recognition. Finally, we expect that the innovation model of prosody can benefit other NLP tasks, such as sarcasm and intent detection, as well as detecting paralinguist information.

Massively Multilingual Adversarial Speech Recognition

Abstract

We report on adaptation of multilingual end-to-end speech recognition models trained on as many as 100 languages. Our findings shed light on the relative importance of similarity between the target and pretraining languages along the dimensions of phonetics, phonology, language family, geographical location, and orthography. In this context, experiments demonstrate the effectiveness of two additional pretraining objectives in encouraging language-independent encoder representations: a context-independent phoneme objective paired with a language-adversarial classification objective.

1 Introduction

The main difficulty in creating automatic speech recognition (ASR) systems for a large number of the world's 7,000 languages is a lack of training data. Such data comes in the form of speech paired with transcriptions, a pronunciation lexicon, and text for language model training. A common technique in data-constrained settings is to learn language-independent representations of speech via multilingual training. Popular approaches include the use of multilingual bottleneck features (Vesely et al., 2012) as well as multilingual model training before fine-tuning to a *target* language (Scanzio et al., 2008; Vu et al., 2012).

Prior work in multilingual and cross-lingual speech recognition has been restricted to a small handful of the world's most-spoken languages, relying on multilingual corpora such as GlobalPhone (Schultz, 2002), the IARPA Babel corpora (Gales et al., 2014), or the VoxForge[1] corpora. Most work typically only reports on models trained on a subset of these languages.

In this paper we explore pretraining multilingual ASR models using speech from as many as 100 languages from the CMU Wilderness Multilingual Speech Dataset (Black, 2019).[2] To the best of our knowledge, this is the greatest number of languages that has been used in multilingual ASR model training to date. We perform experiments to guide the choice of languages used when pretraining the model and assess the relative importance of similarity between the pretraining languages and target language in terms of geographic location, phonology, phonetic inventory, language family and orthography.

We examine these variables in the context of two experimental setups: one where models are adapted to target language and target speakers, and one where models are adapted to target language but non-target speakers. The first task is relevant to language documentation contexts, which often involves transcribing speech of specific speakers for which there already exists some transcribed speech as training data (Michaud et al., 2018). The second case is relevant to incident response as modelled by LORELEI (Strassel and Tracey, 2016), where there may only be a single target-language consultant available for which transcribed speech can be elicited, but the goal is to have an ASR model that generalizes to multiple speakers.

Multilingual ASR training on such a scale presents challenges because of this language diversity. In order to guide the model to learn language-independent representations that are more amenable to adaptation, we experiment with two auxiliary training tasks. The first is context-independent phoneme sequence prediction to help bridge orthographic inconsistencies between languages. The second is a domain-adversarial classification objective (Ganin et al., 2016) over languages to encourage invariance

of the model with respect to language-specific phenomena. The hierarchical combination of grapheme and phoneme objectives has only been used in monolingual end-to-end frameworks (Krishna et al., 2018; Rao and Sak, 2017). Language-adversarial training in ASR (Yi et al., 2018) has not been done at this scale before, nor in an end-to-end framework.

Our experiments are designed to answer the following questions:

1. Is there benefit in scaling multilingual model training to a large number of languages?
2. In what circumstances, if any, does the addition of a phoneme and/or language-adversarial objective improve multilingual models?
3. How should we choose languages with which to pretrain a multilingual model?
4. Do the answers to the above questions change when adapting to target versus non-target speakers in the target language?

We find that using the auxiliary objectives in pretraining facilitates model transfer to unseen languages, especially when the pretraining languages are very dissimilar (Section 6). When the target speakers are seen in adaptation (Section 7), similarity of the pretraining languages and the target language is more important than quantity of pretraining languages. Choosing as pretraining languages geographically proximal languages tends to help more than phonetically and phonologically similar but otherwise distant languages. However, when adapting to a handful of non-target speakers of the target language (Section 8), the domain mismatch caused by the unseen speaker, language, or recording environment degrades performance. Exposing the model to as many pretraining languages as possible becomes vital to minimize this mismatch. Results on this task demonstrate that a massively multilingual seed model substantially outperforms other seed models trained on languages similar to the target. We have provided an ESPnet recipe to train and test our models.[3]

2 Related Work

This paper builds on work on multilingual ASR, end-to-end ASR, and adversarial learning.

Multilingual transfer in ASR often relies on using bottle-neck features (Vesely et al., 2012; Vu et al., 2012; Karafiát et al., 2018) and adapting an acoustic model trained on one language to effectively recognize the sounds of other languages (Schultz and Waibel, 2001; Le and Besacier, 2005; Stolcke et al., 2006; Tóth et al., 2008; Plahl et al., 2011; Thomas et al., 2012; Imseng et al., 2014; Do et al., 2014; Heigold et al., 2013; Scharenborg et al., 2017). However, while most work uses less than 10 languages for model training, we include up to 100 languages in training.

End-to-end ASR has recently become popular, with approaches such as attention-based encoder-decoder models (Chorowski et al., 2015; Chan et al., 2015), the connectionist temporal classification (CTC) objective of Graves et al. (2006, 2013), or a combination of both (Kim et al., 2016; Hori et al., 2017). These approaches have also been deployed in multilingual settings (Toshniwal et al., 2017; Chiu et al., 2018; Müller et al., 2017; Dalmia et al., 2018; Watanabe et al., 2017a). Our baseline approach to multilingual knowledge transfer is most similar to Inaguma et al. (2018), and involves training a hybrid CTC-attention seed model.

Hierarchical and multi-task approaches including combining grapheme and phoneme prediction in monolingual contexts (Rao and Sak, 2017; Krishna et al., 2018) at different levels of the network, or using sub-word units of varying granularity (Sanabria and Metze, 2018), have been shown to improve ASR performance. In this paper we extend the approach of hierarchical placement of additional objectives in order to enforce language independent, transferable models.

Domain-adversarial training is one such method for encouraging the model to learn language independent representations. A key contribution of this paper is the use of a domain-adversarial classification objective (Ganin et al., 2016) over many languages in order to encourage the model to learn representations that are invariant to language. Domain-adversarial training incorporates an auxiliary domain classification task, but negates gradients for encoder weights before the parameter update in order to guide the encoder to produce hidden representations that fool the classifier: i.e. they minimize information about the language while still facilitating the

---

[3] `https://github.com/espnet/espnet/tree/master/egs/cmu_wilderness/asr1`

primary task of speech recognition.

Domain-adversarial training has been used in speech recognition to learn features invariant to noise conditions (Shinohara, 2016), accents (Sun, 2018), and sex (Tripathi et al., 2018). Most closely related to our work is that of Yi et al. (2018), who use a language-adversarial objective when preparing multilingual bottleneck features from four languages for a hidden Markov model (HMM) ASR pipeline. In contrast, our work uses an adversarial objective across many languages, pairing it with a context-independent phoneme objective in an end-to-end framework.

3 Data

We scraped the data that forms the CMU Wilderness dataset, using a freely available script.[4] This dataset consists of dramatized readings of the Bible in hundreds of languages. Each reading is ascribed a rating based on alignment quality which fits into one of these classes: `very good`, `good`, `okay`, and `not okay`.

The script used to preprocess the data uses a universal pronunciation module in Festival (Taylor et al., 1998)[5] to produce pronunciation lexicons using an approach based on that of UniTran (Yoon et al., 2007), which we use to create phonemic transcriptions.

3.1 Characteristics of the Speech

The dataset consists of readings of the Bible, with readings typically of just a few speakers, mostly male. These are often dramatized, with sound effects and background music. For many purposes this could be considered a limitation of the data. Although the characteristics of the speech are unique, it allows us to investigate multilingual models over many languages without the confounds of an overly noisy environment. It is not unreasonable to expect our findings to generalize to other speech recognition domains.

3.2 Evaluation Languages

While the dataset includes only a single reading of the Bible for most languages, there are a number with two or more. We evaluate on languages for which we can find two or more readings. This is so that we can compare adaptation to a target language but not the speakers of the target reading (we refer to this task as *language adaptation*, as explored in Section 8) with adaptation to the target language as well as the target reading (we refer to this task as *reading adaptation*). We additionally restricted the evaluation languages to those that have at least one `good` or `very good` reading in terms of alignment quality. Table 1 presents the evaluation languages and readings grouped by family or geographic location, along with their durations.

	Hours:minutes/quality per reading		
Aymara (ayr)	16:19/G	18:37/G	-
SB Quechua (quh)	27:41/G	20:02/G	-
Kekchi (kek)	19:32/G	18:30/G	-
Ixil (ixl)	35:06/VG	25:35/G	18:29/G
Malagasy (mlg)	12:29/NO	15:52/O	15:59/G
Indonesian (ind)	19:01/G	21:20/G	30:34/G
Garap (kia)	15:34/G	12:17/VG	-
Swedish (swe)	15:55/G	16:46/VG	-
Spanish (spn)	16:35/G	15:19/G	-

Table 1: The duration of each reading in the evaluation languages (ISO 639-3 language codes in parentheses), before our preprocessing. Alignment quality categories are `very good` (VG), `good` (G), `okay` (O), `not okay` (NO). *SB Quechua* denotes South Bolivian Quechua.

4 Auxiliary Training Objectives

In addition to scaling ASR training to 100 languages, a key contribution of our work is the use of a context-independent phoneme objective paired with a language-adversarial classification objective in a end-to-end grapheme-based neural network, as illustrated in Figure 1.

4.1 Baseline Model

Our experiments are conducted within the framework of a hybrid CTC-attention end-to-end neural model using ESPnet (Watanabe et al., 2017b), which uses an encoder-decoder architecture implemented in PyTorch (Paszke et al., 2017). The encoder we use consists of VGG-like convolution layers (Simonyan and Zisserman, 2014; Sercu et al., 2016) followed by a multilayer bidirectional long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997). The decoder uses location-based attention (Chorowski et al., 2015) and an LSTM. In addition to the attention, the decoder also incorporates CTC

---

[4] https://github.com/festvox/datasets-CMU_Wilderness

[5] http://www.cstr.ed.ac.uk/projects/festival/

probabilities over graphemes to encourage monotonicity in decoding.

4.2 Phoneme Objective

The end-to-end neural model performs direct grapheme prediction without recourse to a pronunciation lexicon as traditional hybrid HMM-DNN models do. Since different orthographies may be mutually disjoint or only weakly related to the phonetic content of the input speech, we use a context-independent phoneme CTC objective to encourage learning of representations independent of such orthographic idiosyncrasies.

We performed limited preliminary experiments to determine how best to use the phoneme objective, which corroborated recent work in hierarchical training objectives that supports inserting the phoneme objective in the layers below the final layer (Krishna et al., 2018). We also found that using the phoneme objective during adaptation was harmful and therefore in all reported experiments we use it only during multilingual pretraining.

4.3 Language-Adversarial Pretraining

For language-adversarial training we used a log-linear classifier over all languages seen in pretraining. An utterance-level mean of the penultimate encoder layer states is fed into the classifier. For each batch in training we update the network using the interpolated grapheme and phoneme objectives before a separate update step using the adversarial objective.

We follow the learning rate scheduling of Ganin et al. (2016), where the weight of the adversarial objective relative to the speech recognition tasks follows $\lambda(p) = \frac{2}{1+\exp(-10p)} - 1$ over the course of training, where $p \in [0, 1]$ is a measure of training progress. We drop the adversarial objective during target language adaptation.

5 Experimental Setup

5.1 Language Versus Reading Adaptation

We chose as target adaptation languages those languages for which we have multiple readings of the Bible. This allows us to assess adaptation of the pretrained multilingual model in two scenarios: *language adaptation* and *reading adaptation*. In *reading adaptation*, it is adapted to data from each reading of the target language, including the reading from which we select held-out evaluation utterances. In *language adaptation* it is adapted only to readings that are not represented in the evaluation set. This last case, of adapting to just one or several speakers of a new language (in order to ultimately have a system that generalizes beyond those speakers in the language) is not common in speech recognition experimentation. Results and findings for language adaptation will be presented in Section 8.

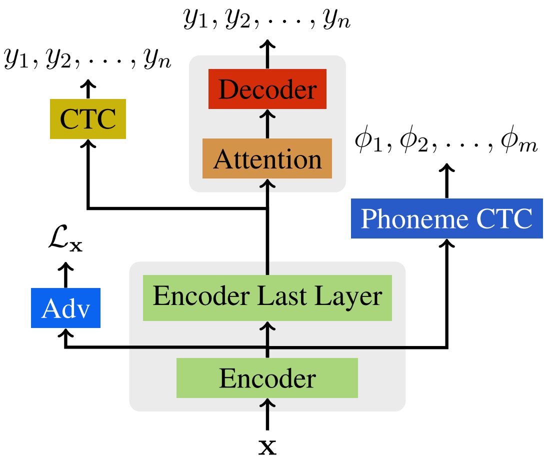

Figure 1: The end-to-end architecture used during pretraining. $\mathbf{x}$ is the input speech features, $y_1, y_2, \ldots, y_n$ is a character sequence the model is trained to output (eg. “knife”). $\phi_1, \phi_2, \ldots, \phi_m$ is a phoneme sequence the model is trained to output (eg. /naɪf/), and $\mathcal{L}_\mathbf{x}$ is the language identity of the input speech $\mathbf{x}$.

5.2 Training Settings

We established training, validation and test sets for each reading using a random 80/10/10 split. When pretraining or adapting the multilingual systems, we used the combined training sets of the constituent readings.

We used 80-dimensional log Mel filterbank features with 3-dimensional pitch features. We tuned hyperparameters for these models using one Aymara reading.[6] We found that a 4 layer encoder, 1 layer decoder with 768 for the encoder hidden size and projections, decoder hidden size, and attention hidden size yielded equal-best results with deeper models. These settings were then used for training the models used in our experiments.

For the training objective, we linearly interpolated the the attentional decoder cross-entropy loss with the grapheme CTC and phoneme CTC objectives. Equal weight was given to all three since we found that to be effective in preliminary experiments. Note however, that the effective weight of

Table 2: Word error rate (%) comparison of multilingual models adapted to target languages, with and without auxiliary training objectives (relative change in parentheses). Additionally including Cyrillic-script languages in pretraining (Cyr) doesn't consistently improve over a model pretrained on Quechuan languages (Que) unless additional phoneme and language-adversarial objectives (`+phn` and `+adv`) are used in combination (`+phn+adv`). The auxiliary objectives help when pretraining languages are varied, but hinder when they are very similar. The final four columns suggest that the objectives are complementary. Average relative word error rate change for each pretraining set when adding in the auxiliary objectives (versus no aditional objectives) is indicated by *Avg. rel.* Δ.

the adversarial objective effectively changes over the course of training because of the learning rate scheduling mentioned in §4.3. We trained for 15 epochs in all cases except where otherwise noted.

Note that during adaptation we initialize the model using both the multilingual encoder and decoder. We found this to work best in preliminary experimentation on a Spanish reading.

6 Preliminary Investigation of the Auxiliary Objectives

In this section we evaluate the use of the auxiliary phoneme and language-adversarial objectives described in Section 4 on two divergent groups of languages that are distinct along a number of dimensions, including orthography, language family and phonology, in order to assess the auxiliary objectives' capacity to bridge the divide between these languages during pretraining. This serves as an initial exploration before further experiments in Section 7 and Section 8, where we choose from a broader set of pretraining languages.

Pretraining languages We pretrained models on two groups of languages separately and together. The first consists of six languages from the Quechuan language family, including subvarieties of Quechua I and II (qub, quf, qvs, qvw, qwh and qvh). We henceforth refer to this group as Que. The second consists of six languages that use the Cyrillic script and we refer to this group as Cyr. These languages include Nogai (nog), Bashkir (bak), Gagauz (gag), Khakas (kjh), Crimean Tatar (crh), and Russian (rus). With the exception of Russian, these languages are all Turkic. The character sets do not overlap between Que and Cyr and this was a deliberate choice in this preliminary experiment to maximize the differences between the two groups.

Evaluation languages To test the pretrained models in varied contexts, we evaluate our models on three languages: Central Aymara (ayr), South Bolivian Quechua (SB Quechua; quh), and Indonesian (ind). These languages vary in a number of dimensions: SB Quechua is very closely related to Que, while Indonesian is distant; Aymara is phonologically very similar to Quechuan languages, but is considered to be from a different family; Aymara had a high monolingual baseline error rate, while the others are lower; and Indonesian has three readings while the others have two. However, all evaluation languages use the Latin script. Note that in this section we assess performance in the reading adaptation case, while Section 8 presents results on the held-out reading case.

Experiments Table 2 compares the performance of monolingual target-language models to models adapted to the target language after being pretrained on Que, Cyr and their combination, Que+Cyr. Cyr pretraining underperforms pretraining with Que for all evaluation languages likely due to the orthographic mismatch with all of the evaluation languages. The model pretrained on Que+Cyr also underperforms Que. Introducing the auxiliary phoneme and language-adversarial objectives helps to overcome this performance loss, making the Que+Cyr-pretrained model the best for adaptation to Aymara and Indonesian. Que remained the best pretraining set for adaptation to SB Quechua, which is unsurprising given how well represented SB Quechua is by the languages included in the Quechuan language group. This suggests that when a substantial

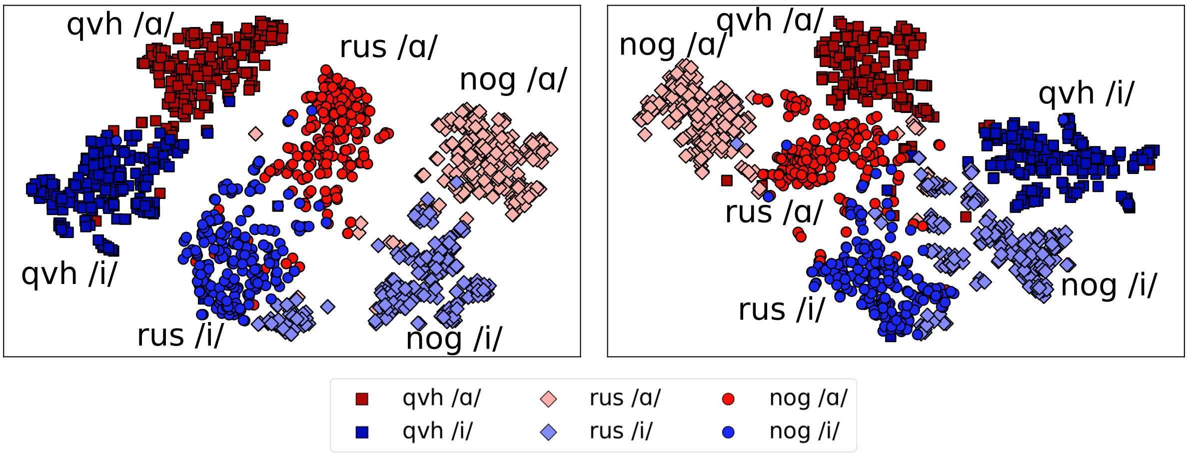

Figure 2: t-SNE representation of encoder states corresponding to /ɑ/ and /i/ across Quechua (Huamalies Dos de Mayo; qvh), Russian (rus), and Nogai (nog). *Left*: the model without the phoneme and adversarial objective. *Right*: the phoneme and language-adversarial objectives are added in, causing phoneme clusters between languages to gather closer together, and language to become less relevant in cluster placement.

amount of data in very closely related languages is available (in this case, close to 100 hours of QUE data), then there is little to be gained from highly unrelated languages.

When pretraining on QUE and CYR separately, the auxiliary objectives underperformed baseline multilingual pretraining on average. The variation in languages within these groups is far less than the variation between groups. Given that the phoneme and adversarial objectives are intended to overcome variation between pretraining languages, this result indicates that there must be a sufficient level of diversity in the pretraining languages before the auxiliary objectives are of benefit when adapting to certain target languages.

Results from pretraining on QUE+CYR showed either objective to help on average, and that the effects are complementary. Because of this, we opted to include them together in subsequent experimentation. We evaluated this best performing model on the larger set of other evaluation languages. Results in Table 3 show that in all cases multilingual pretraining of QUE+CYR with the auxiliary objectives outperformed its counterpart without the objectives (which frequently undeperformed the monolingual model), and in all but one case this led to an improvement over the monolingual baseline.[7]

To gain insight into how the auxiliary objectives change the representation of speech learnt by the models, we applied 2D t-SNE dimensionality reduction (Van Der Maaten and Hinton, 2008). Figure 2 plots the representations of two phonemes in three languages learnt by the encoder[8] in the case without and with the auxiliary objectives. In the multilingual pretraining baseline, six clusters are represented for each language–phoneme combination. These appear stratified by language, with different phoneme clusters within languages close to one another. With the auxiliary objectives, phoneme clusters between languages move closer to one another, while language identity becomes less relevant in determining which phoneme clusters neighbour one another. In the latter plot, the Nogai phonemes become separated by a Russian /ɑ/. This is particularly salient since the Nogai speaker was female, while the Russian speaker had a deep male voice.

7 Reading Adaptation

In the previous section we explored the use of two dissimilar groups of languages in a multilingual setup. Multilingual pretraining of languages from a different language family and script benefitted from an explicit phoneme objective and adversarial objective when there was sufficient diversity in the pretraining languages. However, a change in orthography was conflated with a change in language family, geographic location, and phono-

---

[7] However, this doesn't hold in the *language adaptation* scenario, where the auxiliary objectives help QUE+CYR only slightly; see Section 8.

[8] We established the correspondence between encoder states and phonemes by using forced alignment with Kaldi (Povey et al., 2011), taking the encoder state at the mid-point of the duration on the phonemes.

Table 3: Word error rate (%) comparison of adaptation of models pretrained on: Quechuan and Cyrillic-script languages (Que+Cyr), languages phonologically and phonetically similar to the target (Phon/Inv), geographically proximate languages (Geo), and a massively multilingual set of languages (100-lang). In each case we compared the average relative WER change when adding auxiliary phoneme and language-adversarial objectives (`+phn+adv`). Dashed entries had phonology and phonetic inventories that weren't well attested in URIEL, so were not assessed.

logical/phonetic characteristics. In this section, we investigate which factors are most important in choosing languages for multilingual pretraining and how useful it is to scale up model pretraining to many languages. This exploration is conducted in the reading adaptation scenario; language adaptation with unseen target speakers is addressed in Section 8. Beyond answering these questions, this investigation reveals more information about the utility of the proposed auxiliary objectives in different scenarios.

Phonology & Geography We test across a number of evaluation languages (c.f. Table 1) by determining, for each evaluation language, groups of pretraining languages that are similar to the evaluation languages in different ways. In order to determine language similarity in a principled way we used URIEL and *lang2vec* (Littell et al., 2017) to produce feature vectors for each language based on information from several linguistic resources before calculating their cosine similarity. For each language we used two feature vectors. The first is a concatenation of the lang2vec `phonology_average` and `inventory_average` vectors, characterizing phonological properties and phonetic inventory. The second represents geographic location. We denote these two groups Phon/Inv and Geo respectively.[9] Geographic proximity may serve as a proxy for other similarities not captured in Phon/Inv, including language family, orthographic similarity, and the likelihood of exchanged loan words.

We filtered for languages in the dataset with `good` or `very good` alignments before ranking them by cosine similarity with the evaluation languages in terms of phonological and phonetic similarity as well as geographical proximity. To create each of the pretraining sets, we took between 7 and 14 of the top languages, matching approximately the total duration of the phonetically/phonologically similar groups with the geographically proximate language groups.[10] For most languages, there is no overlap between the Geo and Phon/Inv sets.

Massively multilingual model As a further point of comparison, we pretrain a model on around 100 languages (denoted 100-lang), for approximately 1650 training hours in total.[11]

7.1 Auxiliary Objectives Findings

The results in Table 3 extend on our findings in Section 6, continuing to support the benefit of the use of the auxiliary objectives while shedding more light on the type of language variability the objectives help to overcome. Geo and 100-lang

---

[9] We didn't create Phon/Inv sets for Ixil and Garap because their phonological features and phonetic inventories were not well attested, and we didn't use the lang2vec language family vectors since most of the Quechuan languages were not captured as being highly similar to SB Quechua.

[10] An exhaustive list of the CMU Wilderness language codes for each pretraining group can be found in Appendix A, along with durations of each pretraining set.

[11] These models were pretrained for 6 epochs.

benefitted comparably from the objectives on average, while Phon/Inv did less so. Que+Cyr benefitted the most. This suggests that the objectives may help more when pretraining languages are orthographically, phonetically and phonologically diverse.

Unlike the other languages, the Swedish Phon/Inv vectors were not well attested. As a result the Swedish Phon/Inv group has languages with a similar phonetic inventory that were also unattested phonologically. This model underperformed the monolingual model by a large margin, suggesting that similarity of phonetic inventory alone may not be so useful alone without similarity of phonological features. Models pretrained on this set also benefitted the most from the auxiliary objectives. It may be the case that the auxiliary objectives push together representations of allophones within languages, and pronunciation variations of the same phonemes between languages. When Swedish is discounted, the average relative improvement when adding auxiliary objectives for Phon/Inv becomes negligable.

The Phon/Inv configurations are hurt by the auxiliary objectives for SB Quechua and Aymara and Indonesian. The Phon/Inv sets for the first two of these languages emphasized Quechuan languages, and this corroborates the indication in Section 6 that the auxiliary objectives may not help so much when pretraining languages are similar. On the other hand, the Indonesian Phon/Inv included Afro-Asiatic and Niger-Congo languages, as well an Indo-European language and Huave, a language isolate from Mexico, yet it was not improved by auxiliary objectives.

7.2 Choice of Pretraining Languages

The average relative word error rate (WER) change for Geo against Phon/Inv was -2.2% without auxiliary objectives, and -4.4% with them,[12] suggesting that features correlated with geography are useful for guiding pretraining language selection. Counter-examples were Aymara, SB Quechua and Malagasy, which performed worse when pretrained on Geo. In the case of SB Quechua, only one Quechuan language was represented in Geo (Inga), while Phon/Inv had three (qub, qvh, quf). Madagascar is far removed from where most Austronesian languages are spoken, so Malagasy's Geo set were almost all Niger-Congo languages, while the Phon/Inv had a diverse array of Austronesian, Indo European, Afro-Asiatic, Sino-Tibetan and Mayan languages. However, on average, these results suggest that geographical proximity is a decent guide to pretraining language selection. Another advantage is that it requires no explicit phonological features, making it applicable to a much larger number of languages.

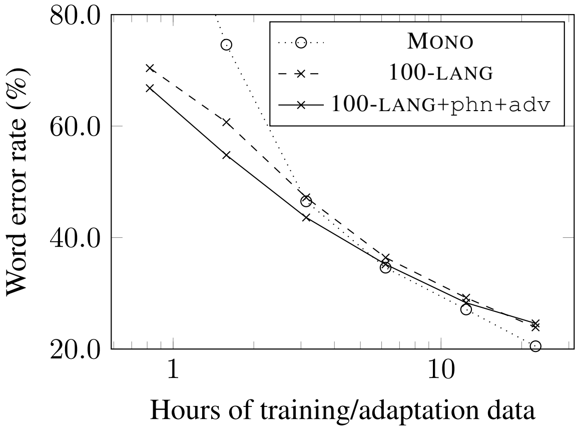

Figure 3: Scaling training/adaptation data for Swedish. Adapting to the full dataset, the auxiliary objectives underperformed both the monolingual and baselines, but yields an advantage when the model is adapted to less target language data.

The average relative WER change of 100-lang against Mono was +1.3%, indicating that massively multilingual pretraining by itself not useful if the target speakers are seen in training. Using the auxiliary objectives overcame the difference, resulting in a -1.6% average relative WER change. However, pretraining with Geo+phn+adv yielded an average relative delta of -7.4% over the monolingual model. Though more languages help, they are not necessarily better than geographically proximal languages (however, results are very different when not adapting to target speakers: see Section 8).

In two cases pretraining with 100-lang was hindered by the auxiliary objective. In one of these cases, Swedish, both 100-lang variations substantially underperformed the monolingual baseline. One possible reason is that there is enough target language and speaker data that the multilingual pretraining and auxiliary objectives offer no benefit. We scaled training/adaptation data for Swedish from under 1 hour. Figure 3 indicates that in this case the auxiliary objectives do lead to better initialization, with gains being lost only when around 5 hours of target language and reading data

---

[12] Discounting Swedish, this becomes +0.2% and -3.1%.

are seen.

8 Language Adaptation

Previous sections have addressed the reading adaptation scenario, where the ASR model is adapted to speech from the target reading (ie. where target speakers have been heard in adaptation). In this section we evaluate in a language adaptation scenario, adapting to readings in the target language, but not the target reading. The question of how well a multilingual model can be adapted to a language on the basis of recordings from a small number of target-language speakers is relevant to incident response situations such as those modelled by LORELEI (Strassel and Tracey, 2016), where a single language consultant is available for which recorded speech can be made. We performed experiments analogous to those of the previous sections where the evaluation reading was not seen in training or adaptation. This is a challenging task as the model must generalize to multiple speakers of a language on the basis of seeing only several in training. Most of the findings corroborate what was found in the previous sections. Here we highlight differences.

Massively multilingual pretraining led to substantially better performance than other methods, unlike in the reading adaptation task. For each evaluation language, the 100-Lang model outperformed the next best method, with one exception: Indonesian. In that case Geo set performed the best, as the languages were not only geographically proximate, but also consisted entirely of other Austronesian languages. The takeaway (c.f. Table 4) is that you should always use more pretraining languages unless you know your target speakers, as in the reading adaptation scenario.

Auxiliary objectives remained useful on the whole. However, while the difference in WER achieved when adding the auxiliary objectives was similar to those reported in Section 7 for Phon/Inv and 100-Lang, Geo and Que+Cyr no longer achieved improvements. Que+Cyr notably only achieved a -0.2% average relative WER change when adding the auxiliary objectives, while achieving -7.8% in the reading adaptation case. While the auxiliary objectives remained useful on the whole, their effect was dwarfed by the value of adding more languages.

Table 4: Adaptation to the non-target reading in the target language. All language sets use the auxiliary training objectives, which again exhibited an relative gain over the corresponding model without. The relative deltas of 100-Lang are with respect to the next closest model on a language-by-language basis.

Phonology versus Geography Geo sets with or without auxiliary objectives lost their edge over Phon/Inv, with high variance in scores. The amount of training data becomes the dominating variable affecting WER.

9 Conclusions

We have explored the utility of pretraining multilingual models on a variety of language sets, scaling to as as many as 100 languages. Our experiments have demonstrated the value of auxiliary phoneme and language-adversarial pretraining objectives in a multilingual end-to-end ASR framework, particularly when the pretraining languages are diverse. Our results suggest how to pick pretraining languages when target speakers are seen in the adaptation data: find geographically proximal languages. When adapting to just several non-target speakers, exposure to more speech in pretraining is the most important thing for model generality, even if from a wide range of dissimilar languages.

Acknowledgments

We would like to thank Tim Baldwin for an off-hand comment that planted the language-adversarial idea in the first author's head, and to Trevor Cohn for some related discussion. Thanks also go to Alexis Michaud and the reviewers for comments.

A List of readings in each language set

Below is a collection of lists of the CMU Wilderness reading codes that comprise different groupings. This includes the target language readings; the Quechuan group; the Cyrillic-script group; the phonologically similar and geographically similar sets for each target language; and the massively multilingual set.

Target language readings MLGEIV, MLGRCV, MLGRPV, IX1WBT, IXIWBT, IXLWBT, INZNTV, INZSHL, INZTSI, QUHRBV, QUHSBB, QEJLLB, QUBPBS, QUFLLB, QVSTBL, QVWTBL, QWHLLB, SPNBDA, SPNWTC, KIABSC, KIAWBT, KEKIBS, KEKSBG, SWESFB, SWESFV, AYMSBU, AYMBSB.

Evaluation readings AYMSBU, MLGRPV, IXIWBT, INZSHL, QUHRBV, SPNBDA, KIAWBT, KEKIBS, SWESFV.

QUE (97.6 training hours) QEJLLB, QUBPBS, QUFLLB, QVSTBL, QVWTBL, QWHLLB.

CYR (59.6 training hours) NOGIBT, BAKIBT, GAGIB1, KJHIBT, RUSS76, CRHIBT.

AYR-PHON/INV (145.3 training hours) QUBPBS, TOBBSA, QUFLLB, QVSTBL, INBWBT, QEJLLB, JICWBT, QU1LSM, QUTIBS.

AYR-GEO (146.2 training hours) IGNSBB, TNATBL, GNWNTM, ESENTM, MCBTBL, GYRSBB, CBSBSP

QUH-PHON/INV (177.9 training hours) TOBBSA, DUGBTL, QUBPBS, TZHSBM, HUSLLB, NYFBTL, NCUWBT, QEJLLB, QUFLLB, HAGGIL, NZIBSG, MNBTBL.

QUH-GEO (178.5 training hours) GNWNTM, IGNSBB, TOBBSA, ENXBSP, GYRSBB, CAXSBB, CEGNTP, TNATBL, ESENTM, TERTBL.

KEK-PHON+INV (142.1 training hours) QU1LSM, QUTIBS, TZTWBT, TUFWYI, QWHLLB, PAGPBS, UDUSIM, YUASBM.

KEK-GEO (137.0 training hours) MOPWBT, POHBSG, CA1WBT, CKIWBT, TZTWBT, QU1LSM, QUTIBS, BZJBSW.

MLG-PHON/INV (198.2 training hours) RONBSR, TGLPBS, KVNWBT, HUVTBL, KBRSIM, TPMWBT, BTXLAI, KACUBS, WMWWYI, IGNSBB, HAEBSE, IBATIV, HILHPV, TZBSBM.

MLG-GEO (205.38 training hours) WMWWYI, VMWBSM, MFEBSM, SEHBSM, TOHSBM, CCESBM, KDCPBT, CWEPBT, KKIBST, NYYBST, KSBBST, KDNBSZ, DUGBTL, GOGBST.

IND-PHON/INV (193.1 training hours) IBATIV, TGLPBS, HAEBSE, KERABT, KACUBS, NYFBTL, RONBSR, CWTATB, HUVTBL, BTXLAI, IGNSBB, JAVNRF, DUGBTL, MNKBSG.

IND-GEO (191.5 training hours) SUNIBS, NIJLAI, JAVNRF, PSELAI, IBATIV, PTULAI, MVPLAI, PPKLAI, BEPLAI, NPYLAI, LEWLAI, MWVLAI.

SWE-PHON/INV (122.4 training hours) KDJBSU, NZIBSG, ANVWBT, DGABSG, SHKBSS, SLDTBL, KUSTBL, MUYWBT, NCUWBT, LIABSL, CKOGIL.

SWE-GEO (122.4 training hours) RMCWFW, EN1NIV, RMORAM, RONBSR, GAGIB1, GAGIBT, CRHIBT, KPVIBT, LTNNVV, ALSBSA, UDMIBT, XALIBT, BAKIBT.

SPN-PHON/INV (123.7 training hours) KVNWBT, HAEBSE, HUVTBL, GUGRPV, HUSLLB, GUMTBL, NYFBTL, KWIWBT.

SPN-GEO (129.5 training hours) PORARA, LTNNVV, EN1NIV, RMORAM, ALSBSA, RMCWFW, RONBSR, GAGIB1, GAGIBT, CRHIBT, TAQWBT, FUQWBT, MYKWBT.

Lost in Interpretation:
Predicting Untranslated Terminology in Simultaneous Interpretation

Nikolai Vogler and **Craig Stewart** and **Graham Neubig**
Language Technologies Institute
Carnegie Mellon University
{nikolaiv,cas1,gneubig}@cs.cmu.edu

Abstract

Simultaneous interpretation, the translation of speech from one language to another in real-time, is an inherently difficult and strenuous task. One of the greatest challenges faced by interpreters is the accurate translation of difficult terminology like proper names, numbers, or other entities. Intelligent computer-assisted interpreting (CAI) tools that could analyze the spoken word and detect terms likely to be untranslated by an interpreter could reduce translation error and improve interpreter performance. In this paper, we propose a task of predicting which terminology simultaneous interpreters will leave untranslated, and examine methods that perform this task using supervised sequence taggers. We describe a number of task-specific features explicitly designed to indicate when an interpreter may struggle with translating a word. Experimental results on a newly-annotated version of the NAIST Simultaneous Translation Corpus (Shimizu et al., 2014) indicate the promise of our proposed method.[1]

1 Introduction

Simultaneous interpretation (SI) is the act of translating speech in real-time with minimal delay, and is crucial in facilitating international commerce, government meetings, or judicial settings involving non-native language speakers (Bendazzoli and Sandrelli, 2005; Hewitt et al., 1998). However, SI is a cognitively demanding task that requires both active listening to the speaker and careful monitoring of the interpreter's own output. Even accomplished interpreters with years of training can struggle with unfamiliar concepts, fast-paced speakers, or memory constraints (Lambert and Moser-Mercer, 1994; Liu et al., 2004). Human short-term memory is particularly at odds with the simultaneous interpreter as he or she must consistently recall and translate specific terminology uttered by the speaker (Lederer, 1978; Darò and Fabbro, 1994). Despite psychological findings that rare words have long access times (Balota and Chumbley, 1985; Jescheniak and Levelt, 1994; Griffin and Bock, 1998), listeners expect interpreters to quickly understand the source words and generate accurate translations. Therefore, professional simultaneous interpreters often work in pairs (Millán and Bartrina, 2012); while one interpreter performs, the other notes certain challenging items, such as dates, lists, names, or numbers (Jones, 2002).

Computers are ideally suited to the task of recalling items given their ability to store large amounts of information, which can be accessed almost instantaneously. As a result, there has been recent interest in developing computer-assisted interpretation (CAI; Plancqueel and Werner; Fantinuoli (2016, 2017b)) tools that have the ability to display glossary terms mentioned by a speaker, such as names, numbers, and entities, to an interpreter in a real-time setting. Such systems have the potential to reduce cognitive load on interpreters by allowing them to concentrate on fluent and accurate production of the target message.

These tools rely on automatic speech recognition (ASR) to transcribe the source speech, and display terms occurring in a prepared glossary. While displaying all terminology in a glossary achieves *high recall* of terms, it suffers from *low precision*. This could potentially have the unwanted effect of cognitively overwhelming the interpreter with too many term suggestions (Stewart et al., 2018). Thus, an important desideratum of this technology is to only provide terminology

---

[1] Code is available at `https://github.com/nvog/lost-in-interpretation`. Term annotations for the NAIST Simultaneous Translation Corpus will be provided upon request after confirmation that you have access to the corpus, available at `https://ahcweb01.naist.jp/resource/stc/`.

Figure 1: The simultaneous interpretation process, which could be augmented by our proposed terminology tagger embedded in a computer-assisted interpreting interface on the interpreter's computer. In this system, automatic speech recognition transcribes the source speech, from which features are extracted, input into the tagger, and term predictions are displayed on the interface in real-time. Finally, machine translations of the terms can be suggested.

assistance when the interpreter requires it. For instance, an NLP tool that learns to predict only terms an interpreter is likely to miss could be integrated into a CAI system, as suggested in Fig. 1.

In this paper, we introduce the task of predicting the terminology that simultaneous interpreters are likely to leave untranslated using *only* information about the source speech and text. We approach the task by implementing a supervised, sliding window, SVM-based tagger imbued with delexicalized features designed to capture whether words are likely to be missed by an interpreter. We additionally contribute new manual annotations for untranslated terminology on a seven talk subset of an existing interpreted TED talk corpus (Shimizu et al., 2014). In experiments on the newly-annotated data, we find that intelligent term prediction can increase average precision over the heuristic baseline by up to 30%.

2 Untranslated Terminology in SI

Before we describe our supervised model to predict untranslated terminology in SI, we first define the task and describe how to create annotated data for model training.

2.1 Defining Untranslated Terminology

Formally, we define untranslated terminology with respect to a source sentence S, sentence created by a translator R, and sentence created by an interpreter I. Specifically, we define any consecutive sequence of words $s_{i:j}$, where $0 \leq i \leq N-1$ (inclusive) and $i < j \leq N$ (exclusive), in source sentence $S_{0:N}$ that satisfies the following criteria to be an untranslated term:

- **Termhood:** It consists of only numbers or nouns. We specifically focus on numbers or nouns for two reasons: (1) based on the interpretation literature, these categories contain items that are most consistently difficult to recall (Jones, 2002; Gile, 2009), and (2) these words tend to have less ambiguity in their translations than other types of words, making it easier to have confidence in the translations proposed to interpreters.

- **Relevance:** A translation of $s_{i:j}$, we denote t, occurs in a sentence-aligned reference translation R produced by a translator in an offline setting. This indicates that in a time-unconstrained scenario, the term *should* be translated.

- **Interpreter Coverage:** It is not translated, literally or non-literally, by the interpreter in interpreter output I. This may reasonably allow us to conclude that translation thereof may have presented a challenge, resulting in the content not being conveyed.

Importantly, we note that the phrase *untranslated* terminology entails words that are either dropped mistakenly, intentionally due to the interpreter deciding they are unnecessary to carry across the meaning, or mistranslated. We contrast this with *literal* and *non-literal* term coverage, which encompasses words translated in a verbatim and a paraphrastic way, respectively.

2.2 Creating Term Annotations

To obtain data with labels that satisfy the previous definition of untranslated terminology, we can leverage existing corpora containing sentence-aligned source, translation, and simultaneous interpretation data. Several of these resources exist, such as the NAIST Simultaneous Translation Corpus (STC) (Shimizu et al., 2014) and the European Parliament Translation and Interpreting Corpus (EPTIC) (Bernardini et al., 2016). Next, we process the source sentences, identifying terms that satisfy the termhood, relevance, and interpreter coverage criteria listed previously.

- **Termhood Tests:** To check termhood for each source word in the input, we first part-of-speech (POS) tag the input, then check the tag of the word and discard any that are not nouns or numbers.

- **Relevance and Interpreter Coverage Tests:** Next, we need to measure relevancy (whether a corresponding target-language term appears in translated output), and interpreter coverage (whether a corresponding term *does not* appear in interpreted output). An approximation to this is whether one of the translations listed in a bilingual dictionary appears in the translated or interpreted outputs respectively, and as a first pass we identify all source terms with the corresponding target-language translations. However, we found that this automatic method did not suffice to identify many terms due to lack of dictionary coverage and also to non-literal translations. To further improve the accuracy of the annotations, we commissioned human translators to annotate whether a particular source term is translated literally, non-literally, or untranslated by the translator or interpreters (details given in §4).

Once these inclusion criteria are calculated, we can convert all untranslated terms into an appropriate format conducive to training supervised taggers. In this case, we use an IO tagging scheme (Ramshaw and Marcus, 1999) where all words corresponding to untranslated terms are assigned the label I, and all others are assigned a label O, as shown in Fig. 2.

Src	In California, there has been a [40] percent O O O O O O I O decline in the [Sierra snowpack]. O O O I I
Interp	カリフォルニアでは、 4 パーセント California 4 percent 少なくなってしまいました。 decline

Figure 2: A source sentence and its corresponding interpretation. Untranslated terms are surrounded by brackets and each word in the term is labeled with an I-tag. The interpreter mistakes the term *40* for *4*, and omits *Sierra snowpack*.

3 Predicting Untranslated Terminology

With supervised training data in hand, we can create a model for predicting untranslated terminology that could potentially be used to provide interpreters with real-time assistance. In this section, we outline a couple baseline models, and then describe an SVM-based tagging model, which we specifically tailor to untranslated terminology prediction for SI by introducing a number of hand-crafted features.

3.1 Heuristic Baselines

In order to compare with current methods for term suggestion in CAI, such as Fantinuoli (2017a), we first introduce a couple of heuristic baselines.

- **Select noun/# POS tag:** Our first baseline recalls all words that meet the termhood requirement from §2. Thus, it will achieve perfect recall at the cost of precision, which will equal the percentage of I-tags in the data.

- **Optimal frequency threshold:** To increase precision over this naive baseline, we also experiment with a baseline that has a frequency threshold, and only output words that are rarer than this frequency threshold in a large web corpus, with the motivation that rarer words are more likely to be difficult for translators to recall and be left untranslated.

3.2 SVM-based Tagging Model

While these baselines are simple and intuitive, we argue that there are a large number of other features that indicate whether an interpreter is

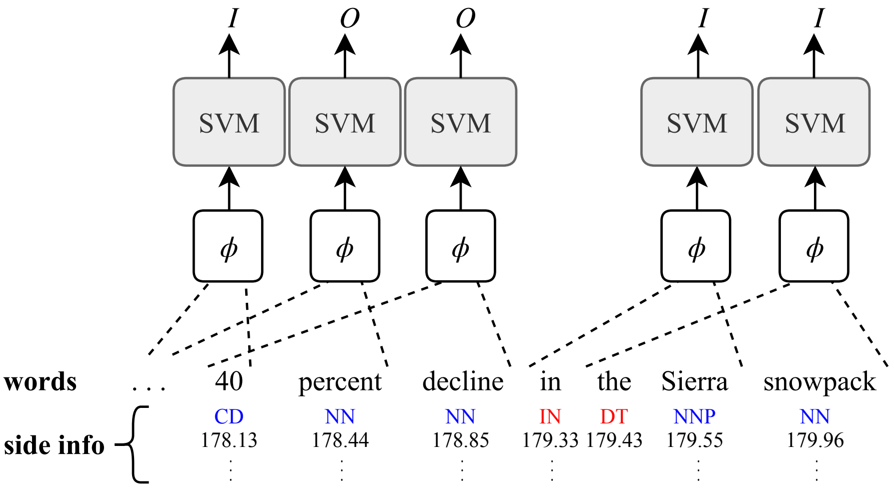

Figure 3: Our tagging model at prediction time. A sliding window SVM, informed by a task-specific feature function ϕ with access to the POS tags, source speech timing (in seconds), and other information, predicts whether or not words matching the termhood constraint (in blue) are likely to be left untranslated in SI.

likely to leave a term untranslated. We thus define these features, and resort to machine-learned classifiers to integrate them and improve performance. State-of-the-art sequence tagging models process sequences in both directions prior to making a globally normalized prediction for each item in the sequence (Huang et al., 2015; Ma and Hovy, 2016). However, the streaming, real-time nature of simultaneous interpretation constrains our model to sequentially process data from left-to-right and make local, monotonic predictions (as noted in Oda et al. (2014); Grissom II et al. (2014), among others). Therefore, we use a sliding-window, linear support vector machine (SVM) classifier (Cortes and Vapnik, 1995; Joachims, 1998) that uses only local features of the history to make independent predictions, as depicted in Fig. 3.[2] Formally, given a sequence of source words with their side information (such as timings or POS tags) $S = s_{0:N}$, we slide a window W of size k incrementally across S, extracting features $\phi(s_{i-k+1:i+1})$ from s_i and its $k-1$ predecessors.

Since our definition of terminology only allows for nouns and numbers, we restrict prediction to words of the corresponding POS tags $Q = \{\text{CD, NN, NNS, NNP, NNPS}\}$ using the Stanford POS tagger (Toutanova et al., 2003). That is, we assign a POS tag p_i to each word from s_i and only extract features/predict using the classifier if $p_i \in Q$; otherwise we always assign the Outside tag. This disallows words that are of other POS tags from being classified as untranslated terminology and greatly reduces the class imbalance issue when training the classifier.[3]

3.3 Task-specific Features

Due to the fact that only a small amount of human-interpreted human-annotated data can be created for this task, it is imperative that we give the model the precise information it needs to generalize well. To this end, we propose multiple task-specific, non-lexical features to inform the classifier about certain patterns that may indicate terminology likely to be left untranslated.

- **Elapsed time:** As discussed in §1, SI is a cognitively demanding task. Interpreters often work in pairs and usually swap between active duty and notetaking roles every 15-20 minutes (Lambert and Moser-Mercer, 1994). Towards the end of talks or long sentences, an interpreter may become fatigued or face working memory issues—especially if working alone. Thus, we monitor the number of minutes elapsed in the talk and the index of the word in the talk/current sentence to inform the classifier.

- **Word timing:** We intuit that a presenter's quick speaking rate can cause the simultaneous interpreter to potentially drop some terminology. We obtain word timing informa-

---

[2] We also experimented with a unidirectional LSTM tagger (Hochreiter and Schmidhuber, 1997; Graves, 2012), but found it ineffective on our small amount of annotated data.

[3] We note that a streaming POS tagger would have to be used in a real-time setting, as in (Oda et al., 2015).

tion from the source speech via forced alignment tools (Ochshorn and Hawkins, 2016; Povey et al., 2011). The feature function extracts both the number of words in the past m seconds and the time deltas between the current word and previous words in the window.

- **Word frequency:** We anticipate that interpreters often leave rarer source words untranslated because they are probably more difficult to recall from memory. On the other hand, we would expect loan words, words adopted from a foreign language with little or no modification, to be easier to recognize and translate for an interpreter. We extract the binned unigram frequency of the current source word from the large monolingual Google Web 1T Ngrams corpus (Brants and Franz, 2006). We define a loan word as an English word with a Katakana translation in the bilingual dictionaries (eij; Breen, 2004).
- **Word characteristics and syntactic features:** We extract the number of characters and number of syllables in the word, as determined by lookup in the CMU Pronunciation dictionary (Weide, 1998). Numbers are converted to their word form prior to dictionary lookup. Generally, we expect longer words, both by character and syllable count, to represent more technical or marked vocabulary, which may be challenging to translate. Additionally, we syntactically inform the model with POS tags and regular expression patterns for numerals.

These features are extracted via sliding a window over the sentence, as displayed in Fig. 3 and discussed in §3.2. Thus, we also utilize previous information from the window when predicting for the current word. This previous information includes past predictions, word characteristics and syntax, and source speech timing.

4 Experimental Annotation and Analysis

In this section, we detail our application of the term annotation procedure in §2 to an SI corpus and analyze our results.

4.1 Annotation of NAIST STC

For SI data, we use a seven-talk, manually-aligned subset of the English-to-Japanese NAIST STC (Shimizu et al., 2014), which consists of source subtitle transcripts, En→Ja offline translations, and interpretations of English TED talk videos from professional simultaneous interpreters with 1, 4, and 15 years of experience, who are dubbed B-rank, A-rank, and S-rank[4]. TED talks offer a unique and challenging format for simultaneous interpreters because the speakers typically talk in-depth about a single topic, and such there are many new terms that are difficult for an interpreter to process consistently and reliably. The prevalence of this difficult terminology presents an interesting testbed for our proposed method.

First, we use the Stanford POS Tagger (Toutanova et al., 2003) on the source subtitle transcripts to identify word chunks with a POS tag in {CD, NN, NNS, NNP, NNPS}, discarding words with other tags. After performing word segmentation on the Japanese data using KyTea (Neubig et al., 2011), we automatically detect for translation coverage between the source subtitles, SI, and translator transcripts with a string-matching program, according to the relevance and coverage tests from §2. The En↔Ja EIJIRO (2.1m entries) (eij) and EDICT (393k entries) (Breen, 2004) bilingual dictionaries are combined to provide term translations. Additionally, we construct individual dictionaries for each TED talk with key acronyms, proper names, and other exclusive terms (e.g., *UNESCO*, *CO2*, *conflict-free*, *Pareto-improving*) to increase this automatic coverage. Nouns are lemmatized prior to lookup in the bilingual dictionary, and we discard any remaining closed-class function words.

While this automatic process is satisfactory for identifying if a translated term occurs in the translator's or interpreters' transcripts (relevancy), it is inadequate for verifying the terms that occur in the translator's transcript, but *not* the interpreters' outputs (interpreter coverage). Therefore, we commissioned seven professional translators to review and annotate those source terms that could not be marked as translated by the automatic process as either *translated*, *untranslated*, or *non-literally translated* in each target sentence. Lastly, we add I-tags to each word in the untranslated terms and O-tags to the words in literally and non-literally translated terms.

---

[4] {B, A, S}-rank is the Japanese equivalent to {C, B, A}-rank on the international scale.

	trans.		non-lit.		raw untrans.	
T/I	**#**	**%**	**#**	**%**	**#**	**%**
T	2,213	80	158	6	401	14
B	1,134	41	92	3	1,546	56
A	1,151	42	114	4	1,507	54
S	1,531	55	170	6	1,071	39

Table 1: Translated, non-literally translated, and raw untranslated term annotations obtained in the annotation process using the NAIST STC for (T)ranslator, and {B,A,S}-rank SI. Note that these *raw* untranslated term figures are directly from the annotation process, prior to filtering based off of the term relevancy constraint from §2.

4.2 Annotation Analysis

Table 1 displays the term coverage annotation statistics for the translators and interpreters. Since translators performed in an offline setting without time constraints, they were able to translate the largest number of source terms into the target language, with 80% being literally translated, and 6% being non-literally translated. On the other hand, interpreters tend to leave many source terms uncovered in their translations. The A-rank and B-rank interpreters achieve roughly the same level of term coverage, with the A-rank being only slightly more effective than B-rank at translating terms literally and non-literally. This is in contrast with Shimizu et al. (2014)'s automatic analysis of translation quality on a three-talk subset, in which A-rank has slightly higher translation error rate and lower BLEU score (Papineni et al., 2002) than the B-rank interpreter. The most experienced S-rank interpreter leaves 17% fewer terms than B-rank uncovered in the translations. More interestingly, the number of non-literally translated terms also correlates with experience-level. In fact, the S-rank interpreter actually exceeds the translator in the number of non-literal translations produced. Non-literal translations can occur when the interpreter fully comprehended the source expression, but chose to generate it in a way that better fit the translation in terms of fluency.

In Table 2, we show the number of terms left untranslated by each interpreter rank after processing our annotations for the relevancy constraint of §2. Since the number of per-word I-tags is only slightly higher than the number of untranslated terms, most such terms consist of only a single word of about 6.5 average characters for all ranks. Capitalized terms (i.e., named entities/locations) constitute about 14% of B-rank, 13% of A-rank, and 15% of S-rank terms. Numbers represent about 5% of untranslated terms for each rank.

		% I-tag of	
SI	**# untrans. terms**	**all**	**noun/#**
B-rank	1,256	10.8	45.4
A-rank	1,206	10.4	43.6
S-rank	812	7.0	29.6

Table 2: Final untranslated term count and number of I-tags after filtering based off of the *relevancy* constraint (§2). That is, only the raw untranslated source terms that appear in the translator's transcript are truly considered untranslated.

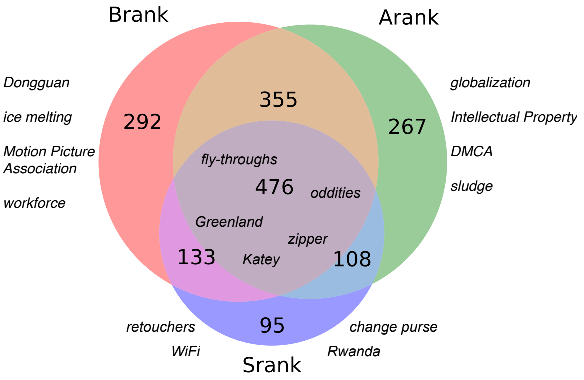

Figure 4: Untranslated term overlap between interpreters.

The untranslated term overlap between interpreters is visualized in Fig. 4. Most difficult terms are shared amongst interpreter ranks as only 23.2% (B), 22.1% (A), and 11.7% (S) of terms are unique for each interpreter. We show a sampling of some unique noun terms on the outside of the Venn diagram, along with the untranslated terms shared among all ranks in the center. Among these unique terms, capitalized terms make up 19% of B-rank/S-rank, but only 13% of A-rank. 7.4% of S-rank's unique terms are numbers compared with about 5% for the other two ranks.

5 Term Prediction Experiments

5.1 Experimental Setting

We design our experiments to evaluate both the effectiveness of a system to predict untranslated terminology in simultaneous interpretation and the usefulness of our features given the small amount

	AP		
Method	**B**	**A**	**S**
Select noun/# POS tag	45.4	43.6	29.6
Optimal freq threshold	49.7	48.1	32.9
SVM (all features)	58.9	53.5	39.1
– elapsed time	58.8	53.0	38.8
– word timing	58.2	53.2	38.5
– word freq	**59.4**	52.5	39.1
– characteristic/syntax	59.3	**55.1**	**42.5**

Table 3: Average precision score cross-validation results with feature ablation for the untranslated term class on test data. Optimal word frequency threshold is determined on dev set of each fold. Evaluation performed on a word-level. Highest numbers per column are bolded. Each setting is statistically significant at $p < 0.05$ by paired bootstrap (Koehn, 2004).

Select POS	in the last 5 years we 've added 70000000 tons of co2 every 24 hours 25000000 tons every day to the oceans
Optimal freq	in the last 5 years we 've added 70000000 tons of co2 every 24 hours 25000000 tons every day to the oceans
SVM	in the last 5 years we 've added 70000000 tons of co2 every 24 hours 25000000 tons every day to the oceans

Table 4: B-rank output from our model contrasted with baselines. Type I errors are in red, type II errors in orange, and correctly tagged untranslated terminology in blue.

of aligned and labeled training data we possess.

We perform leave-one-out cross-validation using five of the seven TED talks as the training set, one as the development set, and one as the test set. Hyperparameters (SVM's penalty term, the number of bins for the word frequency feature=9, and sliding window size=8) are tuned on the dev. fold and the best model, determined by average precision score, is used for the test fold predictions. Both training and predictions are performed on a sentence-level. During training, we weight the two classes inversely proportional to their frequencies in the training data to ensure that the majority O-tag does not dominate the I-tag.

5.2 Results and Analysis

Since we are ultimately interested in the precision and recall trade-off among the methods, we evaluate our results using precision-recall curves in Fig. 5 and the average precision (AP) scores in Table 3. AP[5] summarizes the precision-recall curve by calculating the weighted mean of the precisions at each threshold, where the weights are equal to the increase in recall from the previous threshold. If the method is embedded in a CAI system, then the user could theoretically adjust the precision-recall threshold to balance helpful term suggestions with cognitive load.

Overall, we tend to see that all methods perform best when tested on data from the B-rank interpreter, and observe a decline in performance across all methods with an increase in interpreter experience. We believe that this is due to a decrease in the number of untranslated terminology as experience increases (i.e., class imbalance) coupled with the difficulty of predicting such exclusive word occurrences from only source speech and textual cues. Ablation results in Table 3 show that not all of the features are able to improve classifier performance for all interpreters. While the elapsed time and word timing features tend to cause a degradation in performance when removed, ablating the word frequency and characteristic/syntax features can actually improve average precision score. Word frequency, which is a recall-based feature, seems to be more helpful for B- and S-rank interpreters because it is challenging to recall the smaller number of untranslated terms from the data. Although the characteristic/syntax features are also recall-based, we see a decline in performance for them across all interpreter ranks because they are simply too noisy. When ablating the uninformative features for each rank, the SVM is able to increase AP vs. the optimal word frequency baseline by about 20%, 15%, and 30% for the B, A, and S-rank interpreters, respectively.

In Table 4, we show an example taken from the first test fold with results from each of the three methods. The SVM's increased precision is able to greatly reduce the number of false positives, which we argue could overwhelm the interpreter if left unfiltered and shown on a CAI system. Nevertheless, one of the most apparent false

---

[5] We compute AP using the scikit-learn implementation (Pedregosa et al., 2011).

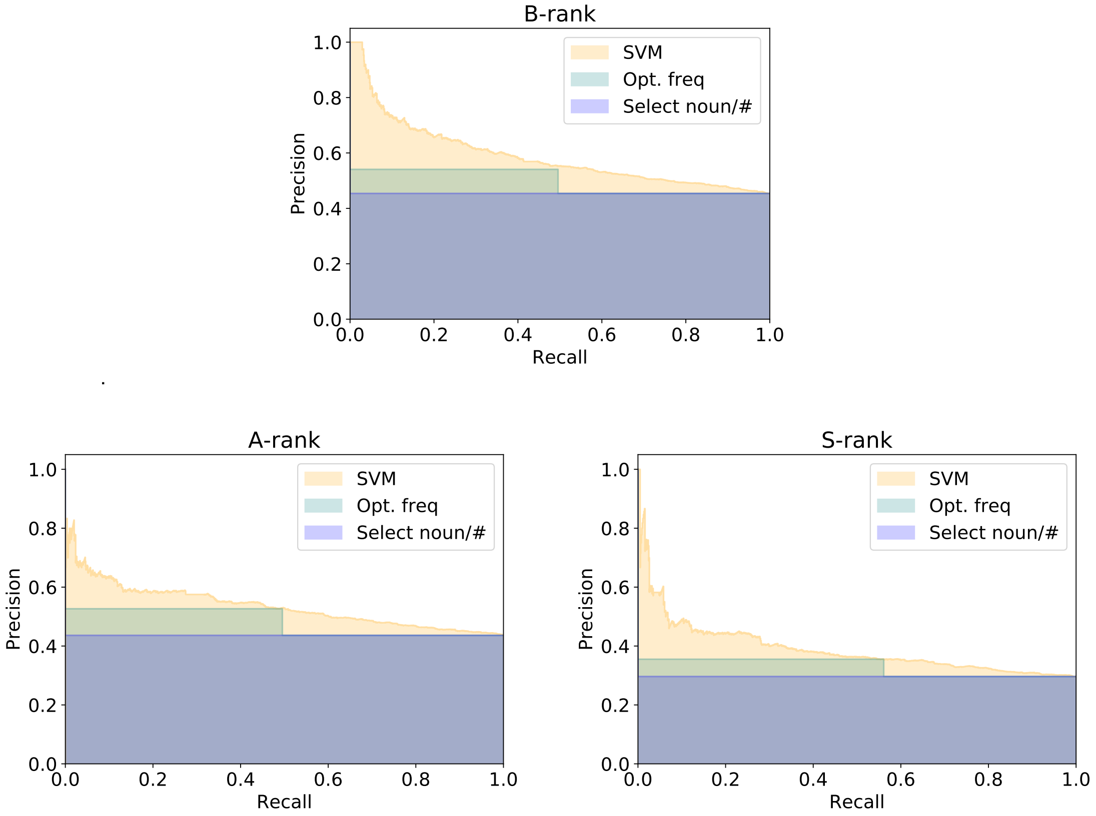

Figure 5: Precision-recall curves for each interpreter rank.

positive errors that still occurs with our method is on units following numbers, such as the word *tons* in the example. Also, because our model prioritizes avoiding this type I error, it is more susceptible to type II errors, such as ignoring untranslated terms *24* and *day*. A user study with our method embedded in a CAI would reveal the true costs of these different errors, but we leave this to future work.

6 Conclusion and Future Work

In this paper, we introduce the task of automatically predicting terminology likely to be left untranslated in simultaneous interpretation, create annotated data from the NAIST ST corpus, and propose a sliding window, SVM-based tagger with task-specific features to perform predictions.

We plan to assess the effectiveness of our approach in the near future by integrating it in a heads-up display CAI system and performing a user study. In this study, we hope to discover the ideal precision and recall tradeoff point regarding cognitive load in CAI terminology assistance and use this feedback to adjust the model.

Other future work could examine the effectiveness of the approach in the opposite direction (Japanese to English) or on other language pairs. Additionally, speech features could be extracted from the source or interpreter audio to reduce the dependence on a strong ASR system.

AudioCaps: Generating Captions for Audios in The Wild

Chris Dongjoo Kim **Byeongchang Kim** **Hyunmin Lee** **Gunhee Kim**

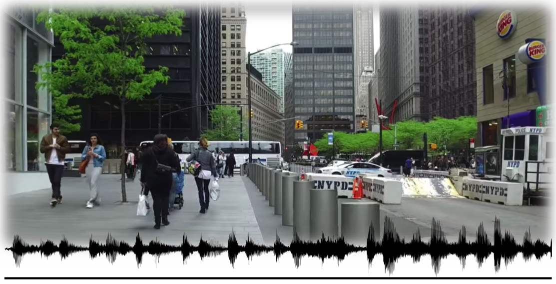
Abstract

We explore the problem of *audio captioning*[1]: generating natural language description for any kind of audio in the wild, which has been surprisingly unexplored in previous research. We contribute a large-scale dataset of 46K audio clips with human-written text pairs collected via crowdsourcing on the AudioSet dataset (Gemmeke et al., 2017). Our thorough empirical studies not only show that our collected captions are indeed loyal to the audio inputs but also discover what forms of audio representation and captioning models are effective for audio captioning. From extensive experiments, we also propose two novel components that are integrable with any attention-based captioning model to help improve audio captioning performance: the top-down multi-scale encoder and aligned semantic attention.

1 Introduction

Captioning, the task of translating a multimedia input source into natural language, has been substantially studied over the past few years. The vast majority of the journey has been through the visual senses ranging from static images to videos. Yet, the exploration into the auditory sense has been circumscribed to human speech transcription (Panayotov et al., 2015; Nagrani et al., 2017), leaving the basic natural form of sound in an uncharted territory of the captioning research.

Recently, sound event detection has gained much attention such as DCASE challenges (Mesaros et al., 2017) along with the release of a large scale *AudioSet* dataset (Gemmeke et al., 2017). However, sound classification (*e.g.* predicting multiple labels for a given sound) and event detection (*e.g.* localizing the sound of interest in a clip) may not be sufficient for a full understanding of the sound. Instead, a natural sentence offers a greater freedom to express a sound, because it allows to characterize objects along with their states, properties, actions and interactions. For example, suppose that suddenly sirens are ringing in the downtown area. As a natural reaction, people may notice the presence of an emergency vehicle, even though they are unable to see any flashing lights nor feel the rush of wind from a passing vehicle. Instead of simply tagging this sound as *ambulance* or *siren*, it is more informative to describe which direction the sound is coming from or whether the source of the sound is moving closer or further away, as shown in Figure 1.



[Audio Classification] rumble | vehicle | speech | car | outside

[Video Captioning] A bus passing by with some people walking by in the afternoon.

[Audio Captioning] A muffled rumble with man and woman talking in the background while a siren blares in the distance.

Figure 1: Comparison of audio captioning with audio classification and video captioning tasks.

To that end, we address the *audio captioning* problem for audios in the wild, which has not been studied yet, to the best of our knowledge. This work focuses on one of the most important bases toward this research direction, *contributing a large-scale dataset*. The overarching sources of in-the-wild sounds are grounded on the *AudioSet* (Gemmeke et al., 2017), so far the largest collection of sound events collected from Youtube

---

Minneapolis, Minnesota, June 2 - June 7, 2019.

videos. We newly collect human-written sentences for a subset of AudioSet audio clips via crowdsourcing on Amazon Mechanical Turk (section 3). We also develop two simple yet effective techniques to generate captions through the joint use of multi-level pretrained features and better attention mechanism named aligned-semantic attention (section 4). Lastly, we perform experiments contrasting between video-based captions and audio-focused captions by employing a variety of features and captioning models (section 5).

The contributions of this work are as follows.

1. To the best of our knowledge, this work is the first attempt to address the audio captioning task for sound in the wild. We contribute its first large-scale dataset named *AudioCaps*, which consists of 46K pairs of audio clips and text description.

2. We perform thorough empirical studies not only to show that our collected captions are indeed true to the audio inputs and but also to discover what forms of audio representations and captioning models are effective. For example, we observe that the embeddings from large-scale pretrained VGGish (Hershey et al., 2017) are powerful in describing the audio input, and both temporal and semantic attention are helpful to enhance captioning performance.

3. From extensive experiments, we propose two simple yet effective technical components that further improve audio captioning performance: the *top-down multi-scale encoder* that enables the joint use of multi-level features and *aligned semantic attention* that advances the consistency between semantic attention and spatial/temporal attention.

2 Related Work

Speech recognition and separation. One of the most eminent tasks for audio understanding may be speech recognition, the task of recognizing and translating human spoken language into text with less emphasis on background sound that may coexist. A multitude of datasets exist for such task *e.g.* Speech Commands dataset (Warden, 2018), Common Voice dataset (Mozilla, 2017), Librispeech (Panayotov et al., 2015), LS Speech (Ito, 2017). As one of similar lineage, automatic speech separation forks an input audio signal into several individual speech sources (Hershey et al., 2016; Ephrat et al., 2018). To most of these tasks, in the wild sound is deemed as background noise to be removed as an obstructer of speech recognition. On the other hand, our work puts the spotlight on these neglected sounds and express them through natural language.

Audio classification and sound event detection. This line of tasks emphasizes categorizing a sound into a set of predefined classes. There exist a number of datasets to aid in achieving this goal, including DCASE series (Stowell et al., 2015; Mesaros et al., 2016, 2017), UrbanSound8k (Salamon et al., 2014), ESC (Piczak, 2015). AudioSet (Gemmeke et al., 2017) is an audio event dataset collected from Youtube that is unsurpassed in terms of coverage and size, structured with an ontology containing 527 classes. Another predominant large-scale dataset is Freesound (Fonseca et al., 2017). It consists of audio samples from *freesound.org* recordings based on the preceding AudioSet ontology. In contrast to audio classification, which uniquely map the audio to a set of labels, our task generates a descriptive sentence. Hence, it needs to not only detect salient sounds of classes but also explores their states, properties, actions or interactions.

Captioning tasks and datasets. The vast majority of captioning tasks and datasets focus on the visual domain. Image captioning generates text description of an image, and numerous datasets are proposed, such as Flickr 8k (Rashtchian et al., 2010), Flickr 30k (Young et al., 2014), MS COCO (Lin et al., 2014), DenseCap (Johnson et al., 2016) and Conceptual Captions (Sharma et al., 2018). Akin to the image captioning is video captioning, for which there are many datasets too, including MSVD (Guadarrama et al., 2013), MSR-VTT (Xu et al., 2016), LSMDC (Rohrbach et al., 2017) and ActivityNet Captions (Krishna et al., 2017).Compared to previous captioning tasks and datasets, our work confines the problem by focusing on in the wild audio inputs.

Recently, there have been some efforts to solve video captioning with audio input (Hori et al., 2017, 2018; Wang et al., 2018). However, the audio input merely serves as auxiliary features for video captioning, and as a result, it only marginally improves the performance (*e.g.* BLEU-4 score: 39.6 (video only) vs. 40.3 (video + MFCC) (Wang et al., 2018)). These results are partly culpable to dataset collection, where the annotators mostly rely on the video input. On the contrary, our collection induces the annotators to mainly abide to audio, hence, increasing the dependency of written text on the audio input as can be shown in our survey analysis in Figure 5.

3 The Audio Captioning Dataset

Our *AudioCaps* dataset entails 46K audio caption pairs. Table 1 outlines its key statistics. The audio sources are rooted in *AudioSet* (Gemmeke et al., 2017), a large-scale audio event dataset, from which we draft the *AudioCaps*, as discussed below. We present more details of data collection and statistics in the Appendix.

3.1 AudioSet Tailoring

It is important to select qualified audio clips as the first step of dataset collection. The chosen categories of clips must be well-rounded in coverage of naturally occurring audios, be relevant to practical applications and appear with high frequency. To that end, we tailor the AudioSet dataset (Gemmeke et al., 2017) that comprises 1,789,621 human-labeled 10 second YouTube excerpts with an ontology of 527 audio event categories. However, an immediate collection of captions from these audios pose several difficulties: (i) too many audio clips, (ii) inconsistent level of abstraction among the classes, (iii) distribution bias of some labels and (iv) noisy labels that are only noticeable from visual cues. We circumvent these issues through a controlled sampling process as described below.

Among 527 audio event categories of AudioSet, we first exclude all the labels whose number of clips are less than 1,000 to promote a balanced distribution within the dataset. We also remove all 151 labels in the *music* super-category, because they are often indiscernible even for a human. For example, a human with no expertise can hardly discriminate the sound of *Guitar* from *Banjo*. Thus, we set aside the musical territory for future exploration. We further discard categories if they do not satisfy the following two constraints. The word labels should be identifiable solely from sound (i) without requiring visuals (*e.g.* remove the category *inside small room*) and (ii) without requiring any expertise (*e.g.* remove *power windows* and *electric windows* because their distinction may be possible only for car experts). Finally, we select 75 word labels derived from 7 augmented super-categories as avoiding the sharp skewness in the word labels (*e.g.* 48.5% clips include *speech* label). We limit the number of instances per category to 2,000 by sampling with preference to audio clips associated with more word labels to prioritize the audios with diverse content. The final number of audio clips is about 115K, from which we obtain captions for 46K as the first version.

Split	# clips	# captions	# words/caption	# labels/clip
Train	38,118	38,118	8.79 (8)	4.25 (4)
Val	500	2,500	10.12 (9)	4.06 (3)
Test	979	4,895	10.43 (9)	4.03 (3)
Total	39,597	45,513	9.03 (9)	4.22 (4)

96006-audio Description:

DO NOT INCLUDE VISUAL INFO YOU CANNOT HEAR.

Video Hint. If Unsure of Source.

Figure 2: The AMT interface for audio annotation.

3.2 Audio Annotation

The collected captions should be precise, specific, diverse, expressive, large-scale and correlated with the paired audios with minimal visual presumptions. Such complex nature of our requirements necessitates employing crowdworkers through Amazon Mechanical Turk (AMT). Some qualification measures are set for the crowdworkers, such as they should hold a +95% HIT approval rate and the total number of approved HITs that are greater than 1,000 and be located at one of [AU, CA, GB, NZ, US]. In total, 108 caption writing workers and 3 caption reviewing workers participate and are compensated at 10 cents per clip.

Annotation Interface. Figure 2 shows our annotation interface, which is designed to minimize the visual presumption while maintaining diversity. Each task page consists of an audio clip of about 10 seconds, word hints and video hints.

The *word hints* are the word labels that are provided by AudioSet for the clip and are employed

(c) AudioCaps

Figure 3: Comparison between two video captioning datasets and AudioCaps. The text from (a) LSMDC (Rohrbach et al., 2017) and (b) MSR-VTT (Xu et al., 2016) includes multiple visually grounded vocabularies (indicated in blue), whereas the text from (c) AudioCaps contains vocabularies relying on auditory cues (in red).

as hints to the crowdworkers. Even to humans, recognizing the true identity of a sound can be ambiguous, and thus the word hints act as a precursor to *accurately* guide the crowdworkers during the description process, while staying aloof from visual bias. Another benefit is that the diversity of the word labels may also enrich the expressiveness of the description. Also derived from AudioSet, the *video hints* are provided as a stronger hint for sounds that are too difficult even to the human ear or for clips associated with some erroneous or missing word hints (weak labels). We advise the workers to use them as a last resort measure.

Some instructions[2] are also provided to demarcate crowdworkers' descriptions as follows. (i) Do not include the words for visuals in the video that are not present in the sound. (ii) Ignore speech semantics. (iii) When applicable, be detailed and expressive. (iv) Do not be imaginative and be literal and present with the descriptions.

Quality Control. We use a qualification test to discern many crowdworkers who frequently violate the given instructions (*e.g.* transcribing instead of describing, just enumerating provided word hints or writing visual captions). Interested crowdworkers must participate in the test and submit a response, which the authors manually check and approve if they are eligible. We employ three additional workers to verify the data in accordance to our guidelines. In order to maintain high approval rates, we periodically blacklist malicious crowdworkers while granting reasonable incentives to benevolent workers.

3.3 Post-processing

We exclude the period symbol from all the captions, convert numbers to words using `num2words`[3] and correct grammar errors by `languagetool`[4]. We then tokenize words with `spacy` [5]. Finally, we build a dictionary $\mathcal{V}$ with a size of 4506 by choosing all the unique tokens.

3.4 Comparison with Other Datasets

Figure 3 qualitatively compares some caption examples between our *AudioCaps* and two captioning datasets with audio: LSMDC (Rohrbach et al., 2017) and MSR-VTT (Xu et al., 2016). Since both LSMDC and MSR-VTT focus more on describing videos than audios, their captions are characterized by visually grounded vocabularies (blue). On the other hand, the captions of *AudioCaps* accompany sound-based vocabularies (red).

4 Approach

We present a hierarchical captioning model that can attend to the fine details of the audio. The backbone of our model is an LSTM (Hochreiter and Schmidhuber, 1997) that we fortify with two novel components which are easily integrable with any attention-based captioning model. The *top-down multi-scale encoder* enables the contextual use of multi-level features, and the *aligned semantic attention* enhances the consistency between semantic attention and temporal attention (see Figure 4). Our experiments in section 5.3 show that these two techniques lead to non-trivial performance improvement.

---

[3] `https://github.com/savoirfairelinux/num2words`.

[4] `https://github.com/languagetool-org/languagetool`.

[5] `https://spacy.io`.

The input to our model are mel-frequency cepstral coefficient (MFCC) audio features (Davis and Mermelstein, 1980) and the output is a sequence of words $\{y_m\}_{m=1}^{M}$, each of which is a symbol from the dictionary. For text representation, we use `fastText` (Bojanowski et al., 2016) trained on the Common Crawl corpus to initialize the word embedding matrix $\mathbf{W}_{emb}$, which is fine-tuned with the model during training. We represent word sequences (*e.g.* attribute words for semantic attention and output words for answer captions) in a distributional space as $\{\mathbf{d}_n\}_{n=1}^{N}$ with $\mathbf{d}_n = \mathbf{W}_{emb}\mathbf{w}_n$ where $\mathbf{w}_n$ is a one-hot vector for n-th word in the word sequence and $\mathbf{d}_n \in \mathbb{R}^{300}$.

4.1 Top-down Multi-scale Encoder

Unlike speech data, sound in the wild is not always continuous. It can be often brief, noisy, occluded, in-the-distance and randomly sparsed throughout the audio. Hence, the lower-level features can be useful to capture such characteristics of natural sound, although they may lack the semantics of the higher-level features. Thus, the joint use of these two levels of features can be mutually beneficial.

The top-down multi-scale encoder takes as input the two-level audio embedding $\{\mathbf{f}_t\}_{t=1}^{T}$, $\{\mathbf{c}_t\}_{t=1}^{T}$ and generates the fused encoding vector, where T is the sequence length of the audio. For input, we use the features from the two layers of the pretrained VGGish network (Hershey et al., 2017): the `fc2` vector $\{\mathbf{f}_t\}_{t=1}^{T}$ as a high-level semantic feature, and the `conv4` vector $\{\mathbf{c}_t\}_{t=1}^{T}$ as a mid-level feature.

The first level of hierarchy encodes high-level features $\{\mathbf{f}_t\}_{t=1}^{T}$ using a bi-directional LSTM. We regard the last hidden state as the global audio embedding $\mathbf{h}^{ctxt} \in \mathbb{R}^{I}$:

$$\overleftrightarrow{\mathbf{h}}^{a1}_{t} = \text{biLSTM}(\mathbf{f}_t, \overrightarrow{\mathbf{h}}^{a1}_{t-1}, \overleftarrow{\mathbf{h}}^{a1}_{t+1}), \qquad (1)$$

$$\mathbf{h}^{ctxt} = \mathbf{W}_c[\overrightarrow{\mathbf{h}}^{a1}_{T}; \overleftarrow{\mathbf{h}}^{a1}_{1}] + \mathbf{b}_c, \qquad (2)$$

where $\mathbf{W}_c \in \mathbb{R}^{I \times D^1}$ and $\mathbf{b}_c \in \mathbb{R}^{I}$ are parameters, I is the dimension of input to the next layer and D^1 is the dimension of the first layer hidden states.

We then reshape and encode mid-level features $\{\mathbf{c}_t\}_{t=1}^{T} \in \mathbb{R}^{512}$ using another bi-directional LSTM. In order to inject the global semantics, we perform an element-wise addition of $\mathbf{h}^{ctxt}$ to the mid-level feature along the time axis, and feed them into the bi-directional LSTM one at a time, producing a hidden state $\overleftrightarrow{\mathbf{h}}^{a2}_{t} \in \mathbb{R}^{D^2}$ at each step:

$$\overleftrightarrow{\mathbf{h}}^{a2}_{t} = \text{biLSTM}(\mathbf{c}_t + \mathbf{h}^{ctxt}, \overrightarrow{\mathbf{h}}^{a2}_{t-1}, \overleftarrow{\mathbf{h}}^{a2}_{t+1}). \qquad (3)$$

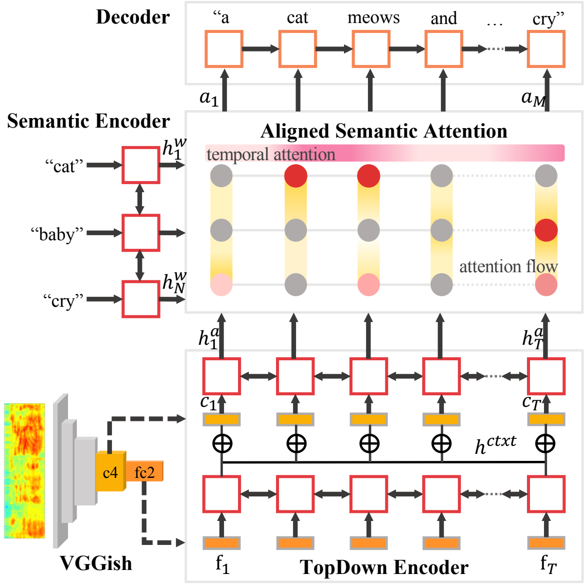

Figure 4: The audio captioning model with *top-down multi-scale encoder* and *aligned semantic attention*.

4.2 Aligned Semantic Attention

In many captioning models (You et al., 2016; Yu et al., 2017; Laokulrat et al., 2018; Long et al., 2018), semantic attention has been independently used from temporal/spatial attention. However, it can be troublesome because there may exist some discrepancies between the two attentions *i.e.* they do not attend to the same part of the input. For instance, given an audio of a cat meowing and a baby crying, temporal attention may attend to the *crying baby* while semantic attention attends to the word *cat*. We propose a simple yet effective approach that implicitly forces both semantic and temporal/spatial attention to be correctly aligned to one another to maximize the mutual consistency.

For semantic attention, we extract a set of N attribute words for each audio: following You et al. (2016), we retrieve the nearest training audio from the subset of AudioSet and transfer its labels as attribute words. We encode each attribute word vector using a bi-directional LSTM (named *semantic encoder*):

$$\overleftrightarrow{\mathbf{h}}^{w}_{n} = \text{biLSTM}(\mathbf{d}_n, \overrightarrow{\mathbf{h}}^{w}_{n-1}, \overleftarrow{\mathbf{h}}^{w}_{n+1}), \qquad (4)$$

where $\mathbf{d}_n$ is the input text representation of the attribute word sequence. We then align these semantic word features $\overleftrightarrow{\mathbf{h}}^{w}_{n}$ to the temporal axis of the audio features $\overleftrightarrow{\mathbf{h}}_t^{a2}$ via the attention flow layer (Seo et al., 2017). For notational simplicity, we omit the bidirectional arrow in the following.

Attention flow layer. We first compute the similarity matrix, $\mathbf{S} \in \mathbb{R}^{T \times N}$ between each pair of audio and word features using the score function $\alpha(\mathbf{h}_t^{a2}, \mathbf{h}_n^w) \in \mathbb{R}$:

$$\alpha(\mathbf{h}_t^{a2}, \mathbf{h}_n^w) = \mathbf{W}_\alpha[\mathbf{h}_t^{a2}; \mathbf{h}_n^w; \mathbf{h}_t^{a2} \circ \mathbf{h}_n^w], \quad (5)$$
$$\mathbf{S}_{tn} = \alpha(\mathbf{h}_t^{a2}, \mathbf{h}_n^w), \quad (6)$$

where $\circ$ is element-wise multiplication.

We then use $\mathbf{S}$ to obtain the attentions and the attended vectors in two directions: word-to-audio $\{\tilde{\mathbf{h}}_t^w\}_{t=1}^T \in \mathbb{R}^{D^2}$ and audio-to-word $\tilde{\mathbf{h}}^{a2} \in \mathbb{R}^{D^2}$:

$$\mathbf{a}_t = \text{softmax}(\mathbf{S}_{t:}), \qquad \tilde{\mathbf{h}}_t^w = \sum_n \mathbf{a}_{tn}\mathbf{h}_n^w, \quad (7)$$
$$\mathbf{b} = \text{softmax}(\max_{row}(\mathbf{S})), \quad \tilde{\mathbf{h}}^{a2} = \sum_t \mathbf{b}_t \mathbf{h}_t^{a2}, \quad (8)$$

where $\mathbf{a}_t \in \mathbb{R}^N$, $\mathbf{b} \in \mathbb{R}^T$.

Lastly, we concatenate them into $\{\mathbf{h}_t^{flow}\}_{t=1}^T \in \mathbb{R}^{4D^2}$, while keeping the temporal axis intact:

$$\mathbf{h}_t^{flow} = [\mathbf{h}_t^{a2}; \tilde{\mathbf{h}}_t^w; \mathbf{h}_t^{a2} \circ \tilde{\mathbf{h}}_t^w; \mathbf{h}_t^{a2} \circ \tilde{\mathbf{h}}^{a2}]. \quad (9)$$

Temporal attention over attention flow. We now have an embedding that aligns the semantic features of words with the time steps of audio features. Subsequently, we apply temporal attention over it; the attention weight is calculated as in Luong et al. (2015). Specifically, we use the global method for each t in $\{\mathbf{h}_t^{flow}\}_{t=1}^T$:

$$\alpha_m = \text{align}(\mathbf{h}_m^{dec}, \mathbf{h}_t^{flow}), \quad (10)$$
$$\mathbf{c}_m = \sum_t \alpha_{mt}\mathbf{h}_t^{flow}, \quad (11)$$
$$\mathbf{a}_m = \tanh(\mathbf{W}_{dec}[\mathbf{c}_m; \mathbf{h}_m^{dec}]), \quad (12)$$

where $\mathbf{h}_m^{dec} \in \mathbb{R}^{D^o}$ is the state of the decoder LSTM, $\mathbf{c}_m \in \mathbb{R}^{4D^2}$ is the context vector, $\alpha_m \in \mathbb{R}^T$ is the attention mask, and $\mathbf{W}_{dec} \in \mathbb{R}^{D^o \times (4D^2 + D^o)}$ is a parameter.

Next, we obtain the output word probability:

$$\mathbf{s}_m = \text{softmax}(\mathbf{W}_o \mathbf{a}_m) \quad (13)$$

where $\mathbf{W}_o \in \mathbb{R}^{V \times D^o}$. Finally, we select the output word as $y_{m+1} = \text{argmax}_{s \in \mathcal{V}}(\mathbf{s}_m)$. We repeat this process until y_{m+1} reaches an EOS token.

The model is trained to maximize the log-likelihood assigned to the target labels via the softmax as done in most captioning models.

5 Evaluation

We perform several quantitative evaluations to provide more insights about our *AudioCaps* dataset. Specifically, our experiments are designed to answer the following questions:

1. Are the collected captions indeed faithful to the audio inputs?
2. Which audio features are useful for audio captioning on our dataset?
3. What techniques can improve the performance of audio captioning?

We present further implementation details and more experimental results in the Appendix. Some resulting audio-caption pairs can be found at https://audiocaps.github.io/supp.

Before presenting the results of our experiments on these three questions, we first explain the experimental setting and baseline models.

5.1 Experimental Setting

Evaluation metrics. Audio captioning can be quantitatively evaluated by the language similarity between the predicted sentences and the ground-truths (GTs) such as BLEU (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004) and SPICE (Anderson et al., 2016). In all metrics, higher scores indicate better performance.

Audio features. Audios are resampled to 16kHz, and stereo is converted into mono by averaging both channels. We zero-pad clips that are shorter than 10 seconds and extract three levels of audio features. For the low-level audio feature, the lengthy raw audios are average-pooled by the WaveNet encoder as in Engel et al. (2017). For the mid-level feature, mel-frequency cepstral coefficients (MFCC) (Davis and Mermelstein, 1980) are extracted using `librosa` (McFee et al., 2015) with a window size of 1024, an overlap of 360 and the number of frames at 240, and encoded further with a bi-directional LSTM followed by a gated convolutional encoder (Xu et al., 2018). Lastly, we use two high-level features: the 24th output layer of SoundNet[6] (Aytar et al., 2016) with a (10×1024) dimension and the final output embedding of VGGish[7] (Hershey et al., 2017) with a (10×128) dimension of (time × embedding).

---

[6] `https://github.com/cvondrick/soundnet`.

[7] `https://github.com/tensorflow/models/tree/master/research/audioset`.

Video features. To contrast with video captioning datasets, we also extract video features at the frame-level and at the sequence-level from YouTube clips. For frame features, we use VGG16 (Simonyan and Zisserman, 2015) pretrained on the ILSVRC-2014 dataset (Russakovsky et al., 2015). For sequence features, we use C3D[8] (Tran et al., 2015) pretrained on the Sport1M dataset (Karpathy et al., 2014). We extract subsequent frames with 50% overlap centered at each time step on the input clips for AudioSet videos, while proceeding with no overlap for MSR-VTT clips as in the original paper. We sample videos at 25fps.

5.2 Baselines

Retrieval methods. As straightforward baselines, we test the 1-nearest search with audio features, denoted by `1NN-MFCC`, `1NN-SoundNet` and `1NN-VGGish`. For a query audio, we find its closest training audio using the ℓ_2 distance on the features and return its text as a prediction. We mean-pool all the audio features over time, because it empirically leads to a strong performance.

LSTM methods. As simple generative baselines, we test with the LSTM decoder, denoted by `-LSTM` postfix, where the encoded audio feature is set as the initial state of the LSTM. For instance, `WaveNet-LSTM` is the model with the WaveNet encoder and the LSTM decoder. We use a single-layer LSTM with dropout (Srivastava et al., 2014) and layer normalization (Ba et al., 2016).

Attention models. We test two popular attention models developed in video captioning research: (i) `TempAtt` (Luong et al., 2015; Yao et al., 2016) generates captions by selectively attending to audio features over time, and (ii) `SemAtt` (You et al., 2016) creates text attending to attribute words as secondary information.

Our models. We denote our top-down multi-scale encoder as the prefix `TopDown-` and aligned semantic attention as `AlignedAtt-`.

Upper-bounds. Given that each test data has five human-generated captions, we perform cross validation on the five GT captions as an upper-bound of performance denoted as `Human`. We regard one of five human annotations as model prediction and compute the performance metric with the other four as ground-truths. After doing this on each of five, we then average the scores.

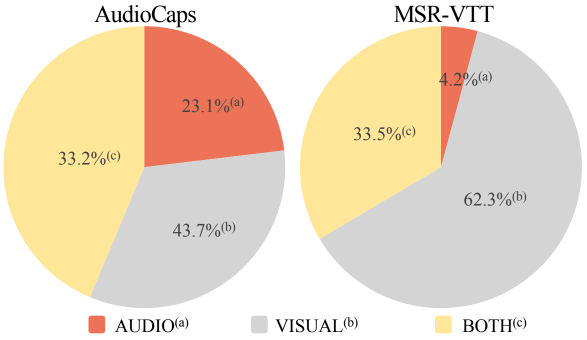

Figure 5: Comparison of vocabulary tag distribution between AudioCaps and MSR-VTT.

5.3 Results

We discuss experimental results in response to the three questions regarding the AudioCaps dataset.

5.3.1 Audio *vs* Video Captioning

We first evaluate whether the collected audio-based captions are indeed loyal to the audio clips. As one possible method to validate it, we perform comparative experiments with the video-oriented MSR-VTT dataset (Xu et al., 2016). Note that MSR-VTT and AudioCaps both provide pairs of audio clips and its corresponding videos, allowing us to perform this comparative study. We hypothesize that the captions from MSR-VTT would not coherently map to audio features, because they are written mainly based on the visual information. In contrast, AudioCaps captions would be better aligned to audio features than visual features.

The results in Table 4 support our hypothesis. In MSR-VTT, the video-based captioning model `C3D-LSTM` attains better scores than the preceding three audio-captioning models `⋆-LSTM`, while in AudioCaps the video-based model performs far worse than the audio models. This may be due to our collection method of AudioCaps, which encourages turkers to submit the descriptions based on the audio rather than the visual.

Vocabulary comparison. We also make comparisons between AudioCaps and MSR-VTT in terms of vocabulary usage in the captions. We select the 1,800 most frequent vocabularies of verbs, adjectives and adverbs from each dataset, and run a user study in which three different workers are asked to categorize each sampled word into one of (*Audio, Visual, Both, Not Applicable*). The category label per word is decided by a majority vote of three workers' opinions. We use AMT once more to collect the unbiased opinions. In or-

Gap (Audio - Video)	-2.0	-10.7	**+3.4**	**+8.2**

Table 4: Comparison of captioning results between video-based and audio-based datasets. The first three methods perform captioning using only audios while the last method `C3D-LSTM`, only use videos. The gaps empirically show how much *AudioCaps* is audio-oriented in contrast to MSR-VTT.

der to guarantee thoughtful submissions, we ask the workers to provide a description using the word. We compensate $0.05 per word to English-speaking workers with a 95% approval rate.

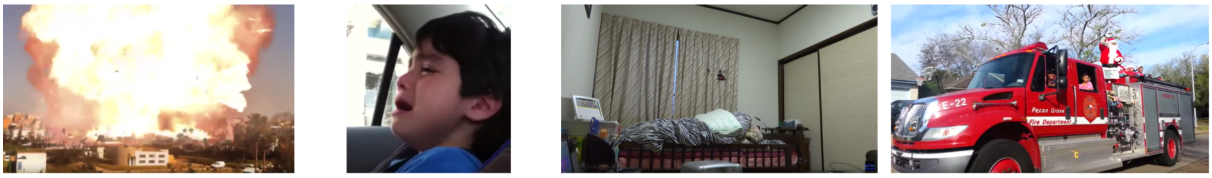
Figure 5 shows that AudioCaps has more vocabularies tagged as *Audio* (*e.g. neighs, rustling*) by 18.9%p more than MSR-VTT. Furthermore, 56.3% of the total vocabularies in AudioCaps are categorized as audio-related, that is, labeled as *Audio* or *Both* (*e.g. vibrating, applauds*). Hence, this vocabulary comparison result reassures that AudioCaps is more audio-oriented than MSR-VTT.

5.3.2 Comparison of Audio Features

The methods in the second group of Table 2 are compared to investigate which audio features are more suitable for captioning on AudioCaps. The best results are obtained by `VGGish-LSTM`. This may be because VGGish is pretrained on YouTube audio clips, similar to AudioCaps. Although the topics of YouTube are extremely diverse, the domain proximity may help VGGish learn more utilizable features for AudioCaps. `SoundNet-LSTM` shows inferior performance compared to `VGGish-LSTM`, one possible reason being because it is pretrained with Flickr videos, which are rather distant in domain from the source of our dataset, in terms of topic diversity and the amount of possible noise. `MFCC-LSTM` does not perform as well as `VGGish-LSTM`, even with the similar convolutional recurrent encoder. This result hints that pretraining with a proper dataset is essential for audio captioning. A comparison between `MFCC-LSTM` and `WaveNet-LSTM` reveals that using MFCC is better than directly taking raw waveform as input. The raw waveform is relatively long (>500× longer than MFCC); hence, it may pose a difficulty for RNN-based encoders to precisely represent the whole audio context.

5.3.3 Comparison of Models

Temporal attention consistently boosts the captioning performance of the LSTM decoder in all audio features, as shown in the models with `TempAtt-` prefix in Table 2. No-



(Ours) a large explosion followed by a loud pop
(1NN-VGGish) a man speaking followed by a loud bang
(SemTempAtt) a large explosion followed by a loud splash and thunder
(GT) a whooshing noise followed by an explosion

(Ours) a man and woman talking, then a baby crying
(1NN-VGGish) an engine runs, and people speak
(SemTempAtt) a dog barks and a woman laughs
(GT) a child cries followed by a man and woman speaking and then the child resumes sobbing

(Ours) a small motor is running, whirring occurs, and a high-pitched whine is present
(1NN-VGGish) a drill is operated, then a man speaks and restarts the drill
(SemTempAtt) a small motor running and a man speaking
(GT) a drone whirring followed by a crashing sound

(Ours) a truck engine is running, a siren is occurring, and an adult male speaks
(1NN-VGGish) a loud fire engine is followed by an emergency siren
(SemTempAtt) emergency sirens and a siren blaring
(GT) a large engine passes as people speak followed by a siren

Figure 6: Four examples of audio captioning with captured video frames, grouthtruths (GT), and generated captions by our method (Ours) and baselines. They can be heard at https://audiocaps.github.io/supp.

tably, a large performance gain is observed for `TempAtt-MFCC-LSTM`. This may be because MFCC features are transformed to temporally longer features than SoundNet and VGGish features ($240 > 10$), and thus allow temporal attention to better aid the model and bypass the vanishing gradient problem.

The semantic attention is also favorable for captioning performance, as `SemTempAtt(1NN)-VGGish-LSTM` in Table 3 slightly outperforms `TempAtt-VGGish(FC2)-LSTM` in Table 2. That is, the additional use of semantic attention enhances the temporal attention model. Obviously, when using GT labels instead of 1NN retrieved labels as attribute words, the performance increases much, hinting that better semantic attributes are more synergetic with the aligned attention.

The comparison between different layers (C4, C3, FC2) confirms the effectiveness of jointly using multi-level features. The fused features by the top-down multi-scale encoder (*i.e.* `TopDown-`) prove the most beneficial as they outperform their counterparts in Table 2. However, a stack of (FC2,C4) layers performs the best, while the three layer stack is slightly inferior, presumably due to overfitting and weak information flow between the upper and lower levels of the stacks. Finally, our best performing model is `TopDown-AlignedAtt` where both the top-down multi-scale encoder and aligned semantic attention are jointly used. We postulate that the two techniques synergize well thanks to rich information provided by `TopDown` allowing for better attention alignment.

5.3.4 Captioning Examples

Figure 6 shows selected examples of audio captioning. In each set, we show a video frame, GT and text descriptions generated by our method and baselines. Many audio clips consist of sounds with multiple sources in sequence, for which baselines often omit some details or mistakenly order the event sequence, whereas our model is better at capturing the details in the correct order.

6 Conclusion

We addressed a new problem of audio captioning for sound in the wild. Via Amazon Mechanical Turk, we contributed a large-scale dataset named *AudioCaps*, consisting of 46K pairs of audio clips and human-written text. In our experiments, we showed that the collected captions were indeed faithful to the audio inputs as well as improve the captions by two newly proposed components: the top-down multi-scale encoder and aligned semantic attention.

There are several possible directions beyond this work. First, we can further expand the scope of *AudioCaps*. Second, our model is integrable with speech counterparts to achieve more complete auditory captioning tasks.

Acknowledgments

We would like to thank SNU Vision & Learning Lab members and Yunseok Jang for the helpful comments and discussions. This work is supported by Kakao and Kakao Brain corporations and the international cooperation program by the NRF of Korea (NRF-2018K2A9A2A11080927). Gunhee Kim is the corresponding author.

A Related Work

Audio-Visual correspondence. Over the past year, a great interest has been shone to the interconnection of auditory and visual senses. The task of localizing the sound source within the visual input have been actively explored (Nagrani et al., 2017; Chung et al., 2018; Senocak et al., 2018; Afouras et al., 2018; Gao et al., 2018; Arandjelovic and Zisserman, 2018; Zhao et al., 2018), along with blind source separation aided by visual features (Ephrat et al., 2018) and learning of audio-visual multisensory representation (Owens and Efros, 2018). These previous studies compensate the lack of information in the auditory input with visual information, whereas this work focuses solely on the auditory input to generate informative descriptions.

B Dataset

The full ontology of selected labels is outlined in Figure 7.

Figure 8 shows the number of clips per word label. The original AudioSet has an extreme label bias. For instance, a difference of 660,282 between the average of top 3 most common and average of top 3 most uncommon classes. Whereas our dataset at the moment has a difference of 971. Notice the label bias is significantly reduced in comparison to the original AudioSet. We plan to reduce this further in the upcoming releases.

Table 5 compares our audio captioning dataset with some representative benchmarks of video captioning: MSR-VTT (Xu et al., 2016) and LSMDC (Rohrbach et al., 2017). One interesting property of our dataset is that the portion of verbs in the vocabularies are larger than the others. This may imply that the captions describe what is *happening* rather than what *is* in the content.

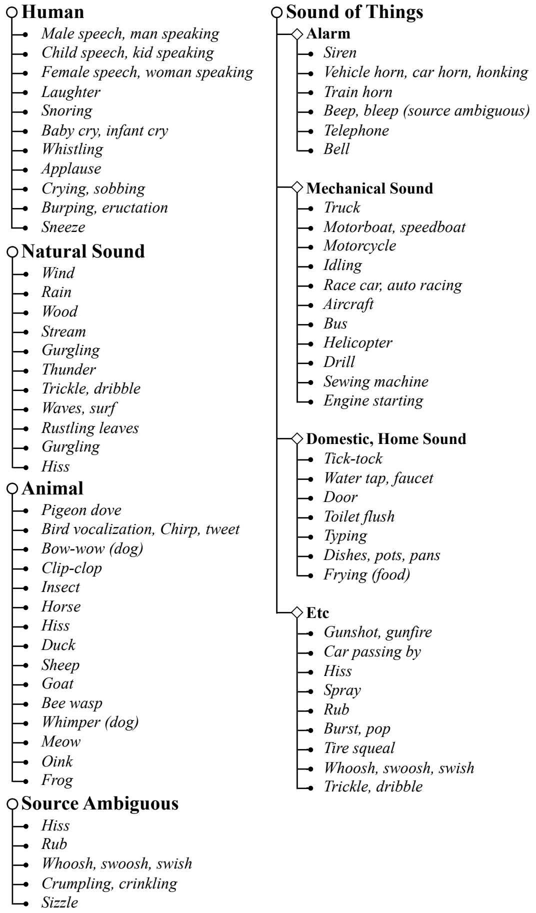

Figure 7: The curated ontology for *AudioCaps* on the basis of *AudioSet*.

C Training Details

All the parameters are initialized with Xavier method (Glorot and Bengio, 2010). We apply the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.999$ and $\epsilon = 1e - 8$.

Dataset	Clips	Sentences	Unique clips	Tokens	Vocabs	Nouns	Verbs	Adjectives	Adverbs	Duration(h)
`MSR-VTT`	10,000	200,000	7,180	1,856,523	29,316	16,437	6,379	3,761	872	41.2
`LSMDC`	128,085	128,118	200	1,157,155	22,500	12,181	3,394	5,633	1,292	147
`AudioCaps`	39,106	43,022	39,106	567,927	4,506	2,747	1,825	766	353	108.6

If First Time, Click to Show Instructions

Natural Audio Captioning

- For each audio below, ***write a one sentence description (caption) for the given audio with the given word hint & when unsure a video hint***.
- Do not describe events that may have happened in the past or future. i.e., describe the audio clip as it is (all instruction examples do this in the link above).
- Use Present Tense.
- We provide Word-labels. Feel free to actively use them in your description. Their purpose is to aid you in choosing the vocab of the sound sources. (Hover over them to obtain their definitions)
- Do not give speaker proper names, but rather give gender and maybe approximate age if salient. e.g., old; young; little; adult; kid; she; he; male; female. **They cannot be presenters; broadcasters; announcers.**
- Try to be Detailed and Expressive (Instruction example 3).
- If video hint is used, DO NOT include visuals in the video that are not present in the sound (Instruction example 1).
- Do not start the caption containing **"this is", "there is", "this is the sound of", "this sounds like", "you can hear", "in this video".. etc.** Get straight to the point.
- Ignore speech semantics (Instruction example 4). This includes no direction of speech!(Instruction example 4.2)
- If youtube link is broken, notify us via email, or type "video unavailable" and submit.
- **Experts will be checking through each of your answers to block and or reject any malicious workers.**
- Common mistake: Simply separating the sounds by multiple commas. It needs to be a connected coherent sentence! try conjunctions(immediately, shortly after, leading up to, followed by, and, along with, together with, concurrently, etc!).
- for Higher Acceptance Rate: **Distance, Frequency (if sound is repeated Instruction 7), Speed, Volume** of the sounds included in the descriptions are some of the best ways for the experts to accept the Hit.
- Common mistake: when we state describe the audio clip as is above, we mean low-level audio sounds. Be less abstract whenever possible. Have a look at **Instruction 8**

The Audio & Hint video

Word Hints (not always accurate):

sizzle stir

67221-audio Description:

DO NOT INCLUDE VISUAL INFO YOU CANNOT HEAR.

Abstract

We introduce, release, and analyze a new dataset, called Humicroedit, for research in computational humor. Our publicly available data consists of regular English news headlines paired with versions of the same headlines that contain simple replacement edits designed to make them funny. We carefully curated crowdsourced editors to create funny headlines and judges to score a to a total of 15,095 edited headlines, with five judges per headline. The simple edits, usually just a single word replacement, mean we can apply straightforward analysis techniques to determine what makes our edited headlines humorous. We show how the data support classic theories of humor, such as incongruity, superiority, and setup/punchline. Finally, we develop baseline classifiers that can predict whether or not an edited headline is funny, which is a first step toward automatically generating humorous headlines as an approach to creating topical humor.

1 Introduction

Humor detection and generation continue to be challenging AI problems. While there have been some advances in automatic humor recognition (Khodak et al., 2017; Davidov et al., 2010; Barbieri and Saggion, 2014; Reyes et al., 2012; Cattle and Ma, 2018; Bertero and Fung, 2016; Yang et al., 2015), computerized humor generation has seen less progress (Binsted et al., 1997; Stock and Strapparava, 2003; Petrović and Matthews, 2013). This is not surprising, given that humor involves in-depth world-knowledge, common sense, and the ability to perceive relationships across entities and objects at various levels of understanding. Even humans often fail at being funny or recognizing humor.

(b) The Headline Grading Task.

Figure 1: Snapshots of the headline editing and grading interfaces. Only the underlined tokens are replaceable.

A big hindrance to progress on humor research is the scarcity of public datasets. Furthermore, the existing datasets address specific humor templates, such as funny one-liners (Mihalcea and Strapparava, 2006) and filling in Mad Libs® (Hossain et al., 2017). Creating a humor corpus is non-trivial, however, because it requires (i) human annotation, and (ii) a clear definition of humor to achieve good inter-annotator agreement.

We introduce **Humicroedit**, a novel dataset for research in computational humor. First, we collect original news headlines from news media posted on Reddit (`reddit.com`). Then, we *qualify* expert annotators from Amazon Mechanical Turk (`mturk.com`) to (i) generate humor by applying small edits to these headlines, and to (ii) judge the humor in these edits. Our resulting dataset contains 15,095 edited news headlines and their numerically assessed humor. Screenshots of our two annotation tasks are shown in Figure 1, and Table 1 shows some of these annotated headlines.

This new dataset enables various humor tasks, such as: (i) understanding what makes an edited headline funny, (ii) predicting whether an edited headline is funny, (iii) ranking multiple edits of the same headline on a funniness scale, (iv) generating humorous news headlines, and (v) recommending funny headlines personalized to a reader.

Our dataset presents several opportunities for computational humor research since:

Proceedings of NAACL-HLT 2019, pages 133–142
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

- Headlines do not have specific templates.
- Headlines contain very few words, but convey a lot of information.
- A deeper understanding of world-knowledge and common-sense is needed to completely understand what makes a headline funny.
- Humorous headlines are often generated using several layers of cognition and reasoning.
- Despite us carefully qualifying annotators, their knowledge, preferences, bias and stance towards information presented in headlines influence whether they perceive a potentially funny headline as humorous, offensive, confusing, etc.

The presence of these factors suggests that thorough humor comprehension in our dataset requires the development of NLP tools that are not only robust at pattern recognition but also capable of deeper semantic understanding and reasoning. As an initial exploration of this proposition, we perform various data analysis against the background of humor theories, and we train and examine classifiers to detect humorous edited headlines in our data.

2 The Humor Dataset

In this section, we describe how we gathered our set of original headlines, directed editors to make them funny, employed graders to assess the level of humor in the modified headlines, and created the Humicroedit dataset.

2.1 Task Description

Our goal is to study how humor is generated by applying short edits to headlines. News headlines are ripe for humor, since they convey rich information using only a few words. While the short form may seem to limit context, readers have rich background information in the form of their existing world knowledge, which helps them understand the headline. Allowing only short edits means we can apply focused analysis on the tipping point between regular and funny.

Therefore, our task is to edit a headline to make it funny, where an edit is defined as the insertion of a single-word noun or verb to replace an existing entity or single-word noun or verb. Note that our rules do not allow:

- Addition/removal of a whole noun/verb phrase, except removal of noun phrases that are entities (e.g., One World, Virtual Reality).
- Removal of sub-tokens within entities (e.g., replacing only “States” in “United States”).

The decision to strictly avoid edits of other parts-of-speech (POS) words was motivated by the observation in our pilot experiments that those edits did not provide enough variety of humor. For example, when substituting adjectives and adverbs, our editors mostly used antonyms or superlatives. Switching nouns and verbs, on the other hand, enables the introduction of diverse novel connections between entities and actions.

To identify the replaceable entities, we apply named entity recognition (NER) and POS tagging using the Stanford CoreNLP toolkit (Manning et al., 2014). We allow for replacement of only those entities that are well-known, according to the Microsoft Knowledge Base[1]. This improves the likelihood that the terms are familiar to both headline editors and humor judges. We allow a noun (or verb) to be replaced if it is an unambiguous noun (or verb) in WordNet (Fellbaum, 1998) (i.e., has a single WordNet POS). Editors are only allowed to replace one of the selected replaceable words/entities in the headline.

We refer to a single-term substitution of this type as a “**micro-edit**”, and we will use this term interchangeably with “edit” in the remainder of this paper. Micro-edits approach the smallest change that can induce humor in text, letting us focus intently on what causes humor.

2.2 Collecting Headlines

We build our dataset from popular news headlines posted on the social media site Reddit. This strategy steers us towards a set of headlines that is part of general discourse, rather than being only of specialized interest, which would make editing them for humor difficult.

We obtain all Reddit posts from the popular subreddits `r/worldnews` and `r/politics` from January 2017 to May 2018 using Google BigQuery[2]. Each of these posts is a headline from a news source. We remove duplicate headlines and headlines that have fewer than 4 words or more than 20 words. Finally, we keep only the headlines from the 25 English news sources that contribute the most headlines in the Reddit data, resulting in a total of 287,076 news headlines.

Table 1: Some headlines in our dataset and their edits, mean funniness grades, and accuracy of funniness prediction by LSTM. We acknowledge that some of these are offensive, but we use them for analysis in Section 4.1.

2.3 Annotation

For our data annotation tasks, we use Mechanical Turk workers who (i) are located in the U.S., (ii) have a HIT approval rate greater than 97%, and (iii) have more than 10,000 HITs approved. To ensure high data quality, we further qualify distinct sets of (i) turker judges for recognizing humor in an edited headline, and (ii) editors adept at editing headlines to generate humor.

2.3.1 Qualifying Humor Judges

We manually collected a set of 20 original news headlines and edited each of them such that some edits are funny and some are not. We asked several members of our research group to assess the funniness of each edited headline using the following integer scale developed by Hossain et al. (2017):

0 - Not funny
1 - Slightly funny
2 - Moderately funny
3 - Funny

We instructed internal and turker judges (i) to grade objectively regardless of their own stance towards issues, entities and information expressed in the headline, and (ii) to grade an edited headline as funny if they believed it would be funny to a large audience. Further, we instructed judges to grade an edited headline as funny if either the headline was funny by itself regardless of the original headline, or the headline was only funny when considering how the original headline was changed.

We labeled the ground truth funniness of each of these 20 edited qualifier headlines as its mean internal judge grade. For the qualification task, we classified as funny any edited headline with a mean grade of 1.0 or above.

Next, we launched the same task on Mechanical Turk until we found 150 qualified judges (60% of the candidates). Turkers were qualified if (i) they had 3 or fewer classification errors according to our 1.0 threshold, and (ii) on average, their grades were within 0.6 of the mean internal judge grades.

We calculated the inter-annotator agreement for assigning headline funniness grades using the Krippendorff's α interval metric (Krippendorff, 1970) — a real number in the range $[-1, 1]$, with -1, 0 and 1, respectively, implying complete disagreement, no consensus and full agreement. The α for the internal judges and qualified turker judges were, respectively, 0.57 and 0.64.

2.3.2 Qualifying Humor Editors

For editor qualification, we randomly sampled 60 headlines, split into 6 separate Mechanical Turk tasks of 10 headlines each. Candidate editors were asked to complete one of these tasks, which was to make each headline as funny as possible to a general audience using a micro-edit. Task participants were instructed not to apply the following edits:

- Cheap humor generation techniques: add profanity, slang, bathroom/potty humor, *crude* sexual references or informal language.
- Squeeze multiple words into one (e.g., Housecat, JumpedOverWall).

Next, we used 7 qualified judges to assess the funniness of each edited headline of each candidate. We qualified all candidates whose mean funniness of edited headlines was above 0.8 or the task's average headline's funniness grade, whichever was higher. In total, we obtained 100 qualified editors (57.5% of the candidates) who met our expectations in their ability to create funny headlines.

2.4 Data Collection and Quality Control

For our final dataset, we randomly sampled a total of 5,170 news headlines from our Reddit dataset, obtaining roughly an equal number of headlines from each news source. We asked 3 editors to edit each headline and 5 judges to grade each edited headline. Multiple micro-edits of the same headline allow us to compare different edits in terms of their effectiveness for generating humor, which we leave for future work.

To avoid turker exhaustion and decision fatigue, we performed the annotation task over a series of mini-batches launched at least 24 hours apart. After each round of editing, we applied tools to (i) check the edits for spelling mistakes which we manually corrected, and (ii) to find and eliminate inserted tokens that were a concatenation of two or more words (e.g., selftanner). To allow diversity in annotations, we applied a maximum HIT limit for annotators per batch. After each batch was completed, we temporarily suspended those editors and judges who had done significantly more HITs than the rest, until the others caught up.

Lastly, as we obtained more and more annotated data, the editors started employing the same humor generation strategies (e.g., inserting words from a small vocabulary). Consequently, judges saw repeated, identical edits, so the element of surprise was gone, and the judges were grading fewer humorous edited headlines as funny. We addressed this by randomly sampling a set of editors and judges for each batch, obtaining new editors and judges over time, and removing those editors who had done a majority of the HITs but whose edits' average funniness grade fell below a threshold (=0.7) after they participated in a batch. We also removed judges who repeatedly assigned very low funniness grades compared to the 4 other judges for the same edit. The judges' agreement score based on α was 0.20, showing modest agreement considering the factors above and others such as judges' personal preferences, bias, political stance, etc. which make consensus difficult.

Our Humicroedit dataset includes 15,095 unique edited headlines graded for funniness. For annotating a single headline, we paid 10 US cents to editors and 2.5 US cents to judges. There were also small costs for qualification. Our total cost for obtaining the dataset is about USD 4,500[3].

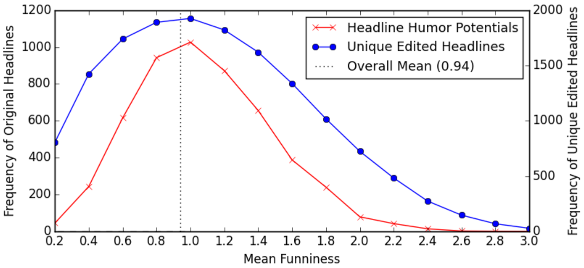

Figure 2: Histograms of humor potentials of headlines and mean funniness of unique edited headlines. The humor potential of a headline is the mean funniness score over all edits, shown as the red curve. The blue curve shows the histogram of the mean score of each distinct edited headline.

3 Humor Analysis

In this section, we analyze what types of micro-edits are effective at creating humor in our dataset, and we discuss our findings against the background of humor theories.

Figure 2 shows the histogram of the mean rating of each edited headline. While the majority of the headlines achieve slight to moderate levels of humor, some of them appear inherently difficult to make humorous by micro-editing. We noticed that editors encountered difficulty making headlines funny when the headlines had very negative themes, such as shootings, death, etc., and when they focused on information less likely to be known by a general audience (e.g., relatively unknown person, an insignificant political issue).

3.1 Humor Generation Strategies

By manual inspection, we can gain insights into humor generation strategies employed by our editors, which we discuss with references to Table 1:

1. Using a word that forms a meaningful n-gram with the adjacent words (e.g., ID 5: Fire and ~~Fury~~ marshmallows; ID 6: ~~Wall~~ sesame street).
2. Connection between replaced word and the replacement: replacements that are semantically distant from (e.g., ID 1: ~~Mexico~~ therapist) or similar in pronunciation to (e.g., ID 10: ~~ties~~ pies) to the replaced word.
3. Using a word that makes a strong connection with an entity in the headline (e.g., ID 2: Trump and hair; ID 9: Obama and ears).
4. Creating sarcasm (ID: 11).
5. Belittling an entity or noun in the headline (e.g., ID 4: Hillary Clinton's ~~turn~~ fault; ID 9: Obama's ~~years~~ ears).

---

[3] Dataset: cs.rochester.edu/u/nhossain/humicroedit.html. Total cost is USD 4,500, not USD $4,500^{3}$ (joke!)

6. Tension suppression[4]: making a serious headline silly (e.g., IDs 5 and 9).
7. Inserting words that generate incongruity (common among most examples in Table 1).
8. Setup and punchline: let the headline build up towards an expected ending, and then change words towards the end to produce a coherent but surprising ending (e.g., IDs 3, 4 and 5).

3.2 Clusters of Replacement Words

Each micro-edit used a new replacement word to change the headline. We clustered these replacement words using their GloVe word vectors (Pennington et al., 2014) and k-means clustering, with $k = 20$. Our manually-generated cluster names are shown in Table 2, where the clusters are ordered by the mean funniness score of the edited headlines whose replacement word is in the cluster. For each cluster, we show the frequency with which the cluster was used for replacement words and frequent sample words from the cluster.

We can compare our automatically generated clusters with those of Westbury and Hollis (2018). They manually created six clusters from the 200 funniest, single words in Engelthaler and Hills (2018) and then they added more words algorithmically. Four of their six manually curated classes have direct correspondences to our automatically curated classes: *sex*, *insults*, *bodily functions*, and *animals*. We did not find an equivalent to their *profanity* class, because we instructed our editors to avoid profanity. There is also a *party* class that we do not have. Overall, though, we find good agreement between their manually curated classes and some of our automatically generated clusters, leading us to believe that our clusters are meaningfully representative of humor generation strategies for our task.

3.3 Support for Theories of Humor

Our rated headlines give us an opportunity to explore theories of humor in a systematic way. We find, in general, that these theories are supported by our data.

3.3.1 Length of Joke

Although some linguists argue that jokes should make economical use of words (Tomoioagă, 2015), Ritchie (2004) argues that jokes often have extra information, which can make a joke funnier. While humorous headlines form a special niche of jokes, we observed that longer headlines generally had higher humor potential.

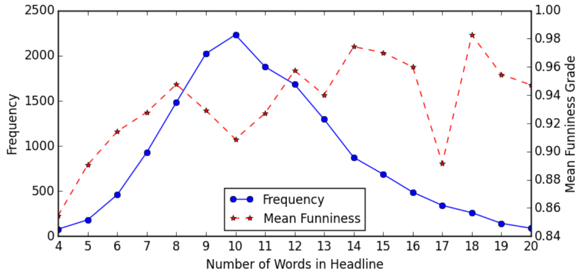

Figure 3: Short headlines did not lend themselves to high humor scores, while longer headlines generally had more potential for humor. The blue line shows the raw distribution of headline lengths in our data, and the red line shows the mean funniness score over different lengths.

Figure 3 shows that the population of our collected headlines from Reddit has a length distribution with a peak at 10 words and a long tail to the right. The least funny edited headlines are the shortest, and the most funny are the longest. This makes sense since very short headlines (4-5 words long) barely have enough contextual information to exploit to make a humorous edit, whereas headlines that have very rich contexts generally allow editors more flexibility to generate humor. We note that Dunbar et al. (2016) also found that longer jokes are funnier, but that some jokes could be too complicated to be funny.

We can also examine the number and proportion of *replaceable* words and how these numbers affect funniness. In our dataset, the number of replaceable words ranged between 1 and 12, and funniness grades of micro-edits were significantly lower at the two extremes. Editors apparently had difficulty generating humor when they were severely constrained in choosing a word to replace, or when they had too many choices for replacement. However, edited headlines with a higher proportion of replaceable words were generally funnier, as shown in Table 3. This suggests that allowing editors more freedom in choosing words from the headline to edit results in better humor, or that high proportion of nouns, entities and verbs in the headline increases the chance of successful humor generation.

3.3.2 Incongruity for Humor

We see evidence for the incongruity theory of humor (Morreall, 2016). Jokes that use incongruity

---

[4] This is also known as the relief theory of humor.

Class Label	Funniness	Frequency %	5 Frequent Sample Words
clothes and fashion	1.213	5.77	hair, pants, haircut, fashion, underwear
sex	1.209	3.52	orgy, spank, mistress, porn, striptease
food (savory)	1.113	3.89	cheese, sandwich, chicken, potato, tacos
eating	1.048	4.18	food, pizza, dinner, restaurant, eat
fantasy characters	1.036	4.94	clown, aliens, penguin, robot, ghost
music and shows	1.023	3.85	dance, circus, music, sings, mime
bodily functions	1.021	3.11	diet, brain, odor, dandruff, pimple
food (snacks)	1.017	5.36	pumpkin, cake, vodka, cookies, candy
animals	1.000	9.22	dog, monkey, puppy, cats, duck
various nouns (1)	0.935	5.82	toupee, hoedown, jaywalking, barbers, seance
jobs and roles	0.890	4.95	children, wife, baby, mother, barber
insults	0.876	3.36	clowns, tantrum, trolls, racist, whining
emotional	0.868	7.74	love, hug, jokes, fights, cry
leisure	0.862	6.01	vacation, shopping, tanning, hotel, pool
sports	0.856	3.03	horse, game, bowling, golf, wrestling
various nouns (2)	0.850	4.90	water, nose, balloon, gas, smoke
human deficiencies	0.803	4.21	lies, ignorance, humor, boredom, stupidity
media	0.787	4.20	tweet, movie, book, video, television
aspirations	0.726	7.28	party, date, people, money, model
corrupted	0.712	4.48	president, bribes, politicians, destroy, prison

Table 2: Twenty clusters of replacement words with manually determined cluster labels.

Repl. Words Prop.	0.2	0.4	0.6	0.8	1.0
Mean Funniness	0.87	0.92	0.95	0.94	1.0

Table 3: Edited headlines were judged funnier when they had a larger proportion of replaceable words.

aim to violate an expectation, with the expectation normally set up by the joke itself. We test incongruity by examining the relationship between the replacement words chosen by our editors and words in the original headline using cosine distances between their GloVe vectors. If incongruity is important, we expect the replacement word to be distant from the headline's original words.

The results of this analysis are shown in Figure 4. Our approach involved computing the correlations between mean funniness scores of edited headlines and different GloVe distances between their replacement words and the other words in the headline serving as context. In order to sharpen the analysis, we looked at subsets of headlines with extreme funniness scores. For instance, the left-most data points in Figure 4 pertain only to those edited headlines that are in the top and bottom 5% of mean scores, which filters out headlines whose scores are in the middle.

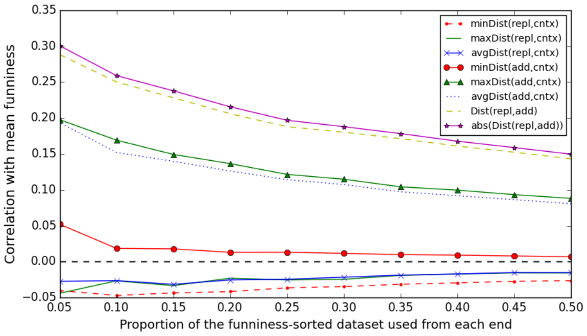

Figure 4: Correlations of word vector based cosine distances with mean funniness at various dataset sizes. We measure distance (and its absolute value) between the replaced word(s) and the added word, and also their minimum, maximum and average distances with the set of other words in the headline.

The four curves higher on the plot show a relatively high correlation between humor scores and the cosine distance between the added word ("add" in legend) and the replaced word ("repl" in legend) or the other words in the headline ("cntx" in legend). This suggests that incongruity leads to humor. The three lower curves show there is not a strong correlation between humor and the distance between the original, replaced word the other words in the headline. Finally, smaller, less humor-ambiguous data leads to stronger positive correlations, which suggests that higher incongruity leads to more quality humor.

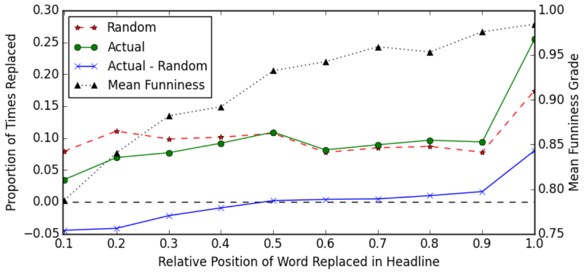

Figure 5: The joke profile graph for setup and punchline humor, showing that word substitutions toward the end of the headline normally lead to better humor.

3.3.3 Setup and Punchline

We specifically studied whether the "setup and punchline" (Rochmawati, 2017) approach is used in funny headline generation, where the humor comes toward the end of the joke after a setup at the beginning. This has been verified numerically for funny cartoon captions by Shahaf et al. (2015). For our analysis, we construct the **joke profile graph**, shown in Figure 5. It shows the proportion of time the editors substituted a word at each relative word position bin compared to if they randomly chose a word to substitute. Specifically, the red curve in the plot shows the proportion of replacement word locations if they were chosen randomly from those available in the editing task. The green curve shows the proportion of word locations actually chosen by our editors, and the blue curve shows the difference. We see that the blue line rises monotonically toward the end of the headline, meaning that editors tend to prefer replacing words later in the headline. The plot also shows the average funniness grade as a dotted line as a function of the position of the replacement word. It rises dramatically toward the end, showing that the funniest headlines were generally those with a replacement word toward the end.

3.3.4 Superiority for Humor

Jokes often express our feelings of superiority over someone else (Morreall, 2016). This can lead to frequent use of negative sentiment in jokes, as found by Mihalcea and Pulman (2007) in their analysis of humorous texts. We find similar support in our clusters of replacement words in Table 2, where the clusters labeled *insults*, *human deficiencies*, and *corrupted* are all comprised of words that tend to denigrate other people, accounting for about 12% of the substitute words inserted by our editors.

4 Humorous Headline Detection

In this section, we develop baseline classifiers to infer whether an edited headline is funny. Given our dataset, there are three possible combinations of information that we can use to detect humor:

1. Using only the edited headline to predict whether it is funny or not.
2. Using only the original headline to predict its potential for funniness.
3. Using both original and edited headlines to jointly predict resulting funniness.

We address the first of these scenarios. A classifier of this type could be used in a generate-and-test setting to create humorous headlines by trying different micro-edits.

To map the range of observed funniness grades (see Figure 2) to the funny/not-funny classes, we sort our full dataset in decreasing order of mean funniness[5] scores, and we take the top $X\%$ of the data from each end, at size intervals of 10%. Note that each train/test split has an equal number of funny and not-funny headlines, establishing a 50% majority class baseline for accuracy.

We first trained a number of non-neural classifiers (logistic regression, random forest, SVM), using two feature sets: n-gram features (1, 2 and 3-grams combined) and features based on GloVe embeddings[6] as shown in Figure 4. We use 80% of the data for training and 20% for testing. We optimized hyperparameters for accuracy on 10-fold cross validation on the training set. The random forest classifier consistently performed best, so we only report its test set performance.

We also applied a neural baseline model using a single-layer bi-directional LSTM (Hochreiter and Schmidhuber, 1997) with 16 hidden units, a dropout of 0.5, and GloVe pre-trained embedding of the sequence of words in the edited headline. The training set was further split into 80%-20% splits for training and validation. We used a mini-batch size of 32 with up to 25 epochs to train our model, optimizing for cross-entropy.

Table 5 shows the results obtained with our classifiers. LSTM performs better than random forest with either n-gram (Rf-ngram) or GloVe features (Rf-Glv), achieving our best accuracy of 68.54%

---

[5] We then sort by increasing standard deviations of grades to further rank headlines which tie on funniness, as lower standard deviation indicates stronger judge agreement.

[6] This is our only feature set that uses the replaced word.

Bin	0-.4	.4-.8	.8-1.2	1.2-1.6	1.6-2.0	2.0-2.4	2.4-3.0
Acc.	71.5	61.1	52.0	61.0	68.6	68.3	76.2

Table 4: LSTM accuracy for distinct grade bins (upper-bounds are inclusive) on the test set for $X = 40$.

using X = 10. We suspect that the reason for the LSTM's superior performance is that it learns predictive interactions between the semantics of the headline's words (via the GloVe embeddings) that trigger the humor[7].

Table 5 also shows that accuracy generally decreases as X increases, which is expected since higher X implies a smaller separation between funny and not-funny classes, making classification harder. This is further corroborated by the observation that annotator-agreement scores (also shown in Table 5) decrease similarly with increasing X, indicating that funny and not-funny classes are easier to distinguish at the extreme ends of the dataset for both humans and machines alike.

4.1 LSTM Classification Analysis

We now investigate the test-set performance of the LSTM trained on the dataset obtained using X = 40, the largest of our experimental datasets for which the class boundaries are distinct.

To analyze how well the classifier predicts the extremes in the test set, we obtained classification accuracy on distinct mean grade bins, presented in Table 4. The LSTM is able to distinguish the far extremes ($\leq$0.4 and $>$1.6) of the test set much more convincingly than the headlines with mean grades in the interval (0.4,1.6]. We found a slightly negative correlation between classification accuracy and standard deviation of grades. Using additional judges for headlines with high standard deviation of grades would possibly improve annotator agreement and classification accuracy.

The LSTM achieved a significantly lower accuracy when an entity (61.8%) was replaced by the micro-edit compared to when a noun (64.5%) or a verb (65.5%) was replaced. For 5 of the 7 bins in Table 4, the entity-replaced headline classification accuracy was lower than when the other two types were replaced, with the LSTM only achieving an accuracy of 47.9% on the (0.8,1.2] bin for entity-replaced headlines. Although the classifier is never shown what has been replaced, it is better at assessing humor when the replaced word is not an entity. Our judges did have access to the replaced word, so we speculate this knowledge is important when the replaced word is an entity, especially when the entity triggers the judge's recollection of their world knowledge surrounding the entity, which the LSTM does not have. Another potential reason is that the pretrained GloVe vectors are trained on web data (840 billion tokens obtained from Common Crawl) no more recent than 2014, which may not appropriately represent common entities in our 2017-2018 headline data.

Next, we qualitatively analyzed the LSTM's classification accuracy towards the two extremes of the dataset, some of which are shown in Table 1. Overall, the LSTM seems to suffer from a relatively high level of brittleness (possibly arising from the unusual writing style in headlines), where correct predictions could be obtained by very little modification to the text. For example, changing "Trump → Trump's" in ID 1 and deleting "Essential Politics:" in ID 3 fix their classification errors. Quotes in headlines also confused the LSTM (e.g., ID 4) since it is sometimes non-trivial to discern the speaker of the quote in a headline.

The classifier often had difficulty figuring out humorous replacements that involve common-sense knowledge (e.g., IDs 7 and 8). Not surprisingly, it also failed to detect offensive replacements as in IDs 13 and 14, where the model probably recognized the incongruity and marked these as funny. World knowledge and cultural references were other challenges (e.g., IDs 4, 9 and 14).

The LSTM was able to figure out some of the obvious negative sentiments which were common in unfunny headlines (e.g., ID 15), and it detected some humor patterns resulting from using words that form a common (but funny in the context) n-gram with the adjacent words (e.g., IDs 5 and 6).

Overall, our results show that there is a discernible signal separating funny and and not-funny headlines, even when using relatively shallow features that only take the content of the headline into account (modulo GloVe embeddings which are pretrained and hence contain semantic information gleaned from a larger corpus). We expect that further work, which could examine deeper relationships to current events, historical context, and common sense knowledge, will improve the ability to distinguish funny from not-funny beyond the baselines provided here.

---

[7] Using only words in the original headline produced accuracy in the mid-50% range, suggesting that the LSTM captures some humor impact of the replacement word as input and that some headlines have high potential for funniness.

X	MaxUF	MinF	α	Rf-Glv	Rf-ngram	Lstm-Glv
10	0.2	1.8	0.66	60.27	65.56	68.54
20	0.4	1.4	0.49	61.67	63.41	67.21
30	0.6	1.2	0.37	59.43	62.96	66.11
40	0.8	1.0	0.27	57.45	59.35	64.07
50	0.8	0.8	0.20	55.63	56.52	60.63

Table 5: Classification accuracy for various funniness-sorted dataset proportions and classifiers/feature sets. MaxUF is the highest score for the not-funny class, MinF is the lowest score for the funny class, and we also provide Krippendorff's α for judge agreement.

5 Related Work

Previous research on automated humor can be divided into work on datasets, analysis, detection, and generation. We will give examples of each.

Datasets are important for automated understanding of humor and for training models. Starting at the simplest linguistic level, Engelthaler and Hills (2018) gathered almost 5,000 English words with funniness ratings for each one. Filatova (2012) found 1,905 Amazon product reviews classified as either regular or ironic/sarcastic, and Khodak et al. (2017) collected 1.3 million sarcastic statements from Reddit and a much larger set of non-sarcastic statements. Mihalcea and Strapparava (2005) collected about 24,000 one-liner jokes, Potash et al. (2017) shared a dataset to rank funny tweets for certain hashtags, and Miller et al. (2017) created a task for pun detection.

Humor analysis, as we have done, is aimed at understanding what makes something funny. Building on the word-level corpus of Engelthaler and Hills (2018), Westbury and Hollis (2018) developed models to predict the funniness of 4,997 words. Looking at multi-word, but still short text, Shahaf et al. (2015) analyzed cartoon captions in order to understand what made some funnier than others. The work that is most similar to ours is from West and Horvitz (2019), who looked at pairs of funny and normal headlines. While we employed editors to create funny headlines from serious ones, they went the other way using a Web-based game, producing and analyzing 2,801 modified versions of 1,191 satirical headlines.

Humor detection is characterized by determining if a given text is funny or not. Examples include Khodak et al. (2017), detecting sarcasm in Reddit and Davidov et al. (2010) detecting sarcasm in Amazon product reviews and Twitter. Barbieri and Saggion (2014) and Reyes et al. (2012) showed how to detect humorous tweets, and Kiddon and Brun (2011) detected double entendres.

Generating humor is a difficult problem. Past work includes Binsted et al. (1997) producing punning riddles, funny acronyms from Stock and Strapparava (2003), jokes of the type "I like my coffee like I like my war, cold" by Petrović and Matthews (2013), and filling in Mad Libs® by Hossain et al. (2017). Our headline work has the potential to help in humor generation, moving away from jokes with a strong template to more free form.

6 Conclusion and Future Work

We have developed and released Humicroedit, a carefully curated dataset of 15,095 headlines with simple edits designed to make them funny. The dataset specifies the edits and also comes with five funniness scores for each edited headline. The simple replacement edits facilitate focused analysis on what causes the humor. We showed how our data supports, in a quantitative way, humor theories about length of joke, incongruity, superiority, and setup/punchline. Finally, we developed baseline classifiers that show how well we can distinguish funny edits from non-funny edits using simple linguistic features.

We expect our dataset will facilitate research in humor and natural language processing. Headlines present unique challenges and opportunities, because their humor is largely topical, depending on a knowledge of current events and prominent people and entities.

Future work with this data could include deeper features for assessing humor. We expect that humor detection would likely improve using features that incorporate world knowledge and common sense. Likewise, there may be something to learn by analyzing topical jokes from professional comedians. With our single-word edits, this analysis becomes easier, because we are looking at the minimal change in a headline to make it funny. Additionally, if we can better understand what makes a headline funny, we may be able to automatically generate funny headlines and even personalize them to particular readers.

Answer-based Adversarial Training for Generating Clarification Questions

Sudha Rao[*]

Abstract

We present an approach for generating clarification questions with the goal of eliciting new information that would make the given textual context more complete. We propose that modeling hypothetical answers (to clarification questions) as latent variables can guide our approach into generating more useful clarification questions. We develop a Generative Adversarial Network (GAN) where the generator is a sequence-to-sequence model and the discriminator is a utility function that models the value of updating the context with the answer to the clarification question. We evaluate on two datasets, using both automatic metrics and human judgments of usefulness, specificity and relevance, showing that our approach outperforms both a retrieval-based model and ablations that exclude the utility model and the adversarial training.

1 Introduction

A goal of natural language processing is to develop techniques that enable machines to process naturally occurring language. However, not all language is clear and, as humans, we may not always understand each other (Grice, 1975); in cases of gaps or mismatches in knowledge, we tend to ask questions (Graesser et al., 2008). In this work, we focus on the task of automatically generating clarification questions: questions that ask for information that is *missing* from a given linguistic context. Our clarification question generation model builds on the sequence-to-sequence approach that has proven effective for several language generation tasks (Sutskever et al., 2014; Serban et al., 2016; Yin et al., 2016; Du et al., 2017). Unfortunately, training a sequence-to-sequence model directly on (context, question) pairs yields questions that are highly generic[1], corroborating a common finding in dialog systems (Li et al., 2016b). Our goal is to be able to generate clarification questions that are useful *and* specific.

To achieve this, we begin with a recent observation of Rao and Daumé III (2018), who consider the task of question reranking: a good clarification question is the one whose answer has a high *utility*, which they define as the likelihood that this question would lead to an answer that will make the context more complete (§2.3). Inspired by this, we construct a model that first generates a question given a context, and then generates a hypothetical answer to that question. Given this (context, question, answer) triple, we train a utility calculator to estimate the usefulness of this question. We then show that this utility calculator can be generalized using ideas for generative adversarial networks (Goodfellow et al., 2014) for text (Yu et al., 2017), wherein the utility calculator plays the role of the "discriminator" and the question generator is the "generator" (§2.2), which we train using the MIXER algorithm (Ranzato et al., 2015). We evaluate our approach on two datasets: Amazon product descriptions (Figure 1) and Stack Exchange posts (Figure 2). Our two main contributions are:

1. An adversarial training approach for generating clarification questions that models the utility of updating a context with an answer to the clarification question. [2]
2. An empirical evaluation using both automatic metrics and human judgments to show that our adversarially trained model generates questions that are more *useful* and *specific to the context* than all the baseline models.

Product title	T-fal Nonstick Cookware Set, 18 pieces, Red
Product description	Easy non-stick 18pc set includes every piece for your everyday meals. Exceptionally durable dishwasher safe cookware for easy clean up. Durable non-stick interior. Oven safe up to 350.F/177.C
Question	Are they induction compatible?
Answer	They are aluminium so the answer is NO.

Figure 1: Sample product description from Amazon paired with a clarification question and answer.

Title	Wifi keeps dropping on 5Ghz network
Post	Recently my wireless has been iffy at my university. I notice I am connected to a 5Ghz network, while I am connected to a 2.4Ghz everywhere else (where things work fine). Sometimes it reconnects, but I have to run 'sudo service network-manager restart'. Is it possible a kernel update caused this?
Question	what is the make of your wifi card ?
Answer	intel corporation wireless 7260 (rev 73)

Figure 2: Sample post from stackexchange.com paired with a clarification question and answer.

2 Training a Clarification Question Generator

Our goal is to build a model that, given a context, can generate an appropriate clarification question. Our dataset consists of (*context*, *question*, *answer*) triples where the *context* is an initial textual context, *question* is the clarification question that asks about some missing information in the context and *answer* is the answer to the clarification question (details in § 3.1). Representationally, our question generator is a standard sequence-to-sequence model with attention (§2.1). The learning problem is: how to train the sequence-to-sequence model to generate good clarification questions.

An overview of our training setup is shown in Figure 3. Given a context, our question generator, which is a sequence-to-sequence model, outputs a question. In order to evaluate the usefulness of this question, we then have a second sequence-to-sequence model called the "answer generator" that generates a hypothetical answer based on the context and the question (§ 2.5). This (context, generated question and generated answer) triple is fed into a UTILITY calculator, whose initial goal is to estimate the probability that this (question, answer) pair is useful in this context (§ 2.3). This UTILITY is treated as a reward, which is used to update the question generator using the MIXER (Ranzato et al., 2015) algorithm (§ 2.2). Finally, we reinterpret the answer-generator-plus-utility-calculator component as a *discriminator* for differentiating between (context, true question, generated answer) triples and (context, generated question, generated answer) triples , and optimize the generator for this adversarial objective using MIXER (§2.4).

2.1 Sequence-to-sequence Model for Question Generation

We use a standard attention based sequence-to-sequence model (Luong et al., 2015) for our question generator. Given an input sequence (context) $c = (c_1, c_2, ..., c_N)$, this model generates an output sequence (question) $q = (q_1, q_2, ..., q_T)$. The architecture of this model is an encoder-decoder with attention. The encoder is a recurrent neural network (RNN) operating over the input word embeddings to compute a source context representation $\tilde{c}$. The decoder uses this source representation to generate the target sequence one word at a time:

$$\begin{aligned} p(q|\tilde{c}) &= \prod_{t=1}^{T} p(q_t|q_1, q_2, ..., q_{t-1}, \tilde{c}_t) \\ &= \prod_{t=1}^{T} \mathit{softmax}(W_s\tilde{h}_t) \quad ; \\ \text{where } \tilde{h}_t &= \tanh(W_c[\tilde{c}_t; h_t]) \end{aligned} \tag{1}$$

In Eq 1, $\tilde{h}_t$ is the attentional hidden state of the RNN at time t and W_s and W_c are parameters of the model.[3] The predicted token q_t is the token in the vocabulary that is assigned the highest probability using the softmax function. The standard training objective for sequence-to-sequence model is to maximize the log-likelihood of all (c, q) pairs in the training data D which is equivalent to minimizing the following loss,

$$L_{\text{mle}}(D) = -\sum_{(c,q)\in D} \sum_{t=1}^{T} \log p(q_t|q_1, ..., q_{t-1}, \tilde{c}_t) \tag{2}$$

---

[3] Details are in Appendix A.

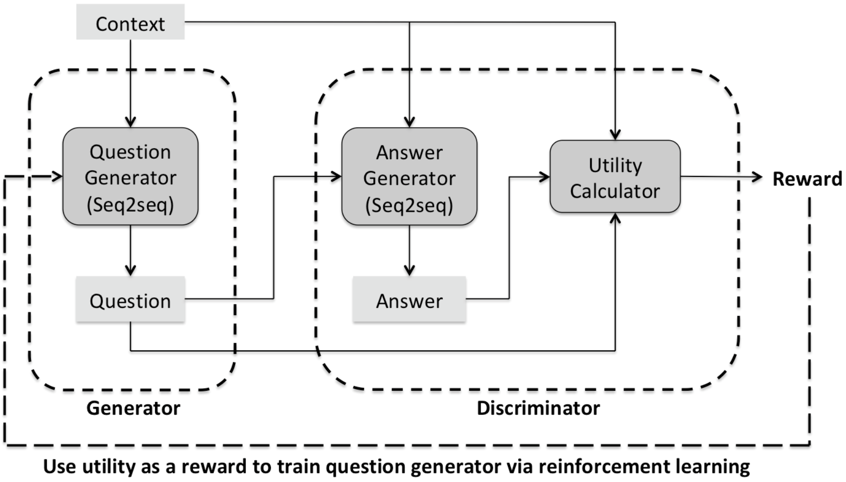

Figure 3: Overview of our GAN-based clarification question generation model (refer preamble of §2)

2.2 Training the Generator to Optimize UTILITY

Training sequence-to-sequence models for the task of clarification question generation (with context as input and question as output) using maximum likelihood objective unfortunately leads to the generation of highly generic questions, such as *"What are the dimensions?"* when asking questions about home appliances. Recently, Rao and Daumé III (2018) observed that the usefulness of a question can be better measured as the *utility* that would be obtained if the context were updated with the answer to the proposed question. Following this observation, we first use a pretrained answer generator (§2.5) to generate an answer given a context and a question. We then use a pretrained UTILITY calculator (§ 2.3) to predict the likelihood that the generated answer would increase the utility of the context by adding useful information to it. Finally, we train our question generator to optimize this UTILITY based reward.

Similar to optimizing metrics like BLEU and ROUGE, this UTILITY calculator also operates on discrete text outputs, which makes optimization difficult due to non-differentiability. A successful recent approach dealing with the non-differentiability while also retaining some advantages of maximum likelihood training is the Mixed Incremental Cross-Entropy Reinforce (Ranzato et al., 2015) algorithm (MIXER). In MIXER, the overall loss L is differentiated as in REINFORCE (Williams, 1992):

$$\begin{aligned} L(\theta) &= -\mathbb{E}_{q^s \sim p_\theta} r(q^s) \quad ; \\ \nabla_\theta L(\theta) &= -\mathbb{E}_{q^s \sim p_\theta} r(q^s) \nabla_\theta \log p_\theta(q^s) \end{aligned} \tag{3}$$

where q^s is a random output sample according to the model p_θ and θ are the parameters of the network. The expected gradient is then approximated using a single sample $q^s = (q_1^s, q_2^s, ..., q_T^s)$ from the model distribution (p_θ). In REINFORCE, the policy is initialized randomly, which can cause long convergence times. To solve this, MIXER starts by optimizing maximum likelihood for the initial Δ time steps, and slowly shifts to optimizing the expected reward from Eq 3 for the remaining $(T - \Delta)$ time steps.

In our model, for the initial Δ time steps, we minimize L_{mle} and for the remaining steps, we minimize the following UTILITY-based loss:

$$L_{\text{max-utility}} = -(r(q^p) - r(q^b)) \sum_{t=1}^{T} \log p(q_t | q_1, ..., q_{t-1}, \tilde{c}_t) \tag{4}$$

where $r(q^p)$ is the UTILITY based reward on the predicted question and $r(q^b)$ is a baseline reward introduced to reduce the high variance otherwise observed when using REINFORCE. To estimate this baseline reward, we take the idea from the self-critical training approach Rennie et al. (2017) where the baseline is estimated using the reward obtained by the current model under greedy decoding during test time. We find that this approach for baseline estimation stabilizes our model better than the approach used in MIXER.

2.3 Estimating UTILITY from Data

Given a (context, question, answer) triple, Rao and Daumé III (2018) introduce a utility calculator UTILITY(c, q, a) to calculate the value of updating a context c with the answer a to a clarification question q. They use the utility calculator to estimate the probability that an *answer* would be a meaningful addition to a context. They treat this as a binary classification problem where the positive instances are the true (context, question, answer) triples in the dataset whereas the negative instances are contexts paired with a random (question, answer) from the dataset. Following Rao and Daumé III (2018), we model our UTILITY calculator by first embedding the words in c and then using an LSTM (long-short term memory) (Hochreiter and Schmidhuber, 1997) to generate a neural representation $\bar{c}$ of the context by averaging the output of each of the hidden states. Similarly, we obtain neural representations $\bar{q}$ and $\bar{a}$ of q and a respectively using a question and an answer LSTM models. Finally, we use a feed forward neural network $F_{\text{UTILITY}}(\bar{c}, \bar{q}, \bar{a})$ to predict the usefulness of the question.

2.4 UTILITY GAN for Clarification Question Generation

The UTILITY calculator trained on true vs random samples from real data (as described in the previous section) can be a weak reward signal for questions generated by a model due to the large discrepancy between the true data and the model's outputs. In order to strengthen the reward signal, we reinterpret the UTILITY calculator (coupled with the answer generator) as a discriminator in an adversarial learning setting. That is, instead of taking the UTILITY calculator to be a fixed model that outputs the expected quality of a (question, answer) pair, we additionally optimize it to distinguish between true (question, answer) pairs and model-generated ones. This reinterpretation turns our model into a form of a generative adversarial network (GAN) (Goodfellow et al., 2014).

GAN is a training procedure for "generative" models that can be interpreted as a game between a generator and a discriminator. The generator is a model $g \in \mathcal{G}$ that produces outputs (in our case, questions). The discriminator is another model $d \in \mathcal{D}$ that attempts to classify between true outputs and model-generated outputs. The goal of the generator is to generate data such that it can fool the discriminator; the goal of the discriminator is to be able to successfully distinguish between real and generated data. In the process of trying to fool the discriminator, the generator produces data that is as close as possible to the real data distribution. Generically, the GAN objective is:

$$L_{\text{GAN}}(\mathcal{D}, \mathcal{G}) = \max_{d \in \mathcal{D}} \min_{g \in \mathcal{G}} \mathbb{E}_{x \sim \hat{p}} \log d(x) + \mathbb{E}_{z \sim p_z} \log(1 - d(g(z))) \tag{5}$$

where x is sampled from the true data distribution $\hat{p}$, and z is sampled from a prior defined on input noise variables p_z.

Although GANs have been successfully used for image tasks, training GANs for text generation is challenging due to the discrete nature of outputs in text. The discrete outputs from the generator make it difficult to pass the gradient update from the discriminator to the generator. Recently, Yu et al. (2017) proposed a sequence GAN model for text generation to overcome this issue. They treat their generator as an agent and use the discriminator as a reward function to update the generative model using reinforcement learning techniques. Our GAN-based approach is inspired by this sequence GAN model with two main modifications: a) We use MIXER algorithm as our generator (§ 2.2) instead of a purely policy gradient approach; and b) We use UTILITY calculator (§ 2.3) as our discriminator instead of a convolutional neural network (CNN).

Theoretically, the discriminator should be trained using (context, true question, true answer) triples as positive instances and (context, generated question, generated answer) triples as the negative instances. However, we find that training a discriminator using such positive instances makes it very strong since the generator would have to not only generate real looking questions but also generate real looking answers to fool the discriminator. Since our main goal is question generation and since we use answers only as latent variables, we instead use (context, true question, *generated answer*) as our positive instances where we use the pretrained answer generator to get the *generated answer* for the true question. Formally, our objective function is:

$$L_{\text{GAN-U}}(\mathcal{U}, \mathcal{M}) = \max_{u \in \mathcal{U}} \min_{m \in \mathcal{M}} \mathbb{E}_{q \sim \hat{p}} \log u(c, q, \mathcal{A}(c, q)) + \mathbb{E}_{c \sim \hat{p}} \log(1 - u(c, m(c), \mathcal{A}(c, m(c)))) \tag{6}$$

where $\mathcal{U}$ is the UTILITY discriminator, $\mathcal{M}$ is the MIXER generator, $\hat{p}$ is our data of (context, question, answer) triples and $\mathcal{A}$ is the answer generator.

2.5 Pretraining

Question Generator. We pretrain our question generator using the sequence-to-sequence model

(§2.1) to maximize the log-likelihood of all (context, question) pairs in the training data. Parameters of this model are updated during adversarial training.

Answer Generator. We pretrain our answer generator using the sequence-to-sequence model (§2.1) to maximize the log-likelihood of all ([context+question], answer) pairs in the training data. Parameters of this model are kept fixed during the adversarial training.[4]

Discriminator. In our UTILITY GAN model (§ 2.4), the discriminator is trained to differentiate between true and generated questions. However, since we want to guide our UTILITY based discriminator to also differentiate between true ("good") and random ("bad") questions, we pretrain our discriminator in the same way we trained our UTILITY calculator. For positive instances, we use a context and its true question, answer from the training data and for negative instances, we use the same context but randomly sample a question from the training data (and use the answer paired with that random question).

3 Experimental Results

We base our experimental design on the following research questions:

1. Do generation models outperform simpler retrieval baselines?
2. Does optimizing the UTILITY reward improve over maximum likelihood training?
3. Does using adversarial training improve over optimizing the pretrained UTILITY?
4. How do the models perform when evaluated for nuances such as specificity & usefulness?

3.1 Datasets

We evaluate our model on two datasets.

Amazon. In this dataset, *context* is a product description on amazon.com combined with the product title, *question* is a clarification question asked to the product and *answer* is the seller's (or other users') reply to the question. To obtain these data triples, we combine the Amazon question-answering dataset (McAuley and Yang, 2016) with the Amazon reviews dataset (McAuley et al., 2015). We show results on the `Home & Kitchen` category of this dataset since it contains a large number of questions and is relatively easier for human-based evaluation. It consists of $19,119$ training, $2,435$ tune and $2,305$ test examples (product descriptions), with 3 to 10 questions (average: 7) per description.

Stack Exchange. In this dataset, *context* is a post on stackexchange.com combined with the title, *question* is a clarification question asked in the comments section of the post and *answer* is either the update made to the post in response to the question or the author's reply to the question in the comments section. Rao and Daumé III (2018) curated a dataset of $61,681$ training, $7,710$ tune and $7,709$ test such triples from three related subdomains on stackexchage.com (askubuntu, unix and superuser). Additionally, for 500 instances each from the tune and the test set, their dataset includes 1 to 6 other questions identified as valid questions by expert human annotators from a pool of candidate questions.

3.2 Baselines and Ablated Models

We compare three variants (ablations) of our proposed approach, together with an information retrieval baseline:

GAN-Utility is our full model which is a UTILITY calculator based GAN training (§2.4) including the UTILITY discriminator and the MIXER question generator.[5]

Max-Utility is our reinforcement learning baseline where the pretrained question generator model is further trained to optimize the UTILITY reward (§2.2) without the adversarial training.

MLE is the question generator model pretrained on context, question pairs using maximum likelihood objective (§2.1).

Lucene[6] is our information retrieval baseline similar to the Lucene baseline described in Rao and Daumé III (2018). Given a context in the test set, we use Lucene, which is a TF-IDF based document ranker, to retrieve top 10 contexts that are most similar to the given context in the train set. We randomly choose a question from the human written questions paired with these 10 contexts in the train set to construct our Lucene baseline[7].

---

[4] We leave the experimentation of updating parameters of answer generator during adversarial training to future work.

[5] Experimental details are in Appendix B.

[6] `https://lucene.apache.org/`

[7] For the Amazon dataset, we ignore questions asked to products of the same brand as the given product since Amazon replicates questions across same brand allowing the true question to be included in that set.

3.3 Evaluation Metrics

We evaluate initially with automated evaluation metrics, and then more substantially with crowdsourced human judgments.

3.3.1 Automatic Metrics

Diversity, which calculates the proportion of unique trigrams in the output to measure the diversity as commonly used to evaluate dialogue generation (Li et al., 2016b).
BLEU (Papineni et al., 2002) [8], which evaluates n-gram precision between the output and the references.
METEOR (Banerjee and Lavie, 2005), which is similar to BLEU but includes stemmed and synonym matches to measure similarity between the output and the references.

3.3.2 Human Judgements

We use Figure-Eight[9], a crowdsourcing platform, to collect human judgements. Each judgement[10] consists of showing the crowdworker a context and a generated question and asking them to evaluate the question along following axes:
Relevance: We ask *"Is the question on topic?"* and let workers choose from: Yes (1) and No (0)
Grammaticality: We ask *"Is the question grammatical?"* and let workers choose from: Yes (1) and No (0)
Seeking new information: We ask *"Does the question ask for new information currently not included in the description?"* and let workers choose from: Yes (1) and No (0)
Specificity: We ask *"How specific is the question?"* and let workers choose from:

4: Specific pretty much only to this product (or same product from different manufacturer)
3: Specific to this and other very similar products
2: Generic enough to be applicable to many other products of this type
1: Generic enough to be applicable to any product under Home and Kitchen
0: N/A (Not applicable) i.e. Question is not on topic OR is incomprehensible

Usefulness: We ask *"How useful is the question to a potential buyer (or a current user) of the product?"* and let workers choose from:

4: Useful enough to be included in the product description
3: Useful to a large number of potential buyers (or current users)
2: Useful to a small number of potential buyers (or current users)
1: Useful only to the person asking the question
0: N/A (Not applicable) i.e. Question is not on topic OR is incomprehensible OR is not seeking new information

Criteria	**Agreement**
Relevance	0.92
Grammaticality	0.92
Seeking new information	0.84
Usefulness	0.65
Specificity	0.72

Table 1: Inter-annotator agreement on the five criteria used in human-based evaluation.

3.3.3 Inter-annotator Agreement

Table 1 shows the inter-annotator agreement (reported by Figure-Eight as confidence[11]) on each of the above five criteria. Agreement on *Relevance*, *Grammaticality* and *Seeking new information* is high. This is not surprising given that these criteria are not very subjective. On the other hand, the agreement on usefulness and specificity is quite moderate since these judgments can be very subjective.

Since the inter-annotator agreement on the usefulness criteria was particularly low, in order to reduce the subjectivity involved in the fine grained annotation, we convert the range [0-4] to a more coarse binary range [0-1] by mapping the scores 4 and 3 to **1** and the scores 2, 1 and 0 to **0**.

3.4 Automatic Metric Results

Table 2 shows the results on the two datasets when evaluated according to automatic metrics.

In the Amazon dataset, GAN-Utility outperforms all ablations on DIVERSITY, suggesting that it produces more diverse outputs. Lucene, on the other hand, has the highest DIVERSITY since it consists of human written questions, which tend to be more diverse because they are much longer compared to model generated questions. This comes at the cost of lower match with the reference as visible in the BLEU and METEOR scores.

[8] `https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl`

[9] `https://www.figure-eight.com`

[10] We paid crowdworkers 5 cents per judgment and collected five judgments per question.

[11] `https://success.figure-eight.com/hc/en-us/articles/201855939-How-to-Calculate-a-Confidence-Score`

	`Amazon`			`StackExchange`		
Model	DIVERSITY	BLEU	METEOR	DIVERSITY	BLEU	METEOR
Reference	0.6934	—	—	0.7509	—	—
Lucene	0.6289	4.26	10.85	0.7453	1.63	7.96
MLE	0.1059	**17.02**	12.72	0.2183	3.49	8.49
Max-Utility	0.1214	16.77	12.69	**0.2508**	3.89	8.79
GAN-Utility	**0.1296**	15.20	**12.82**	0.2256	**4.26**	**8.99**

Table 2: DIVERSITY as measured by the proportion of unique trigrams in model outputs. Bigrams and unigrams follow similar trends. BLEU and METEOR scores using up to 10 references for the Amazon dataset and up to six references for the StackExchange dataset. Numbers in bold are the highest among the models. All results for Amazon are on the entire test set whereas for StackExchange they are on the 500 instances of the test set that have multiple references.

In terms of BLEU and METEOR, there is inconsistency. Although GAN-Utility outperforms all baselines according to METEOR, the fully ablated MLE model has a higher BLEU score. This is because BLEU score looks for exact n-gram matches and since MLE produces more generic outputs, it is much more likely that it will match one of 10 references compared to the specific/diverse outputs of GAN-Utility, since one of those ten is highly likely to itself be generic.

In the StackExchange dataset GAN-Utility outperforms all ablations on both BLEU and METEOR. Unlike in the Amazon dataset, MLE does not outperform GAN-Utility in BLEU. This is because the MLE outputs in this dataset are not as generic as in the amazon dataset due to the highly technical nature of contexts in StackExchange. As in the Amazon dataset, GAN-Utility outperforms MLE on DIVERSITY. Interestingly, the Max-Utility ablation achieves a higher DIVERSITY score than GAN-Utility. On manual analysis we find that Max-Utility produces longer outputs compared to GAN-Utility but at the cost of being less grammatical.

3.5 Human Judgements Analysis

Table 3 shows the numeric results of human-based evaluation performed on the reference and the system outputs on 300 random samples from the test set of the Amazon dataset.[12] All approaches produce relevant and grammatical questions. All models are all equally good at seeking new information, but are weaker than Lucene, which performs better at seeking new information but at the cost of much lower specificity and lower usefulness.

Our full model, GAN-Utility, performs significantly better at the usefulness criteria showing that the adversarial training approach generates more useful questions. Interestingly, all our models produce questions that are more useful than Lucene and Reference, largely because Lucene and Reference tend to ask questions that are more often useful only to the person asking the question, making them less useful for potential other buyers (see Figure 4). GAN-Utility also performs significantly better at generating questions that are more specific to the product (see details in Figure 5), which aligns with the higher DIVERSITY score obtained by GAN-Utility under automatic metric evaluation.

Table 5 contains example outputs from different models along with their usefulness and specificity scores. MLE generates questions such as *"is it waterproof?"* and *"what is the wattage?"*, which are applicable to many other products. Whereas our GAN-Utility model generates more specific question such as *"is this shower curtain mildew resistant?"*. Appendix C includes further analysis of system outputs on both Amazon and Stack Exchange datasets.

4 Related Work

Question Generation. Most previous work on question generation has been on generating reading comprehension style questions i.e. questions that ask about information present in a given text (Heilman, 2011; Rus et al., 2010, 2011; Duan et al., 2017). Our goal, on the other hand, is to generate questions whose answer cannot be found

---

[12] We could not ask crowdworkers evaluate the StackExchange data due to its highly technical nature.

in the given text. Outside reading comprehension questions, Liu et al. (2010) use templated questions to help authors write better related work sections whereas we generate questions to fill information gaps. Labutov et al. (2015) use crowdsourcing to generate question templates whereas we learn from naturally occurring questions. Mostafazadeh et al. (2016, 2017) generate natural and engaging questions, given an image (and some initial text). Whereas, we generate questions specifically for identifying missing information. Stoyanchev et al. (2014) generate clarification questions to resolve ambiguity caused by speech recognition failures during dialog, whereas we generate clarification questions to resolve ambiguity caused by missing information. The recent work most relevant to our work is by Rao and Daumé III (2018). They build a model which given a context and a set of candidate clarification questions, ranks them in a way that more useful clarification questions would be higher up in the ranking. In our work, we build on their ideas to propose a model that generates (instead of ranking) clarification questions given a context.

Neural Models and Adversarial Training for Text Generation. Neural network based models have had significant success at a variety of text generation tasks, including machine translation (Bahdanau et al., 2015; Luong et al., 2015), summarization (Nallapati et al., 2016), dialog (Bordes et al., 2016; Li et al., 2016a; Serban et al., 2017), textual style transfer (Jhamtani et al., 2017; Rao and Tetreault, 2018) and question answering (Yin et al., 2016; Serban et al., 2016). Our task is most similar to dialog, in which a wide variety of possible outputs are acceptable, and where lack of specificity in generated outputs is common. We addresses this challenge using an adversarial network approach (Goodfellow et al., 2014), a training procedure that can generate natural-looking outputs, which have been effective for natural image generation (Denton et al., 2015). Due to the challenges in optimizing over discrete output spaces like text, Yu et al. (2017) introduced a Seq(uence)GAN approach where they overcome this issue by using REINFORCE to optimize. Our GAN-Utility model is inspired by the SeqGAN model where we replace their policy gra-

dient based generator with a MIXER model and their CNN based discriminator with our UTILITY calculator. Li et al. (2017) train an adversarial model similar to SeqGAN for generating next utterance in a dialog given a context. However, unlike our work, their discriminator is a binary classifier trained only to distinguish between human and machine generated utterances.

5 Conclusion

In this work, we describe a novel approach to the problem of clarification question generation. We use the observation of Rao and Daumé III (2018) that the usefulness of a clarification question can be measured by the value of updating a context with an answer to the question. We use a sequence-to-sequence model to generate a question given a context and a second sequence-to-sequence model to generate an answer given the context and the question. Given the (context, generated question, generated answer) triple, we calculate the utility of this triple and use it as a reward to retrain the question generator using reinforcement learning based MIXER model. Further, to improve upon the utility calculator, we reinterpret it as a discriminator in an adversarial setting and train both the utility calculator and the MIXER model in a minimax fashion. We find that our adversarial training approach produces more useful and specific questions compared to both a model trained using maximum likelihood objective and a model trained using utility reward based reinforcement learning.

There are several avenues of future work. Following Mostafazadeh et al. (2016), we could combine text input with image input in the Amazon dataset (McAuley and Yang, 2016) to generate more relevant and useful questions. One significant research challenge in the space of free text generation problems when the set of possible outputs is large, is that of automatic evaluation (Lowe et al., 2016): in our results we saw some correlation between human judgments and automatic metrics, but not enough to trust the automatic metrics completely. Lastly, we hope to integrate such a question generation model into a real world platform like StackExchange or Amazon to understand the real utility of such models and to unearth additional research questions.

A Sequence-to-sequence model details

In this section, we describe some of the details of the attention based sequence-to-sequence model introduced in Section 2.1 of the main paper. In equation 1, $\tilde{h}_t$ is the attentional hidden state of the RNN at time t obtained by concatenating the target hidden state h_t and the source-side context vector $\tilde{c}_t$, and W_s is a linear transformation that maps h_t to an output vocabulary-sized vector. Each attentional hidden state $\tilde{h}_t$ depends on a distinct input context vector $\tilde{c}_t$ computed using a global attention mechanism over the input hidden states as:

$$\tilde{c}_t = \sum_{n=1}^{N} a_{nt} h_n \tag{7}$$

$$a_{nt} = \text{align}(h_n, h_t) \tag{8}$$

$$= \exp\left[h_t^T W_a h_n\right] \Big/ \sum_{n'} \exp\left[h_t^T W_a h_{n'}\right] \tag{9}$$

The attention weights a_{nt} is calculated based on the alignment score between the source hidden state h_n and the current target hidden state h_t.

B Experimental Details

In this section, we describe the details of our experimental setup.

We tokenize and lowercase all inputs (context, question and answers). We set the max length of context to be 100, question to be 20 and answer to be 20. We find that increasing the length of contexts (to 150 or 200) of question/ answer (to 40) yields similar results according to automatic metrics with increased experimentation time.

Our sequence-to-sequence model (Section 2.1) operates on word embeddings which are pretrained on in domain data using Glove (Pennington et al., 2014). As frequently used in previous work on neural network modeling, we use an embeddings of size 200 and a vocabulary with cut off frequency set to 10. During train time, we use teacher forcing (Williams and Zipser, 1989). During test time, we use beam search decoding with beam size 5.

We use a hidden layer of size two for both the encoder and decoder recurrent neural network models with size of hidden unit set to 100. We use a dropout of 0.5 and learning ratio of 0.0001. In the MIXER model, we start with $\Delta = T$ and decrease it by 2 for every epoch (we found decreasing Δ to 0 is ineffective for our task, hence we stop at 2).

C Analysis of System Outputs

C.1 Amazon Dataset

First half of Table 5 shows the system generated questions for three product descriptions in the Amazon dataset.

In the first example, the product is a shower curtain. The Reference question is specific and highly useful. Lucene, on the other hand, picks a moderately specific ("how to clean it?") but useful question. MLE model generates a generic but useful "is it waterproof?". Max-Utility generates comparatively a much longer question but in doing so loses out on relevance. This behavior of generating two unrelated sentences is observed quite a few times in both Max-Utility and GAN-Utility models. This suggests that these models, in trying to be very specific, end up losing out on relevance. In the same example, GAN-Utility also generates a fairly long question which, although awkwardly phrase, is quite specific and useful.

In the second example, the product is a Duvet Cover Set. Both Reference and Lucene questions here are examples of questions that are pretty much useful only to the person asking the question. We find many such questions in both Reference and Lucene outputs which is the main reason for the comparatively lower usefulness scores for their outputs. All three of our models generate irrelevant questions since the product description explicitly says that the set is full size.

In the last example, the product is a set of mopping clothes. Reference question is quite specific but has low usefulness. Lucene picks an irrelevant question. MLE and Max-Utility generate highly specific and useful questions. GAN-Utility generates an ungrammatical question by repeating the last word many times. We observe this behavior quite a few times in the outputs of both Max-Utility and GAN-Utility models suggesting that our sequence-to-sequence models are not very good at maintaining long range dependencies.

C.2 Stack Exchange Dataset

Second half of Table 5 shows the system generated questions for three posts from the Stack Exchange dataset.

The first example is of a post where someone describes their issue of not being able to recover from their boot. Reference and Lucene questions are useful. MLE generates a generic question that is not very useful. Max-Utility generates a useful question but has slight ungrammaticality in it. GAN-Utility, on the other hand, generates a specific and an useful question.

In the second example, again Reference and Lucene questions are useful. MLE generates a generic question. Max-Utility and GAN-Utility both generate fairly specific question but contain unknown tokens. The Stack Exchange dataset contains several technical terms leading to a long tail in the vocabulary. Owing to this, we find that both Max-Utility and GAN-Utility models generate many instances of questions with unknown tokens.

In the third example, the Reference question is very generic. Lucene asks a relevant question. MLE again generates a generic question. Both Max-Utility and GAN-Utility generate specific and relevant questions.

MLE	how long did you wait ?		
Max-Utility	can you post the output of ‘apt-cache policy UNK ?		
GAN-Utility	can you post a screenshot of the output of ‘sudo apt-get install UNK		
Title	full lubuntu installation on usb (uefi capable)		
Post	i want to do a full lubuntu installation on a usb stick that can be booted in uefi mode. i do not want persistent live usb but a full lubuntu installation and that can boot fromanyuefi-capable computer ...		
Reference	hello and welcome on askubuntu . could you please clarify what you want ?		
Lucene	so , ubuntu was installed to the pen drive ?		
MLE	which version of ubuntu ?		
Max-Utility	do you have a live cd or usb stick ?		
GAN-Utility	what is the model of the usb stick ?		

Table 5: Example outputs from each of the systems for three product descriptions from the Home & Kitchen category of the Amazon dataset and for three posts of StackExchange dataset.

Improving Grammatical Error Correction via Pre-Training a Copy-Augmented Architecture with Unlabeled Data

Wei Zhao, Liang Wang, Kewei Shen, Ruoyu Jia, Jingming Liu
Yuanfudao Research / Beijing, China
{zhaowei01,wangliang01,shenkw,jiary,liujm}@fenbi.com

Abstract

Neural machine translation systems have become state-of-the-art approaches for Grammatical Error Correction (GEC) task. In this paper, we propose a copy-augmented architecture for the GEC task by copying the unchanged words from the source sentence to the target sentence. Since the GEC suffers from not having enough labeled training data to achieve high accuracy. We pre-train the copy-augmented architecture with a denoising auto-encoder using the unlabeled One Billion Benchmark and make comparisons between the fully pre-trained model and a partially pre-trained model. It is the first time copying words from the source context and fully pre-training a sequence to sequence model are experimented on the GEC task. Moreover, We add token-level and sentence-level multi-task learning for the GEC task. The evaluation results on the CoNLL-2014 test set show that our approach outperforms all recently published state-of-the-art results by a large margin. The code and pre-trained models are released at https://github.com/zhawe01/fairseq-gec.

1 Introduction

Grammatical Error Correction (GEC) is a task of detecting and correcting grammatical errors in text. Due to the growing number of language learners of English, there has been increasing attention to the English GEC, in the past decade.

The following sentence is an example of the GEC task, where the word in bold needs to be corrected to its adverb form.

*Nothing is [**absolute** → absolutely] right or wrong.*

Although machine translation systems have become state-of-the-art approaches for GEC, GEC is different from translation since it only changes several words of the source sentence. In Table 1, we list the ratio of unchanged words of the target sentence to the source sentence in three different datasets. We can observe that more than 80% of the words can be copied from the source sentence.

Corpus	Sent.	Tok.	Same %
CoNLL-2013	1,381	28,944	96.50%
JFELG	754	14,240	84.23%
Lang-8	4,936	73,705	83.22%

Table 1: The ratio of unchanged words in the target sentence to the source sentence. “Sent.” means the sentence number. “Tok.” means the token number of the target sentence. “Same %” means the same word percentage.

Considering the percentage of unchanged words is high in the GEC task, a more proper neural architecture is needed for it. We enhance the current neural architecture by enabling it to copy the unchanged words and the out-of-vocabulary words directly from the source sentence, just as what humans do when they correct sentences. To our knowledge, this is the first time that neural copying mechanism is used on GEC.

Progresses have been made thanks to large-scale training corpus, including NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013) and the large-scale Lang-8 corpus(Tajiri et al., 2012). However, even with millions of labeled sentences, automatic GEC is challenging due to the lack of enough labeled training data to achieve high accuracy.

To alleviate the problem of insufficient labeled data, we propose a method to leverage the unlabeled data. The concrete way is to pre-train our copy-augmented model with the unlabeled One Billion Benchmark (Chelba et al., 2013) by leveraging denoising auto-encoders.

We also add two multi-tasks for the copy-augmented architecture, including a token-level

Proceedings of NAACL-HLT 2019, pages 156–165
Minneapolis, Minnesota, June 2 - June 7, 2019.

labeling task and a sentence-level copying task, to further improve the performance of the GEC task.

The copying mechanism is for the first time used on the GEC task, which was used on text summarization tasks. On the GEC task, copying mechanism enables training a model with a small vocabulary since it can straightly copy the unchanged and out-of-vocabulary words from the source input tokens. Besides, by separating the constant part of the work from the GEC task, copying makes the generating portion of the architecture more powerful. In the experiment section of this paper, we show that copying does more than just solving the "UNK problem", and it can also recall more edits for the GEC problem.

The copy-augmented architecture outperforms all the other architectures on the GEC task, by achieving a 56.42 $F_{0.5}$ score on the CoNLL 2014 test data set. Combined with denoising auto-encoders and multi-tasks, our architecture achieves 61.15 $F_{0.5}$ on the CoNLL-2014 test data set, improving +4.9 $F_{0.5}$ score than state-of-the-art systems.

In summary, our main contributions are as follows. (1) We propose a more proper neural architecture for the GEC problem, which enables copying the unchanged words and out-of-vocabulary words directly from the source input tokens. (2) We pre-train the copy-augmented model with large-scale unlabeled data using denoising auto-encoders, alleviating the problem of the insufficient labeled training corpus. (3) We evaluate the architecture on the CoNLL-2014 test set, which shows that our approach outperforms all recently published state-of-the-art approaches by a large margin.

2 Our Approach

2.1 Base Architecture

Neural machine translation systems have become the state-of-the-art approaches for Grammatical Error Correction (GEC), by treating the sentence written by the second language learners as the source sentence and the grammatically corrected one as the target sentence. Translation models learn the mapping from the source sentence to the target sentence.

We use the attention based Transformer (Vaswani et al., 2017) architecture as our baseline. The Transformer encodes the source sentence with a stack of L identical blocks, and each of them applies a multi-head self-attention over the source tokens followed by position-wise feedforward layers to produce its context-aware hidden state. The decoder has the same architecture as the encoder, stacking L identical blocks of multi-head attention with feed-forward networks for the target hidden states. However, the decoder block has an extra attention layer over the encoder's hidden states.

The goal is to predict the next word indexed by t in a sequence of word tokens $(y_1, ..., y_T)$, given the source word tokens $(x_1, ..., x_N)$, as follows:

$$h^{src}_{1...N} = encoder(L^{src} x_{1...N}) \tag{1}$$

$$h_t = decoder(L^{trg} y_{t-1...1}, h^{src}_{1...N}) \tag{2}$$

$$P_t(w) = softmax(L^{trg} h_t) \tag{3}$$

The matrix $L \in R^{d_x \times |V|}$ is the word embedding matrix, where d_x is the word embedding dimension and $|V|$ is the size of the vocabulary. $h^{src}_{1...N}$ is the encoder's hidden states and h_t is the target hidden state for the next word. Applying softmax operation on the inner product between the target hidden state and the embedding matrix, we get the generation probability distribution of the next word.

$$l_{ce} = -\sum_{t=1}^{T} log(p_t(y_t)) \tag{4}$$

The loss l_{ce} of each training example is an accumulation of the cross-entropy loss of each position during decoding.

2.2 Copying Mechanism

Copying mechanism was proved effective on text summarization tasks (See et al., 2017; Gu et al., 2016) and semantic parsing tasks (Jia and Liang, 2016). In this paper, we apply the copying mechanism on GEC task, for the first time, enabling the model to copy tokens from the source sentence.

As illustrated in Figure 1, besides generating words from a fixed vocabulary, our copy-augmented network allows copying words from the source input tokens. Defined in Equation 5, the final probability distribution P_t is a mix of the generation distribution P^{gen}_t and the copy distribution P^{copy}_t. As a result, the fixed vocabulary is extended by all the words appearing in the source sentence. The balance between the copying

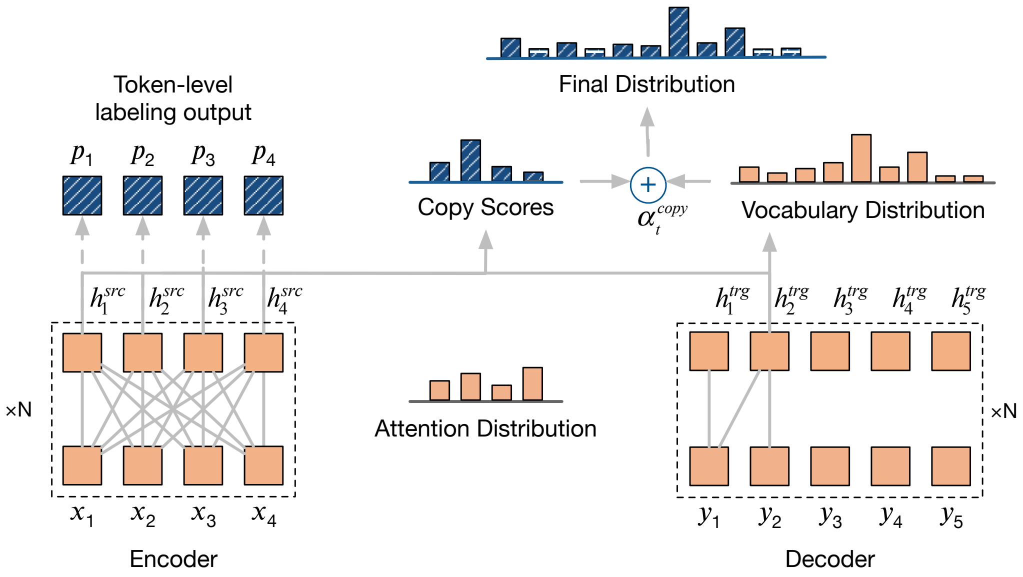

Figure 1: Copy-Augmented Architecture.

and generating is controlled by a balancing factor $\alpha_t^{copy} \in [0, 1]$ at each time step t.

$$p_t(w) = (1-\alpha_t^{copy}) * p_t^{gen}(w) + (\alpha_t^{copy}) * p_t^{copy}(w) \quad (5)$$

The new architecture outputs the generation probability distribution as the base model, by generating the target hidden state. The copying score over the source input tokens is calculated with a new attention distribution between the decoder's current hidden state h^{trg} and the encoder's hidden states H^{src} (same as $h^{src}_{1...N}$). The copy attention is calculated the same as the encoder-decoder attentions, listed in Equation 6, 7, 8 :

$$q_t, K, V = h_t^{trg} W_q^T, H^{src} W_k^T, H^{src} W_v^T \quad (6)$$

$$A_t = q_t^T K \quad (7)$$

$$P_t^{copy}(w) = softmax(A_t) \quad (8)$$

The q_t, K and V are the query, key, and value that needed to calculate the attention distribution and the copy hidden state. We use the normalized attention distribution as the copy scores and use the copy hidden states to estimate the balancing factor α_t^{copy}.

$$\alpha_t^{copy} = sigmoid(W^T \sum (A_t^T \cdot V)) \quad (9)$$

The loss function is as described in Equation 4, but with respect to our mixed probability distribution y_t given in Equation 5.

3 Pre-training

Pre-training is shown to be useful in many tasks when lacking vast amounts of training data. In this section, we propose denoising auto-encoders, which enables pre-training our models with large-scale unlabeled corpus. We also introduce a partially pre-training method to make a comparison with the denoising auto-encoder.

3.1 Denoising Auto-encoder

Denoising auto-encoders (Vincent et al., 2008) are commonly used for model initialization to extract and select features from inputs. BERT (Devlin et al., 2018) used a pre-trained bi-directional transformer model and outperformed existing systems by a wide margin on many NLP tasks. In contrast to denoising auto-encoders, BERT only predicts the 15% masked words rather than reconstructing the entire input. BERT denoise the 15% of the tokens at random by replacing 80% of them with [MASK], 10% of them with a random word and 10% of them unchanged.

Inspired by BERT and denoising auto-encoders, we pre-traine our copy-augmented sequence to sequence model by noising the One Billion Word Benchmark (Chelba et al., 2013), which is a large sentence-level English corpus. In our experiments, the corrupted sentence pairs are generated by the following procedures.

- Delete a token with a probability of 10%.
- Add a token with a probability of 10%.
- Replace a word with a randomly picked word from the vocabulary with a probability of 10%.
- Shuffle the words by adding a normal distribution bias to the positions of the words and re-sort the words by the rectified positions with a standard deviation 0.5.

With a large amount of the artificial training data, the sequence to sequence model learns to reconstruct the input sentence, by trusting most of the input tokens but not always. A sentence pair generated by the corruption process is a GEC sentence pair to some degree, since both of them are translating a not "perfect" sentence to a "perfect" sentence by deleting, adding, replacing or shuffling some tokens.

3.2 Pre-training Decoder

In nature language processing (NLP), pre-training part of the model also improves many tasks' performance. Word2Vec and GloVe (Pennington et al., 2014; Mikolov et al., 2013) pre-trained word embeddings. CoVe (McCann et al., 2017) pre-trained a encoder. ELMo (Peters et al., 2018) pre-trained a deep bidirectional architecture, and etc. All of them are shown to be effective in many NLP tasks.

Following (Ramachandran et al., 2016; Junczys-Dowmunt et al., 2018), we experiment with pre-training the decoder of the copy-augmented sequence-to-sequence architecture as a typical language model. We initialize the decoder of the GEC model with the pre-trained parameters, while initializing the other parameters randomly. Since we use the tied word embeddings between encoder and decoder, most parameters of the model are pre-trained, except for those of the encoder, the encoder-decoder's attention and the copy attention.

4 Multi-Task Learning

The Multi-Task Learning (MTL) solves problems by jointly training multiple related tasks, and has shown its advantages in many tasks, ranging from computer vision (Zhang et al., 2014; Dai et al., 2016) to NLP (Collobert and Weston, 2008; Søgaard and Goldberg, 2016). In this paper, we explore two different tasks for GEC to improve the performance.

4.1 Token-level Labeling Task

We propose a token-level labeling task for the source sentence, and assign each token in the source sentence a label indicating whether this token is right/wrong.

Assuming that each source token x_i can be aligned with a target token y_j, we define that the source token is right if $x_i = y_j$, and wrong otherwise. Each token's label is predicted by passing the final state h_i^{src} of the encoder through a softmax after an affine transformation, as shown in Equation 10.

$$p(label_i|x_{1...N}) = softmax(W^T h_i^{src}) \quad (10)$$

This token-level labeling task explicitly augment the input tokens' correctness to the encoder, which can later be used by the decoder.

4.2 Sentence-level Copying Task

The primary motivation behind the sentence-level copying task is to make the model do more copying when the input sentence looks entirely correct.

During training, we send equal number of sampled correct sentence pairs and the edited sentence pairs to the model. When inputting the right sentences, we remove the decoder's attention over the outputs of the encoder. Without the encoder-decoder attention, the generating work gets hard. As a result, the copying part of the model will be boosted for the correct sentences.

5 Evaluations

5.1 Datasets

As previous studies, we use the public NUCLE (Dahlmeier et al., 2013), Lang-8 (Tajiri et al., 2012) and FCE (Yannakoudakis et al., 2011) corpus as our parrallel training data. The unlabeled dataset we use is the well-known One Billion Word Benchmark (Chelba et al., 2013). We choose the test set of CoNLL-2014 shared task as our test set and CoNLL-2013 test data set (Dahlmeier et al., 2013) as our development benchmark. For the CoNLL data sets, the Max-Match (M^2) scores (Dahlmeier and Ng, 2012) were reported, and for the JFLEG (Napoles et al.,

Corpus	**Sent.**	**Public**	**Type**
Lang-8	1,097,274	Yes	Labeled
NUCLE	57,119	Yes	Labeled
FCE	32,073	Yes	Labeled
One-Billion	30,178,573	Yes	Unlabeled

Table 2: Training Corpus

Corpus	**Sent.**	**Annot.**	**Metric**
CoNLL-2013	1,381	1	M^2
CoNLL-2014	1,312	2	M^2
JFLEG	747	4	GLEU

Table 3: Evaluation Corpus

2017) test set, the GLEU metric (Sakaguchi et al., 2016) were reported.

To make our results comparable to state-of-the-art results in the field of GEC, we limit our training data strictly to public resources. Table 2 and Table 3 list all the data sets that we use in this paper.

We build a statistical-based spell error correction system and correct the spell errors in our training data. Following (Ge et al., 2018; Junczys-Dowmunt et al., 2018; Chollampatt and Ng, 2018) and etc., we apply spell correction before evaluation for our dev/test datasets. A 50,000-word dictionary is extracted from the spell-corrected Lang-8 data corpus. Like previous works, we remove the unchanged sentence pairs in the Lang-8 corpus before training.

5.2 Model and Training Settings

In this paper, we use the Transformer implementation in the public FAIR Sequence-to-Sequence Toolkit [1] (Gehring et al., 2017) codebase.

For the transformer model, we use token embeddings and hidden size of dimension 512, and the encoder and decoder have 6 layers and 8 attention heads. For the inner layer in the position-wise feed-forward network, we use 4096. Similar to previous models we set the dropout to 0.2. A 50,000 vocabulary for the input and output tokens are collected from the training data. In total, this model has 97M parameters.

Models are optimized with Nesterovs Accelerated Gradient (Nesterov, 1983). We set the learning rate with 0.002, the weight decay 0.5, the patience 0, the momentum 0.99 and minimum learning rate 10-4. During training, we evaluate the performance on the development set for every epoch.

We also use edit-weighted MLE objective as (Junczys-Dowmunt et al., 2018), by scaling the loss of the changed words with a balancing factor Λ.

Almost the same architecture and hyper-parameters are used when pre-training using unlabeled data, except the Λ parameter for edit-weighted loss. We set $\Lambda = 3$ when we train the denoising auto-encoder, and set $\Lambda \in [1, 1.8]$ when we train GEC models.

During decoding, we use a beam-size of 12 and normalize model scores by length. We do not use reranking when evaluating the CoNLL-2014 data sets. But we rerank the top 12 hypothesizes using the language model trained on Common Crawl (Junczys-Dowmunt and Grundkiewicz, 2016) for the JFLEG test sets.

5.3 Experimental Results

We compare our results with the well-known GEC systems, as shown in Table 4. Rule, classification, statistical machine translation (SMT), and neural machine translation (NMT) based systems were built for the GEC task. We list the well-known models on the top section of Table 4 and our results in the middle. Almost all the previous systems reranked their top 12 results using a big language model and some of them used partially pre-trained parameters, which improve their results by 1.5 to 5 $F_{0.5}$ score. Our copy-augmented architecture achieve a 56.42 $F_{0.5}$ score on the CoNLL-2014 dataset and outperforms all the previous architectures even without reranking or pre-training.

Combined with denoising auto-encoders and multi-tasks, our model achieve a 61.15 $F_{0.5}$ score on the CoNLL-2014 data set. This result exceeds the previous state-of-the-art system +4.9 $F_{0.5}$ points.

In the bottom section of Table 4, we list the results of (Ge et al., 2018). No direct comparison can be made between us, because they used the non-public Cambridge Learner Corpus (CLC) (Nicholls, 2003) and their own collected non-public Lang-8 corpus, making their labeled training data set 3.6 times larger than ours. Even so, our results on the CoNLL 2014 test data set and JFLEG test data set are very close to theirs.

In Table 4, "SMT (with LM)" refers to (Junczys-Dowmunt and Grundkiewicz, 2014);

5.4 Ablation Study

5.4.1 Copying Ablation Results

In this section, we compare the Transformer architecture's results with and without copying mechanism on the GEC task. As illustrated in Table 5, copy-augmented model increases the $F_{0.5}$ score from 48.07 to 54.67, with a +6.6 absolute increase. Most of the improvements come from the words that are out of the fixed vocabulary, which will be predicted as a UNK word in the base model but will be copied as the word itself in the copy-augmented model.

Copying is generally known as good at handling the UNK words. To verify if copying is more than copying UNK words, we do experiments by ignoring all UNK edits. From Table 5, we can see that even ignoring the UNK benefits, the copy-augmented model is still 1.62 $F_{0.5}$ points higher than the baseline model, and most of the benefit comes from the increased recall.

5.4.2 Pre-training Ablation Results

From Table 5, we can observe that by partially pre-training the decoder, the $F_{0.5}$ score is improved from 54.67 to 57.21 (+2.54). It is an evident improvment compared to the un-pre-trained ones. However, the denoising auto-encoder improves the single model from 54.67 to 58.8 (+4.13). We can also see that both the precision and recall are improved after pre-training.

To further investigate how good the pre-trained parameters are, we show the results of the early stage with and without the denoising auto-encoder's pre-trained parameters in Table 6. The results show, if we finetune the model for 1 epoch with the labeled training data, the pre-trained model beats the un-pretrained one with a big gap (48.89 vs 17.19). Even without finetune, the pre-trained model can get a $F_{0.5}$ score of 31.33. This proves that pre-training gives the models much better initial parameters than the randomly picked ones.

5.4.3 Sentence-level Copying Task Ablation Results

We add the sentence-level copying task to encourage the model outputs no edits when we input a correct sentence. To verify this, we create a correct sentence set by sampling 500 sentences from

Model	**Pre.**	**Rec.**	$F_{0.5}$	**Imp.**
Transformer	55.96	30.73	48.07	-
+ Copying	65.23	33.18	**54.67**	+6.60
Ignoring UNK words as edits				
Transformer	65.26	30.63	53.23	-
+ Copying	65.54	33.18	54.85	+1.62
+ Pre-training				
Copy-Augmented Transformer	65.23	33.18	54.67	-
+ Pre-training Decoder (partially pre-trained)	68.02	34.98	57.21	+2.54
+ Denosing Auto-encoder (fully pre-trained)	68.97	36.98	**58.80**	+4.13
+ Multi-tasks				
Copy-Augmented Transformer	67.74	40.62	**59.76**	-

Table 5: Single Model Ablation Study on CoNLL 2014 Test Data Set.

Finetune	**Pre.**	**Rec.**	$F_{0.5}$
with the denoising auto-encoder			
no finetune	36.61	19.87	31.33
finetune 1 epoch	68.58	22.76	48.89
without the denoising auto-encoder			
finetune 1 epoch	32.55	05.96	17.19

Table 6: Denoising Auto-encoder's Results on CoNLL-2014 Test Data Set.

Wikipedia. Also, we generate an error sentence set by sampling 500 sentences from CoNLL-2013 test data set, which is an error-annotated dataset. Then we calculate the average value of the balance factor α^{copy} of the two sets.

Before we add the sentence-level copying task, the α^{copy} is 0.44/0.45 for the correct and error sentence sets. After adding the sentence-level copying task, the value changed to 0.81/0.57. This means that 81% of the final score comes from copying on the correct sentence set, while only 57% on the error sentence set. By adding the sentence-level copying task, models learn to distinguish correct sentences and error sentences.

5.5 Attention Visualization

To analyze how copying and generating divide their work. We visualized the copying attention alignment and the encoder-decoder attention alignment in Figure 2. In Figure 2(a), copying focus their weights on the next word in good order, while in Figure 2(b), generating moves its attention more on the other words, e.g., the nearby words, and the end of the sentence. As explained in (Raganato et al., 2018), this means that the generating part tries to find long dependencies and attend more on global information.

By separating the copying work from the generation work, the generation part of the model can focus more on the "creative" works.

Error Type	**%**	**Recall**
Article Or Determiner	14.31%	44.54%
Wrong Collocation/Idiom	12.75%	**10.38%**
Spelling, Punctuation, etc.	12.47%	45.66%
Preposition	10.38%	49.03%
Noun number	9.38%	**72.65%**
Verb Tense	5.41%	28.15%
Subject-Verb Agreement	4.93%	**61.79%**
Verb form	4.69%	57.26%
Redundancy	4.65%	25.86%
Others	20.99%	23.28%

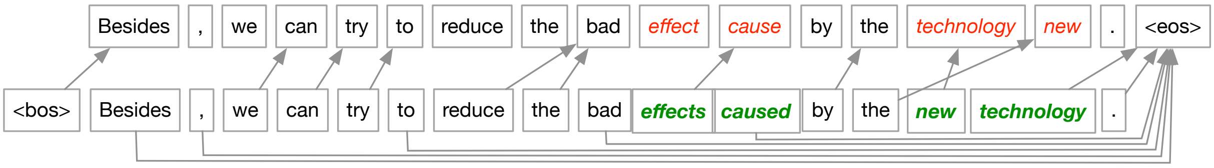
Table 7: Recall on Different Error Types. % is the percentage of this error type in the test data set. Recall is the percentage of the fixed errors in each error type.

6 Discussion

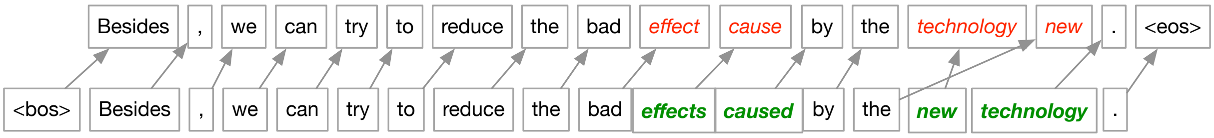
6.1 Recall on Different Error Types

Automatic grammatical error correction is a complicated task since there are different kinds of errors and various correction ways. In this section, we analyze our systems' performance on different grammatical error types. (Ng et al., 2014) labeled CoNLL-2014 test set with 28 error types, and we list the recall percentage on the top 9 error types. We summarize the other 19 types in the last line of the table.

Our approach recalls 72.65% errors on the "Noun number" type and 61.79% on the "Subject-



(a) Copy Alignment



(b) Encoder-Decoder Atttention Alignment

Figure 2: An example of the different behaviors between the copy and encoder-decoder attention. In each figure, the above line is the source sentence, where the error words are in italic. The bottom line is the corrected sentence, where the corrected words are in bold italic. The arrow means which source token the copy and encoder-decoder attention mainly focus on, when predicting the current word. "$\langle bos \rangle$" refers to the begin of the sentence and "$\langle eos \rangle$" refers to the end of the sentence.

Verb Agreement" type. However, only 10.38% errors are recalled on the "Wrong Collocation/Idiom" type.

Computers are good at the definite and mechanical errors, but still have a big gap with humans on the error types that are subjective and with cultural characteristics.

7 Related Work

Early published works in GEC develop specific classifiers for different error types and then use them to build hybrid systems. Later, leveraging the progress of statistical machine translation(SMT) and large-scale error corrected data, GEC systems are further improved treated as a translation problem. SMT systems can remember phrase-based correction pairs, but they are hard to generalize beyond what was seen in training. The CoNLL-14 shared task overview paper (Ng et al., 2014) provides a comparative evaluation of approaches. (Rozovskaya and Roth, 2016) detailed classification and machine translation approaches to grammatical error correction problems, and combined the strengths for both methods.

Recently, neural machine translation approaches have been shown to be very powerful. (Yannakoudakis et al., 2017) developed a neural sequence-labeling model for error detection to calculate the probability of each token in a sentence as being correct or incorrect, and then use the error detecting model's result as a feature to re-rank the N best hypotheses. (Ji et al., 2017) proposed a hybrid neural model incorporating both the word and character-level information. (Chollampatt and Ng, 2018) used a multilayer convolutional encoder-decoder neural network and outperforms all prior neural and statistical based systems on this task. (Junczys-Dowmunt et al., 2018) tried deep RNN (Barone et al., 2017) and transformer (Vaswani et al., 2017) encoder-decoder models and got a higher result by using transformer and a set of model-independent methods for neural GEC.

The state-of-the-art system on GEC task is achieved by (Ge et al., 2018), which are based on the sequence-to-sequence framework and fluency boost learning and inference mechanism. However, the usage of the non-public CLC corpus (Nicholls, 2003) and self-collected non-public error-corrected sentence pairs from Lang-8 made their training data 3.6 times larger than the others and their results hard to compare.

8 Conclusions

We present a copy-augmented architecture for GEC, by considering the characteristics of this problem. Firstly, we propose an enhanced copy-augmented architecture, which improves the sequence-to-sequence model's ability by directly copying the unchanged words and out-of-vocabulary words from the source input tokens. Secondly, we fully pre-train the copy-augmented architecture using large-scale unlabeled data, leveraging denoising auto-encoders.

Thirdly, we introduce two auxiliary tasks for multi-task learning. Finally, we outperform the state-of-the-art automatic grammatical error correction system by a large margin. However, due to the complexity of the GEC problem, there is still a long way to go to make the automatic GEC systems as reliable as humans.

Abstract

We propose a topic-guided variational autoencoder (TGVAE) model for text generation. Distinct from existing variational autoencoder (VAE) based approaches, which assume a simple Gaussian prior for the latent code, our model specifies the prior as a Gaussian mixture model (GMM) parametrized by a neural topic module. Each mixture component corresponds to a latent topic, which provides guidance to generate sentences under the topic. The neural topic module and the VAE-based neural sequence module in our model are learned jointly. In particular, a sequence of invertible Householder transformations is applied to endow the approximate posterior of the latent code with high flexibility during model inference. Experimental results show that our TGVAE outperforms alternative approaches on both unconditional and conditional text generation, which can generate semantically-meaningful sentences with various topics.

1 Introduction

Text generation plays an important role in various natural language processing (NLP) applications, such as machine translation (Cho et al., 2014; Sutskever et al., 2014), dialogue generation (Li et al., 2017a), and text summarization (Nallapati et al., 2016; Rush et al., 2015). As a competitive solution to this task, the variational autoencoder (VAE) (Kingma and Welling, 2013; Rezende et al., 2014) has been widely used in text-generation systems (Bowman et al., 2015; Hu et al., 2017; Serban et al., 2017). In particular, VAE defines a generative model that propagates latent codes drawn from a simple prior through a decoder to manifest data samples. The generative model is further augmented with an inference network, that feeds observed data samples through an encoder to yield a distribution on the corresponding latent codes.

Compared with other potential methods, *e.g.*, those based on generative adversarial networks (GANs) (Yu et al., 2017; Guo et al., 2017; Zhang et al., 2017b, 2018; Chen et al., 2018), VAE is of particular interest when one desires not only text generation, but also the capacity to infer meaningful latent codes from text. Ideally, semantically-meaningful latent codes can provide high-level guidance while generating sentences. For example, when generating text, the vocabulary could potentially be narrowed down if the input latent code corresponds to a certain topic (*e.g.*, the word "military" is unlikely to appear in a sports-related document).

However, in practice this desirable property is not fully achieved by existing VAE-based text generative models, because of the following two challenges. First, the sentences in documents may associate with different semantic information (*e.g.*, topic, sentiment, etc.) while the latent codes of existing VAE-based text generative models often employ a simple Gaussian prior, which cannot indicate the semantic structure among sentences and may reduce the generative power of the decoder. Although some variants of VAE try to impose some structure on the latent codes (Jiang et al., 2016; Dilokthanakul et al., 2016), they are often designed with pre-defined parameter settings without incorporating semantic meanings into the latent codes, which may lead to over-regularization (Dilokthanakul et al., 2016).

The second issue associated with VAE-based text generation is "posterior collapse," first identified in Bowman et al. (2015). With a strong auto-regressive decoder network (*e.g.*, LSTM), the model tends to ignore the information from the latent code and merely depends on previous generated tokens for prediction. Several strategies are proposed to mitigate this problem, including making the decoder network less auto-regressive (*i.e.*,

(a) The scheme of our method.

(b) The extension to text summarization.

Figure 1: Illustration of the proposed Topic-Guided Variational Autoencoder (TGVAE) for text generation. (a) For generation (the red arrows), the topics inferred from a neural topic model are used to guide a Gaussian mixture prior of the latent code, which is further fed into the decoder to generate a sentence. For inference (the black arrows), the sentence is encoded into a vector and then propagated through the Householder flow to obtain the approximate posterior. (b) An attention module is further added for text summarization. The same neural topic model is also applied, but omitted here for simplicity of illustration. "LT" denotes a linear transformation.

using less conditional information while generating each word) (Yang et al., 2017; Shen et al., 2017a), or bridging the amortization gap (between the log-likelihood and the ELBO) using semi-amortized inference networks (Kim et al., 2018). However, these methods mitigate the issue by weakening the conditional dependency on the decoder, which may fail to generate high-quality continuous sentences.

To overcome the two problems mentioned above, we propose a topic-guided variational autoencoder (TGVAE) model, permitting text generation with designated topic guidance. As illustrated in Figure 1(a), TGVAE specifies a Gaussian mixture model (GMM) as the prior of the latent code, where each mixture component corresponds to a topic. The GMM is learnable based on a neural topic model — the mean and diagonal covariance of each mixture component is parameterized by the corresponding topic. Accordingly, the degree to which each component of the GMM is used to generate the latent code and the corresponding sentence is tied to the usage of the topics. In the inference phase, we initialize the latent code from a GMM generated via the encoder, and apply the invertiable Householder transformation (Bischof and Sun, 1994; Sun and Bischof, 1995) to derive the latent code with high flexibility and low complexity.

As shown in Figure 1(b), besides unconditional text generation, the proposed model can be extended for conditional text generation, *i.e.*, abstractive text summarization (Nallapati et al., 2016) with an attention module. By injecting the topics learned by our model (semantic information), we are able to make better use of the source document and improve a sequence-to-sequence summarization model (Sutskever et al., 2014).

We highlight the contributions of our model as follows: (*i*) A new Topic-Guided VAE (TGVAE) model is proposed for text generation with designated topic guidance. (*ii*) For the model inference, Householder flow is introduced to transform a relatively simple mixture distribution into an arbitrarily flexible approximate posterior, achieving powerful approximate posterior inference. (*iii*) Experiments for both unconditional and conditional text generation demonstrate the effectiveness of the proposed approach.

2 Model

The proposed TGVAE, as illustrated in Figure 1(a), consists of two modules: a neural topic model (NTM) and a neural sequence model (NSM). The NTM aims to capture long-range semantic meaning across the document, while the NSM is designed to generate a sentence with designated topic guidance.

2.1 Neural Topic Model

Let $\boldsymbol{d} \in \mathbb{Z}_+^D$ denote the bag-of-words representation of a document, with $\mathbb{Z}_+$ denoting non-negative integers. D is the vocabulary size, and each element of $\boldsymbol{d}$ reflects a count of the number of times the corresponding word occurs in the document. Let a_n represent the topic assignment for word w_n. Following Miao et al. (2017), a Gaussian random vector is passed through a softmax function to parameterize the multinomial document topic distributions. Specifically, the generative process of the NTM is

$$\boldsymbol{\theta} \sim \mathcal{N}(0, \mathbf{I}), \quad \boldsymbol{t} = g(\boldsymbol{\theta}), \tag{1}$$
$$a_n \sim \text{Discrete}(\boldsymbol{t}), \quad w_n \sim \text{Discrete}(\boldsymbol{\beta}_{a_n}),$$

where $\mathcal{N}(0, \mathbf{I})$ is an isotropic Gaussian distribution, $g(\cdot)$ is a transformation function that maps sample $\boldsymbol{\theta}$ to the topic embedding $\boldsymbol{t}$, defined here as $g(\boldsymbol{\theta}) = \text{softmax}(\hat{\mathbf{W}}\boldsymbol{\theta} + \hat{\boldsymbol{b}})$, where $\hat{\mathbf{W}}$ and $\hat{\boldsymbol{b}}$ are trainable parameters; $\boldsymbol{\beta}_{a_n}$ represents the distribution over words for topic a_n; $n \in [1, N_d]$, and N_d is the number of words in the document. The marginal likelihood for document $\boldsymbol{d}$ is:

$$\begin{aligned} p(\boldsymbol{d}|\boldsymbol{\beta}) &= \int_{\boldsymbol{t}} p(\boldsymbol{t}) \prod\nolimits_n \sum\nolimits_{a_n} p(w_n|\boldsymbol{\beta}_{a_n}) p(a_n|\boldsymbol{t}) d\boldsymbol{t} \quad (2) \\ &= \int_{\boldsymbol{t}} p(\boldsymbol{t}) \prod\nolimits_n p(w_n|\boldsymbol{\beta}, \boldsymbol{t}) d\boldsymbol{t} \\ &= \int_{\boldsymbol{t}} p(\boldsymbol{t}) p(\boldsymbol{d}|\boldsymbol{\beta}, \boldsymbol{t}) d\boldsymbol{t} = \int_{\boldsymbol{\theta}} p(\boldsymbol{\theta}) p(\boldsymbol{d}|\boldsymbol{\beta}, \boldsymbol{\theta}) d\boldsymbol{\theta}. \end{aligned}$$

The second equation in (2) holds because we can marginalize out the sampled topic words a_n by

$$p(w_n|\boldsymbol{\beta}, \boldsymbol{t}) = \sum\nolimits_{a_n} p(w_n|\boldsymbol{\beta}_{a_n}) p(a_n|\boldsymbol{t}) = \boldsymbol{\beta}\boldsymbol{t}, \tag{3}$$

where $\boldsymbol{\beta} = \{\boldsymbol{\beta}_i\}_{i=1}^T$ are trainable parameters of the decoder; T is the number of topics and each $\boldsymbol{\beta}_i \in \mathbb{R}^D$ is a topic distribution over words (all elements of $\boldsymbol{\beta}_i$ are nonnegative, and sum to one).

2.2 Neural Sequence Model

Our neural sequence model for text generation is built upon the VAE proposed in Bowman et al. (2015). Specifically, a continuous latent code $\boldsymbol{z}$ is first generated from some prior distribution $p(\boldsymbol{z})$, based on which the text sequence $\boldsymbol{y}$ is then generated from a conditional distribution $p(\boldsymbol{y}|\boldsymbol{z})$ parameterized by a neural network (often called the decoder). Since the model incorporates a latent variable $\boldsymbol{z}$ that modulates the entire generation of the sentence, it should be able to capture the high-level source of variation in the data.

Topic-Guided Gaussian Mixture Prior The aforementioned intuition is hard to be captured by a standard VAE, simply imposing a Gaussian prior on top of $\boldsymbol{z}$, since the semantic information associated with a document intrinsically contains different subgroups (such as topics, sentiment, etc.). In our model, we consider incorporating the topic information into latent variables. Our model assumes each $\boldsymbol{z}$ is drawn from a *topic-dependent* GMM, that is,

$$\begin{aligned} p(\boldsymbol{z}|\boldsymbol{\beta}, \boldsymbol{t}) &= \sum\nolimits_{i=1}^T t_i \mathcal{N}(\boldsymbol{\mu}(\boldsymbol{\beta}_i), \boldsymbol{\sigma}^2(\boldsymbol{\beta}_i)) \\ \boldsymbol{\mu}(\boldsymbol{\beta}_i) &= f_\mu(\boldsymbol{\beta}_i) \\ \boldsymbol{\sigma}^2(\boldsymbol{\beta}_i) &= \text{diag}(\exp(f_\sigma(\boldsymbol{\beta}_i))), \end{aligned} \tag{4}$$

where t_i is the usage of topic i in a document and $\boldsymbol{\beta}_i$ is the i-th topic distribution over words. Both of them are inherited from the NTM discussed above. Both $f_\mu(\cdot)$ and $f_\sigma(\cdot)$ are implemented as feedforward neural networks, with trainable parameters $\mathbf{W}_\mu$ and $\mathbf{W}_\sigma$, respectively. Compared with a normal GMM prior that sets each mixture component to be $\mathcal{N}(0, \mathbf{I})$, the proposed topic guided GMM prior provides semantic meaning for each mixture component, and hence makes the model more interpretable and controllable for text generation.

Decoder The likelihood of a word sequence $\boldsymbol{y} = \{y_m\}_{m=1}^M$ conditioned on the latent code $\boldsymbol{z}$ is defined as:

$$\begin{aligned} p(\boldsymbol{y}|\boldsymbol{z}) &= p(y_1|\boldsymbol{z}) \prod\nolimits_{m=2}^M p(y_m|y_{1:m-1}, \boldsymbol{z}) \\ &= p(y_1|\boldsymbol{z}) \prod\nolimits_{m=2}^M p(y_m|\boldsymbol{h}_m), \end{aligned} \tag{5}$$

where the conditional probability of each word y_m given all the previous words $y_{1:m-1}$ and the latent code $\boldsymbol{z}$ is defined through the hidden state $\boldsymbol{h}_m$: $\boldsymbol{h}_m = f(\boldsymbol{h}_{m-1}, y_{m-1}, \boldsymbol{z})$, where the function $f(\cdot)$ is implemented as a Gated Recurrent Unit (GRU) cell (Cho et al., 2014) in our experiments.

3 Inference

The proposed model (see Figure 1(a)) takes the bag-of-words as input and embeds a document into a topic vector. The topic vector is then used to reconstruct the bag-of-words input, and the learned topic distribution over words is used to model a topic-dependent prior to generate a sentence in the VAE setup. Specifically, the joint marginal likelihood can be written as:

$$\begin{aligned} p(\boldsymbol{y}, \boldsymbol{d}|\boldsymbol{\beta}) = \int_{\boldsymbol{\theta}} \int_{\boldsymbol{z}} & p(\boldsymbol{\theta}) p(\boldsymbol{d}|\boldsymbol{\beta}, \boldsymbol{\theta}) \\ & \cdot p(\boldsymbol{z}|\boldsymbol{\beta}, \boldsymbol{\theta}) p(\boldsymbol{y}|\boldsymbol{z}) \, d\boldsymbol{\theta} d\boldsymbol{z}. \end{aligned} \tag{6}$$

Since direct optimization of (6) is intractable, auto-encoding variational Bayes is employed (Kingma and Welling, 2013). Denote $q(\boldsymbol{\theta}|\boldsymbol{d})$ and $q(\boldsymbol{z}|\boldsymbol{y})$ as the variational distributions for $\boldsymbol{\theta}$ and $\boldsymbol{z}$, respectively. The variational objective function, also called the evidence lower bound (ELBO), is constructed as

$$\mathcal{L} = \underbrace{\mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})}\left[\log p(\boldsymbol{d}|\boldsymbol{\beta},\boldsymbol{\theta})\right] - \mathrm{KL}\left(q(\boldsymbol{\theta}|\boldsymbol{d})||p(\boldsymbol{\theta})\right)}_{\text{neural topic model},\mathcal{L}_t} + \quad (7)$$

$$\underbrace{\mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{y})}\left[\log p(\boldsymbol{y}|\boldsymbol{z})\right] - \mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})}\left[\mathrm{KL}\left(q(\boldsymbol{z}|\boldsymbol{y})||p(\boldsymbol{z}|\boldsymbol{\beta},\boldsymbol{\theta})\right)\right]}_{\text{neural sequence model},\mathcal{L}_s}.$$

By assuming

$$q(\boldsymbol{\theta}|\boldsymbol{d}) = \mathcal{N}(\boldsymbol{\theta}|g_\mu(\boldsymbol{d}), \mathrm{diag}(\exp\left(g_\sigma(\boldsymbol{d})\right))),$$

where both $g_\mu(\cdot)$ and $g_\sigma(\cdot)$ are implemented as feed-forward neural networks, the reparameterization trick (Kingma and Welling, 2013) can be applied directly to build an unbiased and low-variance gradient estimator for the $\mathcal{L}_t$ term in (7). Below, we discuss in detail how to approximate the $\mathcal{L}_s$ term in (7) and infer an arbitrarily complex posterior for $\boldsymbol{z}$. Note that $\boldsymbol{z}$ is henceforth represented as $\boldsymbol{z}_K$ in preparation for the introduction of Householder flows.

3.1 Householder Flow for Approximate Posterior

Householder flow (Zhang et al., 2017a; Tomczak and Welling, 2016) is a volume-preserving normalizing flow (Rezende and Mohamed, 2015), capable of constructing an arbitrarily complex posterior $q_K(\boldsymbol{z}_K|\boldsymbol{y})$ from an initial random variable $\boldsymbol{z}_0$ with distribution q_0, by composing a sequence of invertible mappings, *i.e.*, $\boldsymbol{z}_K = f_K \circ \cdots \circ f_2 \circ f_1(\boldsymbol{z}_0)$. By repeatedly applying the chain rule and using the property of Jacobians of invertible functions, $q_K(\boldsymbol{z}_K|\boldsymbol{y})$ is expressed as:

$$\log q_K(\boldsymbol{z}_K|\boldsymbol{y}) = \log q_0(\boldsymbol{z}_0|\boldsymbol{y}) - \sum\nolimits_{k=1}^{K} \log\left|\det \frac{\partial f_k}{\partial \boldsymbol{z}_{k-1}}\right|, \quad (8)$$

where $|\det \frac{\partial f_k}{\partial \boldsymbol{z}_{k-1}}|$ is the absolute value of the Jacobian determinant. Therefore, the $\mathcal{L}_s$ term in (7) may be rewritten as

$$\mathbb{E}_{q_0(\boldsymbol{z}_0|\boldsymbol{y})}[\log p(\boldsymbol{y}|\boldsymbol{z}_K)] + \sum\nolimits_{k=1}^{K} \log\left|\det \frac{\partial f_k}{\partial \boldsymbol{z}_{k-1}}\right|$$
$$-\mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})}\left[\mathrm{KL}(q_0(\boldsymbol{z}_0|\boldsymbol{y})||p(\boldsymbol{z}_K|\boldsymbol{\beta},\boldsymbol{\theta}))\right]. \quad (9)$$

Here $q_0(\boldsymbol{z}_0|\boldsymbol{y})$ is also specified as a GMM, *i.e.*, $q_0(\boldsymbol{z}_0|\boldsymbol{y}) = \sum_{i=1}^{T} \pi_i(\boldsymbol{y})\mathcal{N}(\boldsymbol{\mu}_i(\boldsymbol{y}), \boldsymbol{\sigma}_i^2(\boldsymbol{y}))$. As illustrated in Figure 1(a), $\boldsymbol{y}$ is first represented as a hidden vector $\boldsymbol{h}$, by encoding the text sequence with an RNN. Based on this, the mixture probabilities $\boldsymbol{\pi}$, the means and diagonal covariances of all the mixture components are all produced by an encoder network, which is a linear layer with the input $\boldsymbol{h}$. In (9), the first term can be considered as the reconstruction error, while the remaining two terms act as regularizers, the tractability of which is important for the whole framework.

KL Divergence between two GMMs Since both the prior $p(\boldsymbol{z}_K|\boldsymbol{\beta},\boldsymbol{\theta})$ and the initial density $q_0(\boldsymbol{z}_0|\boldsymbol{y})$ for the posterior are GMMs, the calculation of the third term in (9) requires the KL divergence between two GMMs. Though no closed-form solutions exist, the KL divergence has an explicit upper bound (Dilokthanakul et al., 2016), shown in Proposition 1.

Proposition 1. *For any two mixture densities $p = \sum_{i=1}^{n} \pi_i g_i$ and $\hat{p} = \sum_{i=1}^{n} \hat{\pi}_i \hat{g}_i$, their KL divergence is upper-bounded by*

$$\mathrm{KL}\left(p||\hat{p}\right) \leq \mathrm{KL}\left(\pi||\hat{\pi}\right) + \sum\nolimits_{i=1}^{n} \pi_i \mathrm{KL}\left(g_i||\hat{g}_i\right), \quad (10)$$

where equality holds if and only if $\frac{\pi_i g_i}{\sum_{i=1}^{n} \pi_i g_i} = \frac{\hat{\pi} \hat{g}_i}{\sum_{i=1}^{n} \hat{\pi} \hat{g}_i}$.

Proof. With the log-sum inequality

$$\begin{aligned}\mathrm{KL}\left(p||\hat{p}\right) &= \int \left(\sum_i \pi_i g_i\right) \log \frac{\sum_i \pi_i g_i}{\sum_i \hat{\pi} \hat{g}_i} \\ &\leq \int \sum_i \pi_i g_i \log \frac{\pi_i g_i}{\hat{\pi} \hat{g}_i} \\ &= \sum_i \pi_i \log \frac{\pi_i}{\hat{\pi}} + \sum_i \pi_i \int g_i \log \frac{g_i}{\hat{g}_i} \\ &= \mathrm{KL}(\pi||\hat{\pi}) + \sum_i \pi_i \mathrm{KL}(g_i||\hat{g}_i). \end{aligned} \quad (11)$$

Since the KL divergence between two Gaussian distributions has a closed-form expression, the upper bound of the KL divergence between two GMMs can be readily calculated. Accordingly, the third term in (9) is upper bounded as

$$\mathcal{U}_{KL} = \mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})}\Big[\mathrm{KL}\left(\boldsymbol{\pi}(\boldsymbol{y})||\boldsymbol{t}\right) \quad (12)$$
$$+ \sum\nolimits_{i=1}^{T} \pi_i(\boldsymbol{y})\mathrm{KL}\left(\mathcal{N}(\boldsymbol{\mu}_i(\boldsymbol{y}), \boldsymbol{\sigma}_i^2(\boldsymbol{y})||\mathcal{N}(\boldsymbol{\mu}(\boldsymbol{\beta}_i), \boldsymbol{\sigma}^2(\boldsymbol{\beta}_i)))\right)\Big],$$

where the expectation $\mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})}[\cdot]$ can be approximated by a sample from $q(\boldsymbol{\theta}|\boldsymbol{d})$.

Householder Flow Householder flow (Tomczak and Welling, 2016) is a series of Householder transformations, defined as follows. For a given vector $\boldsymbol{z}_{k-1}$, the reflection hyperplane can be defined by a Householder vector $\boldsymbol{v}_t$ that is orthogonal to the hyperplane. The reflection of this point about the hyperplane is

$$\boldsymbol{z}_k = \left(\mathbf{I} - 2\frac{\boldsymbol{v}_k \boldsymbol{v}_k^T}{||\boldsymbol{v}_k||^2}\right) \boldsymbol{z}_{k-1} = \mathbf{H}_k \boldsymbol{z}_{k-1}, \quad (13)$$

where $\mathbf{H}_k = \mathbf{I} - 2\frac{\boldsymbol{v}_k\boldsymbol{v}_k^T}{||\boldsymbol{v}_k||^2}$ is called the *Householder matrix*. An important property of the *Householder matrix* is that the absolute value of the Jacobian determinant is equal to 1, therefore $\sum_{k=1}^{K} \log \left| \det \frac{\partial f_k}{\partial \boldsymbol{z}_{k-1}} \right| = \sum_{k=1}^{K} \log |\det \mathbf{H}_k| = 0$, significantly simplifying the computation of the lower bound in (9). For $k = 1, \ldots, K$, the vector $\boldsymbol{v}_k$ is produced by a linear layer with the input $\boldsymbol{v}_{k-1}$, where $\boldsymbol{v}_0 = \boldsymbol{h}$ is the last hidden vector of the encoder RNN that encodes the sentence $\boldsymbol{y}$.

Finally, by combining (7), (9) and (12), the ELBO can be rewritten as

$$\mathcal{L} \geq \mathcal{L}_t + \mathbb{E}_{q_0(\boldsymbol{z}_0|\boldsymbol{y})}[\log p(\boldsymbol{y}|\boldsymbol{z}_K)] - \mathcal{U}_{KL} \, . \quad (14)$$

3.2 Extension to text summarization

When extending our model to text summarization, we are interested in modeling $p(\boldsymbol{y}, \boldsymbol{d}|\boldsymbol{x})$, where $(\boldsymbol{x}, \boldsymbol{y})$ denotes the document-summary pair, and $\boldsymbol{d}$ denotes the bag-of-words of the input document. The marginal likelihood can be written as $p(\boldsymbol{y}, \boldsymbol{d}|\boldsymbol{x}) = \int_{\boldsymbol{\theta}} \int_{\boldsymbol{z}} p(\boldsymbol{\theta}) p(\boldsymbol{d}|\boldsymbol{\beta}, \boldsymbol{\theta}) p(\boldsymbol{z}|\boldsymbol{\beta}, \boldsymbol{\theta}) p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{z}) \, d\boldsymbol{\theta} d\boldsymbol{z}$. Assume the approximate posterior of $\boldsymbol{z}$ is only dependent on $\boldsymbol{x}$, *i.e.*, $q(\boldsymbol{z}|\boldsymbol{x})$ is proposed as the variational distribution for $\boldsymbol{z}$. The ELBO is then constructed as

$$\begin{aligned} \mathcal{L} = & \mathcal{L}_t + \mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{x})} \left[\log p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{z}) \right] \\ & - \mathbb{E}_{q(\boldsymbol{\theta}|\boldsymbol{d})} \left[\mathrm{KL} \left(q(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z}|\boldsymbol{\beta}, \boldsymbol{\theta}) \right) \right] \, , \quad (15) \end{aligned}$$

where $\mathcal{L}_t$ is the same as used in (7). The main difference when compared with unconditional text generation lies in the usage of $p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{z})$ and $q(\boldsymbol{z}|\boldsymbol{x})$, illustrated in Figure 1(b). The generation of $\boldsymbol{y}$ given $\boldsymbol{x}$ is not only dependent on a standard Seq2Seq model with attention (Nallapati et al., 2016), but also affected by $\boldsymbol{z}$ (*i.e.*, $\boldsymbol{z}_K$), which provides the high-level topic guidance.

3.3 Diversity Regularizer for NTM

Redundancy in inferred topics is a common issue existing in general topic models. In order to address this, it is straightforward to regularize the row-wise distance between paired topics to diversify the topics. Following Xie et al. (2015); Miao et al. (2017), we apply a topic diversity regularization while carrying out the inference.

Specifically, the distance between a pair of topics is measured by their cosine distance $a(\boldsymbol{\beta}_i, \boldsymbol{\beta}_j) = \arccos\left(\frac{|\boldsymbol{\beta}_i \cdot \boldsymbol{\beta}_j|}{|\boldsymbol{\beta}_i|_2 |\boldsymbol{\beta}_j|_2}\right)$. The mean angle of all pairs of T topics is $\phi = \frac{1}{T^2} \sum_i \sum_j a(\boldsymbol{\beta}_i, \boldsymbol{\beta}_j)$, and the variance is $\nu = \frac{1}{T^2} \sum_i \sum_j (a(\boldsymbol{\beta}_i, \boldsymbol{\beta}_j) - \phi)^2$. Finally, the topic-diversity regularization is defined as $R = \phi - \nu$.

4 Related Work

The VAE was proposed by Kingma and Welling (2013), and since then, it has been applied successfully in a variety of applications (Gregor et al., 2015; Kingma et al., 2014; Chen et al., 2017; Wang et al., 2018b; Shen et al., 2018). Focusing on text generation, the methods in Miao et al. (2017, 2016); Srivastava and Sutton (2017) represent texts as bag-of-words, and Bowman et al. (2015) proposed the usage of an RNN as the encoder and decoder, and found some negative results. In order to improve the performance, different convolutional designs (Semeniuta et al., 2017; Shen et al., 2017a; Yang et al., 2017) have been proposed. A VAE variant was further developed in Hu et al. (2017) to control the sentiment and tense of generated sentences. Additionally, the VAE has also been considered for conditional text generation tasks, including machine translation (Zhang et al., 2016), image captioning (Pu et al., 2016), dialogue generation (Serban et al., 2017; Shen et al., 2017b; Zhao et al., 2017) and text summarization (Li et al., 2017b; Miao and Blunsom, 2016). In particular, distinct from the above works, we propose the usage of a topic-dependent prior to explicitly incorporate topic guidance into the text-generation framework.

The idea of using learned topics to improve NLP tasks has been explored previously, including methods combining topic and neural language models (Ahn et al., 2016; Dieng et al., 2016; Lau et al., 2017; Mikolov and Zweig, 2012; Wang et al., 2017), as well as leveraging topic and word embeddings (Liu et al., 2015; Xu et al., 2018). Distinct from them, we propose the use of topics to guide the prior of a VAE, rather than only the language model (*i.e.*, the decoder in a VAE setup). This provides more flexibility in text modeling and also the ability to infer the posterior on latent codes, which could be useful for visualization and downstream tasks.

Neural abstractive summarization was pioneered in Rush et al. (2015), and it was followed and extended by Chopra et al. (2016). Currently the RNN-based encoder-decoder framework with attention (Nallapati et al., 2016; See et al., 2017) remains popular in this area. Attention models typically work as a keyword detector, which is similar to topic modeling in spirit. This fact motivated us to extend our topic-guided VAE model to text summarization.

5 Experiments

We evaluate our TGVAE on text generation and text summarization, and interpret its improvements both quantitatively and qualitatively.

5.1 Text Generation

Dataset We conduct experiments on three publicly available corpora: APNEWS, IMDB and BNC.[1] APNEWS[2] is a collection of Associated Press news articles from 2009 to 2016. IMDB is a set of movie reviews collected by Maas et al. (2011), and BNC (BNC Consortium, 2007) is the written portion of the British National Corpus, which contains excerpts from journals, books, letters, essays, memoranda, news and other types of text. For the three corpora, we tokenize the words and sentences, lowercase all word tokens, and filter out word tokens that occur less than 10 times. For the topic model, we remove stop words in the documents and exclude the top 0.1% most frequent words and also words that appear less than 100 documents. A summary statistics is provided in Table 1.

Evaluation We first compare the perplexity of our neural sequence model with a variety of baselines. Further, we evaluate BLEU scores on the generated sentences, noted as *test*-BLEU and *self*-BLEU. *test*-BLEU (higher is better) evaluates the quality of generated sentences using a group of real test-set sentences as the reference, and *self*-BLEU (lower is better) mainly measures the diversity of generated samples (Zhu et al., 2018).

Setup For the neural topic model (NTM), we consider a 2-layer feed-forward neural network to model $q(\boldsymbol{\theta}|\boldsymbol{d})$, with 256 hidden units in each layer; ReLU is used as the activation function. The hyper-parameter λ for the neural topic model diversity regularizer is fixed to 0.1 across all the experiments. All the sentences in the paragraph are used to obtain the bag-of-words presentation $\boldsymbol{d}$. The maximum number of words in a paragraph is set to 300. For the neural sequence model (NSM), we use bidirectional-GRU as the encoder and a standard GRU as the decoder. The hidden state of our GRU is fixed to 600 across all the three corpora. For the input sequence, we fix the sequence length to 30. In order to avoid overfitting, dropout with a rate of 0.4 is used in each GRU layer.

Baseline We test the proposed method with different numbers of topics (components in GMM) and different numbers of Householder flows ($i.e.$, K), and compare it with six baselines: (*i*) a standard language model (LM); (*ii*) a standard variational RNN auto-encoder (VAE); (*iii*) a Gaussian prior-based VAE with Householder Flow (VAE+HF); (*iv*) a standard LSTM language model with LDA as additional feature (LDA+LSTM); (*v*) Topic-RNN (Dieng et al., 2016), a joint learning framework which learns a topic model and a language model simultaneously; (*vi*) TDLM (Lau et al., 2017), a joint learning framework which learns a convolutional based topic model and a language model simultaneously.

Results The results in Table 3 show that the models trained with a VAE and its Householder extension does not outperform a well-optimized language model, and the KL term tends to be annealed with the increase of K. In comparison, our TGVAE achieves a lower perplexity upper bound, with a relative larger $\mathcal{U}_{KL}$. We attribute the improvements to our topic guided GMM model design, which provides additional topical clustering information in the latent space; the Householder flow also boosts the posterior inference for our TGVAE. We also observe consistent improvements with the number of topics, which demonstrates the efficiency of our TGVAE.

To verify the generative power of our TGVAE, we generate samples from our *topic-dependent* prior and compare various methods on the BLEU scores in Table 2. With the increase of topic numbers, our TGVAE yields consistently better *self*-BLEU and a boost over *test*-BLEU relative to standard VAE models. We also show a group of sampled sentences drawn from a portion of topics in Table 5. Our TGVAE is able to generate diverse sentences under topic guidance. When generating sentences under a mixture of topics, we draw multiple samples from the GMM and take $\boldsymbol{z}$ as the averaged sample.

Though this paper focuses on generating coherent topic-specific sentences rather than the learned topics themselves, we also evaluate the topic coherence (Lau et al., 2017) to show the rationality of our joint learning framework. We compute topic coher-

ence using normalized PMI (NPMI). In practice, we average topic coherence over the top 5/10/15/20 topic words. To aggregate topic coherence score, we further average the coherence scores over topics. Results are summarized in Table 4.

5.2 Text Summarization

Dataset We further test our model for text summarization on two popular datasets. First, we follow the same setup as in Rush et al. (2015) and consider the GIGAWORDS corpus[3], which consists of 3.8M training pair samples, 190K validation samples and 1,951 test samples for evaluation. An input-summary pair consists of the first sentence and the headline of the source articles. We also evaluate various models on the DUC-2004 test set[4], which has 500 news articles. Different from GIGAWORDS, each article in DUC-2004 is paired with four expert-generated reference summaries. The length of each summary is limited to 75 bytes.

Evaluation We evaluate the performance of our model with the ROUGE score (Lin, 2004), which counts the number of overlapping content between the generated summaries and the reference summaries, *e.g.*, overlapped n-grams. Following practice, we use F-measures of ROUGE-1 (RF-1), ROUGE-2 (RF-2) and ROUGE-L (RF-L) for GIGAWORDS and Recall measures of ROUGE-1 (RR-1), ROUGE-2 (RR-2) and ROUGE-L (RR-L) for DUC-2004.

Setup We have a similar data tokenization as we

have in text generation. Additionally, for the vocabulary, we count the frequency of words in both the source article the target summary, and maintain the top 30,000 tokens as the source article and target summary vocabulary. For the NTM, we further remove top 0.3% words and infrequent words to get a topic model vocabulary in size of 8000. For the NTM, we follow the same setup as our text generation. In the NSM, we keep using bidirectional-GRU as the encoder and a standard GRU as the decoder. The hidden state is fixed to 400. An attention mechanism (Bahdanau et al., 2015) is applied in our sequence-to-sequence model.

Baseline We compare our method with the following alternatives: (*i*) a standard sequence-to-sequence model with attention (Bahdanau et al., 2015) (Seq2Seq); (*ii*) a model similar to our TGVAE, but without the usage of the topic-dependent prior and Householder flow (Var-Seq2Seq); and (*iii*) a model similar to our TGVAE, but without the usage of the topic dependent prior (Var-Seq2Seq-

Table 8: 10 topics learned from our model on APNEWS, IMDB, BNC and Gigawords.

HF).

Results The results in Table 7 show that our TGVAE achieves better performance than a variety of strong baseline methods on both GIGAWORDS and DUC-2004, demonstrating the practical value of our model. It is worthwhile to note that recently several much more complex CNN/RNN architectures have been proposed for abstract text summarization, such as SEASS (Zhou et al., 2017), ConvS2S (Gehring et al., 2017), and Reinforced-ConvS2S (Wang et al., 2018a). In this work, we focus on a relatively simple RNN architecture for fair comparison. In such a way, we are able to conclude that the improvements on the results are mainly from our topic-guided text generation strategy. As can be seen, though the Var-Seq2Seq model achieves comparable performance with the standard Seq2Seq model, the usage of Householder flow for more flexible posterior inference boosts the performance. Additionally, by combining the proposed topic-dependent prior and Householder flow, we yield further performance improvements, demonstrating the importance of topic guidance for text summarization.

To demonstrate the readability and diversity of the generated summaries, we present typical examples in Table 6. The words in blue are the topic words that appear in the source article but do not exist in the reference, while the words in red are neither in the reference nor in the source article. When the topic information is provided, our model is able to generate semantically-meaningful words which may not even exist in the reference summaries and the source articles. Additionally, with our topic-guided model, we can always generate a summary with meaningful initial words. These phenomena imply that our model supplies more insightful semantic information to improve the quality of generated summaries.

Finally, to demonstrate that our TGVAE learns interpretable topic-dependent GMM priors, we draw multiple samples from each mixture component and visualize them with t-SNE (Maaten and Hinton, 2008). As can be seen from Figure 2, we have learned a group of separable *topic-dependent* components. Each component is clustered and also maintains semantic meaning in the latent space, *e.g.*, the clusters corresponding to the topic "stock" and "finance" are close to each other, while the clusters for "finance" and "disease" are far away from each other. Additionally, to understand the topic model we have learned, we provide the top 5 words for 10 randomly chosen topics on each dataset (the boldface word is the topic name summarized by us), as shown in Table 8.

6 Conclusion

A novel text generator is developed, combining a VAE-based neural sequence model with a neural topic model. The model is an extension of conditional VAEs in the framework of unsupervised learning, in which the topics are extracted from the data with clustering structure rather than predefined labels. An effective inference method based on Householder flow is designed to encourage the complexity and the diversity of the learned topics. Experimental results are encouraging, across multiple NLP tasks.

Abstract

Constituent parsing has been studied extensively in the last decades. Chomsky-Schützenberger parsing as an approach to constituent parsing has only been investigated theoretically, yet. It uses the decomposition of a language into a regular language, a homomorphism, and a bracket language to divide the parsing problem into simpler subproblems. We provide the first implementation of Chomsky-Schützenberger parsing. It employs multiple context-free grammars and incorporates many refinements to achieve feasibility. We compare its performance to state-of-the-art grammar-based parsers.

1 Introduction

The description of the syntax of natural languages (such as Danish, English, and German) with the help of formal grammars has been studied since Chomsky (1956). With a formal grammar, computers can calculate a syntactic representation (called *parse*) of a sentence in a natural language. Of the grammar classes in the Chomsky hierarchy (Chomsky, 1959), context-free grammars (short: CFGs) lack the expressive power necessary to model natural languages (Shieber, 1985) and parsing with context-sensitive grammars cannot be done efficiently (i.e. in polynomial time). This led to the introduction of a series of classes of *mildly context-sensitive grammars* (Joshi, 1985) that allow parsing in polynomial time but also capture an increasing amount of phenomena present in natural languages. Tree adjoining grammars (Joshi et al., 1975), linear context-free string-rewriting systems (short: LCFRSs, Vijay-Shanker et al., 1987), and multiple CFGs (short: MCFGs, Seki et al., 1991) are among those classes.

Chomsky-Schützenberger (short: CS) parsing was introduced by Hulden (2011) for CFGs and extended to MCFGs by Denkinger (2017). It uses a classical theorem by Chomsky and Schützenberger (1963, or the generalisation by Yoshinaka et al., 2010), which states that the language $\mathcal{L}(G)$ of a CFG (or an MCFG) G can be represented by a regular language R, a homomorphism h, and a Dyck language (resp. multiple Dyck language) D such that $\mathcal{L}(G) = h(R \cap D)$. The elements of $R \cap D$ correspond to parses in G. For a sentence w, a CS parser calculates the elements of $h^{-1}(w) \cap R \cap D$ and transforms them into parses. CS parsing can be viewed as a coarse-to-fine mechanism where R corresponds to the coarse grammar and $R \cap D$ to the fine grammar. The respective coarse-to-fine pipeline consists of (conceptually) simple operations such as h^{-1} or the intersection with R, which provides great flexibility. The flexibility is used to provide a fallback mechanism in case a finer stage of the pipeline rejects all proposals of a coarser stage. It also permits CS parsing in a broader setting than usual (for parsing) with minimal modification (see sec. 6).

We suspected that the coarse-to-fine view on CS parsing leads to an efficient implementation. Since initial tests revealed that the original algorithm for MCFGs (Denkinger, 2017, alg. 3, recalled in sec. 2) is not feasible in practice, we explore numerous optimisations (sec. 4), one of which is the use of a context-free approximation of the multiple Dyck language D. We introduce *component-wise derivations* (sec. 3) to relate this context-free approximation to D. Employing the optimisations, we provide the first implementation of a CS parser. In sec. 5, we compare our parser's performance to Grammatical Framework (Angelov and Ljunglöf, 2014), rparse (Kallmeyer and Maier, 2013), and disco-dop (van Cranenburgh et al., 2016). We restrict our comparison to (discontinuous) grammar-based parsers (excluding e.g. transition systems, Maier, 2015, Coavoux and Crabbé, 2017) since the principle of CS parsing requires a grammar.

Proceedings of NAACL-HLT 2019, pages 178–191
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Preliminaries

The sets of *non-negative integers* and *positive integers* are denoted by $\mathbb{N}$ and $\mathbb{N}_+$, respectively. We abbreviate $\{1, \dots, n\}$ by $[n]$ for each $n \in \mathbb{N}$.

Let A and B be sets. The *powerset of* A and the *set of (finite) strings over* A are denoted by $\mathcal{P}(A)$ and A^*, respectively. The *set of possibly infinite sequences of elements of* A is denoted by A^ω. A *partition of* A is a set $\mathfrak{P} \subseteq \mathcal{P}(A)$ whose elements (called *cells*) are non-empty, pairwise disjoint, and cover A (i.e. $\bigcup_{\mathfrak{p} \in \mathfrak{P}} \mathfrak{p} = A$). For each $a \in A$ and each equivalence relation $\approx$ on A, we denoted the *equivalence class of* a *w.r.t.* $\approx$ by $[a]_\approx$. The set of *functions from* A *to* B is denoted by $A \to B$. Note that $(A \to B) \subseteq (A \times B)$. The *composition* of two binary relations R_1 and R_2 is $R_2 \circ R_1 = \{(a, c) \mid \exists b\colon (a, b) \in R_1, (b, c) \in R_2\}$.

Finite state automata. We assume that the reader is familiar with finite state automata. For details, we refer to Hopcroft and Ullman (1979).

A *finite state automaton* (short: FSA) is a tuple $\mathcal{A} = (Q, \Delta, q_\mathrm{i}, q_\mathrm{f}, T)$ where Q and Δ are finite sets (*states* and *terminals*, respectively), $q_\mathrm{i}, q_\mathrm{f} \in Q$ (*initial* and *final state*, respectively), and $T \subseteq Q \times \Delta^* \times Q$ is finite (*transitions*). We call q the *source* and q' the *target* of a transition (q, u, q'). A *run* is a string θ of transitions such that the target of a transition is the source of the next transition in θ. The *language of* $\mathcal{A}$ is denoted by $\mathcal{L}(\mathcal{A})$.

Sorts. Sorts are a widespread concept in computer science: one can think of sorts as data types in a programming language. Let S be a set (of *sorts*). An S*-sorted set* is a tuple (Ω, sort) where Ω is a set and $\mathit{sort}\colon \Omega \to S$. We abbreviate (Ω, sort) by Ω and $\mathit{sort}^{-1}(s)$ by Ω_s for $s \in S$.

Now let Ω be an $(S^* \times S)$-sorted set. The *set of trees over* Ω is the S-sorted set T_Ω where $(\mathrm{T}_\Omega)_s = \{\omega(t_1, \dots, t_k) \mid s_1, \dots, s_k \in S, \omega \in \Omega_{(s_1 \cdots s_k, s)}, t_1 \in (\mathrm{T}_\Omega)_{s_1}, \dots, t_k \in (\mathrm{T}_\Omega)_{s_k}\}$ for each $s \in S$.

Multiple context-free grammars. A rule of a context-free grammar has the ability to concatenate the strings generated by its right-hand side non-terminals. *Multiple* context-free grammars extend this ability to concatenating string-*tuples*. This is done with the help of composition functions. Let Σ be a finite set. A *composition function w.r.t.* Σ is a function c that takes tuples of strings over Σ as arguments and returns a tuple of strings over Σ (i.e. there are $k \in \mathbb{N}$ and $s_1, \dots, s_k, s \in \mathbb{N}_+$ such that $c\colon (\Sigma^*)^{s_1} \times \dots \times (\Sigma^*)^{s_k} \to (\Sigma^*)^s$), and is defined by an equation $c((x_1^1, \dots, x_1^{s_1}), \dots, (x_k^1, \dots, x_k^{s_k})) = (u_1, \dots, u_s)$ where $u_1, \dots, u_s$ are strings of x_i^j's and symbols from Σ. We call c *linear* if each x_i^j occurs at most once in $u_1 \cdots u_s$. We sometimes write $[u_1, \dots, u_s]$ instead of c. Furthermore, setting $\mathit{sort}(c) = (s_1 \cdots s_k, s)$, the composition functions w.r.t. Σ form a sorted set.

The following example shows how linear composition functions are used in the rules of a multiple context-free grammar.

Example 1. Consider $G = (N, \Sigma, S, P)$ where $N = \{S, A, B\}$ and $\Sigma = \{\mathrm{a}, \mathrm{b}, \mathrm{c}, \mathrm{d}\}$ are finite sets (*non-terminals* and *terminals*, respectively), $S \in N$ (*initial non-terminal*) and P is a finite set (*rules*) that contains the following five objects:

$$\begin{aligned} &\rho_1 = S \to [x_1^1 x_2^1 x_1^2 x_2^2](A, B) \\ &\rho_2 = A \to [\mathrm{a}x_1^1, \mathrm{c}x_1^2](A) \qquad \rho_4 = A \to [\varepsilon, \varepsilon]() \\ &\rho_3 = B \to [\mathrm{b}x_1^1, \mathrm{d}x_1^2](B) \qquad \rho_5 = B \to [\varepsilon, \varepsilon](). \end{aligned}$$

We call G a multiple context-free grammar. Consider the rule ρ_1. Similar to a rule of a context-free grammar, ρ_1 rule has one left-hand side non-terminal (S) and zero or more right-hand side non-terminals (A and B). A *derivation of* G can be build by combining rules in P to form a tree according to their left- and right-hand side non-terminals. If a derivation starts with the initial non-terminal (here S), then it is called *complete*. Hence, each complete derivation in G has the form $d_{m,n} = \rho_1(\rho_2^m(\rho_4), \rho_3^n(\rho_5))$ for some $m, n \in \mathbb{N}$. If we replace each rule in a derivation by its composition function, we obtain a term of composition functions which can be evaluated. We call the resulting value the *yield* of a derivation. A derivation $d_{m,n}$ has yield $\mathrm{yd}(d_{m,n}) = \mathrm{a}^m \mathrm{b}^n \mathrm{c}^m \mathrm{d}^n$. The set of yields of all complete derivations is the *language of* G: $\mathcal{L}(G) = \{\mathrm{a}^m \mathrm{b}^n \mathrm{c}^m \mathrm{d}^n \mid m, n \in \mathbb{N}\}$. ☐

The following definition formalises the notions of ex. 1 and introduces some additional concepts.

Definition 2 (Seki et al., 1991)**.** A *multiple context-free grammar* (short: MCFG) is a tuple $G = (N, \Sigma, S, P)$ where N is a finite $\mathbb{N}_+$-sorted set (*non-terminals*), Σ is a finite set (*terminals*), $S \in N_1$ (*initial non-terminal*), P is a finite $(N^* \times N)$-sorted set of strings ρ of the form $A \to c(B_1, \dots, B_k)$ such that $A, B_1, \dots, B_k \in N$, c is a linear composition function, and $\mathit{sort}(c) =$

$(sort(B_1)\cdots sort(B_k), sort(A))$. The sort of ρ is $(B_1\cdots B_k, A)$. The *left-hand side* (short: lhs) of ρ is A. The *fanout of* ρ is $\mathrm{fanout}(\rho) = sort(A)$ and the *rank of* ρ is $rank(\rho) = k$. The elements of P are called *rules*.

The *set of derivations (resp. complete derivations) of* G is $\mathrm{D}_G = \mathrm{T}_P$ (resp. $\mathrm{D}^{\mathrm{c}}_G = (\mathrm{T}_P)_S$). Let $w \in \Sigma^*$ and $d = \rho(d_1,\dots,d_k) \in \mathrm{D}_G$ with $\rho = A \to c(B_1,\dots,B_k)$. The *yield of* d is $\mathrm{yd}(d) = c(\mathrm{yd}(d_1),\dots,\mathrm{yd}(d_k))$. The *set of derivations of* w *in* G is $\mathrm{D}^{\mathrm{c}}_G(w) = \mathrm{yd}^{-1}(w)\cap\mathrm{D}^{\mathrm{c}}_G$. The *language of* A *in* G is $\mathcal{L}(G,A) = \{\mathrm{yd}(d) \mid d \in (\mathrm{T}_P)_A\}$. The *language of* G is $\mathcal{L}(G) = \mathcal{L}(G,S)$. Any language generated by an MCFG is called *multiple context-free* (short: mcf). ☐

A *context-free grammar* (short: CFG) is an MCFG where each non-terminal has sort 1. Each rule of a CFG has the form $A \to [u_0 x^1_{i(1)} u_1 \cdots x^1_{i(n)} u_n](B_1,\dots,B_k)$. We abbreviate this rule by $A \to u_0 B_{i(1)} u_1 \cdots B_{i(n)} u_n$.

Weighted multiple context-free grammars. A weighted MCFG is obtained by assigning a weight to each rule of an (unweighted) MCFG. In this paper, the weights will be taken from a **p**artially **o**rdered **c**ommutative **mo**noid with **z**ero (short: POCMOZ). A *POCMOZ* is an algebra $(M,\odot,\mathbb{1},\mathbb{0},\trianglelefteq)$ where $\trianglelefteq$ is a partial order on M; $\odot$ is associative, commutative, decreasing (i.e. $m\odot m' \trianglelefteq m$), and monotonous (i.e. $m_1 \trianglelefteq m_2$ implies $m_1\odot m \trianglelefteq m_2\odot m$); $\mathbb{1}$ is neutral w.r.t. $\odot$; and $\mathbb{0}$ is absorbing w.r.t. $\odot$. We call M *factorisable* if for each $m \in M\setminus\{\mathbb{1}\}$, there are $m_1, m_2 \in M\setminus\{\mathbb{1}\}$ with $m = m_1\odot m_2$. The *probability algebra* $\mathrm{Pr} = ([0,1],\cdot,1,0,\leq)$ is a factorisable POCMOZ where $r = \sqrt{r}\cdot\sqrt{r}$ for each $r \in [0,1)$.

Example 3 (continues ex. 1). Consider the tuple (G,μ) where $\mu\colon P \to \mathrm{Pr}$ is a function where $\mu(\rho_1) = 1$, $\mu(\rho_2) = \mu(\rho_4) = 1/2$, $\mu(\rho_3) = 1/3$, and $\mu(\rho_5) = 2/3$. We call (G,μ) a weighted MCFG. The *weight* of the a derivation $d_{m,n}$ is obtained by multiplying the weights of all rule occurrences in it: $\mathrm{wt}(d_{m,n}) = 1/2^{m+1}\cdot 2/3^{n+1}$. ☐

Definition 4. A *weighted MCFG* (short: wMCFG) is a tuple (G,μ) where $G = (N,\Sigma,S,P)$ is an MCFG (*underlying MCFG*), $\mu\colon P \to M\setminus\{\mathbb{0}\}$ (*weight assignment*), and $(M,\odot,\mathbb{1},\mathbb{0},\trianglelefteq)$ is a factorisable POCMOZ.

(G,μ) inherits all objects associated with G. Let $d = \rho(d_1,\dots,d_k) \in \mathrm{D}_G$. The *weight of* d is $\mathrm{wt}(d) = \mu(\rho)\odot\bigodot_{i=1}^k \mathrm{wt}(d_i)$. ☐

For the rest of this paper, we fix a wMCFG (G,μ) *with underlying MCFG* $G = (N,\Sigma,S,P)$ *and weight assignment* $\mu\colon P \to M$.

Chomsky-Schützenberger theorem. In the Chomsky-Schützenberger theorem for CFGs (cf. sec. 1), D contains strings of brackets where each opening bracket is matched by the corresponding closing bracket. This property can be described with an equivalence relation. Let Δ be a set (of opening brackets) and $\bar\Delta$ be the set (of closing brackets) that contains $\bar\delta$ for each $\delta \in \Delta$. We define $\equiv_\Delta$ as the smallest equivalence relation where $u\,\delta\bar\delta\,v \equiv_\Delta uv$ for each $\delta \in \Delta$ and $u, v \in \Delta^*$. The *Dyck language w.r.t.* Δ is $\mathrm{D}_\Delta = [\varepsilon]_{\equiv_\Delta}$.

In the Chomsky-Schützenberger representation for MCFGs, the brackets fulfil three functions: (i) *terminal brackets* $[\![_\sigma\,]\!]_\sigma$ stand for a terminal symbol σ, (ii) *component brackets* $[\![^\ell_\rho$ and $]\!]^\ell_\rho$ denote beginning and end of substrings produced by the ℓ-th component of a rule ρ, and (iii) *variable brackets* $[\![^j_{\rho,i}$ and $]\!]^j_{\rho,i}$ denote beginning and end of substrings produced by variable x^j_i in a rule ρ. As for CFGs, each opening bracket must be matched by the corresponding closing bracket. Furthermore, because applying a rule of an MCFG produces multiple strings simultaneously, we need to ensure that the brackets corresponding to the same application of a rule occur simultaneously. This is described with another equivalence relation. Let $\mathfrak{P}$ be a partition of Δ. Intuitively, each cell of $\mathfrak{P}$ is a set of (opening) brackets that occur simultaneously. We define $\equiv_{\mathfrak{P}}$ as the smallest equivalence relation on $\mathcal{P}\big((\Delta\cup\bar\Delta)^*\big)$ where for each $\{\delta_1,\dots,\delta_s\} \in \mathfrak{P}$ with $|\{\delta_1,\dots,\delta_s\}| = s$, $u_0,\dots,u_s,v_1,\dots,v_s \in \mathrm{D}_\Delta$, and $L \subseteq (\Delta\cup\bar\Delta)^*$:

$$\begin{aligned} &\{u_0\;\delta_1 v_1\bar\delta_1\;u_1\cdots\;\delta_s v_s\bar\delta_s\;u_s\}\cup L\\ \equiv_{\mathfrak{P}}\;&\{u_0\cdots u_s,\;\;v_1\cdots v_s\}\qquad\;\cup L.\end{aligned}$$

The *multiple Dyck language w.r.t.* $\mathfrak{P}$ is $\mathrm{mD}_{\mathfrak{P}} = \bigcup(L \mid L \in [\{\varepsilon\}]_{\equiv_{\mathfrak{P}}})$. Note that $\mathrm{mD}_{\mathfrak{P}} \subseteq \mathrm{D}_\Delta$.

Theorem 5 provides a representation of each mcf language by a multiple Dyck language (see above), a recognisable language (to ensure local consistency), and a homomorphism (to decode the bracket sequences into terminal strings). The corresponding construction is recalled in def. 6.

Theorem 5 (cf. Yoshinaka et al., 2010, thm. 3). For every mcf language $L \subseteq \Sigma^*$ there are a homomorphism $h\colon(\Delta\cup\bar\Delta)^* \to \Sigma^*$, a regular language $R \subseteq (\Delta\cup\bar\Delta)^*$, and a multiple Dyck language $mD \subseteq (\Delta\cup\bar\Delta)^*$ such that $L = h(R\cap mD)$. ■

Definition 6 (Denkinger, 2017, def. 3.6, 4.9, 5.15)**.** The *multiple Dyck language w.r.t. G* is $\mathrm{mD}_G = \mathrm{mD}_{\mathfrak{P}_G}$ where $\mathfrak{P}_G$ is the smallest set that contains the cell $\{\llbracket_\sigma\}$ for each $\sigma \in \Sigma$ and the cells $\{\llbracket_\rho^\ell \mid \ell \in [sort(A)]\}$ and $\{\llbracket_{\rho,i}^j \mid j \in [sort(B_i)]\}$ for each $\rho = A \to c(B_1, \ldots, B_k) \in P$ and $i \in [k]$. Let $\Delta_G = \bigcup_{\mathfrak{p} \in \mathfrak{P}_G} \mathfrak{p}$. We denote the elements of $\overline{\Delta_G}$ by closing brackets, e.g. $\overline{\llbracket_\sigma} = \rrbracket_\sigma$, and let $\Omega_G = \Delta_G \cup \overline{\Delta_G}$.

The *homomorphism w.r.t. G*, denoted by hom_G, is the unique extension of $h\colon \Omega_G \to \Sigma \cup \{\varepsilon\}$ to strings where $h(\delta) = \sigma$ if δ is of the form $\llbracket_\sigma$ and $h(\delta) = \varepsilon$ otherwise.

The *automaton w.r.t. G*, denoted by $\mathcal{A}_G$, is the FSA $(Q, \Omega_G, S^1, \overline{S^1}, T)$ where $Q = \{A^\ell, \overline{A^\ell} \mid A \in N, \ell \in [sort(A)]\}$ and T is the smallest set such that for each rule $\rho \in P$ of the form

$$A \to [u_{1,0}y_{1,1}u_{1,1} \cdots y_{1,n_1}u_{1,n_1},\ \ldots,\\ u_{s,0}y_{s,1}u_{s,1} \cdots y_{s,n_s}u_{s,n_s}](B_1, \ldots, B_k)$$

where the ys are elements of X and the us are elements of Σ^*, we have (abbreviating $\llbracket_{\sigma_1}\rrbracket_{\sigma_2} \cdots \llbracket_{\sigma_k}\rrbracket_{\sigma_k}$ by $\widetilde{\sigma_1 \cdots \sigma_k}$) the following transitions in T:

(i) $\big(A^\ell,\ \llbracket_\rho^\ell \widetilde{u_{\ell,0}} \rrbracket_\rho^\ell,\ \bar{A}^\ell\big) \in T$ for every $\ell \in [s]$ with $n_\ell = 0$,

(ii) $\big(A^\ell,\ \llbracket_\rho^\ell \widetilde{u_{\ell,0}} \llbracket_{\rho,i}^j,\ B_i^j\big) \in T$ for every $\ell \in [s]$ where $n_\ell \neq 0$ and $y_{\ell,1}$ is of the form x_i^j,

(iii) $\big(\bar{B}_i^j,\ \rrbracket_{\rho,i}^j \widetilde{u_{\ell,\kappa}} \llbracket_{\rho,i'}^{j'},\ B_{i'}^{j'}\big) \in T$ for every $\ell \in [s]$ and $\kappa \in [n_\ell - 1]$ where $y_{\ell,\kappa}$ is of the form x_i^j and $y_{\ell,\kappa+1}$ is of the form $x_{i'}^{j'}$, and

(iv) $\big(\bar{B}_i^j,\ \rrbracket_{\rho,i}^j \widetilde{u_{\ell,n_\ell}} \rrbracket_\rho^\ell,\ \bar{A}^\ell\big) \in T$ for every $\ell \in [s]$ where $n_\ell \neq 0$ and y_{ℓ,n_ℓ} is of the form x_i^j.

We abbreviate $\mathcal{L}(\mathcal{A}_G)$ by $\mathcal{R}_G$. ☐

Example 7 (continues ex. 1)**.** The automaton w.r.t. G is shown in fig. 1. An illustration of the application of $\equiv_{\mathfrak{P}_G}$ is given in the appendix (p. 11). ☐

The vanilla parser. The *vanilla parser* (i.e. alg. 3 from Denkinger, 2017), is shown in fig. 2 (top). Similar to the parser proposed by Hulden (2011), we divide it in three essential phases: (i) FSA constructions for the intersection of $\mathrm{hom}_G^{-1}(w)$ and $\mathcal{R}_G$, (ii) an extraction of (in our case *multiple*) Dyck words from the intersection, and (iii) the conversion of words into derivations.

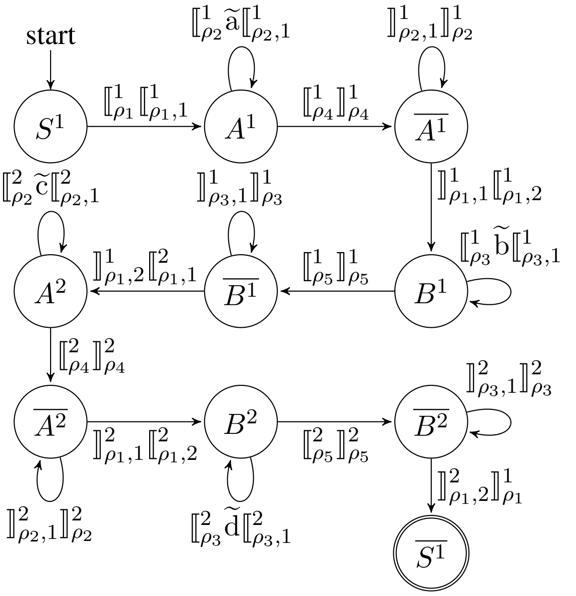

Figure 1: Automaton w.r.t. G, cf. ex. 7.

Formally, the vanilla parser is the function $V\colon \Sigma^* \to (\mathrm{D}_G^{\mathrm{c}})^\omega$ defined as

$$V = \textsc{map}(\textsc{toDeriv}) \circ \textsc{filter}(\mathrm{mD}_G)\\ \circ \textsc{sort}(\mu') \circ (\cap\, \mathcal{R}_G) \circ \mathrm{hom}_G^{-1}$$

where $\mathrm{hom}_G^{-1}(w) \cap \mathcal{R}_G$ is represented by an FSA for each $w \in \Sigma^*$ (phase (i)). $\mu'(u)$ is the product of the weights of each occurrence of a bracket of the form $\llbracket_\rho^\ell$ or $\rrbracket_\rho^\ell$ in u. These weights are fixed such that $\mu'\big(\llbracket_\rho^1\rrbracket_\rho^1 \cdots \llbracket_\rho^\ell\rrbracket_\rho^\ell\big) = \mu(\rho)$ for each $\rho \in P$ with fanout ℓ. $\textsc{sort}(\mu')$ brings the elements of its argument, which is a subset of $\Omega_G{}^*$, in some descending order w.r.t. μ' and $\trianglelefteq$, returning a (possibly infinite) sequence of elements of $\Omega_G{}^*$, which we call *candidates*. Sequences are implemented as iterators. $\textsc{filter}(\mathrm{mD}_G)$ removes the candidates from its argument sequence that are not in mD_G while preserving the order (cf. Denkinger, 2017, alg. 2). (Both steps, $\textsc{sort}(\mu')$ and $\textsc{filter}(\mathrm{mD}_G)$, are phase (ii).) $\textsc{toDeriv}$ returns the derivation in G that corresponds to its argument (which is from the set $\mathcal{R}_G \cap \mathrm{mD}_G$), cf. Denkinger (2017, function fromBrackets, p. 20). $\textsc{map}(\textsc{toDeriv})$ applies $\textsc{toDeriv}$ to each candidate in its argument while preserving the order (phase (iii)).

Denkinger (2017, thm. 5.22) showed that $\textsc{take}(n) \circ V$ solves the n-best parsing problem.[1] We omit the additional restrictions that he imposed on the given wMCFG because they are only necessary to show the termination of his algorithm.

---

[1] In the following, we will gloss over the distinction between derivations and parses.

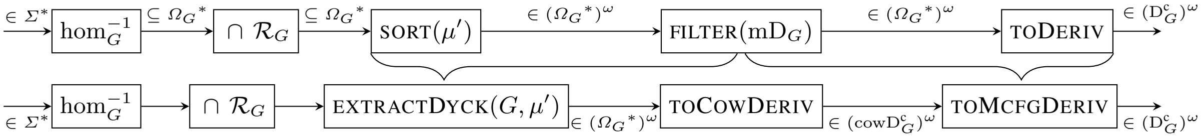

Figure 2: Visualisation of the vanilla parser (top) and the parser with the optimisations from sec. 4 (bottom).

3 Component-Wise Derivations

In sec. 4, we will outline modifications to the vanilla parser that make the extraction of the elements of mD_G from $\mathrm{hom}_G^{-1}(w) \cap \mathcal{R}_G$ efficient (items 2–4). To facilitate this, we first decompose FILTER(mD_G) into FILTER(mD_G) $\circ$ FILTER(D_{Δ_G}), which is possible because $\mathrm{D}_{\Delta_G} \supseteq \mathrm{mD}_G$. Secondly, we implement FILTER(D_{Δ_G}) $\circ$ SORT(μ') with a dynamic programming algorithm (cf. Hulden, 2011, alg. 1, similar to Bar-Hillel et al., 1961, sec. 8). And lastly, we replace FILTER(mD_G) by steps that exploit the well-bracketing of the elements of D_{Δ_G}.

The elements of $\mathcal{R}_G \cap \mathrm{D}_{\Delta_G}$ can be represented as trees over rules of G.[2] We label the edges of those trees to allow us to check if vertices that correspond to the same application of a rule of the MCFG G match. The resulting objects are called *component-wise derivations*. The set $\mathcal{R}_G \cap \mathrm{D}_{\Delta_G}$ is characterised in terms a CFG G_{cf}.

Definition 8. Let $\rho \in P$ be a rule of the form $A \to [u_1, \ldots, u_s](B_1, \ldots, B_k)$, $\ell \in [s]$, and u_ℓ be of the form $w_0 x_{i(1)}^{j(1)} w_1 \cdots x_{i(n)}^{j(n)} w_n$ for some $w_0, \ldots, w_n \in \Sigma^*$. We define the rule

$$\rho^{(\ell)} = A^\ell \to \llbracket^\ell_\rho \widetilde{w_0} v_1 \widetilde{w_1} \cdots v_n \widetilde{w_n} \rrbracket^\ell_\rho$$

where each $v_\kappa = \llbracket^{j(\kappa)}_{\rho,i(\kappa)} B^{j(\kappa)}_{i(\kappa)} \rrbracket^{j(\kappa)}_{\rho,i(\kappa)}$. The *context-free CS approximation of G* (short: *CFA*), denoted by G_{cf}, is the CFG $(N_{\mathrm{cf}}, \Omega_G, S^1, P_{\mathrm{cf}})$ where $N_{\mathrm{cf}} = \{A^\ell \mid A \in N, \ell \in [\mathit{sort}(A)]\}$ and $P_{\mathrm{cf}} = \{\rho^{(\ell)} \mid \rho \in P, \ell \in [\mathrm{fanout}(\rho)]\}$. ☐

Observation 9. $\mathrm{D}_{\Delta_G} \cap \mathcal{R}_G = \mathcal{L}(G_{\mathrm{cf}})$. ■

We introduce *component-wise derivations* to relate the derivations of G_{cf} with those of G.

Definition 10. Let $\ell \in \mathbb{N}_+$ and t be a tree whose vertices are labelled with elements of P and whose edges are labelled with elements of $\mathbb{N}_+ \times \mathbb{N}_+$. The *label at the root of t* is denoted by $\mathrm{root}(t)$. The *set of labels of the outgoing edges from the root of t* is denoted by $\mathrm{out}(t)$. A (i,j)-*subtree of t*, is a sub-graph of t consisting of all the vertices (and their edges) reachable from some target vertex of the outgoing edge from the root that is labelled with (i,j). If there is a unique (i,j)-subtree of t, then we denote it by $\mathrm{sub}_{(i,j)}(t)$. Now let $\mathrm{root}(t) = A \to [u_1, \ldots, u_s](B_1, \ldots, B_k)$. We call t an *(ℓ-)component-wise derivation, short: (ℓ-)cow derivation, of G* if the following four requirements are met: (i) $\mathrm{out}(t)$ contains exactly the pairs (i,j) such that x_i^j occurs in u_ℓ, (ii) a unique (i,j)-subtree of t exists, (iii) $\mathrm{root}(\mathrm{sub}_{(i,j)}(t))$ has lhs B_i, and (iv) $\mathrm{sub}_{(i,j)}(t)$ is a j-cow derivation for each $(i,j) \in \mathrm{out}(t)$. We denote the set of cow derivations of G whose root's lhs is S by $\mathrm{cowD}^{\mathrm{c}}_G$. The set of ℓ-cow derivations whose root's label has lhs A is denoted by $\ell\text{-}\mathrm{cowD}^{A}_G$. ☐

An example of a cow derivation is shown in fig. 3a. The root is the top-most vertex.

Definition 11. Let $\rho = A \to c(B_1, \ldots, B_k) \in P$, $\ell \in [\mathrm{fanout}(\rho)]$, and the ℓ-th component of c be $u_0 x_{i(1)}^{j(1)} u_1 \cdots x_{i(n)}^{j(n)} u_n$ with $u_1, \ldots, u_n \in \Sigma^*$. Furthermore, for each $\kappa \in [n]$, let $t_\kappa \in j(\kappa)\text{-}\mathrm{cowD}^{B_{i(\kappa)}}_G$. By $\rho\langle (i(\kappa), j(\kappa))/t_\kappa \mid \kappa \in [n] \rangle$, we denote the cow derivation t such that $\mathrm{root}(t) = \rho$, $\mathrm{out}(t) = \{(i(\kappa), j(\kappa)) \mid \kappa \in [n]\}$, and for each $\kappa \in [n]$: $\mathrm{sub}_{(i(\kappa), j(\kappa))}(t) = t_\kappa$. ☐

Lemma 12. There is a bijection toCowD between $\mathcal{L}(G_{\mathrm{cf}})$ and $\mathrm{cowD}^{\mathrm{c}}_G$. ■

Proof sketch. We define the partial function toCowD from ${\Omega_G}^*$ to cow derivations of G as follows: $\mathrm{toCowD}(u) = \rho\langle (i(\kappa), j(\kappa))/\mathrm{toCowD}(v_\kappa) \mid \kappa \in [n] \rangle$ if u is of the form

$$\llbracket^\ell_\rho \widetilde{u_0} \llbracket^{j(1)}_{\rho,i(1)} v_1 \rrbracket^{j(1)}_{\rho,i(1)} \widetilde{u_1} \ldots \llbracket^{j(n)}_{\rho,i(n)} v_n \rrbracket^{j(n)}_{\rho,i(n)} \widetilde{u_n} \rrbracket^\ell_\rho$$

for some rule $\rho = A \to c(B_1, \ldots, B_k)$ where the ℓ-th component of c is $u_0 x_{i(1)}^{j(1)} u_1 \cdots x_{i(n)}^{j(n)} u_n$ with $u_1, \ldots, u_n \in \Sigma^*$; otherwise, $\mathrm{toCowD}(u)$ is undefined. The partial function toCowD is a bijection between $\mathcal{L}(G_{\mathrm{cf}})$ and $\mathrm{cowD}^{\mathrm{c}}_G$ (proven in appendix A.2). ■

---

[2] Those trees correspond to the derivations of the *guiding grammar* in the coarse-to-fine parsing approach of Barthélemy et al. (2001, sec. 3).

Example 13 (continues ex. 1)**.** We construct $G_{\text{cf}} = (\{S^1, A^1, A^2, B^1, B^2\}, \varOmega_G, S^1, P_{\text{cf}})$ where P_{cf} contains, among others, the following rules:

$$\begin{aligned}
\rho_1^{(1)} &= S^1 \to \llbracket^1_{\rho_1} \llbracket^1_{\rho_1,1} A^1 \rrbracket^1_{\rho_1,1} \llbracket^1_{\rho_1,2} B^1 \rrbracket^1_{\rho_1,2} \\
&\qquad\qquad \llbracket^2_{\rho_1,1} A^2 \rrbracket^2_{\rho_1,1} \llbracket^2_{\rho_1,2} B^2 \rrbracket^2_{\rho_1,2} \rrbracket^1_{\rho_1}, \\
\rho_3^{(1)} &= B^1 \to \llbracket^1_{\rho_3} \widetilde{\mathrm{b}} \llbracket^1_{\rho_3,1} B^1 \rrbracket^1_{\rho_3,1} \rrbracket^1_{\rho_3}, \\
\rho_4^{(1)} &= A^1 \to \llbracket^1_{\rho_4} \rrbracket^1_{\rho_4}, \quad \rho_4^{(2)} = A^2 \to \llbracket^2_{\rho_4} \rrbracket^2_{\rho_4}, \\
\rho_5^{(1)} &= B^1 \to \llbracket^1_{\rho_5} \rrbracket^1_{\rho_5}, \quad \ldots .
\end{aligned}$$

Figure 3a shows the image of the word

$$\begin{aligned}
&\llbracket^1_{\rho_1} \llbracket^1_{\rho_1,1} \llbracket^1_{\rho_4} \rrbracket^1_{\rho_4} \rrbracket^1_{\rho_1,1} \\
&\quad \llbracket^1_{\rho_1,2} \llbracket^1_{\rho_3} \widetilde{\mathrm{b}} \llbracket^1_{\rho_3,1} \llbracket^1_{\rho_5} \rrbracket^1_{\rho_5} \rrbracket^1_{\rho_3,1} \rrbracket^1_{\rho_3} \rrbracket^1_{\rho_1,2} \\
&\quad \llbracket^2_{\rho_1,1} \llbracket^2_{\rho_4} \rrbracket^2_{\rho_4} \rrbracket^2_{\rho_1,1} \quad \llbracket^2_{\rho_1,2} \llbracket^2_{\rho_5} \rrbracket^2_{\rho_5} \rrbracket^2_{\rho_1,2} \rrbracket^1_{\rho_1}
\end{aligned}$$

in $\mathcal{L}(G_{\text{cf}})$ under toCowD. □

In the following, we define a property called *consistency* to discern those cow derivations that correspond to derivations of the MCFG G.

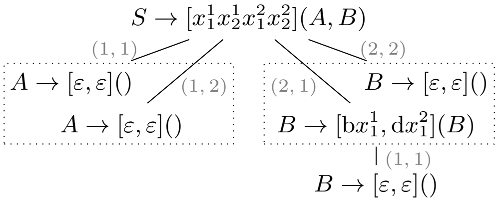
Definition 14. Let $s \in \mathbb{N}_+$ and $t_1, \ldots, t_s$ be cow derivations of G. We call the set $\{t_1, \ldots, t_s\}$ *consistent* if there is a rule $\rho = A \to c(B_1, \ldots, B_k) \in P$ such that $\mathrm{root}(t_1) = \ldots = \mathrm{root}(t_s) = \rho$, $s = \mathit{sort}(A)$, and for each $i \in [k]$: the set $\{\mathrm{sub}_{(i,j)}(t_\ell) \mid \ell \in [s], j \in [\mathit{sort}(B_i)]\colon (i,j) \in \mathrm{out}(t_\ell)\}$ is consistent. If $s = 1$, then we also call t_1 *consistent*. □

The cow derivation shown in fig. 3a is *not* consistent. If we consider the set of nodes that is reachable from the root via edges labelled with a tuple whose first component is 2 (the right dotted box), then it is easy to see that the rules at these nodes are not equal. A consistent cow derivation is shown in the appendix (fig. 6).

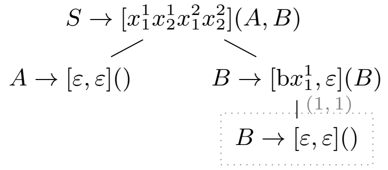
Proposition 15. $\textsc{toDeriv} \circ \mathrm{toCowD}^{-1}$ is a bijection between the consistent cow derivations in $\mathrm{cowD}^{\mathrm{c}}_G$ and $\mathrm{D}^{\mathrm{c}}_G$. ■

4 Optimisations

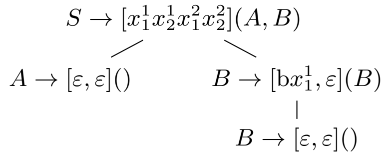
In this section, we describe several improvements to the vanilla parser (cf. end of sec. 2). Since the definitions of $\mathcal{A}_G$, hom_G, and mD_G do not depend on the word w, we may compute appropriate representations for these objects before the beginning of the parsing process, and store them persistently.



(a) A cow derivation. The dotted boxes show clusters of nodes that are reachable from the root via edges labelled with matching first components.



(b) Construction of new rules for each cluster in fig. 3a. If there were any unused nonterminals in these constructed rules, they are removed and the indices of variables changed accordingly. For each cluster, all reachable nodes are clustered via the first component of the labels as in fig. 3a.



(c) Construction of new rules from the clusters in fig. 3b.

Figure 3: A strategy to convert a non-consistent cow derivation into a complete derivation of an MCFG.

In the following, we briefly describe each improvement that we applied to the vanilla parser:

1. Let us call a rule ρ in G *w-consistent* if each string of terminals that occurs in (the composition function of) ρ is a substring of w. A rule is called *useful w.r.t. w* if it occurs in some complete derivation of G in which each rule is w-consistent. In the construction of the FSA for $\mathcal{R}_G \cap \mathrm{hom}_G^{-1}(w)$, we only calculate the transitions that relate to rules of G that are useful w.r.t. w.

2. The function $\textsc{filter}(\mathrm{mD}_G)$ is decomposed into $\textsc{filter}(\mathrm{mD}_G) \circ \textsc{filter}(\mathrm{D}_{\Delta_G})$ in preparation for the next two items.

3. $\textsc{filter}(\mathrm{D}_{\Delta_G}) \circ \textsc{sort}(\mu')$ is implemented with the algorithm $\textsc{extractDyck}(G, \mu')$ that uses dynamic programming to extract Dyck words from the language of the given FSA more efficiently. For this, we extend alg. 1 by Hulden (2011) to use weights such that it returns the elements in descending order w.r.t. μ' and $\trianglelefteq$ (see appendix A.3, alg. 3). In our implementation, we change this al-

Algorithm 1 reads off cow derivations from words of the CFA of G.

Input: $v \in \mathcal{L}(G_{\mathrm{cf}})$

Output: $\mathrm{toCowD}(v)$

```
function TOCOWDERIV($v$)
    $t \leftarrow$ empty graph
    $v \leftarrow$ new vertex
    $pd \leftarrow \varepsilon$                    ▷ pushdown of vertices
    for all $\sigma$ in $v$ from left to right do
        if $\sigma$ is of the form $[\![^{\ell}_{\rho}$ then
            add vertex $v$ to $t$ with label $\rho$
            push vertex $v$ on top of $pd$
        else if $\sigma$ is of the form $[\![^{j}_{\rho,i}$ then
            $v' \leftarrow$ top-most vertex on $pd$
            $v \leftarrow$ new vertex
            add edge $(v' \to v)$ to $t$ with label $(i, j)$
        else if $\sigma$ is of the form $]\!]^{j}_{\rho,i}$ then
            remove top-most vertex from $pd$
    return $t$
```

gorithm even further such that items are explored in a similar fashion as in the CKY-algorithm (Kasami, 1966; Younger, 1967; Cocke and Schwartz, 1970).

4. For FILTER(mD_G), instead of *isMember*$'$ by Denkinger (2017, p. 28–30), which runs in quadratic time, we use the composition of two algorithms that run in linear time:
    - alg. 1, which reads a cow derivation off a given word in $\mathcal{R}_G \cap \mathrm{D}_{\Delta_G}$, and
    - an algorithm that checks a given cow derivation for consistency. (This is similar to alg. 2; but instead of derivations, we return Boolean values. The algorithm is given explicitly in sec. A.3.)

5. Algorithm 2 computes the bijection between $\mathrm{cowD}^{\mathrm{c}}_G$ and $\mathrm{D}^{\mathrm{c}}_G$ (see prop. 15). Analogously to def. 14, the function TOMCFGDERIV' checks a set of cow derivations for equivalence of the root symbol and the function COLLECTCHILDREN groups the subtrees via the first component of the successor labels. It is easy to see that TOMCFGDERIV(t) is only defined if the cow derivation t is consistent (cf. item 4). Thus, we use TOMCFGDERIV in combination with TOCOWDERIV to replace MAP(TODERIV) $\circ$ FILTER(mD_G).

Algorithm 2 converts a consistent element of $\mathrm{cowD}^{\mathrm{c}}_G$ into a complete derivation of G.

Input: $t \in \mathrm{cowD}^{\mathrm{c}}_G$

Output:
$$\begin{cases} \text{TODERIV}\big(\mathrm{toCowD}^{-1}(t)\big) & \text{if } t \text{ is consistent} \\ \text{undefined} & \text{otherwise} \end{cases}$$

```
function TOMCFGDERIV($t$)
    return TOMCFGDERIV'($\{t\}$)

function TOMCFGDERIV'($T$)
    if not $\bigwedge_{t,t' \in T} \big(\mathrm{root}(t) = \mathrm{root}(t')\big)$ then
        return undefined
    $(T_1, \ldots, T_k) \leftarrow$ COLLECTCHILDREN($T$)
    for $i \in [k]$ do
        $t_i \leftarrow$ TOMCFGDERIV'($T_i$)
        if $t_i =$ undefined then
            return undefined
    $\{\sigma\} \leftarrow \big\{\mathrm{root}(t) \mid t \in T\big\}$
    return $\sigma(t_1, \ldots, t_k)$

function COLLECTCHILDREN($T$)
    $\{k\} \leftarrow \big\{rank(\mathrm{root}(t)) \mid t \in T\big\}$
    for $i \in [k]$ do
        $T_i \leftarrow \big\{\mathrm{sub}_{(i,j)}(t) \mid t \in T, (i, j) \in \mathrm{out}(t)\big\}$
    return $(T_1, \ldots, T_k)$
```

The time complexity of alg. 2 is linear in the number of vertices of the given cow derivation. This number, in turn, is linear in the length of the processed candidate.

The parser obtained by applying items 1 to 5 to the vanilla parser is visualised in fig. 2 (bottom). It is sound and complete.[3] The following two modifications (items 6 and 7) destroy both soundness and completeness. Item 6 allows only the best intermediate results to be processed further and limits the results to a subset of those of the vanilla parser. In item 7, we compensate this by an approximation we consider useful in practise.

6. EXTRACTDYCK is extended with an optional implementation of beam search by limiting the amount of items for certain groups of state spans to a specific number (*beam width*), cf. Collins (1999). In our implementation, we chose these groups of state spans such that they correspond to equal states in

---

[3] A parser is *complete* if it (eventually) computes all complete derivations of the given word in the given grammar. A parser is called *sound* if all computed parses are complete derivations of the given word in the given grammar.

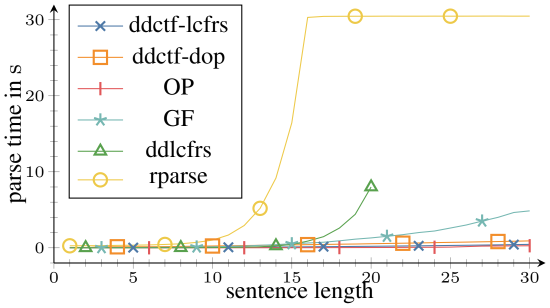
the automaton for $\hom_G^{-1}(w)$. Moreover, we introduce a variable that limits the number of candidates that are yielded by Algorithm 3 (*candidate count*). Both variables are the *meta-parameters* of our parser.

7. We introduce a fallback mechanism for the case that $\text{FILTER}(\text{mD}_G)$ has input candidates but an empty output. Usually, in that case, we would suggest there is no derivation for w in G, yet for robustness, it is preferable to output some parse. Figure 3 illustrates a strategy to construct a complete derivation from any complete *cow* derivation with an example.

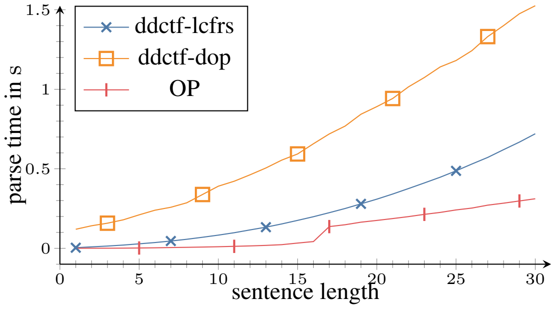
5 Evaluation and Conclusion

We implemented the parser with the modifications sketched in sec. 4 for ε-free and simple wMCFGs,[4] but no problems should arise generalising this implementation to arbitrary wMCFGs. The implementation is available as a part of Rustomata,[5] a framework for weighted automata with storage written in the programming language Rust. We used the *NeGra corpus* (German newspaper articles, 20,602 sentences, 355,096 tokens; Skut et al., 1998) to compare our parser to *Grammatical Framework* (Angelov and Ljunglöf, 2014), *rparse* (Kallmeyer and Maier, 2013), and *disco-dop* (van Cranenburgh et al., 2016) with respect to parse time and accuracy.[6] Our experiments were conducted on defoliated trees, i.e. we removed the leaves from each tree in the corpus. Parsing was performed on gold part-of-speech tags.

We performed a variant of *ten-fold cross validation* (short: TFCV; cf. Mosteller and Tukey, 1968), i.e. we split the corpus into ten consecutive parts; each part becomes the validation set in one iteration while the others serve as training set. We used the first iteration to select suitable values for our meta-parameters and the remaining nine for validation. In case of Rustomata, a binarised and markovized grammar was induced with discodop (head-outward binarisation, $v = 1$, $h = 2$, cf. Klein and Manning, 2003) in each iteration. For all other parsers, we induced a probabilistic LCFRS with the respective default configurations (for details, cf. the evaluation scripts). After that, we ran our parser on each sentence of the validation set and recorded the parse time and the computed 1-best parse. The computed parses were evaluated against the gold parses of the validation set w.r.t. precision, recall, and f_1-score (according to the labelled parseval measures, cf. Black et al., 1991; Collins, 1997, we used the implementation by van Cranenburgh et al., 2016).



(a) NeGra corpus, $|w| \leq 30$ (for ddlcfrs: $|w| \leq 20$)



(b) Lassy corpus, $|w| \leq 30$

Figure 4: Median parse times

Previous experiments with an implementation of the vanilla parser already struggled with small subsets (we used grammars extracted from 250–1500 parse trees) of the NeGra corpus. Therefore, we omit evaluation of the vanilla parser.

Meta-parameters. A grid search for meta-parameters was performed on sentences of up to 20 tokens (see the appendix, tab. 2, for a detailed listing). The results suggested to set the beam width to 200 and the candidate count to 10,000.

Comparison to other parsers. The experiments were performed on sentences with up to 30 tokens. We instructed rparse, Grammatical Framework (short: GF) and Rustomata (short: OP) to stop parsing each sentence after 30 seconds (*timeout*). Disco-dop did not permit passing a timeout. In the case of disco-dop's LCFRS parser (short: ddlcfrs), we limited the validation set to sentences

---

[4] A wMCFG G is called ε-free and simple if each composition function that occurs in the rules of G is either of the form $[u_1, \ldots, u_s]$ for some non-empty strings of variables $u_1, \ldots, u_s$, or of the form $[t]$ for some terminal symbol t.

[5] available on `https://github.com/tud-fop/rustomata`. We used commit `867a451` for evaluation.

[6] The evaluation scripts are available on `https://github.com/truprecht/rustomata-eval`.

parser	precision	recall	f_1-score	coverage
NeGra corpus, $\lvert w\rvert \leq 20$				
ddctf-dop	81.34	81.44	81.39	100%

Lassy corpus, $\lvert w\rvert \leq 30$				
ddctf-dop	73.78	73.37	73.57	100%
ddctf-lcfrs	61.23	59.73	60.52	100%
OP	50.92	51.42	51.17	100%

Table 1: Precision, recall, f_1-score, and coverage

of at most 20 tokens, since ddlcfrs frequently exceeded 30 seconds of parse time for longer sentences in preliminary tests. Disco-dop's coarse-to-fine data-oriented parser (short: ddctf-dop) and disco-dop's coarse-to-fine LCFRS parser (short: ddctf-lcfrs) rarely exceeded 30 seconds of parse time in preliminary tests and we let them run on sentences of up to 30 tokens without the timeout.

Figure 4a shows the parse times for each sentence length and parser. The parsers ddctf-dop, ddctf-lcfrs, GF, and OP perform similar for sentences of up to 20 tokens. The parse times of rparse and ddlcfrs grow rapidly after 10 and 16 tokens, respectively. Rparse even exceeds the timeout for more than half of the test sentences that are longer than 15 tokens. For sentences with up to 30 tokens, the parse times of ddctf-dop, ddctf-lcfrs and OP seem to remain almost constant.

Table 1 shows the accuracy (i.e. precision, recall, and f_1-score) and the coverage (i.e. the percentage of sentences that could be parsed) for each parser on the validation set. We report these scores to assert a correct implementation of our parser and to compare the different approximation strategies (and our fallback mechanism) implemented in the parsers. The low coverage of rparse stems from the frequent occurrences of timeouts. They also depress the recall for rparse. For sentences with at most 20 tokens, ddlcfrs, ddctf-lcfrs and OP perform very similar. These three parsers are outperformed by ddctf-dop in all aspects. For sentences of up to 30 tokens, the scores of all tested parsers drop similarly. However, ddctf-dop's scores drop the least amount.

We repeated a part of the experiments with the Lassy corpus (Lassy Small, various kinds of written Dutch, 65,200 sentences, 975,055 tokens; van Noord et al., 2013). Since it is considerably larger than the NeGra corpus, we limited the experiments to one iteration of TFCV, and we only investigate OP, ddctf-lcfrs, and ddctf-dop. The results are shown in fig. 4b (parse time) and at the bottom of tab. 1 (accuracy). Figure 4b shows the difference of ddctf-lcfrs, ddctf-dop and OP in terms of parse times (which is not discernible in fig. 4a). This plot shows that OP maintains very small parse times – even for large copora – compared to the state-of-the-art parser disco-dop.

All in all, our parser performs comparable to state-of-the-art MCFG parsers (GF, rparse, ddlcfrs, ddctf-lcfrs) and, using the NeGra corpus, it shows excellent results in parse time and good results in accuracy. Moreover, our parser can deal with any ε-free and simple MCFG provided by an external tool, making it more flexible than disco-dop and rparse. However, we are not able to compete with ddctf-dop in terms of accuracy, since discontinuous data-oriented parsing is a more accurate formalism (van Cranenburgh and Bod, 2013).

6 Future Work

We see potential to improve the fallback mechanism explained in sec. 4. For now, we only considered reporting the first cow derivation. By introducing some *degree of consistency* of cow derivations, we could select a cow derivation that is closer to a derivation of G.

Since recognisable languages are closed under inverse homomorphisms, we can use any recognisable language as input for $\hom_G^{-1}$ (cf. fig. 2) without changing the rest of the pipeline. This is useful when the input of the parsing task is ambiguous, as in lattice-based parsing (e.g. Goldberg and Tsarfaty, 2008).

Moreover, since weighted recognisable languages are closed under inverse homomorphisms and scalar product, we can even use a weighted recognisable language as input for $\hom_G^{-1}$, as in the setting of Rastogi et al. (2016).

A Appendices

A.1 Additional Examples

Example 1 (continuing from p. 2)**.** Figure 5 shows graphical representations of a derivation and the corresponding term over composition functions. □

Example 7 (continuing from p. 4)**.** The following calculation reduces a word of $\mathcal{A}_G$ to ε using the equivalence relation $\equiv_{\mathfrak{P}_G}$ (abbreviated by $\equiv$) and thereby proves that it is an element of mD_G. In each step, we point out, which cell of $\mathfrak{P}_G$ was/were used. Note that the set obtained after two applications of $\equiv$ has two elements.

$$\begin{aligned}
&\Big\{ \llbracket^1_{\rho_1} \llbracket^1_{\rho_{1,1}} \llbracket^1_{\rho_4} \rrbracket^1_{\rho_4} \rrbracket^1_{\rho_{1,1}} \llbracket^1_{\rho_{1,2}} \llbracket^1_{\rho_3} \widetilde{\mathrm{b}} \llbracket^1_{\rho_{3,1}} \llbracket^1_{\rho_5} \rrbracket^1_{\rho_5} \rrbracket^1_{\rho_{3,1}} \rrbracket^1_{\rho_3} \rrbracket^1_{\rho_{1,2}} \\

\end{aligned}$$

A.2 Additional Proofs

Lemma 12. There is a bijection toCowD between $\mathcal{L}(G_{\mathrm{cf}})$ and $\mathrm{cowD}^{\mathrm{c}}_G$.

Proof. For each $\ell \in \mathbb{N}_+$, we define the partial function f_ℓ from $(\varDelta_G \cup \overline{\varDelta_G})^*$ to ℓ-cow derivations of G as follows: $f_\ell(u) = \rho\big\langle (i(\kappa), j(\kappa))/f_{j(\kappa)}(v_\kappa) \mid \kappa \in [n]\big\rangle$ if u is of the

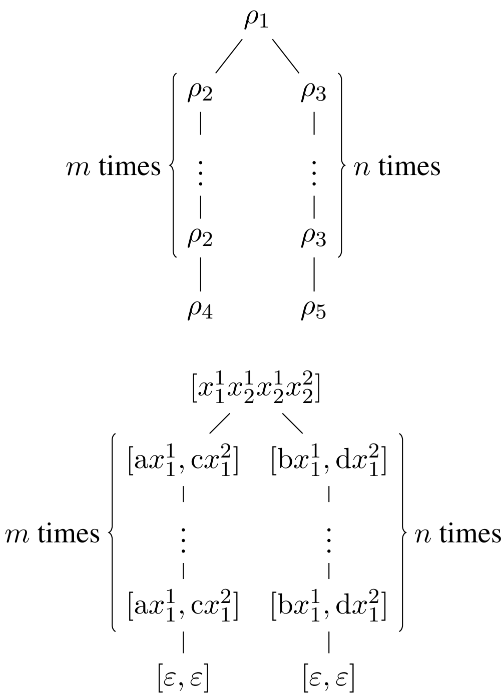

Figure 5: A derivation $d_{m,n}$ (top) together with the corresponding term over composition functions (bottom), cf. ex. 1.

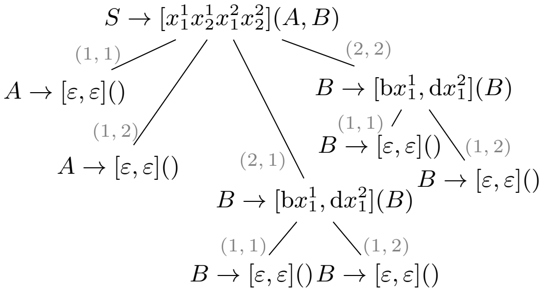

Figure 6: A consistent cow derivation.

form

$$\llbracket^{\ell}_{\rho}\ \widetilde{u_0}\llbracket^{j(1)}_{\rho,i(1)} v_1\rrbracket^{j(1)}_{\rho,i(1)}\widetilde{u_1}\cdots\llbracket^{j(n)}_{\rho,i(n)} v_n\rrbracket^{j(n)}_{\rho,i(n)}\widetilde{u_n}\ \rrbracket^{\ell}_{\rho}$$

for some rule $\rho = A \to c(B_1, \ldots, B_k)$ where the ℓ-th component of c is $u_0 x^{j(1)}_{i(1)} u_1 \cdots x^{j(n)}_{i(n)} u_n$ with $u_1, \ldots, u_n \in \Sigma^*$; otherwise, $f_\ell(u)$ is undefined. Note that $f_1, f_2, \ldots$ are pairwise disjoint (in the set-theoretic sense).

To prove that the function f_ℓ is bijective, we show that it is injective and surjective.

(Injectivity) We show, for each $\ell \in \mathbb{N}_+$, by induction on the structure of cow derivations that $f_\ell(v) = f_\ell(v')$ implies $v = v'$ for each v, v' in the domain of f_ℓ (i.e. $f_\ell(v)$ and $f_\ell(v')$ are both defined).

Let $v, v' \in (\Delta_G \cup \overline{\Delta_G})^*$ be in the domain of f_ℓ and let $t = f_\ell(v) = f_\ell(v')$. Furthermore, let $\rho = A \to c(B_1, \ldots, B_k) = \mathrm{root}(t)$, $t_{(i,j)} = \mathrm{sub}_{(i,j)}(t)$ for each $(i,j) \in \mathrm{out}(t)$, and let the ℓ-th component of c be of the form $u_0 x^{j(1)}_{i(1)} u_1 \cdots x^{j(n)}_{i(n)} u_n$ with $u_1, \ldots, u_n \in \Sigma^*$. By definition of f_ℓ, we know that u is the string

$$\llbracket^{\ell}_{\rho}\ \widetilde{u_0}\llbracket^{j(1)}_{\rho,i(1)} v_1\rrbracket^{j(1)}_{\rho,i(1)}\widetilde{u_1}\cdots\llbracket^{j(n)}_{\rho,i(n)} v_n\rrbracket^{j(n)}_{\rho,i(n)}\widetilde{u_n}\ \rrbracket^{\ell}_{\rho}$$

for some $v_1, \ldots, v_n \in (\Delta_G \cup \overline{\Delta_G})^*$, u' is the string

$$\llbracket^{\ell}_{\rho}\ \widetilde{u_0}\llbracket^{j(1)}_{\rho,i(1)} v'_1\rrbracket^{j(1)}_{\rho,i(1)}\widetilde{u_1}\cdots\llbracket^{j(n)}_{\rho,i(n)} v'_n\rrbracket^{j(n)}_{\rho,i(n)}\widetilde{u_n}\ \rrbracket^{\ell}_{\rho}$$

for some $v'_1, \ldots, v'_n \in (\Delta_G \cup \overline{\Delta_G})^*$, and $f_{j(\kappa)}(v_\kappa) = f_{j(\kappa)}(v'_\kappa) = t_{(i(\kappa),j(\kappa))}$ for each $\kappa \in [n]$. By principle of induction, we get $v_\kappa = v'_\kappa$ for each $\kappa \in [n]$. Hence $v = v'$.

(Surjectivity) We show by induction on the structure of cow derivations that for each $A \in N$, $\ell \in \mathit{sort}(A)$, and $t \in \ell\text{-cowD}^A_G$, there is a string $v \in \mathcal{L}(G_{\mathrm{cf}}, A^\ell)$ such that $f_\ell(v) = t$.

Let $A \in N$, $\ell \in \mathit{sort}(A)$, and $t \in \ell\text{-cowD}^A_G$. Furthermore, let $\rho = A \to c(B_1, \ldots, B_k) = \mathrm{root}(t)$, $t_{(i,j)} = \mathrm{sub}_{(i,j)}(t)$ for each $(i,j) \in \mathrm{out}(t)$, and let the ℓ-th component of c be of the form $u_0 x^{j(1)}_{i(1)} u_1 \cdots x^{j(n)}_{i(n)} u_n$ with $u_1, \ldots, u_n \in \Sigma^*$. By principle of induction, we know that there are $v_\kappa \in \mathcal{L}(G_{\mathrm{cf}}, B^{j(\kappa)}_{i(\kappa)})$ with $f_{j(\kappa)}(v_\kappa) = t_{(i(\kappa),j(\kappa))}$ for each $\kappa \in [n]$. Now let v be the string

$$\llbracket^{\ell}_{\rho}\ \widetilde{u_0}\llbracket^{j(1)}_{\rho,i(1)} v_1\rrbracket^{j(1)}_{\rho,i(1)}\widetilde{u_1}\cdots\llbracket^{j(n)}_{\rho,i(n)} v_n\rrbracket^{j(n)}_{\rho,i(n)}\widetilde{u_n}\ \rrbracket^{\ell}_{\rho}.$$

By definition of the rule $\rho^{(\ell)}$ (def. 8), we know that $v \in \mathcal{L}(G_{\mathrm{cf}}, A^\ell)$. By definition of f_ℓ, we know that $f_\ell(v) = t$. Hence, f_ℓ is surjective.

It is easy to see that $\mathrm{toCowD} = \bigcup_{\ell \in \mathbb{N}_+} f_\ell$. If we restrict the domain of toCowD to $\mathcal{L}(G_{\mathrm{cf}})$, then (since each element of $\mathcal{L}(G_{\mathrm{cf}})$ starts with a bracket of the form $\llbracket^1_\rho$ for some $\rho \in P$) the resulting function is a subset of f_1. Since f_1 is bijective, we know that toCowD is a bijection between $\mathcal{L}(G_{\mathrm{cf}})$ and $\mathrm{cowD}^{\mathrm{c}}_G$. ■

Lemma 16. Let $v \in \mathcal{L}(G_{\mathrm{cf}})$. Then

$$v \in \mathrm{mD}_G \iff \mathrm{toCowD}(v) \text{ is consistent.}$$

Proof. Let $s \in \mathbb{N}_+$ and let $t^1, \ldots, t^s$ be cow derivations in G. We abbreviate the following property by $\mathfrak{C}(t^1, \ldots, t^s)$: (i) $\{t^1, \ldots, t^s\}$ is consistent, (ii) $s = \mathrm{fanout}(\mathrm{root}(t^1))$, and (iii) t^ℓ is an ℓ-cow derivation for each $\ell \in [s]$. Now, we show by structural induction that $\mathfrak{C}(\mathrm{toCowD}(v^1), \ldots, \mathrm{toCowD}(v^s))$ holds iff each permutation of $v^1, \ldots, v^s$ is in mD_G. Let $\rho = A \to [c_1, \ldots, c_s](B_1, \ldots, B_k)$ be a rule in P. Let $v_i^j \in \mathcal{L}(G, B_i^j)$ for each $i \in [k]$ and $j \in [sort(B_i)]$ such that

$$\begin{aligned} &\mathrm{Per}(v_i^1, \ldots, v_i^{sort(B_i)}) \subseteq \mathrm{mD}_G \\ &\quad \iff \mathfrak{C}\big(t_i^1, \ldots, t_i^{sort(B_i)}\big) \end{aligned} \tag{IH}$$

for each $i \in [k]$ where t_i^j abbreviates $\mathrm{toCowD}(v_i^j)$ and $\mathrm{Per}(v_i^1, \ldots, v_i^{sort(B_i)})$ is the set of permutations of $v_i^1, \ldots, v_i^{sort(B_i)}$. For each $\ell \in [s]$, let v^ℓ be obtained from the right-hand side of $\rho^{(\ell)}$ by replacing each non-terminal of the form B_i^j by v_i^j. Clearly, for each $\ell \in [s]$, the sequence v^ℓ is an element of $\mathcal{L}(G, A^\ell)$. From now on, we will abbreviate $\mathrm{toCowD}(v^\ell)$ by t^ℓ for each $\ell \in [s]$. Now, let $B_{i(\ell,1)}^{j(\ell,1)}, \ldots, B_{i(\ell,n_\ell)}^{j(\ell,n_\ell)}$ be the nonterminals on the rhs of $\rho^{(\ell)}$, then t^ℓ is the cow derivation

$$\rho\big\langle (i(\ell,\kappa), j(\ell,\kappa))/t_{i(\ell,\kappa)}^{j(\ell,\kappa)} \quad \big| \quad \kappa \in [n_\ell]\big\rangle.$$

Note that ρ is the root symbol of each $t^1, \ldots, t^s$ and the set of indices $\{(i(\ell,\kappa), j(\ell,\kappa)) \mid \ell \in [s], \kappa \in [n_\ell]\}$ is the set $\{(i,j) \mid i \in [k], j \in [sort(B_i)]\}$. We derive

$$\begin{aligned} &\mathfrak{C}(t^1, \ldots, t^s) \\ &\iff \{t^1, \ldots, t^s\} \text{ is consistent} && \text{(by def. 10)} \\ &\iff \forall i \in [k]\colon \{t_i^1, \ldots, t_i^{sort(B_i)}\} \text{ is consistent} && \text{(by def. 14)} \\ &\iff \forall i \in [k]\colon \mathrm{Per}(v_i^1, \ldots, v_i^{sort(B_i)}) \subseteq \mathrm{mD}_G && \text{(by eq. (IH))} \\ &\iff \mathrm{Per}(v^1, \ldots, v^s) \subseteq \mathrm{mD}_G && \text{(by defs. 6 and 8)} \end{aligned}$$

Since the v_i^js and ρ were selected arbitrarily, we can obtain any element of $\mathcal{L}(G, A^\ell)$ in that manner. In particular, for each $v^1 \in \mathcal{L}(G_{\mathrm{cf}}, S^1) = \mathcal{L}(G_{\mathrm{cf}})$, the cow derivation $\mathrm{toCowD}(v^1)$ is consistent iff v^1 is in mD_G. ■

Proposition 15. TODERIV $\circ\, \mathrm{toCowD}^{-1}$ is a bijection between the consistent cow derivations in $\mathrm{cowD}_G^{\mathrm{c}}$ and $\mathrm{D}_G^{\mathrm{c}}$.

Proof. By lems. 12 and 16, there is a bijection between the consistent cow derivations in $(1\text{-cowD}_G)_S$ and $\mathcal{R}_G \cap \mathrm{mD}_G$, and there is a bijection between $\mathcal{R}_G \cap \mathrm{mD}_G$ and $\mathrm{D}_G^{\mathrm{c}}$ (Denkinger, 2017, cor. 3.9). ■

A.3 Additional Algorithms

Algorithm 3 is a modification of the algorithm given by Hulden (2011, alg. 1). The changes involve an introduction of weights in the algorithm; elements of A are drawn by maximum weight instead of being drawn randomly. In our implementation, we defined the weight of an item (p, v, q) as the weight $\mu'(v)$ defined in def. 6.

Algorithm 3 extracts Dyck words from an FSA.

Input: a weight assignment $wt\colon Q \times (\Delta \cup \overline{\Delta})^* \times Q \to \mathcal{M}$, and an automaton $\mathcal{A} = (Q, \Delta \cup \overline{\Delta}, q_{\mathrm{init}}, q_{\mathrm{final}}, T)$

Output: a sequence $v_1, v_2, \ldots$ of elements in $\mathcal{L}(\mathcal{A}) \cap \mathrm{D}_\Delta$ such that $wt(q_{\mathrm{init}}, v_1, q_{\mathrm{final}}) \trianglerighteq wt(q_{\mathrm{init}}, v_2, q_{\mathrm{final}}) \trianglerighteq \ldots$

```
procedure EXTRACTDYCK($wt$)($\mathcal{A}$)
  $(A, C) \leftarrow (\varnothing, \varnothing)$
  for $(p, \delta, q), (q, \overline{\delta}, r) \in T$ do
    $A \leftarrow A \cup \{(p, \delta\overline{\delta}, r)\}$
  for $(p, v, q) \in \mathrm{argmax}_{\trianglelefteq, wt} A$ do
    if $(p, q) = (q_{\mathrm{init}}, q_{\mathrm{final}})$ then yield $v$
    $A \leftarrow A \setminus \{(p, v, q)\}$
    $C \leftarrow C \cup \{(p, v, q)\}$
    for $(r, \delta, p), (q, \overline{\delta}, s) \in T$ do
      $A \leftarrow A \cup \{(r, \delta v \overline{\delta}, s)\}$
    for $(q, w, r) \in C$ do
      $A \leftarrow A \cup \{(p, vw, r)\}$
    for $(o, u, p) \in C$ do
      $A \leftarrow A \cup \{(o, uv, q)\}$
```

Since the function given in alg. 4 is very similar to def. 14, we omit further discussions.

Algorithm 4 checks consistency of a set of cow derivations.

Input: a set T of cow derivations

Output: $\begin{cases} \text{true} & \text{if } T \text{ is consistent} \\ \text{false} & \text{otherwise} \end{cases}$

```
function ISCONSISTENT($T$)
  if not $\bigwedge_{t,t' \in T} \big(\mathrm{root}(t) = \mathrm{root}(t')\big)$ then
    return false
  $(T_1, \ldots, T_k) \leftarrow$ COLLECTCHILDREN($T$)
  return $\bigwedge_{i=1}^{k}$ ISCONSISTENT'($T_i$)
```

Table 2: Results of the grid search for meta-parameters.

A.4 Results of Grid Search for Meta-Parameters

Table 2 shows the results of the grid search for the two introduced meta-parameters. For each combination of *beam width* and *candidate count*, we list the *median* and *mean parse time*s (since medians hide outliers, those two may differ drastically) for all sentences of length 20 and f_1-*score* over all test sentences. Moreover, we show the percentage of sentences (*coverage*) that we were able to parse with and without the fallback mechanism. The results for the combination of meta-parameters that was selected for later experiments (i.e. a beam width of 200 and a candidate count of 10^4) are written in bold.

Phylogenetic Multi-Lingual Dependency Parsing

Abstract

Languages evolve and diverge over time. Their evolutionary history is often depicted in the shape of a phylogenetic tree. Assuming parsing models are representations of their languages grammars, their evolution should follow a structure similar to that of the phylogenetic tree. In this paper, drawing inspiration from multi-task learning, we make use of the phylogenetic tree to guide the learning of multi-lingual dependency parsers leveraging languages structural similarities. Experiments on data from the Universal Dependency project show that phylogenetic training is beneficial to low resourced languages and to well furnished languages families. As a side product of phylogenetic training, our model is able to perform zero-shot parsing of previously unseen languages.

1 Introduction

Languages change and evolve over time. A community that spoke once a single language can be split geographically or politically, and if the separation is long enough their language will diverge in direction different enough so that at some point they might not be intelligible to each other. The most striking differences between related languages are often of lexical and phonological order but grammars also change over time.

Those divergent histories are often depicted in the shape of a tree in which related languages whose common history stopped earlier branch off higher than languages that have shared a longer common trajectory (Jäger, 2015). We hypothesize that building on this shared history is beneficial when learning dependency parsing models. We thus propose to use the phylogenetic structure to guide the training of multi-lingual graph-based neural dependency parsers that will tie parameters between languages according to their common history.

As our phylogenetic learning induces parsing models for every inner node in the phylogenetic tree, it can also perform zero-shot dependency parsing of unseen languages. Indeed, one can use the model of the lowest ancestor (in the tree) of a new language as an approximation of that language grammar.

We assess the potential of phylogenetic training with experiments on data from the Universal Dependencies project version 2.2. Our results show that parsers indeed benefit from this multi-lingual training regime as models trained with the phylogenetic tree outperform independently learned models. The results on zero-shot parsing show that a number of factors such as the genre of the data and the writing system have a significant impact on the quality of the analysis of an unseen language, with morphological analysis being of great help.

The remaining of this paper is organized as follows. Section 2 presents both the neural parsing model as well as the phylogenetic training procedure. Section 3 presents some experiments over data from UD 2.2. Section 4 presents some related works on multi-task learning and multi-lingual parsing. Finally, Section 5 closes the paper and gives some future perspectives.

2 Model

We propose a multi-task learning framework that shares information between tasks using a tree structure. The tree structure allows us to both share model parameters and training samples between related tasks. We instantiate it with a graph-based neural parser and use the language phylogenetic tree to guide the learning process, but it can in principle be used with any tree that encodes tasks relateness and any learning algorithm that supports fine-tuning.

In this section we first describe the intuition be-

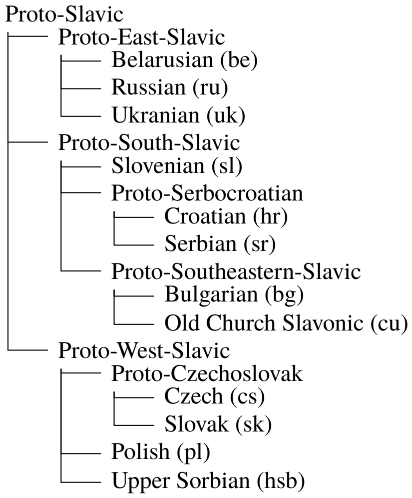

Figure 1: A possible phylogenetic tree for languages in the Slavic family.

hind phylogenetic training, then the neural parser and then the phylogenetic training itself.

2.1 Phylogenetic Hypothesis

Languages evolve from earlier stages and sometimes a language will change differently in different places leading to different languages with a common ancestor. This evolution process is often depicted in the shape of a tree in which leaves are actual languages and inner nodes can be either attested ancestral languages or their idealized reconstruction. Figure 1 gives an example of such a tree for a subset of the Slavic family of Indo-European languages (Simons and Fennig, 2018).

Just as languages evolve and diverge, so do their grammars. Assuming a parsing model is a parameterized representation of a grammar, then we can expect those models to evolve in a similar way. We thus take a multi-task approach to the problem of multi-lingual dependency parsing. What was once a single problem (e.g. parsing sentences in Proto-West-Slavic) becomes a set of distinct but related problems (parsing sentences in Czech, Polish, Slovak and Sorbian) as Proto-West-Slavic was evolving into its modern descendants.

We assume that the grammar of the last common ancestor is a good approximation of those languages grammars. Thus it should be easier to learn a language's grammar starting from its ancestor grammar than from scratch. There are however some issues with this assumption. First, a language grammar can be very different from its ancestor one from two millennia earlier. Consider the difference between modern French and early Classical Latin for example, in two millennia Latin has witnessed the loss of its case system and a complete refoundation of its verbal system. And the ”last common” ancestors can have very different age depending on the languages we consider. We expect the common ancestor of Tagalog and Indonesian to be much much older than the common ancestor of Portuguese and Galician. Second, a lot of languages have only started to be recorded very recently thus lacking historical data all together. And when historical records are available, much work still needs to be done to render those data usable by parsers. For example the Universal Dependencies Project (Nivre et al., 2018) only has annotated corpora for Latin, old Greek, old Church Slavonic and Sanskrit. And even for those classical languages, it is not clear to which extent their modern counterparts really descend from them. Thus we need to find another way to access the ancestor language grammar than using historical data.

We propose to use all the data from descendent languages to represent an ancestor language. In principle, one could give more weight to older languages or to languages that are known to be more conservative, but this knowledge is not available for all languages families. Thus we resort to using all the available data from descendent languages without distinction.

Another problem is that the tree view is too simple to represent the complete range of phenomena involved in language evolution, such as language contacts. Furthermore, languages do not evolve completely randomly, but follow some linguistic universals and have to keep a balance between speakability, learnability and understandability. Thus, languages can share grammatical features without necessarily being genetically related, either by contact or by mere chance. However, the tree model is still a good starting point in practice and language families align well with grammatical similarity as recent works on typological analysis of UD treebanks have shown (Chen and Gerdes, 2017; Schluter and Agić, 2017). We thus make the simplifying assumption that a language grammar evolves only from an older stage and can be approximated by that previous stage.

2.2 Neural Model

Our scoring model is an edge factored graph-based neural model in the vein of recent works by Dozat et al. (Dozat et al., 2017). There are two major differences here compared to the parser of Dozat

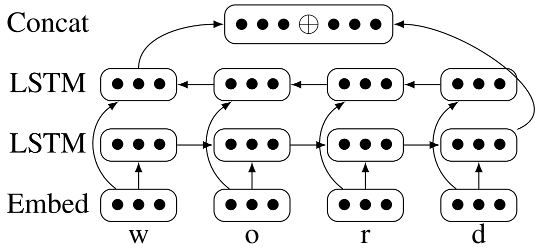

Figure 2: Bi-LSTM architecture for character based word representation. The final representation is the concatenation of the final cells of each layer.

et al. The first difference is in individual word representation, for which we use only the UPOS[1] tag, morphological information provided by UD treebanks and a character based word representation, whilst Dozat et al. use also the XPOS[2] tag, holistic word vectors (from Word2Vec (Mikolov et al., 2013) and their own) and they do not use morphological information beside what might already be given by the XPOS. The second difference is the scoring function proper. While they use biaffine scoring functions and decouple edge scoring from label scoring, we use a simple multi-layer perceptron to compute label scores and pick the max over the label as the edge score.

Let $x = (w_1 w_2 ... w_l)$ be a sentence of length l. Each word w_i is represented as the concatenation of 3 subvectors, one for its part-of-speech, one for its morphological attributes and one for its form:

$$\mathbf{w}_i = \mathbf{pos}_i \oplus \mathbf{morph}_i \oplus \mathbf{char}_i.$$

The part-of-speech vector ($\mathbf{pos}_i$) is from a look up table. The morphological vector ($\mathbf{morph}_i$) is the sum of the representation $\mathbf{m}_m$ of each morphological attribute m of the word given by the treebanks:

$$\mathbf{morph}_i = \sum_{m \in morph_i} \mathbf{m}_m.$$

We add a special dummy attribute representing the absence of morphological attributes.

The form vector ($\mathbf{char}_i$) is computed by a character BiLSTM (Hochreiter and Schmidhuber, 1997). Characters are fed one by one to the recurrent neural network in each direction. The actual form vector is then the concatenation of the outputs of the forward character LSTM and of the backward character LSTM as depicted in Figure 2.

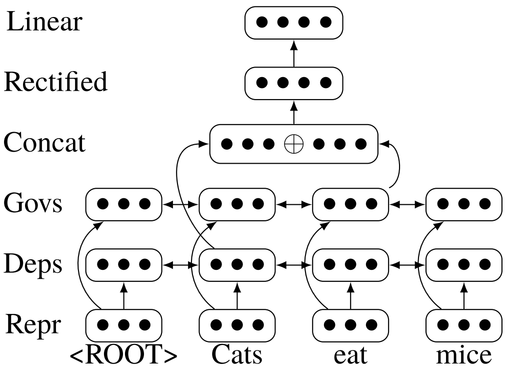

Figure 3: Neural network architecture for edge scoring. The contextualised representation of the governor (eat) and the dependent (Cats) are concatenated and passed through a rectified linear layer and a final plain linear layer to get a vector of label scores.

Once, each word has been given a representation in isolation, those representations are passed to two other BiLSTMs. Each word is then represented as the concatenation of its contextualised vector from the forward and backward layers:

$$\mathbf{c}_i = forward(\mathbf{w}_1, ..., \mathbf{w}_i) \oplus backward(\mathbf{w}_i, ..., \mathbf{w}_l).$$

We actually train two different BiLSTMs, one representing words as dependents ($\mathbf{c}$) and one words as governors ($\hat{\mathbf{c}}$). An edge score is then computed as follows. Its governor word vector $\hat{\mathbf{c}}_i$ and its dependent word vector $\mathbf{c}_j$ are concatenated and fed to a two layer perceptron (whose weights are $\mathbf{L}_1$ and $\mathbf{L}_2$) with a rectifier (noted $[...]^+$) after the first layer in order to compute the score s_{ijl} of the edge for every possible relation label l:

$$s_{ij} = \max_l s_{ijl} = \max_l (\mathbf{L}_2 \cdot [\mathbf{L}_1 \cdot (\hat{\mathbf{c}}_i \oplus \mathbf{c}_j)]^+)_l.$$

All the neural model parameters $\boldsymbol{\theta}$ (part-of-speech, character and morphological embeddings, character, dependant and governor BiLSTMs and the two layer perceptron weights) are trained end to end via back propagation one sentence at a time. Given a sentence x, we note j the index of the governor of w_i and l the relation label of w_i, the loss function is:

$$loss(x) = \sum_{w_i} \Big[\sum_{\substack{j' \neq j \\ j' \neq i}} \max(0, s_{ij'} - s_{ij} + 1)^2 + \sum_{l' \neq l} \max(0, s_{ijl'} - s_{ijl} + 1)^2 \Big]$$

---

[1] Universal part-of-speech for a set of 17 tags. Does not encode morphology.

[2] Language specific part-of-speech. Might include morphological information, but is not available for all languages.

For each word, there are two terms. The first term enforces that for all potential governors that are neither the word itself nor its actual governor, their highest score (irrespective of the relation label) should be smaller than the score of the actual governor and actual label by a margin of 1. The second term is similar and enforces that for the actual governor, any label that is not the true label should have a score smaller than the score of the actual label again by a margin of 1.

2.3 Phylogenetic Training

Let $\mathcal{L} = \{l_1, l_2, ..., l_{n_l}\}$ be a set of n_l languages and let $\mathcal{P} = \{p_1, p_2, ..., p_{n_p}\}$ be a set of n_p proto-languages (hypothesized ancestors of languages in $\mathcal{L}$). Let $\mathcal{T}$ be a tree over $\mathcal{L}^* = \mathcal{L} \cup \mathcal{P}$ such that languages of $\mathcal{L}$ are leaves and proto-languages of $\mathcal{P}$ are inner nodes. This means that we assume no two languages in $\mathcal{L}$ share a direct parenthood relation, but they at best descend both from a hypothesized parent. We could in principle have data appearing only in inner nodes. Tree $\mathcal{T}$ has a single root, a proto-language from $\mathcal{P}$ that all grammars descend from. This ancestor of all languages shall model linguistic universals[3] and ensure we deal with a well formed tree. We use the notation $p > l$ for the fact that language/node l descends from language/node p.

For each language $l \in \mathcal{L}$, we assume access to a set of n annotated examples $\mathcal{D}_l$. For each proto-language $p \in \mathcal{P}$, we create an annotated set $\mathcal{D}_p = \bigcup_{p>l} \mathcal{D}_l$ as the union of its descendent sets.

For each language $l \in \mathcal{L}^*$, we want to learn a parsing model $\boldsymbol{\theta}_l$.

2.3.1 Model Evolution

The main idea behind phylogenetic training is to initialize a new model with the model of its parent, thus effectively sharing information between languages and letting models diverged and specialize over time. The training pocedure is summarized in Algorithm 1.

At the beginning, we initialize a new blank/random model that will be the basic parsing model for all the world languages. Then, we sample sentences (we will discuss sampling issues in next section) randomly from all the available languages, parse them, compute the loss and update the model accordingly. Since the training sentences are sampled from all the available languages, the model will learn to be as good as possible for all the languages at the same time.

```
Data: a train set $\mathcal{D}_l$ and a dev set $\mathcal{D}'_l$ per
      language, a tree $\mathcal{T}$, two sampling
      sizes $k$, $k'$ and a maximum number
      of reboot $r$
Result: a model $\boldsymbol{\theta}$ per node in $\mathcal{T}$
begin
    Instantiate empty queue $Q$
    $Q.push(\mathcal{T}.root)$
    while $Q$ is not empty do
        $l = Q.pop()$
        if $l = \mathcal{T}.root$ then
            initialize $\boldsymbol{\theta}^0_{\mathcal{T}.root}$ randomly
        else
            $\boldsymbol{\theta}^0_l = \boldsymbol{\theta}_{l.parent}$
        $reboot = 0, i = 1, a_0 = 0$
        while $reboot < r$ do
            $\boldsymbol{\theta}^i_l = train(\boldsymbol{\theta}^{i-1}_l, \mathcal{D}_l, k)$
            $a_i = test(\boldsymbol{\theta}^i_l, \mathcal{D}'_l, k')$
            if $a_i \leq a_{i-1}$ then
                $reboot \mathrel{+}= 1$
            else
                $reboot = 0, i \mathrel{+}= 1$
        $\boldsymbol{\theta}_l = \boldsymbol{\theta}^i_l$
        for $c$ in l.children do
            $Q.push(c)$
```

Algorithm 1: Phylogenetic training procedure.

When the model $\boldsymbol{\theta}_p$ has reached an optimum (that we defined hereafter), we pass a copy of it to each of its children. Thus, for each child c of p, we initialize $\boldsymbol{\theta}^0_c = \boldsymbol{\theta}_p$ to its parent (p) final state. Each model $\boldsymbol{\theta}_c$ is then refined on its own data set $\mathcal{D}_c$ which is a subset of $\mathcal{D}_p$, until it reaches its own optimum state and is passed down to its own children. This process is repeated until the model reaches a leaf language, where the model $\boldsymbol{\theta}_c$ is eventually refined over its mono-lingual data set $\mathcal{D}_c$.

By passing down optimal models from older/larger languages sets to newer/smaller ones, models get the chance to learn relevant information from many different languages while specializing as time goes by.

The question now is to find when to pass down a model to its children. In other words, at which stage has a model learned the most it could from its data and should start to diverge to improve again?

Following the principle of cross-validation, we

---

[3] It does not imply anything about our belief or not in the monoglotto genesis hypothesis.

propose to let held-out data decide when is the right time to pass the model down. Let $\mathcal{D}'_p$ be a set of held-out sentences from the same languages as $\mathcal{D}_p$. Then, after every epoch i of k training examples, we freeze the model $\boldsymbol{\theta}_p^i$, and test it on k' sentences from $\mathcal{D}'_p$. This gives a score a_i (UAS/LAS) to the current model. If the score is higher than the score of the previous model $\boldsymbol{\theta}_p^{i-1}$ then training goes on, otherwise we discard it and retrain $\boldsymbol{\theta}_p^{i-1}$ for another k sentences. If after having discarded r epochs in a raw we have not yet found a better one, then we assume we have reached an optimal model $\boldsymbol{\theta}_p^{i-1}$ and pass it on to its children (unless it is a leaf, in which training is over for that language).

2.3.2 Sentence Sampling

There are a few things we should consider when drawing examples from a proto-language distribution. Beside the question of whether some languages are more conservative than others with respect to their ancestor, which we have decided to simplify saying that all languages are as representative of their ancestors, there is the problem of data unbalance and tree unbalance.

Sampling sentences uniformly across languages is not a viable option for the size of datasets varies a lot across languages and that they do not correlate with how close a language is to its ancestor. For example, there are 260 Belarusian training sentences against 48814 Russian ones. The basic question is thus whether one should draw examples from languages or branches. Basic linguistic intuition tells us that drawing should be performed on branches. Modern languages distribution has no reason to reflect their proximity to their ancestor language. Amongst Indo-European languages, there are one or two Armenian languages as well as one or two Albanian languages (depending on the criteria for being a language), while there are tens of Slavic languages and Romance languages. However, there is no reason to believe that Slavic or Romance languages are better witnesses of proto-Indo-European than Armenian or Albanian.

Drawing examples from languages would bias the intermediate models toward families that have more languages (or more treebanks). It might be a good bias depending on the way one compute the overall accuracy of the system. If one uses the macro-average of the individual language parsers, then biasing models toward families with many members should improve the accuracy overall.

In this work, at a given inner node, we decided to sample uniformly at random over branches spanning from this node, then uniformly at random over languages and then uniformly at random over sentences. It boils down to flattening the subtree below an inner node to have a maximum depth of 2. For example in Figure 1, at the root (Proto-Slavic) we pick a branch at random (e.g. Proto-South-Slavic), then a language at random (e.g. Croatian) then a sentence at random. Given that we have picked the Proto-South-Slavic branch, all South-Slavic languages are then as likely to be chosen. This biases slightly the model toward bigger sub-families. In our example, Croatian and Serbian have the same chances to be sampled than Slovenian, therefore their family, Proto-Serbocroatian is twice as likely to be chosen as Slovenian is, while being at the same depth in the tree.

We could otherwise sample over branches, then over sub-branches again and again until we reach a leaf and only then pick a sentence. In this case, Proto-Serbocroatian and Slovenian would have the same probability to be chosen. This would give much more weight to languages high in the tree than languages low in the tree. While this would give more balance to the actual model, it could be detrimental to the averaged results since the data distribution is itself unbalanced. It would of course be possible to try any variation between those two, picking sub-branches according to a probability that would depend on the number of languages in that family for example, therefore mitigating the unbalance problem.

2.4 Zero-Shot Parsing

An interesting property of the phylogenetic training procedure is that it provides a model for each inner node of the tree and thus each intermediary grammar. If one were to bring a new language with its position in the tree, then we can use the pre-trained model of its direct ancestor as an initialization instead of learning a new model from scratch. Similarly, one can use this ancestor model directly to parse the new language, effectively performing zero-shot dependency parsing. We investigate this possibility in the experiment section.

3 Experiments

To assess the potential of phylogenetic training both in terms of multi-task learning and zero-shot parsing capabilities, we experimented with data from the Universal Dependencies project version

2.2 (Nivre et al., 2018). When several corpora are available for a language, we chose one to keep a good balance between morphological annotation and number of sentences. For example, the Portuguese GSD treebank has slightly more sentences than the Bosque treebank but it is not well morphologically annotated. The zero-shot parsing models have been directly tested on languages that lack of training set. The treebanks names are given in the tree 4 and the result table 1.

3.1 Setting

As some languages have no training data and unique writing systems making the character model inefficient for them, we resorted to use gold parts-of-speech and morphological attributes rather than predicted ones. For example, Thai has no training data, no language relative and a unique script, which altogether make it really hard to parse (from a phylogenetic perspective).

The phylogenetic tree used for the experiment is adapted from the Ethnologue (2018). For space reasons, it is reported in the appendix in Figures 4 and 5. We tried to have a tree as consensual as possible, but there are still a few disputable choices, mostly about granularity and consistency. Sanskrit could have its own branch in the Indic family just as Latin in the Romance family, but because Sanskrit has no training data, that would not actually change the results. Likewise, as Czechoslovak and Dutch-Afrikaans have their own branches, Scandinavian languages could also distributed between east and west Scandinavian. As an English based Creole, Naija could as well be put in the Germanic family, but we kept it as a separate (Creole) family.

Regarding model training proper, we used $k = 500$ training sentences per iteration, $k' = 500$ held-out sentences from the developpement set to compute running LAS and a maximum number of reboot $r = 5$. Following Dozat et al (2017), we use Eisner algorithm (Eisner, 1996) at test time to ensure outputs are well formed trees. The neural model is implemented in Dynet (Neubig et al., 2017) and we use Adadelta with default parameters as our trainer. We averaged the results over 5 random initializations. Independent models are trained in the same manner but with mono-lingual data only. We report both labeled and unlabeled edge prediction accuracy (UAS/LAS). In the appendix we also report results averaged per family.

3.2 Multi-Task Learning

Table 1 reports parsing results for languages that have a training set. Note that a few languages do not have a separate developpement set, then we used the training set for both training and validation. The training set size of those languages is reported in square brackets. This has low to no impact on other languages results but it can be problematic for the language itself as it can over-fit its training data especially when they are very few as is the case of Buryat for example. To be fair, we report two different averages. Avg is the average over languages that have a separate developpement set, and Avg No Dev is the average over languages that do not have a separate developpement set. For each language, the best UAS/LAS are reported in bold.

On average, phylogenetic training improves parsing accuracy, both labeled and unlabeled. This is especially true for languages that have very small training sets (50 sentences or less) and lack of developpement set. Those languages show an averaged 7 points improvement and up to 15 points (hsb, kmr). Since independent mono-lingual models follow the exact same training procedure but without phylogenetic initialization and that every sentence will be seen several times both at training and validation, the sampling method cannot explain such a difference. This shows that the ancestor's model is a good initialization and acts as a form of regularization, slowing down over-fitting.

Phylogenetic training is also beneficial as one gains information from related languages. Indo-European languages gain from sharing information. This is especially true for Balto-Slavic (sk +5.82, lt +5.07 UAS) and Indo-Iranian languages (mr +2.05 UAS). It is less consistent for Romance and Germanic languages. This might be due to the tree not representing well typology for those families. Typically, English tends to group syntactically with Scandinavian languages more than with West-Germanic. Turkic and Uralic languages show the same benefits overall (ug +2.67, fi +3.39 UAS).

Dravidian and Afro-Asiatic languages are not as consistent. While Telugu seems to gain from Tamil data, the reverse is not true. Result variation for Arabic, Hebrew and Coptic are marginal. This is likely due to the fact that we only have three quite different languages from that family and that they all have their own script.

Similarly, phylogenetic training is not consistently useful for languages that do not have rela-

yue	Sino-Tibetan*	41.68	25.02
Avg		58.04	40.83

Table 2: Accuracy of languages without a training set.

tives. While Buryat (bxr) that has a very small training set benefits from universal linguistic information and gain almost 11 points UAS, Basque (eu) that has a very different grammatical structure than other languages and enough training data (5396 sentences) looses 3.25 LAS. Gains and losses are marginal for the other five languages (id, ja, ko, vi, zh).

Overall results are a bit below the state of the art, but the model is very simple and relies on gold morphology, so it is not really comparable.

3.3 Zero-Shot Parsing

Table 2 reports parsing results for languages that do not have a training set. Because of phylogenetic training and the tree structure that guides it, it can happen that a language ancestor's model is in fact trained on data only accounting for a narrow range of later stages. For example, while Faroese uses the North-Germanic model refined on both Norwegians, Swedish and Danish data, Tagalog uses the Austronesian model only refined with Indonesian data thus making it more an Indonesian model than an actual Austronesian model. Those cases are marked by an asterisk in the table. Komi (kpv) model is refined on Finno-Samic data, Breton (br) model on Irish data, Cantonese (yue) model on Mandarin data.

Looking at Table 2, we make the following observations. As expected scores are on average lower than for languages with training data, however the UAS/LAS gap is substantially bigger from 6.781 to 17.08 points. It is hard to compare to other works on zero-shot parsing since they use different data and scores span a big range, but our results are comparable to those of Aufrant et al. (2016) and Naseem et al. (2012), while our zero-shot models are given for free by the phylogenetic training method.

On a language per language basis, we see that there are a few important factors, the most striking being genre. Tagalog (tl) and more surprisingly Warlpiri (wbp) have relatively high parsing accuracy despite being either completely isolated or having only one relative (Indonesian). This is likely because their data are well annotated stereotypical sentences extracted from grammars, thus making them easy to parse.

Then we see that Naija (pcm) and Yoruba (yo) are about 25 points higher than Thai (th) despite them three having low morphology (in the treebanks). As they have different genres (spoken, bible, news and wiki), without a deeper look at the trees themselves, our best guess is that this is due to Thai having a different script. Naija and Yoruba both use the Latin alphabet, and as such they can rely to some extent on the character model to share information with other languages, to at least organise the character space. This analysis would also carry for Cantonese (yue). It is a morphologically simple language, and despite having a relative (Mandarin), its score is rather low. The genre alone (spoken) would not explain everything as Naija has also a spoken treebank and a higher score. The writing system might be at blame once again. Indeed, Chinese characters are very different from alphabetic characters and are much harder to use in character models because of sparsity. Comparing Mandarin and Cantonese test sets with Mandarin train set, the amount of out-of-vocabulary words is 32.47% of types (11.90% of tokens) for Mandarin and 54.88% of types (56.50% of tokens) for Cantonese. The results for out-of-vocabulary characters are even more striking with 3.73% of types (0.49% of tokens) for Mandarin and 12.97% of types (34.29% of tokens) for Cantonese. This shows that not only there are a lot of OOV in Cantonese test set, but that those words/characters are common ones as 12.97% of character types missing make up for more than a third of all character tokens missing, where on the contrary Mandarin OOV are seldom and account for less tokens percentage than types. This is one more argument supporting the importance of the character vector.

Other important factors are typology and morphology. Amharic (am) despite its unique script has a higher score than Cantonese that actually shares its scripts (to some extent as we have seen) with Mandarin. The key point for Amharic score, is that all its relatives (Hebrew, Arabic and Coptic) have their own scripts and are morphologically rich, thus the model learns to use morphological information. The analysis is similar for Komi which on top of sharing morphology with its relatives also share the writing system which provides it an extra gain. However, this might word in the opposite direction as well, as we can see with Faroese, Breton and Sanskrit. Faroese (fo) is morphologically rich and that should help, however its North-Germanic relatives are morphologically much simpler. Thus the model does not learn to rely on morphological attributes nor on word endings for the character model as much. The same is true for Sanskrit (sa), which is morphologically richer than its modern Indic relatives, with an extra layer of specific writing systems. Eventually, Breton model (br) is refined over Irish data only and while Irish is a typological outlier amongst Indo-European languages because of its Verb-Subject-Object word order, Breton has the standard Subject-Verb-Object, thus using Irish data might actually be detrimental.

These arguments show the respective importance of the writing system, the genre of the data, the morphological analysis and the typology in phylogenetic zero-shot dependency parsing. Those factors can either work together positively (Komi) or negatively (Cantonese) or cancel each other out (Amharic, Faroese).

4 Related Work

The goal of multi-task learning is to learn related tasks (either sharing their input and/or output space of participating of the same pipeline) jointly in order to improve their models over independently learned one (Caruana, 1997). In Søgaard et al. (2016), task hierarchy is directly encoded in the neural model allowing tasks with different output space to share parts of their parameters (POS tagging comes at a lower level than CCG parsing and only back-propagates to lower layers). Likewise, in Johnson et al. (2017), the encoder/decoder architecture allows to learn encoders that target several output languages and decoders than handle data from various input languages. However, in multi-task learning literature, task relationships are often fixed. In Cavallanti et al. (2010) tasks with the same output spaces share parameter updates through a fixed similarity graph. In this work, changing level in the tree can be seen as splitting the similarity graph into disjoint sub graphs. It is a way to have tasks relationships evolving during training and to encode information about task evolution that lacks in other multi-task methods.

In multi-lingual parsing, Ammar et al. (2016) propose to train a single model to parse many languages using both typological information, cross-lingual word representations and language specific information. While their model gives good results, they only apply it to 7 Germanic and Romance languages. It would be worth doing the experiment with 50+ languages and see how the results would change. However, because of language specific information their model would probably become very big. In this work, language specific information is not added on the top of the model, but is just language generic information that refines over time.

Che et al. (2017; 2018) and Stymne et al. (2018) propose to train parsers on several concatenated treebanks either from the same language or from related languages and to fine-tune the parsers on individual treebanks afterward to fit specific languages/domains. The main difference with our method, is that instead of one step of fine-tuning, we perform as many fine-tuning as there are ancestors in the tree, each time targeting more and more specific data. This in turn requires that we handle data imbalance therefore using sampling rather than plain concatenation.

Aufrant et al. (2016) propose to tackle zero-shot parsing by rewriting source treebanks to better fit target language typology. Assuming that typology is homogeneous in a language family, the phylogeny should drive models to be typologically aware. However, as we have seen for Breton and Irish, that assumption might not always hold.

Eventually, the closest work from our in spirit is the one of Berg-Kirkpatrick et al. (2010). They use a phylogenetic tree to guide the training of unsupervised dependency parsing models of several languages, using ancestor models to tie descendent ones. The main difference here beside supervision, is that we do not use ancestor models as biases but rather as initialization of descendent models.

5 Conclusion

We have presented a multi-task learning framework that allows one to train models for several tasks that have diverged over time. Leveraging their common evolutionary history through a phylogenetic tree, models share parameters and training samples until they need to diverge. As a by product of this phylogenetic training, we are provided with intermediary models that can be used to zero-shot a new related task, given its position in the evolutionary history.

We have applied this framework to dependency parsing using a graph-based neural parser and the phylogenetic tree of the languages from UD 2.2 to guide the training process. Our results show that phylogenetic training is beneficial for well populated families such as Indo-European and Uralic. It also helps generalization and prevents over-fitting when very few data are available. For zero-shot parsing, genre, writing system and morphology are crucial factors for the quality of parse predictions.

Some works have been done on automatically learning task relationship in multi-task setting. It would be interesting to see how the algorithm could figure out when and how to cluster languages automatically as phylogenetic trees do not directly depict grammar evolution.

Our model does not know that Latin came before Old French and before modern French, or that despite being Germanic, English underwent a heavy Romance influence. It would be worth investigating softening the tree constraints and instigating more evolutionary information in the structure.

Another important point is that we use gold part-of-speech and morphological information which is unlikely to be available in real scenarios. However, our new training procedure can be applied to any task, so a future work would be to use it to perform phylogenetic POS tagging.

Other directions for the future are designing better sampling methods as well as better ways to measure training convergence at each level.

Table 3: Parsing results for phylogenetic and independent neural models averaged by language family. Families are sorted in the same order as they appear in Table 1. Indo-European averages include Armenian (hy) and Irish (ga). Global averages are repeated for completeness. Best results are reported in bold.

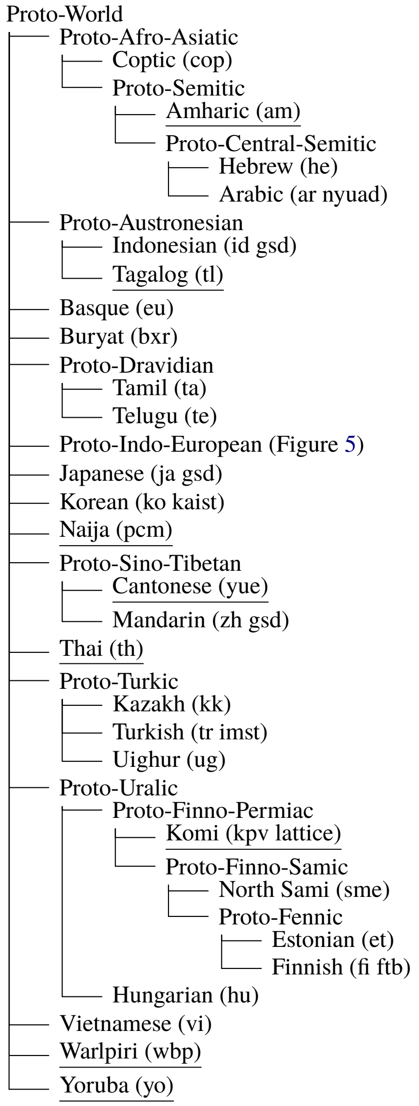

Figure 4: Phylogenetic tree used to guide the training process of the multi-lingual parser. Underlined languages are those that do not have a training set. The code of the language and if necessary the name of the treebank are given in parentheses. The Indo-European sub-tree is depicted on the right.

Figures 4 and 5 represent the phylogenetic tree used for guiding the training process. As we only use data from the UD project 2.2, we collapse unique child so that Vietnamese is not an Austro-Asiatic language, it is just Vietnamese. We also only use well attested families, thus Buryat, a Mongolic language, is alone and not linked to Turkic languages. Maybe, the most disputable choice is to put Naija in its own Creole family instead of the Germanic family.

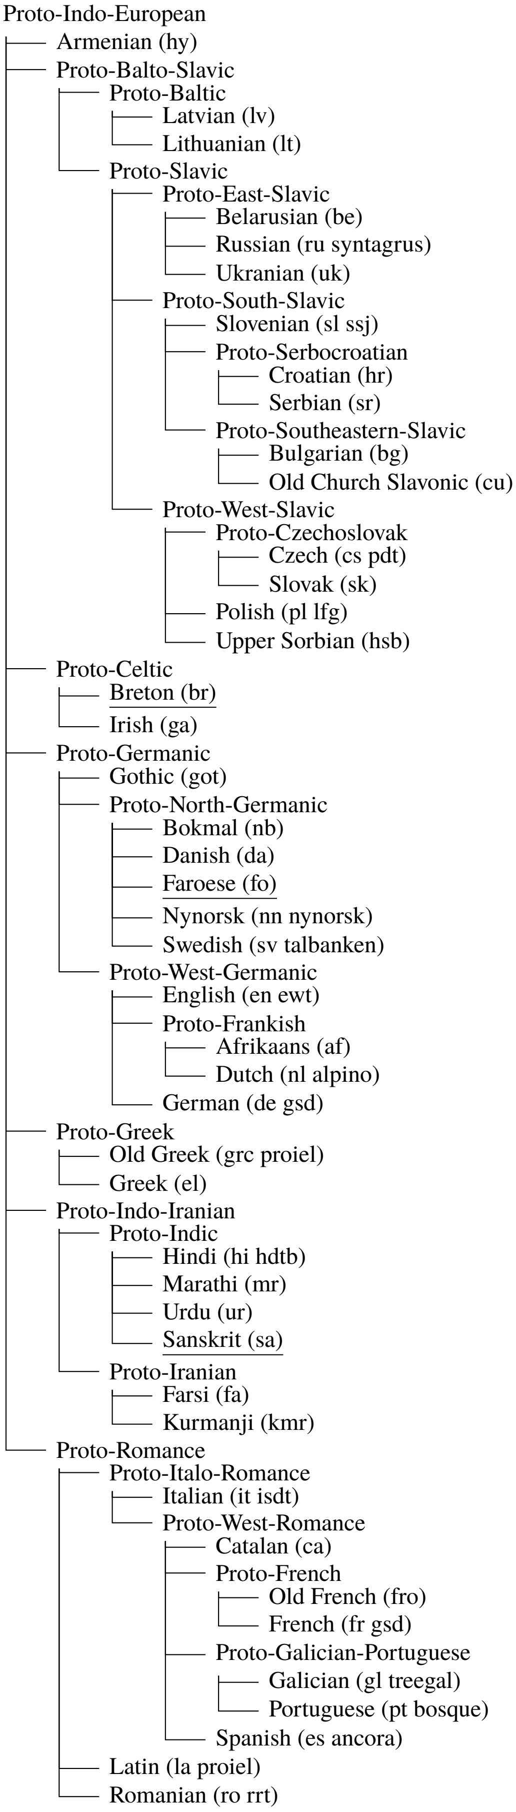

Figure 5: The Indo-European phylogenetic tree.

Discontinuous Constituency Parsing with a Stack-Free Transition System and a Dynamic Oracle

Abstract

We introduce a novel transition system for discontinuous constituency parsing. Instead of storing subtrees in a stack –i.e. a data structure with linear-time *sequential access*– the proposed system uses a *set* of parsing items, with constant-time *random access*. This change makes it possible to construct any discontinuous constituency tree in exactly $4n-2$ transitions for a sentence of length n, whereas existing systems need a quadratic number of transitions to derive some structures. At each parsing step, the parser considers every item in the set to be combined with a *focus* item and to construct a new constituent in a bottom-up fashion. The parsing strategy is based on the assumption that most syntactic structures can be parsed incrementally and that the set –the memory of the parser– remains reasonably small on average. Moreover, we introduce a dynamic oracle for the new transition system, and present the first experiments in discontinuous constituency parsing using a dynamic oracle. Our parser obtains state-of-the-art results on three English and German discontinuous treebanks.

1 Introduction

Discontinuous constituency trees extend standard constituency trees by allowing crossing branches to represent long distance dependencies, such as the *wh*-extraction in Figure 1. Discontinuous constituency trees can be seen as derivations of Linear Context-Free Rewriting Systems (LCFRS, Vijay-Shanker et al., 1987), a class of formal grammars more expressive than context-free grammars, which makes them much harder to parse. In particular, exact CKY-style LCFRS parsing has an $\mathcal{O}(n^{3f})$ time complexity where f is the fan-out of the grammar (Kallmeyer, 2010).

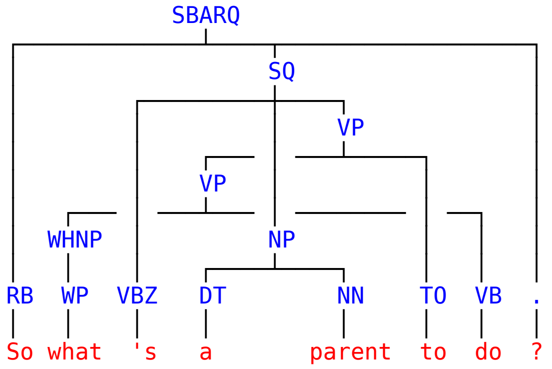

Figure 1: Discontinuous constituency tree from the Discontinuous Penn treebank.

A natural alternative to grammar-based chart parsing is transition-based parsing, that usually relies on fast approximate decoding methods such as greedy search or beam search. Transition-based discontinuous parsers construct discontinuous constituents by reordering terminals with the SWAP action (Versley, 2014a,b; Maier, 2015; Maier and Lichte, 2016; Stanojević and Garrido Alhama, 2017), or by using a split stack and the GAP action to combine two non-adjacent constituents (Coavoux and Crabbé, 2017a; Coavoux et al., 2019). These proposals represent the memory of the parser (i.e. the tree fragments being constructed) with data structures with **linear-time sequential access** (either a stack, or a stack coupled with a double-ended queue). As a result, these systems need to perform at least n actions to construct a new constituent from two subtrees separated by n intervening subtrees. Our proposal aims at avoiding this cost when constructing discontinuous constituents.

We design a novel transition system in which a discontinuous constituent is constructed in a single step, without the use of reordering actions such as SWAP. The main innovation is that the memory of the parser is not represented by a stack,

Labelling actions			
LABEL-X	$(S,\ s_f,\ i,\ C) : j$	$\Rightarrow (S,\ s_f,\ i,\ C \cup \{(X,\ s_f)\}) : j+1$	j is odd
NO-LABEL	$(S,\ s_f,\ i,\ C) : j$	$\Rightarrow (S,\ s_f,\ i,\ C) : j+1$	$i \neq n$ or $S \neq \emptyset$, j is odd

Table 1: Set-based transition system description. Variable j is the number of steps performed since the start of the derivation.

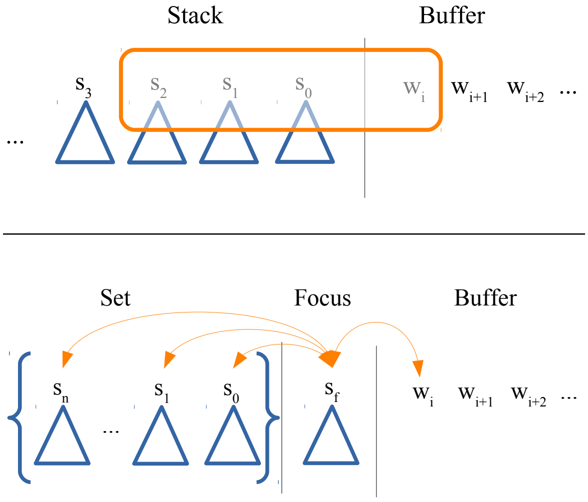

Figure 2: In a stack-based system like shift-reduce-swap (upper part), the parser extracts features from a *local* region of the configuration (orange part), to predict the next action such as: construct a new tree with label X and children s_0 and s_1 (REDUCE-X). In our proposed set-based system (lower part), we consider every item in the set to be combined bottom-up with the focus item s_f and score independently each possible transition.

as is usual in shift-reduce systems, but by an unordered **random-access** set. The parser considers every constituent in the current memory to construct a new constituent in a bottom-up fashion, and thus instantly models interactions between parsing items that are not adjacent. As such, we describe a left-to-right parsing model that deviates from the standard stack-buffer setting, a legacy from pushdown automata and classical parsing algorithms for context-free grammars.

Our contributions are summarized as follows:

- We design a novel transition system for discontinuous constituency parsing, based on a memory represented by a *set* of items, and that derives any tree in exactly $4n - 2$ steps for a sentence of length n;
- we introduce the first dynamic oracle for discontinuous constituency parsing;
- we present an empirical evaluation of the transition system and dynamic oracle on two German and one English discontinuous treebanks.

The code of our parser is released as an open-source project at `https://gitlab.com/mcoavoux/discoparset`.

2 Set-based Transition System

System overview We propose to represent the memory of the parser by (i) a set of parsing items and (ii) a single *focus item*. Figure 2 (lower part) illustrates a configuration in our system. The parser constructs a tree with two main actions: shift the next token to make it the new focus item (SHIFT), or combine any item in the set with the focus item to make a new constituent bottom-up (COMBINE action).

Since the memory is not an ordered data structure, the parser considers equally every pending parsing item, and thus constructs a discontinuous constituent in a single step, thereby making it able to construct any discontinuous tree in $\mathcal{O}(n)$ transitions.

The use of an unordered random-access data structure to represent the memory of the parser also leads to a major change for the scoring system (Figure 2). Stack-based systems use a *local view* of a parsing configuration to extract features and score actions: features only rely on the few topmost elements on the stack and buffer. The score of each transition depends on the totality of this local view. In constrast, we consider equally every item in the set, and therefore rely on a *global*

Table 2: Full derivation for the sentence in Figure 1. As a convention, we index elements in the set with their left-index and use COMB-i to denote COMB-s_i. We also use tokens instead of their indexes for better legibility.

view of the memory (Section 3). However, we score each possible combinations independently: the score of a single combination only depends on the two constituents that are combined, regardless of the rest of the set.

2.1 System Description

Definitions We first define an *instantiated (discontinuous) constituent* (X, s) as a nonterminal label X associated with a set of token indexes s. We call $\min(s)$ the *left-index* of c and $\max(s)$ its *right-index*. For example in Figure 1, the two VPs are respectively represented by (VP, $\{1, 6\}$) and (VP, $\{1, 5, 6\}$), and they have the same right index (6) and left index (1).

A *parsing configuration* is a quadruple (S, s_f, i, C) where:

- S is a set of sets of indexes and represents the memory of the parser;
- s_f is a set of indexes called the *focus item*, and satisfies $\max(s_f) = i - 1$;
- i is the index of the next token in the buffer;
- C is a set of instantiated constituents.

Each new constituent is constructed bottom-up from the *focus* item and another item in the set S.

Transition set Our proposed transition system is based on the following types of actions:

- SHIFT constructs a singleton containing the next token in the buffer and assigns it as the new focus item. The former focus item is added to S.
- COMBINE-s computes the union between the focus item s_f and another item s from the set S, to form the new focus item $s \cup s_f$.
- LABEL-X instantiates a new constituent (X, s_f) whose yield is the set of indexes in the focus item s_f.
- NO-LABEL has no effect; its semantics is that the current focus set is not a constituent.

Following Cross and Huang (2016b), transitions are divided into **structural** actions (SHIFT, COMBINE-s) and **labelling** actions (LABEL-X, NO-LABEL). The parser may only perform a structural action on an even step and a labelling action on an odd step. For our system, this distinction has the crucial advantage of keeping the number of possible actions low at each parsing step, compared to a system that would perform a COMBINE action and a labelling action in a single REDUCE-s-X action.[1]

Table 1 presents each action as a deduction rule associated with preconditions. In Table 2, we describe how to derive the tree from Figure 1.

2.2 Oracles

Training a transition-based parser requires an oracle, i.e. a function that determines what the best action is in a specific parsing configuration to serve as a training signal. We first describe a static oracle that provides a canonical derivation for a given gold tree. We then introduce a dynamic oracle that determines what the best action is in any parsing configuration.

---

[1] In such a case, we would need to score $|S| \times |N| + 1$ actions, where N is the set of nonterminals, instead of $|S| + 1$ actions for our system.

2.2.1 Static Oracle

Our transition system exhibits a fair amount of *spurious ambiguity*, the ambiguity exhibited by the existence of many possible derivations for a single tree. Indeed, since we use an unordered memory, an n-ary constituent (and more generally a tree) can be constructed by many different transition sequences. For example, the set $\{0, 1, 2\}$ might be constructed by combining

- $\{0\}$ and $\{1\}$ first, and the result with $\{2\}$; or
- $\{1\}$ and $\{2\}$ first, and the result with $\{0\}$; or
- $\{0\}$ and $\{2\}$ first, and the result with $\{1\}$.

Following Cohen et al. (2012), we eliminate spurious ambiguity by selecting a canonical derivation for a gold tree. In particular, we design the static oracle (i) to apply COMBINE as soon as possible in order to minimize the size of the memory (ii) to combine preferably with the most recent set in the memory when several combinations are possible. The first choice is motivated by properties of our system: when the memory is smaller, there are fewer choices, therefore decisions are simpler and less expensive to score.

2.2.2 Dynamic Oracle

Parsers are usually trained to predict the gold sequence of actions, using a static oracle. The limitation of this method is that the parser only sees a tiny portion of the search space at train time and only trains on gold input (i.e. configurations obtained after performing gold actions). At test time, it is in a different situation due to error propagation: it must predict what the best actions are in configurations from which the gold tree is probably no longer reachable.

To alleviate this limitation, Goldberg and Nivre (2012) proposed to train a parser with a *dynamic oracle*, an oracle that is defined for any parsing configuration and outputs the set of best actions to perform. In contrast, a *static oracle* is deterministic and is only defined for gold configurations.

Dynamic oracles were proposed for a wide range of dependency parsing transition systems (Goldberg and Nivre, 2013; Gómez-Rodríguez et al., 2014; Gómez-Rodríguez and Fernández-González, 2015), and later adapted to constituency parsing (Coavoux and Crabbé, 2016; Cross and Huang, 2016b; Fernández-González and Gómez-Rodríguez, 2018b,a).

In the remainder of this section, we introduce a dynamic oracle for our proposed transition system. It can be seen as an extension of the oracle of Cross and Huang (2016b) to the case of discontinuous parsing.

Preliminary definitions For a parsing configuration c, the relation $c \vdash c'$ holds iff c' can be derived from c by a single transition. We note $\vdash^*$ the reflexive and transitive closure of $\vdash$. An instantiated constituent (X, s) is **reachable** from a configuration $c = (S, s_f, i, C)$ iff there exists $c' = (S', s'_f, i', C')$ such that $(X, s) \in C'$ and $c \vdash^* c'$. Similarly, a set of constituents t (possibly a full discontinuous constituency tree) is reachable iff there exists a configuration $c' = (S', s'_f, i', C')$ such that $t \subseteq C'$ and $c \vdash^* c'$. We note $\mathsf{reach}(c, t^*)$ the set of constituents that are (i) in the gold set of constituents t^* (ii) reachable from c.

We define a total order $\preceq$ on index sets:

$$s \preceq s' \Leftrightarrow \begin{cases} \max(s) < \max(s'), \\ \textbf{or} \\ \max(s) = \max(s') \\ \text{and } s \subseteq s'. \end{cases}$$

This order naturally extends to the constituents of a tree: $(X, s) \preceq (X', s')$ iff $s \preceq s'$. If (X, s) precedes (X', s'), then (X, s) must be constructed before (X', s'). Indeed, since the right-index of the focus item is non-decreasing during a derivation (as per the transition definitions), constituents are constructed in the order of their right-index (first condition). Moreover, since the algorithm is bottom-up, a constituent must be constructed before its parent (second condition).

From a configuration $c = (S, s_f, i, C)$ at an odd step, a constituent $(X, s_g) \notin C$ is reachable iff both the following properties hold:

1. $\max(s_f) \leq \max(s_g)$;
2. $\forall s \in S \cup \{s_f\}, (s \subseteq s_g)$ or $(s \cap s_g = \emptyset)$.

Condition 1 is necessary because the parser can only construct new constituents (X, s) such that $s_f \preceq s$. Condition 2 makes sure that s_g can be constructed from a union of elements from $S \cup \{s_f\}$, potentially augmented with terminals from the bufffer: $\{i, i+1, \dots, \max(s_g)\}$.

Following Cross and Huang (2016b), we define $\mathsf{next}(c, t^*)$ as the smallest reachable gold constituent from a configuration c. Formally:

$$\mathsf{next}(c, t^*) = \operatorname*{argmin}_{\preceq} \mathsf{reach}(c, t^*).$$

Oracle algorithm We first define the oracle o for the odd step of a configuration $c = (S, s_f, i, C)$:

$$\mathsf{o}_{\mathsf{odd}}(c, t^*) = \begin{cases} \{\text{LABEL-X}\} & \text{if } \exists(X, s_f) \in t^*, \\ \{\text{NO-LABEL}\} & \text{otherwise.} \end{cases}$$

For even steps, assuming $\mathsf{next}(c, t^*) = (X, s_g)$, we define the oracle as follows:

$$\mathsf{o}_{\mathsf{even}}(c, t^*) = \begin{cases} \{\text{COMB-}s | (s_f \cup s) \subseteq s_g\} \\ \qquad \text{if } \max(s_g) = \max(s_f), \\ \{\text{COMB-}s | (s_f \cup s) \subseteq s_g\} \cup \{\text{SH}\} \\ \qquad \text{if } \max(s_g) > \max(s_f). \end{cases}$$

We provide a proof of the correctness of the oracle in Appendix A.

3 A Neural Network based on Constituent Boundaries

We first present an encoder that computes context-aware representations of tokens (Section 3.1). We then discuss how to compute the representation of a set of tokens (Section 3.2). We describe the action scorer (Section 3.3), the POS tagging component (Section 3.4), and the objective function (Section 3.5).

3.1 Token Representations

As in recent proposals in dependency and constituency parsing (Cross and Huang, 2016a; Kiperwasser and Goldberg, 2016), our scoring system is based on a sentence transducer that constructs a context-aware representation for each token.

Given a sequence of tokens $x_1^n = (x_1, \dots, x_n)$, we first run a single-layer character bi-LSTM encoder $\mathbf{c}$ to obtain a character-aware embedding $\mathbf{c}(x_i)$ for each token. We represent a token x_i as the concatenation of a standard word embedding $\mathbf{e}(x_i)$ and the character-aware embedding: $\mathbf{w}_{x_i} = [\mathbf{c}(x_i); \mathbf{e}(x_i)]$.

Then, we run a 2-layer bi-LSTM transducer over the sequence of token representations:

$$(\mathbf{h}_1^{(1)}, \dots, \mathbf{h}_n^{(1)}) = \text{bi-LSTM}(\mathbf{w}_{x_1}, \dots, \mathbf{w}_{x_n}),$$
$$(\mathbf{h}_1^{(2)}, \dots, \mathbf{h}_n^{(2)}) = \text{bi-LSTM}(\mathbf{h}_1^{(1)}, \dots, \mathbf{h}_n^{(1)}).$$

The parser uses the context-aware token representations $\mathbf{h}_i^{(2)}$ to construct vector representations of sets or constituents.

3.2 Set Representations

An open issue in neural discontinuous parsing is the representation of discontinuous constituents. In projective constituency parsing, it has become standard to use the boundaries of constituents (Hall et al., 2014; Crabbé, 2015; Durrett and Klein, 2015), an approach that proved very successful with bi-LSTM token representations (Cross and Huang, 2016b; Stern et al., 2017).

Although constituent boundary features improves discontinuous parsing (Coavoux and Crabbé, 2017a), relying only on the left-index and the right-index of a constituent has the limitation of ignoring gaps inside a constituent. For example, since the two VPs in Figure 1 have the same right-index and left-index, they would have the same representations. It may also happen that constituents with identical right-index and left-index do not have the same labels.

We represent a (possibly partial) constituent with the yield s, by computing 4 indexes from s: $(\min(s), \max(s), \min(\overline{s}), \max(\overline{s}))$. The set $\overline{s}$ represents the gap in s, i.e. the tokens between $\min(s)$ and $\max(s)$ that are not in the yield of s:

$$\overline{s} = \{i | \min(s) < i < \max(s) \text{ and } i \notin s\}.$$

Finally, we extract the corresponding token representations of the 4 indexes and concatenate them to form the vector representation $\mathbf{r}(s)$ of s:

$$\mathbf{r}(s) = [\mathbf{h}^{(2)}_{\min(s)}; \mathbf{h}^{(2)}_{\max(s)}; \mathbf{h}^{(2)}_{\min(\overline{s})}; \mathbf{h}^{(2)}_{\max(\overline{s})}].$$

For an index set that does not contain a gap, we have $\overline{s} = \emptyset$. To handle this case, we use a parameter vector $\mathbf{h}_{\mathsf{nil}}$, randomly initialized and learned jointly with the network, to embed $\max(\emptyset) = \min(\emptyset) = \mathsf{nil}$.

For example, the constituents (VP, $\{1, 6\}$) and (VP, $\{1, 5, 6\}$) will be respectively vectorized as:

$$\mathbf{r}(\{1,6\}) = [\mathbf{h}_1^{(2)}; \mathbf{h}_6^{(2)}; \mathbf{h}_2^{(2)}; \mathbf{h}_5^{(2)}],$$
$$\mathbf{r}(\{1,5,6\}) = [\mathbf{h}_1^{(2)}; \mathbf{h}_6^{(2)}; \mathbf{h}_2^{(2)}; \mathbf{h}_4^{(2)}].$$

This representation method makes sure that two distinct index sets have distinct representations, as long as they have at most one gap each. This property no longer holds if one index sets has more than one gap.

3.3 Action Scorer

For each type of action –structural or labelling– we use a feedforward network with two hidden layers.

Structural actions At structural steps, for a configuration $c = (S, s_f, i, C)$, we need to compute the score of $|S|$ COMBINE actions and possibly a SHIFT action. In our approach, the score of a combine-s action only depends on s and s_f and is independent of the rest of the configuration (i.e. other items in the set). We first construct input matrix M as follows:

$$M = \begin{pmatrix} \mathbf{r}(s_1) & \cdots & \mathbf{r}(s_n) & \mathbf{r}(\{i\}) \\ \mathbf{r}(s_f) & \cdots & \mathbf{r}(s_f) & \mathbf{r}(s_f) \end{pmatrix}.$$

Each of the first n columns of matrix M represents the input for a COMBINE action, whereas the last column is the input for the SHIFT action. We then compute the score of each structural action:

$$P(\cdot|c) = \text{Softmax}(\text{FF}_s(M)),$$

where FF_s is a feedforward network with two hidden layers, a $\tanh$ activation and a single output unit. In other words, it outputs a single scalar for each column vector of matrix M. This part of the network can be seen as an attention mechanism, where the focus item is the query, and the context is formed by the items in the set and the first element in the buffer.

Labelling actions We compute the probabilities of labelling actions as follows:

$$P(\cdot|s_f) = \text{Softmax}(\text{FF}_l(\mathbf{r}(s_f))),$$

where FF_l is a feedforward network with two hidden layers activated with the $\tanh$ function, and $|N| + 1$ output units, where N is the set of nonterminals.

3.4 POS Tagger

Following Coavoux and Crabbé (2017b), we use the first layer of the bi-LSTM transducer as input to a Part-of-Speech (POS) tagger that is learned jointly with the parser. For a sentence x_1^n, we compute the probability of a sequence of POS tags $t_1^n = (t_1, \ldots, t_n)$ as follows:

$$P(t_1^n|x_1^n) = \prod_{i=1}^{n} \text{Softmax}(\mathbf{W}^{(t)} \cdot \mathbf{h}_i^{(1)} + \mathbf{b}^{(t)})_{t_i},$$

where $\mathbf{W}^{(t)}$ and $\mathbf{b}^{(t)}$ are parameters.

3.5 Objective Function

In the static oracle setting, for a single sentence x_1^n, we optimize the sum of the log-likelihood of gold POS-tags t_1^n and the log-likelihood of gold parsing actions a_1^n:

$$\begin{aligned} \mathcal{L} &= \mathcal{L}_t + \mathcal{L}_p, \\ \mathcal{L}_t &= -\sum_{i=1}^{n} \log P(t_i|x_1^n), \\ \mathcal{L}_p &= -\sum_{i=1}^{4n-2} \log P(a_i|a_1^{i-1}, x_1^n). \end{aligned}$$

We optimize this objective by alternating a stochastic step for the tagging objective and a stochastic step for the parsing objective, as is standard in multitask learning (Caruana, 1997).

In the dynamic oracle setting, instead of optimizing the likelihood of the gold actions (assuming all previous actions were gold), we optimize the likelihood of the best actions, as computed by the dynamic oracle, from a configuration sampled from the space of all possible configurations. In practice, before each epoch, we sample each sentence from the training corpus with probability p and we use the current (non-averaged) parameters to parse the sentence and generate a sequence of configurations. Instead of selecting the highest-scoring action at each parsing step, as in a normal inference step, we sample an action using the softmax distribution computed by the parser, as done by Ballesteros et al. (2016). Then, we use the dynamic oracle to calculate the best action from each of these configurations. In case there are several best actions, we deterministically choose a single action by favoring a COMBINE over a SHIFT (to bias the model towards a small memory), and to COMBINE with the item with the highest right-index (to avoid spurious discontinuity in partial constituents). We train the parser on these sequences of potentially non-gold configuration-action pairs.

4 Experiments

We carried out experiments to assess the adequacy of our system and the effect of training with the dynamic oracle. We present the three discontinuous constituency treebanks that we used (Section 4.1), our experimental protocol (Section 4.2), then we discuss the results (Section 4.3) and the efficiency of the parser (Section 4.4).

4.1 Datasets

We perform experiments on three discontinuous constituency corpora. The discontinuous Penn Treebank was introduced by Evang and Kallmeyer (2011) who converted the long distance dependencies encoded by indexed traces in the original Penn treebank (Marcus et al., 1993) to discontinuous constituents. We used the standard split (sections 2-21 for training, 22 for development and 23 for test). The Tiger corpus (Brants et al., 2004) and the Negra corpus (Skut et al., 1997) are both German treebanks natively annotated with discontinuous constituents. We used the SPMRL split for the Tiger corpus (Seddah et al., 2013), and the split of Dubey and Keller (2003) for the Negra corpus.

4.2 Implementation and Protocol

We implemented our parser in Python using the Pytorch library (Paszke et al., 2017). We trained each model with the ASGD algorithm (Polyak and Juditsky, 1992) for 100 epochs. Training a single model takes approximately a week with a GPU. We evaluate a model every 4 epochs on the validation set and select the best performing model according to the validation F-score. We refer the reader to Table 5 of Appendix B for the full list of hyperparameters.

We evaluate models with the dedicated module of `discodop`[2] (van Cranenburgh et al., 2016). We use the standard evaluation parameters (`proper.prm`), that ignore punctuations and root symbols. We report two evaluation metrics: a standard Fscore (F) and an Fscore computed only on discontinuous constituents (Disc. F), which provides a more qualitative evaluation of the ability of the parser to recover long distance dependencies.

---

4.3 Results

Effect of Dynamic Oracle We present parsing results on the development sets of each corpus in Table 3. The effect of the oracle is in line with other published results in projective constituency parsing (Coavoux and Crabbé, 2016; Cross and Huang, 2016b) and dependency parsing (Goldberg and Nivre, 2012; Gómez-Rodríguez et al., 2014): the dynamic oracle improves the generalization capability of the parser.

External comparisons In Table 4, we compare our parser to other transition-based parsers (Maier, 2015; Coavoux and Crabbé, 2017a; Stanojević and Garrido Alhama, 2017; Coavoux et al., 2019), the pseudo-projective parser of Versley (2016), grammar-based chart parsers (Evang and Kallmeyer, 2011; van Cranenburgh et al., 2016; Gebhardt, 2018) and parsers based on dependency parsing (Fernández-González and Martins, 2015; Corro et al., 2017). Note that some of them only report results in a gold POS tag setting (the parser has access to gold POS tags and use them as features), a setting that is much easier than ours.

Our parser matches the state of the art of Coavoux et al. (2019). This promising result shows that it is feasible to design accurate transition systems without an ordered memory.

4.4 Efficiency

Our transition system derives a tree for a sentence of n words in exactly $4n-2$ transitions. Indeed, there must be n SHIFT actions, and $n-1$ COMBINE actions. Each of these $2n-1$ transitions must be followed by a single labelling action.

The statistical model responsible for choosing which action to perform at each parsing step needs to score $|S|+1$ actions for a structural step and $|N|+1$ actions for a labelling step (where N is the set of possible nonterminals). Since in the worst case, $|S|$ contains $n-1$ singletons, the parser has an $\mathcal{O}(n(|N|+n))$ time complexity.

In practice, the memory of the parser S remains relatively small on average. We report in Figure 3 the distribution of the size of S across configurations when parsing the development sets of three corpora. For the German treebanks, the memory contains 7 or fewer elements for more than 99 percents of configurations. For the Penn treebank, the memory is slighlty larger, with 98 percents of configuration with 11 or fewer items.

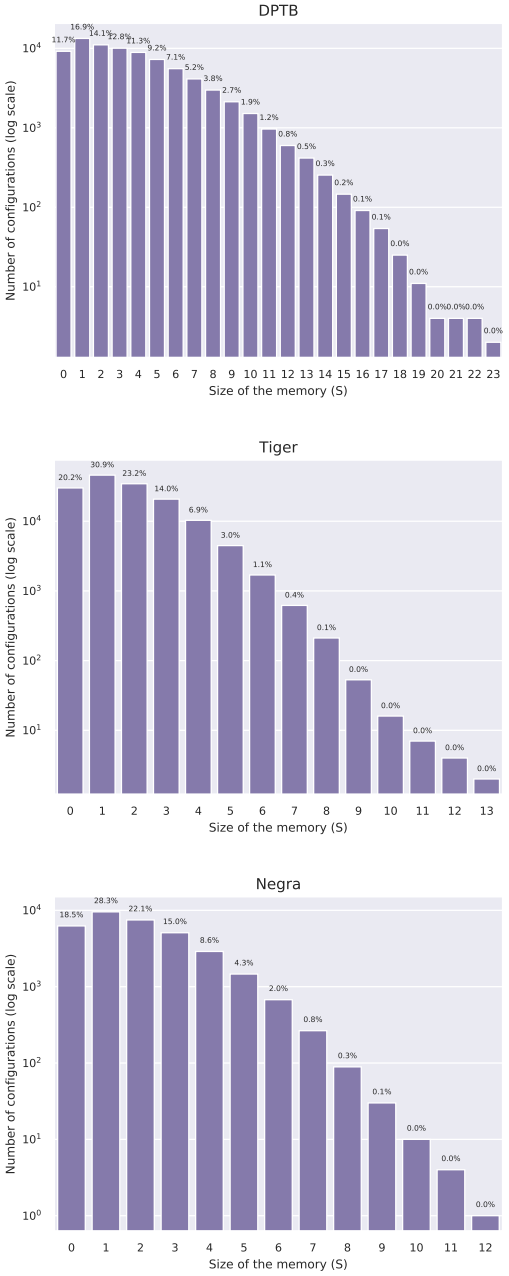

Figure 3: Distribution of the size of the memory of the parser S across configurations derived when parsing the development set of the three corpora. In practice, we observe that the memory remains small.

We report empirical runtimes in Table 6 of Appendix C. Our parser compares decently with other transition-based parsers, despite being written in Python.

5 Related Work

Existing transition systems for discontinuous constituency parsing rely on three main strategies for constructing discontinuous constituents: a swap-based strategy, a split-stack strategy, and the use of non-local transitions.

Swap-based systems Swap-based transition systems are based on the idea that any discontinuous constituency tree can be transformed into a projective tree by reordering terminals. They reorder terminals by swapping them with a dedicated action (SWAP), commonly used in dependency parsing (Nivre, 2009). The first proposals in transition-based discontinuous constituency parsing used the SWAP action on top of an easy-first parser (Versley, 2014a,b). Subsequent proposals relied on a shift-reduce system (Maier, 2015; Maier and Lichte, 2016) or a shift-promote-adjoin system (Stanojević and Garrido Alhama, 2017).

The main limitation of swap-based system is that they tend to require a large number of transitions to derive certain trees. The choice of an oracle that minimizes derivation lengths has a substantially positive effect on parsing (Maier and Lichte, 2016; Stanojević and Garrido Alhama, 2017).

Split-stack systems The second parsing strategy constructs discontinuous constituents by allowing the parser to reduce pairs of items that are not adjacent in the stack. In practice, Coavoux and Crabbé (2017a) split the usual stack of shift-reduce parsers into two data structures (a stack and a double-ended queue), in order to give the parser access to two focus items: the respective tops of the stack and the dequeue, that may or may not be adjacent. A dedicated action, GAP, pushes the top of the stack onto the bottom of the queue to make the next item in the stack available for a reduction.

The split stack associated with the GAP action can be interpreted as a linear-access memory: it is possible to access the i^{th} element in the stack, but it requires i operations.

Non-local transitions Non-local transitions generalize standard parsing actions to non-adjacent elements in the parsing configurations. Maier and Lichte (2016) introduced a non-local transition SKIPSHIFT-i which applies SHIFT to the i^{th} element in the buffer. Non-local transitions are also widely used in non-projective dependency parsing (Attardi, 2006; Qi and Manning, 2017; Fernández-González and Gómez-Rodríguez, 2018).

The key difference between these systems and ours is that we use an unordered memory. As a result, the semantics of the COMBINE-s action we introduce in Section 2 is independent from a specific position in the stack or the buffer. A system with an action such as SKIPSHIFT-i needs to learn parameters with every possible i, and will only learn parameters with the SKIPSHIFT-i actions that are required to derive the training set. In contrast, we use the same parameters to score each possible COMBINE-s action.

6 Conclusion

We have presented a novel transition system that dispenses with the use of a stack, i.e. a memory with linear sequential access. Instead, the memory of the parser is represented by an unordered data structure with random-access: a set. We have designed a dynamic oracle for the resulting system and shown their empirical potential with state-of-the-art results on discontinuous constituency parsing of one English and two German treebanks. Finally, we plan to adapt our system to non-projective dependency parsing and semantic graph parsing.

A Oracle Correctness

The oracle o leads to the reachable tree with the highest F-score with respect to the gold tree. The F-score of a predicted tree $\hat{t}$ (represented as a set of instantiated constituents) with respect to a gold tree t^* is defined as:

$$\mathsf{precision}(\hat{t}, t^*) = p = \frac{|\hat{t} \cap t^*|}{|\hat{t}|},$$

$$\mathsf{recall}(\hat{t}, t^*) = r = \frac{|\hat{t} \cap t^*|}{|t^*|},$$

$$F_1(\hat{t}, t^*) = \frac{2pr}{p + r}.$$

By definition, $\mathsf{o}_{\mathsf{odd}}$ is optimal for precision because it constructs a constituent only if it is gold, and optimal for recall because it will construct a gold constituent if it is possible to do so.

Moreover, $\mathsf{o}_{\mathsf{even}}$ is optimal for recall because any gold constituent reachable from c will still be reachable after any transition in $\mathsf{o}_{\mathsf{even}}(c, t^*)$. Assuming a configuration $c = (S, s_f, i, C)$ and $\mathsf{next}(c, t^*) = s_g$, we consider separately the SHIFT case and the COMBINE-s case:

- SHIFT case ($\max(s_g) > \max(s_f)$): constituents (X, s) reachable from c and not reachable from SHIFT(c) satisfy $\max(s) = i$. If a gold constituent satisfies this property, we have $s \preceq s_g$, which contradicts the assumption that $s_g = \mathsf{next}(c, t^*)$ (see definition of oracle in Section 2.2.2).
- COMBINE-s case: Let (X, s') be a reachable gold constituent. Since it is compatible with s_g, there are three possible cases:
    - if (X, s') is an ascendant of s_g, then $(s \cup s_f) \subseteq s_g \subset s'$, therefore (X, s') is still reachable from COMBINE-$s(c)$.
    - if (X, s') is a descendant of s_g then $s' \preceq s_g$, which contradicts the definition of s_g.
    - if s' and s_g are completely disjoint, we have $s' \cap s = s' \cap s_f = \emptyset$, therefore $s' \cap (s \cup s_f) = \emptyset$, and s' is still reachable from COMBINE-$s(c)$.

Finally, since $\mathsf{o}_{\mathsf{even}}$ does not construct new constituents (it is the role of labelling actions), it is optimal for precision.

B Hyperparameters

The list of hyperparameters is presented in Table 5.

- We use learning rate warm-up (linear increase from 0 to t_{1000} during the first 1000 steps).
- Before the t^{th} update, we add Gaussian noise to the gradient of every parameter with mean 0 and variance $\frac{0.01}{(1+t)^{0.55}}$ (Neelakantan et al., 2015).
- All experiments use greedy search decoding (we did not experiment with beam search).

Architecture hyperparameters	
Dimension of word embeddings	32
Dimension of character embeddings	100
Dimension of character bi-LSTM state	50 for each direction
Dimension of sentence-level bi-LSTM	200 for each direction
Dimension of hidden layers for the action scorer	200
Activation functions	$\tanh$ for all hidden layers
Optimization hyperparameters	
Initial learning rate	$l_0 = 0.01$
Learning rate decay	$l_t = \dfrac{l_0}{1 + t \cdot 10^{-7}}$ for step number t
Dropout for tagger input	0.5
Dropout for parser input	0.2
Training epochs	100
Batch size	1 sentence
Optimization algorithm	Averaged SGD (Polyak and Juditsky, 1992; Bottou, 2010)
Word and character embedding initialization	$\mathcal{U}([-0.1, 0.1])$
Other parameters initialization (including LSTMs)	Xavier (Glorot and Bengio, 2010)
Gradient clipping (norm)	100
Dynamic oracle p	0.15

Table 5: Hyperparameters of the model.

Parser	Setting	Tiger		DPTB	
		tok/s	sent/s	tok/s	sent/s
This work	Python, neural, greedy, CPU	978	64	910	38
MTG (Coavoux et al., 2019)	C++, neural, greedy, CPU	1934	126	1887	80

rparse (Maier, 2015)	Java, perceptron, beam=8, CPU		80		
rparse (Maier, 2015)	Java, perceptron, beam=1, CPU		640		
Corro et al. (2017)	C++, neural, CPU				≈ 7.3

Table 6: Parsing times on development sets in tokens per second (tok/s) and sentences per second (sent/s). The parsing times are presented as reported by authors, they are not comparable across parsers (since the experiments were run on different hardware). Our parser is run on a single core of an Intel i7 CPU.

- Before each training step, we replace a word embedding by an 'UNK' pseudo-word embedding with probability 0.3. We only do this replacement for the least frequent word-types ($\frac{2}{3}$ least frequent word-types). The 'UNK' embedding is then used to represent unknown words.
- We apply dropout at the input of the tagger and the input of action scorers: each single prediction has its own dropout mask.

C Detailed Results

We report indicative parsing times in Table 6. Detailed parsing results —including precision, recall, F-score and part-of-speech tag accuracy— are presented in Table 7.

		All const.			Disc. const.			POS

How Bad are PoS Taggers in Cross-Corpora Settings? Evaluating Annotation Divergence in the UD Project

Guillaume Wisniewski and **François Yvon**
LIMSI, CNRS, Univ. Paris-Sud, Université Paris-Saclay, F-91405 Orsay, France
`{guillaume.wisniewski,francois.yvon}@limsi.fr`

Abstract

The performance of Part-of-Speech tagging varies significantly across the treebanks of the Universal Dependencies project. This work points out that these variations may result from divergences between the annotation of train and test sets. We show how the annotation variation principle, introduced by Dickinson and Meurers (2003) to automatically detect errors in gold standard, can be used to identify inconsistencies between annotations ; we also evaluate their impact on prediction performance.

1 Introduction

The performance of Part-of-Speech (PoS) taggers significantly degrades when they are applied to test sentences that depart from training data. To illustrate this claim, Table 1 reports the error rate achieved by our in-house PoS tagger on the different combinations of train and test sets of the French treebanks of the Universal Dependencies (UD) project (Nivre et al., 2018). [1] It shows that depending on the train and test sets considered, the performance can vary by a factor of more than 25.

Many studies (Foster, 2010; Plank et al., 2014) attribute this drop in accuracy to *covariate shift* (Shimodaira, 2000), characterizing the differences between domains by a change in the marginal distribution $p(\mathbf{x})$ of the input (e.g. increase of out-of-vocabulary words, missing capitalization, different usage of punctuation, etc), while assuming that the conditional label distribution remains unaffected.

This work adopts a different point of view : we believe that the variation in tagging performance is due to a *dataset shift* (Candela et al., 2009), i.e. a change in the joint distribution of the features and labels. We assume that this change mainly results from incoherences in the annotations between corpora or even within the same corpus. Indeed, ensuring inter-annotator agreement in PoS tagging is known to be a difficult task as annotation guidelines are not always interpreted in a consistent manner (Marcus et al., 1993). For instance, Manning (2011) shows that many errors in the WSJ corpus are just mistakes rather than uncertainties or difficulties in the task ; Table 2 reports some of these *annotation divergences* that can be found in UD project. The situation is naturally worse in cross-corpora settings, in which treebanks are annotated by different laboratories or groups.

The contribution of this paper is threefold :

— we show that, as already pointed out by de Marneffe et al. (2017), the variation principle of Boyd et al. (2008) can be used to flag potential annotation discrepancies in the UD project. Building on this principle, we introduce, to evaluate the annotation consistency of a corpus, several methods and metrics that can be used, during the annotation to improve the quality of the corpus.

— we generalize the conclusions of Manning (2011), highlighting how error rates in PoS tagging are stemming from the poor quality of annotations and inconsistencies in the resources ; we also systematically quantify the impact of annotation variation on PoS tagging performance for a large number of languages and corpora.

— we show that the evaluation of PoS taggers in cross-corpora settings (typically in domain adaptation experiments) is hindered by systematic annotation discrepancies between the corpora and quantify the impact of this divergence on PoS tagger evaluation. Our observations stress the fact that comparing in- and out-domain scores as many

works do (e.g. to evaluate the quality of a domain adaptation method or the measure the difficulty of the domain adaptation task) can be flawed and that this metrics has to be corrected to take into account the annotation divergences that exists between corpora.

The rest of this paper is organized as follows. We first present the corpora and the tools used in our experiments (§ 2). We then describe the annotation variation principle of Dickinson and Meurers (2003) (§ 3) and its application to the treebanks of the Universal Dependencies project (§ 4). We eventually assess the impact of annotation variations on prediction performance (§ 5 and § 6).

The code and annotations of all experiments are available on the first author website.[2] For the sake of clarity, we have only reported our observations for the English treebanks of the UD project and, sometimes, for the French treebanks (because it has seven treebanks). Similar results have however been observed for other languages and corpora.

2 Experimental Setting

Data All experiments presented in this work use the Universal Dependencies (UD) 2.3 dataset (Nivre et al., 2018) that aims at developing cross-linguistically consistent treebank annotations for a wide array of languages.

This version of the UD project contains 129 treebanks covering 76 languages. Among those, 97 treebanks define a train set that contains between 19 sentences and 68,495 sentences and a test set that contains between 34 and 10,148 sentences. For 21 languages, several test sets are available : there are, for instance, 7 test sets for French, 6 for English, 5 for Czech and 4 for Swedish, Chinese, Japanese, Russian and Italian. Overall, it is possible to train and test 290 taggers (i.e. there are 290 possible combinations of a train and a test set of the same language), 191 of these *conditions* (i.e. pairs of a train set and a test set) correspond to a cross-corpus setting and can be considered for domain adaptation experiments.

Many of these corpora[3] result from an automatic transformation (with, for some of them, manual corrections) from existing dependency or constituent treebanks (Bosco et al., 2013; Lipenkova and Souček, 2014). Because most treebanks have been annotated and/or converted independently by different groups,[4] the risk of inconsistencies and errors in the application of annotation guidelines is increased. There may indeed be several sources of inconsistencies in the gold annotations : in addition to the divergences in the theoretical linguistic principles that governed the design of the original annotation guidelines, inconsistencies may also result from automatic (pre-)processing, human post-editing, or human annotation. Actually, several studies have recently pointed out that treebanks for the same language are not consistently annotated (Vilares and Gómez-Rodríguez, 2017; Aufrant et al., 2017). In a closely related context, Wisniewski et al. (2014) have also shown that, in spite of common annotation guidelines, one of the main bottleneck in cross-lingual transfer between UD corpora is the difference in the annotation conventions across treebanks and languages.

---

[2] `https://perso.limsi.fr/wisniews/recherche/#coherence`

[3] For PoS, only 23 treebanks have been manually annotated natively with the Universal PoS tagset.

[4] almost 65% of the UD contributors have participated in the annotation of only one corpus; for more than 15% of the treebanks all contributors have annotated a single corpus.

Table 2: Examples of annotation divergences in the English Web Treebank (EWT) corpus : these sentences share some common words (in bold) that do not have the same annotation. Only the labels that differ are represented.

PoS tagger In all our experiments, we use a history-based model (Black et al., 1992) with a LaSO-like training method (Daumé III and Marcu, 2005). This model reduces PoS tagging to a sequence of multi-class classification problems : the PoS of the words in the sentence are predicted one after the other using an averaged perceptron. We consider the standard feature set for PoS tagging (Zhang and Nivre, 2011) : current word, two previous and following words, the previous two predicted labels, etc. This 'standard' feature set has been designed for English and has not been adapted to the other languages considered in our experiments.

Our PoS tagger achieves an average precision of 91.10% over all UD treebanks, a result comparable to the performance of `UDPipe` 1.2 (Straka and Straková, 2017), the baseline of CoNLL'17 Shared Task '*Multilingual Parsing from Raw Text to Universal Dependencies*' that achieves an average precision of 91.22%. When not otherwise specified, all PoS tagging scores reported below are averaged over 10 runs (i.e. independent training of a model and evaluation of the test performance).

3 Annotation variation principle

The *annotation variation principle* (Boyd et al., 2008) states that if two identical sequences appear with different annotations, one of these two label sequences may be inconsistently annotated. Our work relies on this principle to identify discrepancies in the PoS annotation of treebanks.

We call *repeat* a sequence of words that appears in, at least, two sentences and *suspicious repeat* a repeat that is annotated in at least two different ways. Identifying suspicious repeats requires, first, to find all sequences of words that appear in two different sentences ; this is an instance of the *maximal repeat problem* : a *maximal repeat*, is a substring that occurs at least in two different sentences and cannot be extended to the left or to right to a longer common substring. Extracting maximal repeats allows us to find all sequence of words common to at least two sentences without extracting all their substrings. This problem can be solved efficiently using Generalized Suffix Tree (GST) (Gusfield, 1997) : if the corpus contains n words, extracting all the maximal repeats takes $\mathcal{O}(n)$ to build the GST and $\mathcal{O}(n)$ to list all the repeats. PoS annotations for these repeats can then be easily extracted and the ones that are identical can be filtered out to gather all suspicious repeats in a set of corpora. A detailed description of our implementation can be found in (Wisniewski, 2018).

Filtering heuristics Suspicious repeats can of course correspond to words or structures that are

ambiguity	◇ The early voting suggests that this time the Latin Americans **will come out to**$_{\text{PART}}$ vote in greater numbers , but it is unclear whether the increase will have an impact . ◇ Keep his cage open and go on your computer , or read a book , etc and maybe he **will come out to**$_{\text{ADP}}$ you .
inconsistency	◇ Trudeau will extend that invitation to the 45th **president**$_{\text{NOUN}}$ **of the United**$_{\text{ADJ}}$ **States**$_{\text{NOUN}}$, whoever he or she may be . ◇ I am GEORGE WALKER BUSH , son of the former **president**$_{\text{PROPN}}$ **of the United**$_{\text{PROPN}}$ **States**$_{\text{PROPN}}$ of America George Herbert Walker Bush , and currently serving as President of the United States of America .

Table 3: Example of an actual ambiguity and of an annotation inconsistency between the English EWT and PUD corpora. Repeated words are in bold and words with different PoS in red.

truly ambiguous. We consider two heuristics to filter out suspicious repeats. First with the *size heuristic*, we assume that longer suspicious repeats are more likely to result from annotation errors than shorter ones. For instance, Table 2 displays suspicious repeats with at least 10 words that all stem from an annotation error.

Second, with the *disjoint heuristic*, we assume that actual ambiguities will be reflected in intra-corpus suspicious repeats, whereas errors will likely correspond to cases where differences in labelings are observed in different corpora. Formally, the *disjoint heuristic* flags repeats m occurring in at least two corpora A and B, and such that the set of labelings of m observed in A are disjoint from the set of labelings observed in B.

For instance, in French, *“la porte”* can either be a determiner and a noun (e.g. in the sentence *“la porte est fermée”* — the door is closed) or a pronoun followed by a verb (e.g. in the sentence *“je la porte”* — I carry her). Observing these two possible labelings in at least two corpora is a good sign of an actual ambiguity. The disjoint heuristic allows us to detect that this suspicious repeat is an actual ambiguity. To reiterate, the intuition beyond the disjoint heuristic is that for ambiguities, the two possible annotations will appear in, at least, one of the two corpora.

Conversely, systematic divergences in labeling observed across corpora are likely to be errors : for instance, in English, depending on the treebank, cardinal points are labeled as either proper nouns or as nouns. In this case, the set of labelings of the repeats in the first corpus is disjoint from the set of labeling in the second corpus and the disjoint heuristic captures the annotation inconsistency.

Analyzing filtering heuristics To further analyze these two heuristics, we have manually annotated the suspicious repeats between the train set of the English EWT corpus and the test set of the English PUD corpus. For each suspicious repeat, we record whether it is an annotation error or an actual ambiguity. Examples of annotations are given in Table 3.

Results are in Table 4. It appears that, for the heuristics considered, a large part of the suspicious repeats correspond to annotation discrepancies rather than ambiguities. In many cases, these discrepancies result from systematic divergences in the interpretation of the UD guidelines. [5] For instance, the contraction “`n't`” is always labeled as a particle in the train set of the EWT corpus, but either as particle or an adverb in the PUD corpus. Most of these systematic differences involve distinction between nouns and proper nouns, auxiliaries and verbs and adjectives and verbs (for past participles).

4 Quantifying Annotation Divergence in the UD Corpora

4.1 Annotation Variations in the UD

We will first show how the annotation variation principle allows us to characterize the noise and/or the difficulty of PoS tagging. Table 5 reports the number of repeats and suspicious repeats in the English corpora of the UD project. These numbers have been calculated by applying the method described in the previous section to the concatenation of train, development and test sets of each treebanks. To calibrate these measures, we conducted

---

[5] Discrepancies are not only due to improper interpretations of the guidelines, but also sometimes to actual ambiguities in the annotation rules.

heuristic	# susp. repeats	# inconsistencies
size=4	28	22 78.6%
size=3	214	153 71.5%
disjoint	580	407 70.3%
none	2507	—

Table 4: Percentage of suspicious repeats between the EWT and PUD corpora that contain an annotation inconsistency according to a human annotator either when the disjoint heuristic is used or when only suspicious repeats with at least *n* words are considered.

the same experiments with the Wall Street Journal (Marcus et al., 1993),[6] the iconic corpus of PoS tagging for which a thorough manual analysis of the annotation quality is described in (Manning, 2011).

The observations reported in Table 5 show that the number of repeats varies greatly from one corpus to another, which is not surprising considering the wide array of genres covered by the treebanks that includes sentences written by journalists or learner of English (the genres with the largest number of repeats) or sentences generated by users on social media (that contain far less repeated parts). These observations also show that the percentage of repeats that are not consistently annotated is slightly larger in the UD treebanks than in the WSJ, a corpus in which a manual inspection of the corpus reveals that many variations are 'mistakes' rather than representing uncertainties or difficulties in the PoS prediction (Manning, 2011).

More interestingly, Table 6 shows the percentage of repeats that are not consistently annotated for all possible combinations of a train and a test sets (ignoring sequences of words that do not appear at least once in both corpora). It appears that in all cases there are (sometimes significantly) more variations in annotations in cross-treebank settings than in situations where the train and the test sets belong to the same treebank. This observation suggests that there may be systematic differences in the annotations of different treebanks which could make the domain adaptation setting artificially more difficult.

Treebank	# sent.	% sent. repeat	% var.
ESL	5,124	79.0	10.4
EWT	16,622	13.1	9.0

WSJ	21,928	66.1	8.4

Table 5: Percentage of sentences with a repeat of at least three words in the English treebanks (`% sent. repeat`) and percentage of these repeats that are not labeled consistently (`% var.`).

4.2 How do treebanks differ ?

To characterize the difference between two treebanks, we measure the error rate of a binary classifier deciding from which corpus an annotated sentence is coming from.[7] Intuitively, the higher this error rate, the more difficult it is to distinguish sentences of the two corpora and the more similar the treebanks are. More formally, it can be shown (Ben-David et al., 2010) that this error rate is an estimation of the $\mathcal{H}$-divergence (Kifer et al., 2004), a metric introduced in machine learning theory to quantify the impact of a change in domains by measuring the divergence between the distributions of examples sampled from two datasets.

In our experiments, we use a Naive Bayes classifier[8] and three sets of features to describe a sentence pair and their annotation : *words*, in which each example is represented by the bag of its 1-gram and 2-gram of words ; *labels*, in which examples are represented in the same way, but this time, considering PoS ; and *combi* which uses the same representation after the words of all the treebanks have been concatenated with their PoS. The first set aims at capturing a potential covariate shift, the last two target divergence in annotations. To reduce the impact of the strong between-class imbalance,[9] in all our experiments we sub-sample the largest set to ensure that the two datasets we try to distinguish always have the same number of examples. All scores in this experiment are averaged over 20 train-test splits.

---

[6] The Penn Treebank tagset has been manually converted to the Universal PoS tagset using the mapping of (Petrov et al., 2012) generalized to the extended UD PoS tagset.

[7] More precisely, the classifier analyses pairs of sentences and predicts whether they belong to th same corpus or not.

[8] We used the implementation provided by (Pedregosa et al., 2011) without tuning any hyper-parameters. Experiments with a logistic regression show similar results.

[9] The ratio between the number of examples in the two corpora can be as large as 88.

↓ train / test →	ESL	EWT	GUM	LinES	ParTUT	WSJ	PUD
ESL	**10.0%**	11.7%	10.6%	11.1%	10.0%	12.9%	10.9%
EWT	11.8%	**8.7%**	9.1%	10.1%	8.9%	18.8%	9.2%
GUM	14.3%	9.0%	**8.2%**	11.6%	8.5%	15.8%	11.1%
LinES	16.9%	12.8%	12.6%	**12.4%**	12.5%	16.6%	14.2%
ParTUT	13.8%	10.5%	9.9%	12.0%	**9.0%**	14.9%	12.5%

Table 6: Percentage of repeats between a train and a test sets that are not annotated consistently. In-domain settings (i.e. when the train and test sets come from the same treebank) are reported in bold; for each train set, the most consistent setting is underlined.

Table 7 reports the results achieved with the different features sets averaged over all combinations of a train and a test set of the same language and gives the percentage of conditions for which each feature set achieved the best results; Figure 1 details these results for the English and French treebanks. Results for other languages show similar patterns. These results suggest that, in many cases, it is possible to accurately identify from which treebank a sentence and its annotation are coming, although these raw numbers are difficult to interpret as prediction performances are averaged over many different experimental conditions. In more than 50% of the cases, combining words to their PoS results in the best performance, which is consistent to the qualitative study reported in Section 3 : some words appear in two corpora with different PoS allowing to distinguish these corpora. This observation strongly suggests that divergence in annotations across corpora are often genuine.

5 Impact of annotation variation on prediction performance

To study annotation divergence in the UD project, we propose to analyze suspicious repeats (i.e. sequence of repeated words with different annotations). We start by extracting all the suspicious repeats that can be found when considering all the possible combinations of a train set and a test or development set of a given language. These matches are then filtered using the heuristics described in §3. There are, overall, 357,301 matches in the UD project, 69,157 of which involve 3 words or more and 14,142 5 words or more; the disjoint heuristic selects 122,634 of these matches (see Table 8 in §A).

features	median	% best
words	78.2	31.0
labels	70.9	13.5
combi	78.8	55.5

Table 7: Precision (%) achieved over all cross-treebank conditions by a classifier identifying to which treebank a sentence belongs to.

To highlight the connection between prediction errors and annotation divergence, we compute, for each possible combination of a train and a test set (considering all languages in the UD project), the correlation between the error rate achieved on a corpus `B` when training our PoS on a corpus `A` and the number of suspicious repeats between `A` and `B` normalized by the number of tokens in `A` and `B`. The Spearman correlation coefficient between these two values is 0.72 indicating a correlation generally qualified as ‘strong’ following the interpretation proposed by (Cohen, 1988) : the more there are sequences of words with different annotations in the train and test sets, the worse the tagging performance, which shows that annotation inconsistencies play an important role in explaining the poor performance of PoS tagger on some conditions.

For a more precise picture, we also estimate the number of suspicious repeats that contain a prediction error. Using the disjoint heuristics to filter suspicious repeats, it appears that 70.2% (resp. 73.0%) of the suspicious repeats for English (resp. French) contain a prediction error. As expected, these numbers fall to 51.7% (resp. 49.9%) when the suspicious repeats are not filtered and therefore contain more ambiguous words. Figure 2 displays a similar trend when the suspicious repeats are filtered by their length; similar results are observed for all other languages.

These observations suggest that annotation variations often results in prediction errors, espe-

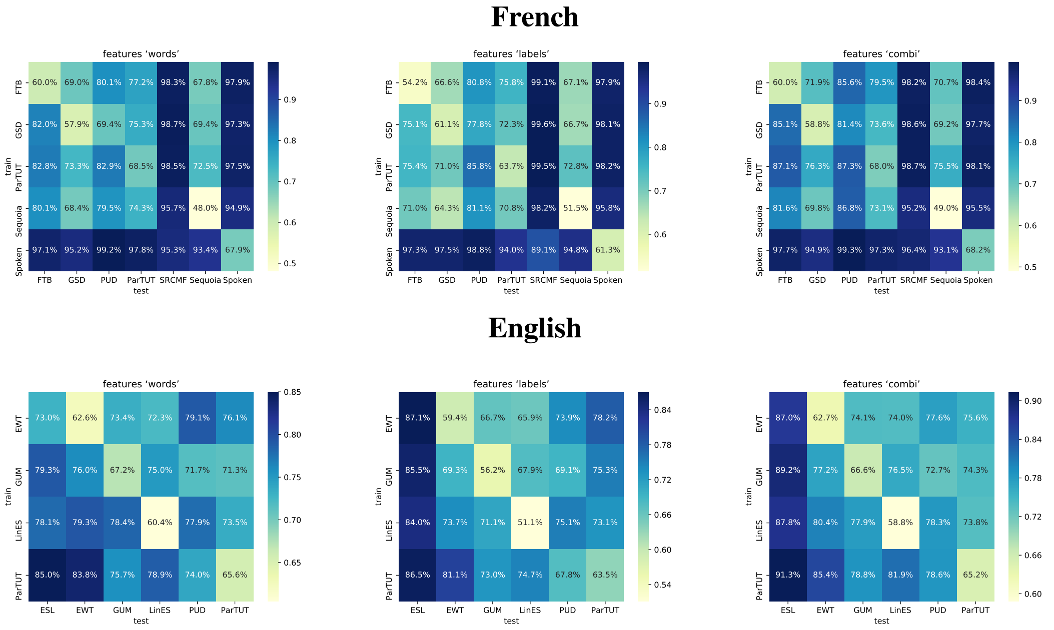

Figure 1: Precision of a classifier identifying to which French (top) or English (bottom) treebank a sentence belongs to. Train corpora are on the y-axis and test corpora on the x-axis.

cially when there are good reasons to assume that the variation actually stems from an inconsistency.

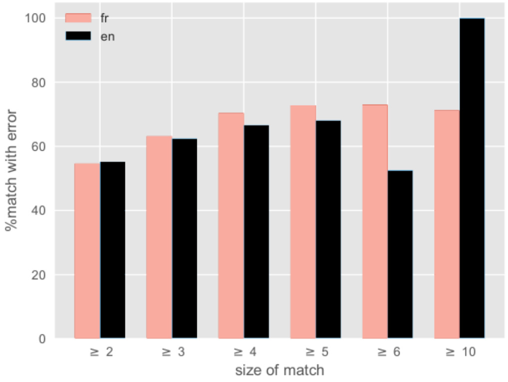

Figure 2: Percentage of suspicious repeats that contain at least one prediction error in function of their size.

6 Re-Assessing the Performance of PoS Tagger in Cross-Corpus Setting

To evaluate the impact of annotation errors on prediction performance, we propose, for each combination of a train and a test set, to train a PoS tagger and compare $\varepsilon_{\text{full}}$, the error rate achieved on the full test set to $\varepsilon_{\text{ignoring}}$ the error rate achieved ignoring errors that occur in a suspicious repeat. More precisely, $\varepsilon_{\text{ignoring}}$ is defined as :

$$\varepsilon_{\text{ignoring}} = \frac{\#\{\text{err}\} - \#\{\text{err in suspicious repeats}\}}{\#\{\text{words}\}} \quad (1)$$

where $\#\{\text{err in suspicious repeats}\}$ in the number of errors in the suspicious repeats that have survived filtering. Intuitively $\varepsilon_{\text{ignoring}}$ can be seen as an 'oracle' score corresponding to a tagger that would always predict the labels of suspicious repeat correctly. In the following, We will consider three different filters : the disjoint heuristic, keeping only suspicious repeats with more than three words and keeping all of them.

Figure 3 reports these errors rates for French and English. Results for other languages show similar results. As expected, ignoring errors in suspicious repeats significantly improve prediction performance. It even appears that $\varepsilon_{\text{ignoring}}$ is often on par with the score achieved on in-domain sets. Overall, in more than 43% (resp. 25%) of all the conditions the error rate ignoring errors in suspicious repeats filtered with the disjoint heuristic (resp. minimum heuristic) is lower than the error rate achieved on in-domain data. These values are naturally over-estimated as, in these experiments, we remove all potential annotation errors as well as words and structures that are ambiguous and therefore are more difficult to label. They can however be considered as lower-bound on the predic-

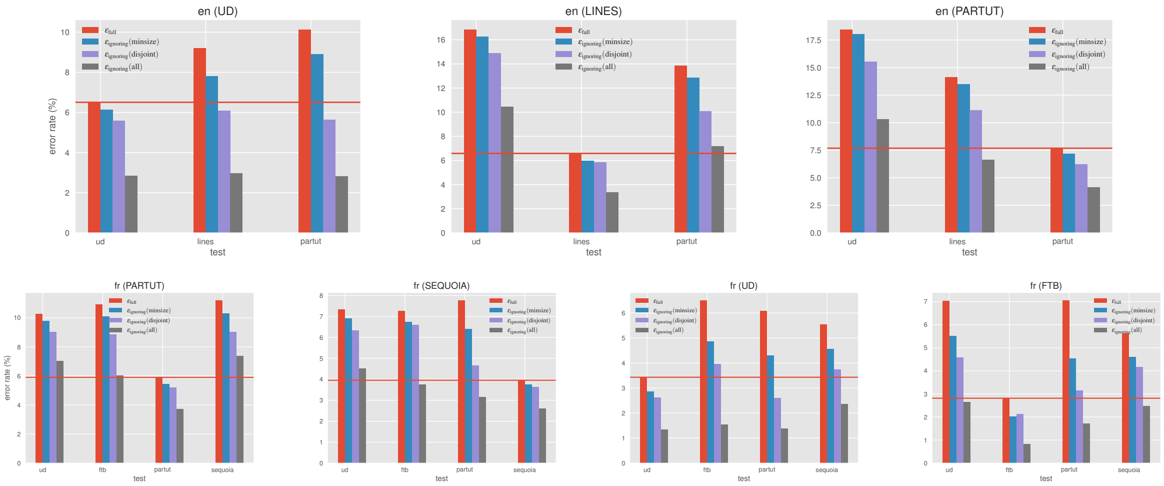

Figure 3: Error rate achieved by a PoS tagger on the different English treebanks of the UD project when errors in suspicious repeats are ignored. The red line indicates the error rate on in-domain data.

tion quality.

To assess their quality, we have manually checked all the suspicious repeats between the train set of French UD and the test set of the French FTB correcting inconsistencies and errors (almost 2,000 PoS were modified). [10] When trained on the original UD corpus, the PoS tagger achieved an error rate of 6.78% on the FTB corpus (4.51% on in-domain data). After correcting inconsistencies, the out-domain error rate falls down to 5.11%. This value is close to the error rate ignoring suspicious repeats containing three and more words, showing the validity of the heuristics we have considered.

7 Conclusion

In this work, we have shown that, for PoS tagging, many prediction errors in cross-corpora settings (which is a typical domain adaptation scenario) stem from divergence between annotations. We have also described a method to quantify this divergence. We have only considered here corpora from the UD project and PoS annotation, but we consider that our method is very generic and can be easily applied to other corpora or tasks (e.g. tokenization, dependency parsing, etc.) that we will address in future work. We also plan to see how the different experiments we have made to identify annotation errors and inconsistencies can be used during the annotation process to reduce the workload of annotators and help them creating high-quality corpora.

CCG Parsing Algorithm with Incremental Tree Rotation

Abstract

The main obstacle to incremental sentence processing arises from right-branching constituent structures, which are present in the majority of English sentences, as well as from optional constituents that adjoin on the right, such as right adjuncts and right conjuncts. In CCG, many right-branching derivations can be replaced by semantically equivalent left-branching incremental derivations.

The problem of right-adjunction is more resistant to solution, and has been tackled in the past using *revealing*-based approaches that often rely either on the higher-order unification over lambda terms (Pareschi and Steedman, 1987) or heuristics over dependency representations that do not cover the whole CCGbank (Ambati et al., 2015).

We propose a new incremental parsing algorithm for CCG following the same *revealing* tradition of work but having a purely syntactic approach that does not depend on access to a distinct level of semantic representation. This algorithm can cover the whole CCGbank, with greater incrementality and accuracy than previous proposals.

1 Introduction

Combinatory Categorial Grammar (CCG) (Ades and Steedman, 1982; Steedman, 2000) is a mildly context sensitive grammar formalism that is attractive both from a cognitive and an engineering perspective. Compared to other grammar formalisms, the aspect in which CCG excels is incremental sentence processing. CCG has a very flexible notion of constituent structure which allows (mostly) left-branching derivation trees that are easier to process incrementally. Take for instance the derivation tree in Figure 1a. If we use a non-incremental shift-reduce parser (as done in the majority of transition-based parsers for CCG (Zhang and Clark, 2011; Xu et al., 2014; Xu, 2016)) we will be able to establish the semantic connection between the subject "Nada" and the verb "eats" only when we reach the end of the sentence. This is undesirable for several reasons. First, human sentence processing is much more incremental, so that the meaning of the prefix "Nada eats" is available as soon as it is read (Marslen-Wilson, 1973). Second, if we want a predictive model—either for better parsing or language modelling—it is crucial to establish relations between the words in the prefix as early as possible.

To address this problem, a syntactic theory needs to be able to represent partial constituents like "Nada eats" and have mechanisms to build them just by observing the prefix. In CCG solutions for these problems come out of the theory naturally. CCG categories can represent partial structures and these partial structures can combine into bigger (partial) structures using CCG combinators recursively. Figure 1b shows how CCG can incrementally process the example sentence via a different derivation tree that generates the same semantics more incrementally by being left-branching.

This way of doing incremental processing seems straightforward except for one obstacle: optional constituents that attach from the right, i.e. right adjuncts. Because they are optional, it is impossible to predict them with certainty. This forces an eager incremental processor to make an uninformed decision very early and, if later that decision turns out to be wrong, to backtrack to repair the mistake. This behaviour would imply that human processors have difficulty in processing right adjuncts, but that does not seem to be the case. For instance, let's say that after incrementally processing "Nada eats apples" we encounter right adjunct "regularly" as in Figure 2a. The parser will be stuck at this point because there is no way to at-

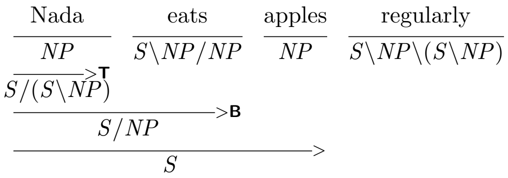
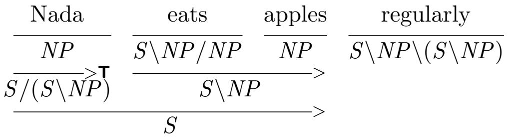
(b) Left-branching derivation.

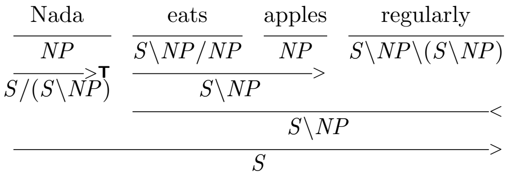
Figure 1: Semantically equivalent CCG derivations.



(a) Problem – $S\backslash NP$ that needs to be modified was never built.



(b) Incremental tree rotation *reveals* $S\backslash NP$.



(c) Right adjunct is attached to the revealed node.

Figure 2: Right adjunction.

tach the right adjunct of a verb phrase to a sentence constituent. A simple solution would be some sort of limited back-tracking where we would look if we could extract the verb-phrase, attach its right adjunct, and then put the derivation back together. But how do we do the extraction of the verb-phrase "eats apples" when that constituent was never built during the incremental left-branching derivation?

Pareschi and Steedman (1987) proposed to *reveal* the constituent that is needed, the verb-phrase in our example, by having an elegant way of reanalysing the derivation. This reanalysis does not repeat parsing from scratch but instead runs a single CCG combinatory rule backwards. In the example at hand, first we recognise that right adjunction needs to take place because we have a category of shape $X\backslash X$ (concretely $(S\backslash NP)\backslash(S\backslash NP)$ but in the present CCG notation slashes "associate to the left", so we drop the first pair of brackets). Thanks to the type of the adjunct we know that the constituent that needs to be revealed is of type X, in our case $S\backslash NP$. Now, we take the constituent on the left of the right adjunct, in our example constituent S, and look for CCG category Y and combinatory rule C that satisfies the following relation: $C(Y, S\backslash NP) = S$. The solution to this type equation is $Y{=}NP$ and $C{=}{<}$.

To confine revealing to delivering constituents that the parser *could have* built if it had been less greedy for incrementality, and exclude revelation of unsupported types, such as PP in Figure 2a, the process must be constrained by the actual derivation. Pareschi and Steedman proposed to do so by accessing the semantic representation in parallel, using higher-order unification, which is in general undecidable and may be unsound unless defined over a specific semantic representation.

Ambati et al. (2015) propose an alternative method for revealing where dependencies are used as a semantic representation (instead of first-order logic) and special heuristics are used for revealing (instead of higher order unification). This is computationally a much more efficient approach and appears sound, but requires distinct revealing rules for each constituent type and has specific difficulties with punctuation.

In this paper we propose a method of revealing that does not depend on any specific choice of semantic representation, can discover multiple possible revealing options if they are available, is sound and complete and computationally efficient, and gives state-of-the-art parsing results. The algorithm works by building left-branching derivations incrementally, but, following Niv (1993, 1994), as soon as a left branching derivation is built, its derivation tree is rebalanced to be right-branching. When all such constituents' derivation trees are right-branching, revealing becomes a trivial operation where we just traverse the right spine looking for the constituent(s) of the right type to be modified by the right adjunct.

We call this rebalancing operation *tree rota-*

tion since it is a technical term established in the field of data structures for similar operation of balanced binary search trees (Adelson-Velskii and Landis, 1962; Guibas and Sedgewick, 1978; Okasaki, 1999; Cormen et al., 2009). Figure 2b shows the right rotated derivation "Nada eats apples" next to the adjunct. Here we can just look up the required $S\backslash NP$ and attach the right adjunct to it as in Figure 2c.

2 Combinatory Categorial Grammar

CCG is a lexicalized grammar formalism where each lexical item in a derivation has a category assigned to it which expresses the ways in which the lexical item can be used in the derivation. These categories are put together using combinatory rules.

The binary combinatory rules we use are:

$$\begin{array}{llcll}
X/Y & Y & \Rightarrow & X & (>) \\
Y & X\backslash Y & \Rightarrow & X & (<) \\
X/Y & Y/Z & \Rightarrow & X/Z & (>\mathbf{B}) \\
Y\backslash Z & X\backslash Y & \Rightarrow & X\backslash Z & (<\mathbf{B}) \\
Y/Z & X\backslash Y & \Rightarrow & X/Z & (<\mathbf{B}_{\times}) \\
Y/Z|W & X\backslash Y & \Rightarrow & X/Z|W & (<\mathbf{B}^2_{\times}) \\
X/Y & Y/Z|W & \Rightarrow & X/Z|W & (>\mathbf{B}^2)
\end{array}$$

Each binary combinatory rule has one primary and one secondary category as its inputs. The primary functor is the one that selects; while the secondary category is the one that is selected. In forward combinatory rules the primary functor is always the left argument, while in the backward combinatory rules it is always the right.

It is useful to look at the mentioned combinatory rules in a generalised way. For instance, if we look at forward combinatory rules we can see that they all follow the same pattern of combining X/Y with a category that starts with Y. The only difference among them is how many subcategories follow Y in the secondary category. In case of forward function application there will be nothing following Y so we can treat forward function application as a generalised forward composition combinator of the zeroth order $>\mathbf{B0}$. Standard forward function composition $>\mathbf{B}$ will be a generalised composition of first order $>\mathbf{B1}$ while $>\mathbf{B}^2$ will be $>\mathbf{B2}$. Same generalisation can be applied to backward combinators. There is a low bound on the order of combinatory rules, around 2 or 3.

Following Hockenmaier and Steedman (2007), the proclitic character of conjunctions is captured in a syncategorematic rule combining them with the right conjunct, with the result later combining with the left conjunct [1] :

$$\begin{array}{llcll}
conj & X & \Rightarrow & X[conj] & (>\mathbf{\Phi}) \\
X & X[conj] & \Rightarrow & X & (<\mathbf{\Phi})
\end{array}$$

Some additional unary and binary type-changing rules are also needed to process the derivations in CCGbank (Hockenmaier and Steedman, 2007). We use the same type-changing rules as those described in (Clark and Curran, 2007).

Among the unary combinatory rules the most important one is type-raising. The first reason for that is that it allows CCG to handle constructions like argument cluster coordination in a straightforward way. Second, it allows CCG to be much more incremental as seen from the example in Figure 1b. Type-raising rules are expressed in the following way:

$$\begin{array}{lcll}
X & \Rightarrow & Y/(Y\backslash X) & (>\mathbf{T}) \\
X & \Rightarrow & Y\backslash(Y/X) & (<\mathbf{T})
\end{array}$$

Type-raising, is strictly limited to applying to category types that are *arguments*, such as NP, PP, etc., making it analogous to grammatical *case* in languages like Latin and Japanese, in spite of the lack of morphological case in English.

3 Parsing

CCG derivations can be parsed with the same shift-reduce mechanism used for CFG parsing (Steedman, 2000). In the context of CFG parsing, the shift-reduce algorithm is not incremental, because CFG structures are mostly right-branching, but in CCG by changing the derivation via the combinatory rules we also change the level of incrementality of the algorithm.

As usual, the shift-reduce algorithm consists of a stack of the constituents built so far and a buffer with words that are yet to be processed. Parsing starts with the stack empty and the buffer containing the whole sentence. The end state is a stack with only one element and an empty buffer. Transitions between parser states are:

- *shift(X)* – moves the first word from the buffer to the stack and labels it with category *X*,
- *reduceUnary(C)* – applies a unary combinatory rule *C* to the topmost constituent on the stack,
- *reduceBinary(C)* – applies a binary combinatory rule *C* to the two topmost constituents on

---

[1] This notation differs unimportantly from Steedman (2000) who uses a ternary coordination rule, and more recent work in which conjunctions are $X\backslash X/X$.

the stack.

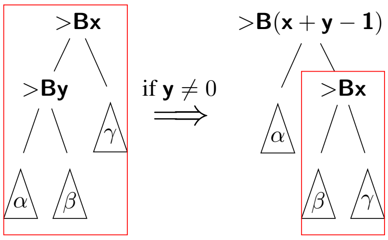
CCG shift-reduce parsers are often built over right-branching derivations that obey Eisner normal form (Eisner, 1996). Processing left-branching derivations is not any different except that it requires an opposite normal form.

Our revealing algorithm adds a couple of modifications to this default shift-reduce algorithm. First, it guarantees that all the trees stored on the stack are right-branching – this still allows left-branching parsing and only adds the requirement of adjusting newly reduced trees on the stack to be right leaning. Second, it adds *revealing* transitions that exploit the right-branching guarantee to apply right adjunction. Both tree rotation and revealing are performed efficiently as described in the following subsections.

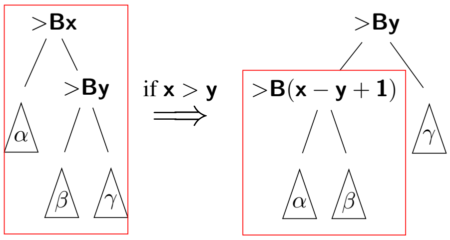
3.1 Tree rotation

A naïve way of enforcing right-branching guarantee is to do a complete transformation of the subtree on the stack into a right-branching one. However, that would be unnecessarily expensive. Instead we do *incremental tree rotation* to right. If we assume that all the elements on the stack are respecting this right-branching form (our inductive case), this state can be disturbed only by *reduceBinary* transition (*shift* just adds a single word which is trivially right-branching and *reduceUnary* does not influence the direction of branching). The *reduceBinary* transition will take two topmost elements on the stack that are already right-branching and put them as children of some new binary node. We need to repair that potential "imperfection" on top of the tree. This is done by recursively rotating the nodes as in Figure 3a.[2]

This figure shows one of the sources of CCG's spurious ambiguity: parent-child relation of the combinatory rules with the same directionality. Here we concentrate on forward combinators because they are the most frequent in our data—most backward combinators disappear with the addition of forward type-raising and the addition of special right adjunct transitions—but the same method can be applied to backward combinatory rules as a mirror image. Having two combinatory rules of the same directionality is necessary but not sufficient condition for spurious ambiguity. As visible on the Figure 3a side condition, the lower combinator must not be >**B0**. The tree rotation function assumes that both of the children are "perfect"—meaning right-branching[3]— and that the only imperfection is on the root node. The method repairs this imperfection on the root by applying the tree rotation transformation, but it also creates a new node as a right child and that node might be imperfect. That is why the method goes down the right node recursively until all the imperfections are removed and the whole tree becomes fully right-branching. In the worst case the method will reach the bottom of the tree, but often only 3 or 4 nodes need to be transformed to make the tree perfectly the right branching The worst case complexity of repairing the imperfection is $O(n)$ which makes the complexity of the whole parsing algorithm $O(n^2)$ for building a single derivation.



(a) Rotate to right.



(b) Rotate to left.

Figure 3: Tree rotation operations. The red square signifies recursion. Variables x and y represent the orders of the combinatory rules.

As a running example we will use a derivation tree in Figure 4a for which a transition sequence is given in Figure 4b. Here tree rotation is used in transitions 6 and 8 that introduce imperfections. In transition 6 a single tree rotation at the top was enough to correct the imperfection, while in transition 8 recursive tree rotation function went to depth two.

If the upper and lower combinators are both >**B2** the topmost combinator on the right will be-

---

[2] Although we do not discuss the operations on the semantic predicate-argument structure that correspond to tree-rotation, the combinatory semantics of the rules themselves guarantees that such operations can be done uniformly and in parallel.

[3] By right branching we mean as right branching as it is allowed by CCG formalism and predicate-argument structure.

(b) Transition sequence for the derivation tree.

Figure 4: Example of the algorithm run over a sentence with tensed VP coordination.

come >**B3**, a combinatory rule that may be unnecessary for defining the competence grammar of human languages, but which is required if parsing performance is to be as incremental as possible. Fortunately, the configuration with two connected >**B2** combinatory rules appears very rarely in CCGbank.

Many papers have been published on using left-branching CCG derivations but, to the best of our knowledge, none of them explains how are they constructed from right-branching CCGbank trees. A very simple algorithm for that can be made using our tree rotation function. Here we use rotation in the opposite direction i.e. rotation to left (Figure 3b). We cannot apply this operation from the top node of the CCGbank tree because that tree does not satisfy the assumption of the algorithm: immediate children are not "perfect" (here perfect means being left-branching). That is why we start from the bottom of the tree with terminal nodes that are trivially "perfect" and apply tree transformation to each node in post-order traversal.

This incremental tree rotation algorithm is inspired by the AVL self-balancing binary search trees (Adelson-Velskii and Landis, 1962) and Red-Black trees (Guibas and Sedgewick, 1978; Okasaki, 1999). The main difference is that here we are trying to do the opposite of AVLs: instead of making the tree perfectly balanced we are trying to make it perfectly unbalanced, i.e. leaning to the right (or left). Also, our imperfections start at the top and are pushed to the bottom of the tree which is in contrast to AVLs trees where imperfections start at the bottom and get pushed to the top.

The last important point about tree rotation concerns punctuation rules. All punctuation is attached to the left of the highest possible node in case of left-branching derivations (Hockenmaier and Bisk, 2010), while in the right-branching derivations we lower the punctuation to the bottom left neighbouring node. Punctuation has no influence on the predicate-argument structure so it is safe to apply this transformation.

3.2 Revealing transitions

If the topmost element on the stack is of the form $X\backslash X$ and the second topmost element on the stack has on its right edge one or more constituents of a type $X|\$$ we allow *reveal* transition.[4] This is a more general way of revealing than approaches of Pareschi and Steedman (1987) and Ambati et al. (2015) who attempt to reveal only constituents of type X while we reveal any type that has X as its prime element (that is the meaning of $X|\$$ notation).

We also treat X[conj] as right adjuncts of the left conjunct. Similarly to the previous case, if the topmost element on the stack is X[conj] and the right edge of the second topmost element on the stack has constituent(s) of type X, they are revealed for possible combination via $<\mathbf{\Phi}$ combinator.

If *reveal* transition is selected, as in transition 14 in Figure 4b, the parser enters into a mode of choosing among different constituents labelled $X|\$$ that could be modified by the right adjunct $X\backslash X$. After particular $X|\$$ node is chosen $X\backslash X$ is combined with it and the rest of the tree above X node is rebuilt in the same way. This rebuild is fully deterministic and is done quickly even though in principle it could take $O(n)$ to compute. Even in the worst case scenario, it does not make the complexity of the algorithm go higher than $O(n^2)$.

The ability of our algorithm to choose among different possible revealing options is unique among all the proposals for revealing. For transition 15 in Figure 4b the parser can choose whether to adjoin (coordinate) to a verb phrase that already contains a left modifier or without. This is similar to *Selective Modifier Placement* strategy from older Augmented Transition Network (ATN) systems (Woods, 1973) which finds all the attachment options that are syntactically legal and then allows the parser to choose among those using some criteria. Woods (1973) suggests using lexical semantic information for this selection, but in his ATN system only handwritten semantic selection rules were used. Here we will also use selection based on the lexical content but it will be broad coverage and learned from the data. This ability to semantically select the modifier's attachment point is essential for good parsing results as will be shown.

4 Neural Model

The neural probabilistic model that chooses which transition should be taken next conditions on the whole state of the configuration in a similar way to RNNG parser (Dyer et al., 2016). The words in the sentence are first embedded using the concatenation of top layers of ELMo embeddings (Peters et al., 2018) that are normalised to L2 norm and then refined with two layers of bi-LSTM (Graves et al., 2005). The neural representation of the terminal is composed of concatenated ELMo embedding and supertag embedding.

The representation of a subtree combines:

- span representation – we subtract representation of the leftmost terminal from the representation of the rightmost terminal as done in LSTM-Minus architecture (Wang and Chang, 2016),
- combinator and category embeddings,
- head words encoding – because each constituent can have a set of heads, for instance arising from coordination, we model representation of heads with DeepSet architecture (Zaheer et al., 2017) over representations of head terminals.

We do not use recursive neural networks like Tree-LSTM (Tai et al., 2015) to encode subtrees because of the frequency of tree rotation. These operations are fast, but they would trigger frequent recomputation of the neural tree representation, so we opted for a mechanism that is invariant to re-branching.

The stack representation is encoded using Stack-LSTM (Dyer et al., 2015). The configuration representation is the concatenation of the stack representation and the representation of the rightmost terminal in the stack. The next *non-revealing* transition is chosen by a two-layer feed-forward network.

If the *reveal* transition is triggered, the system needs to choose which among the candidate nodes $X|\$$ to adjoin the right modifier $X\backslash X$ to. The number of these modifiers can vary so we cannot use a simple feed-forward network to choose among them. Instead, we use the mechanism of *Pointer networks* (Vinyals et al., 2015), which works in a similar way to attention (Bahdanau et al., 2014) except that attention weights are interpreted as probabilities of selecting any particular node. Attention is computed over representations of each candidate node. Because we expect that there

could be some preference for attaching adjuncts high or low in the tree we add to the context representation of each node two position embeddings (Vaswani et al., 2017) that encode the candidate node's height and depth in the current tree.

We optimize for maximum log-likelihood on the training set, using only the most frequent supertags and the most important combinators. To avoid discarding sentences with rare supertags and type-changing rules we use all supertags and combinatory rules during training but do not add their probability to the loss function. The number of supertags used is 425, as in the EasyCCG parser, and the combinatory rules that are used are the same as in C&C parser. The loss is minimised for 15 epochs on the training portion of CCGbank (Hockenmaier and Steedman, 2007) using Adam with learning rate 0.001. Dimensionality is set to 128 in all cases, except for ELMo set at 300. Dropout is applied only to the ELMo input with a rate of 0.2. The parser is implemented in Scala using the DyNet toolkit (Neubig et al., 2017) and is available at https://github.com/stanojevic/Rotating-CCG.

5 Experiments

5.1 How incremental is the Revealing algorithm?

To measure the incrementality of the proposed algorithm we use two evaluation metrics: *waiting time* and *connectedness*. Waiting time is the average number of nodes that need to be shifted before the dependency between two nodes is established. The minimal value for a fully incremental algorithm is 0 (the single shift that is always necessary is not counted). Connectedness is defined as the average stack size before a shift operation is performed (the initial two shifts are forced so they are not taken in the average). The minimal value for connectedness is 1. We have computed these measures on the training portion of the CCGbank for standard non-incremental right-branching derivations, the more incremental left-branching derivations and our revealing derivations. We also put in the results numbers for the previous proposal of revealing by Ambati et al. (2015) taken from their paper but these numbers should be taken with caution, because it is not clear from the paper whether the authors computed them in the same way and on the same portion of the dataset as we did. Table 1 results shows that our revealing derivations are significantly more incremental even in comparison to previous revealing proposals, and barely use more than the minimal amount of stack memory.

Revealing	yes	yes	**89.5**	**95.4**	**95.1**

Table 2: Development set F1 results with greedy decoding for CCG dependencies.

5.2 Which algorithm gives the best parsing results?

We have tested on the development set which of the parsing algorithms gives best parsing accuracy. All the algorithms use the same neural architecture and training method except for the revealing operations that require additional mechanisms to choose the node for revealing. This allows us to isolate machine learning factors and see which of the parsing strategies works the best.

There are two methods that are often used for evaluating CCG parsers. They are both based on "deep" dependencies extracted from the derivation trees. The first is from (Clark et al., 2002) and is closer to categorial grammar view of dependencies. The second is from (Clark and Curran, 2007) and is meant to be more formalism independent and closer to standard dependencies (Caroll et al., 1998). We opt for the first option for development as we find it more robust and reliable but we report both types on the test set.

Table 2 shows the results on development set. The *heads* column shows if the head words representation is used for computing the representation of the nodes in the tree. The *SMP* column shows if Selective Modifier Placement is used: whether we choose where to attach right adjunct based only

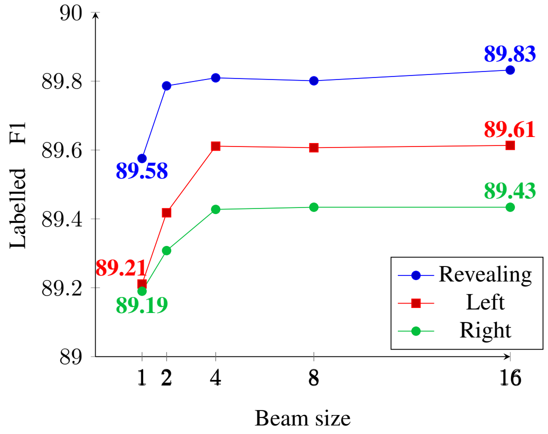

Figure 5: Influence of beam size on the dev results.

on the position embeddings or also on the node's lexical content. First we can see that Revealing approach that uses head representation and does selective modifier placement outperforms all the models both on labelled and unlabelled dependencies. Ablation experiments show that SMP was the crucial component: without it the Revealing model is much worse. This is a clear evidence that attachment heuristics are not enough and also that previous approaches that extract only single revealing option are sub-optimal.

A possible reason why Revealing model works better than Left and Right branching models is that Left and Right models need to commit early on whether there will be a right adjunct in the future or not. If they make a mistake during greedy decoding there will be no way to repair that mistake. This is not an issue for the Revealing model because it can attach right adjuncts at any point and does not need to forecast them. A natural question then is if these improvements of Revealing model will stay if we use a bigger beam. Figure 5 shows exactly that experiment. We see that the model that gains the most from the biggest beam is for the Left-branching condition, which is expected since that is the model that commits to its predictions the most — it commits with type-raising, unlike Right model, and it commits with predicting right adjunction, unlike Revealing model. With an increased beam Left model equals the Revealing greedy model. But if all the models use the same beam the Revealing model remains the best. An interesting result is that the small beam of size 4 is enough to get the maximal improvement. This probably reflects the low degree of lexical ambiguity that is unresolved at each point during parsing.

5.3 Comparison to other published models

We compute test set results for our Revealing model and compare it to most of the previous results on CCGbank using both types of dependencies. Table 3 shows results with (Clark et al., 2002) style dependencies. Here we get state-of-the-art results by a large margin, probably mostly thanks to the machine learning component of our parser. An interesting comparison to be made is against EasyCCG parser of Lewis and Steedman (2014). This parser uses a neural supertagger of accuracy that is not too far from ours, but the dependencies extracted by our parser are much more accurate. This shows that a richer probabilistic model that we use contributes more to the good results than the exact $A^{\star}$ search that EasyCCG does with a more simplistic model. Another comparison of relevance would be with the revealing model of Ambati et al. (2015) but the comparison of the algorithms is difficult since the machine learning component is very different: Ambati uses a structured perceptron while our model is a heavily parametrized neural network.

In Table 4 we show results with the second type of dependencies used for CCG evaluation. All the models, except Clark and Curran (2007), are neural and use external embeddings. From the presented models only Revealing and Xu et al. (2016) are transition based. All other models have a global search either via CKY or A* search. Our revealing-based parser that does only greedy search is outperforming all of them including those trained on large amounts of unlabelled data using semi-supervised techniques like tri-training (Lewis et al., 2016; Lee et al., 2016; Yoshikawa et al., 2017).

In some sense, all the neural models in Table 4 are implicitly trained in semi-supervised way because they use pretrained embeddings that are estimated on unlabelled data. The quality of ELMo embeddings is probably one of the reasons why our parser achieves such good results. However, another semi-supervised training method, namely tri-training, is particularly attractive because, unlike ELMo, it is trained on a CCG parsing objective which is more closely aligned to what we want to do. All tri-training models are trained on much larger dataset that in addition to CCGbank also includes 43 million word corpus automatically annotated with silver CCG derivations by Lewis et al. (2016). It is likely that incorporating tri-training into our training setup will further increase the improvement over other models.

6 Other relevant work

Recurrent Neural Network Grammar (RNNG) (Dyer et al., 2016) is a fully incremental top-down parsing model. Because it is top-down it has no issues with right branching structures, but right adjuncts would still make parsing more difficult for RNNG because they will have to be predicted even earlier than in Left- and Right- branching derivations in CCG.

Left-corner parsers (which can be seen as a more constrained version of CCG Left-branching parsing strategy) seem more psychologically realistic than top-down parsers (Abney and Johnson, 1991; Resnik, 1992; Stanojević and Stabler, 2018). Some proposals about handling right adjunction in left-corner parsing are based on extension to generalized left-corner parsers (Demers, 1977; Hale, 2014) that can force some grammar rules (in particular right-adjunction rules) to be less incremental. Our approach does not decrease incrementality of the parser in this way. On the contrary, having a special mechanism for right adjunction makes parser both more incremental and more accurate.

Revealing based on higher order unification by Pareschi and Steedman (1987) was also proposed by Steedman (1990) as the basis for CCG explanation of gapping. The present derivation-based mechanism for revealing does not extend to gapping, and is targeting to model only derivations that could be explained with a standard CCG grammar derived from CCGbank. While that guarantees that we stay in the safe zone of sound and complete "standard" CCG derivations, it would be good as a future work to extend support for gapping and other types of derivations not present in CCGbank.

Niv (1993, 1994) proposed an alternative to the unification-based account of Pareschi and Steedman similar to our proposal for online tree rotation. Niv's parser is mostly a formal treatment of left-to-right rotations evaluated against psycholinguistic garden paths, but lacks the wide coverage implementation and statistical parsing model as a basis for resolving attachment ambiguities.

7 Conclusion

We have presented a revealing-based incremental parsing algorithm that has special transitions for handling right-adjunction. The parser is neutral with regard to the particular semantic representation used. It is computationally efficient, and can reveal all possible constituents types. It is the most incremental CCG parser yet proposed, and has state-of-the-art results against all published parsers trained on the CCGbank under both dependency recovery measures that are in use for the purpose.

Abstract

Variational autoencoders (VAEs) with an auto-regressive decoder have been applied for many natural language processing (NLP) tasks. The VAE objective consists of two terms, (i) reconstruction and (ii) KL regularization, balanced by a weighting hyper-parameter β. One notorious training difficulty is that the KL term tends to vanish. In this paper we study scheduling schemes for β, and show that KL vanishing is caused by the lack of good latent codes in training the decoder at the beginning of optimization. To remedy this, we propose a cyclical annealing schedule, which repeats the process of increasing β multiple times. This new procedure allows the progressive learning of more meaningful latent codes, by leveraging the informative representations of previous cycles as warm re-starts. The effectiveness of cyclical annealing is validated on a broad range of NLP tasks, including language modeling, dialog response generation and unsupervised language pre-training.

1 Introduction

Variational autoencoders (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014) have been applied in many NLP tasks, including language modeling (Bowman et al., 2015; Miao et al., 2016), dialog response generation (Zhao et al., 2017; Wen et al., 2017), semi-supervised text classification (Xu et al., 2017), controllable text generation (Hu et al., 2017), and text compression (Miao and Blunsom, 2016). A prominent component of a VAE is the distribution-based latent representation for text sequence observations. This flexible representation allows the VAE to explicitly model holistic properties of sentences, such as style, topic, and high-level linguistic and semantic features. Samples from the prior latent distribution can produce diverse and well-formed sentences through simple deterministic decoding (Bowman et al., 2015).

Due to the sequential nature of text, an auto-regressive decoder is typically employed in the VAE. This is often implemented with a recurrent neural network (RNN); the long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) RNN is used widely. This introduces one notorious issue when a VAE is trained using traditional methods: the decoder ignores the latent variable, yielding what is termed the *KL vanishing* problem.

Several attempts have been made to ameliorate this issue (Yang et al., 2017; Dieng et al., 2018; Zhao et al., 2017; Kim et al., 2018). Among them, perhaps the simplest solution is monotonic KL annealing, where the weight of the KL penalty term is scheduled to gradually increase during training (Bowman et al., 2015). While these techniques can effectively alleviate the KL-vanishing issue, a proper unified theoretical interpretation is still lacking, even for the simple annealing scheme.

In this paper, we analyze the variable dependency in a VAE, and point out that the auto-regressive decoder has two paths (formally defined in Section 3.1) that work together to generate text sequences. One path is conditioned on the latent codes, and the other path is conditioned on previously generated words. KL vanishing happens because (i) the first path can easily get blocked, due to the lack of good latent codes at the beginning of decoder training; (ii) the easiest solution that an expressive decoder can learn is to ignore the latent code, and relies on the other path only for decoding. To remedy this issue, a promising approach is to remove the blockage in the first path, and feed meaningful latent codes in training the decoder, so that the decoder can easily adopt them to generate controllable observations (Bowman et al., 2015).

This paper makes the following contributions: (i) We provide a novel explanation for the KL-

vanishing issue, and develop an understanding of the strengths and weaknesses of existing scheduling methods (*e.g.*, constant or monotonic annealing schedules). (*ii*) Based on our explanation, we propose a cyclical annealing schedule. It repeats the annealing process multiple times, and can be considered as an inexpensive approach to leveraging good latent codes learned in the previous cycle, as a warm restart, to train the decoder in the next cycle. (*iii*) We demonstrate that the proposed cyclical annealing schedule for VAE training improves performance on a large range of tasks (with negligible extra computational cost), including text modeling, dialog response generation, and unsupervised language pre-training.

2 Preliminaries

2.1 The VAE model

To generate a text sequence of length T, $\boldsymbol{x} = [x_1, \cdots, x_T]$, neural language models (Mikolov et al., 2010) generate every token x_t conditioned on the previously generated tokens:

$$p(\boldsymbol{x}) = \prod_{t=1}^{T} p(x_t | x_{<t}),$$

where $x_{<t}$ indicates all tokens before t.

The VAE model for text consists of two parts, generation and inference (Kingma and Welling, 2013; Rezende et al., 2014; Bowman et al., 2015). The *generative model* (*decoder*) draws a continuous latent vector $\boldsymbol{z}$ from prior $p(\boldsymbol{z})$, and generates the text sequence $\boldsymbol{x}$ from a conditional distribution $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$; $p(\boldsymbol{z})$ is typically assumed a multivariate Gaussian, and $\boldsymbol{\theta}$ represents the neural network parameters. The following auto-regressive decoding process is usually used:

$$p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) = \prod_{t=1}^{T} p_{\boldsymbol{\theta}}(x_t | x_{<t}, \boldsymbol{z}). \tag{1}$$

Parameters $\boldsymbol{\theta}$ are typically learned by maximizing the marginal log likelihood $\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) = \log \int p(\boldsymbol{z}) p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \mathrm{d}\boldsymbol{z}$. However, this marginal term is intractable to compute for many decoder choices. Thus, variational inference is considered, and the true posterior $p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x}) \propto p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})p(\boldsymbol{z})$ is approximated via the variational distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ is (often known as the *inference model* or *encoder*), implemented via a $\boldsymbol{\phi}$-parameterized neural network. It yields the *evidence lower bound* (ELBO) as an objective:

$$\begin{aligned} \log p_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq \mathcal{L}_{\text{ELBO}} = \\ \mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})} \big[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \big] - \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z})) \end{aligned} \tag{2}$$

Typically, $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ is modeled as a Gaussian distribution, and the re-parametrization trick is used for efficient learning (Kingma and Welling, 2013).

2.2 Training Schedules and KL Vanishing

There is an alternative interpretation of the ELBO: the VAE objective can be viewed as a regularized version of the autoencoder (AE) (Goodfellow et al., 2016). It is thus natural to extend the negative of $\mathcal{L}_{\text{ELBO}}$ in (2) by introducing a hyperparameter β to control the strength of regularization:

$$\mathcal{L}_{\beta} = \mathcal{L}_E + \beta \mathcal{L}_R, \quad \text{with} \tag{3}$$

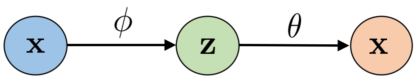
$$\mathcal{L}_E = -\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})} \big[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \big] \tag{4}$$

$$\mathcal{L}_R = \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z})) \tag{5}$$

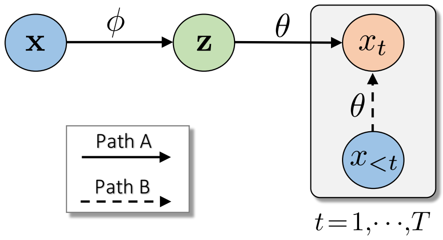
where $\mathcal{L}_E$ is the reconstruction error (or negative log-likelihood (NLL)), and $\mathcal{L}_R$ is a KL regularizer.

The cost function $\mathcal{L}_{\beta}$ provides a unified perspective for understanding various autoencoder variants and training methods. When $\beta = 1$, we recover the VAE in (2). When $\beta = 0$, and $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ is a delta distribution, we recover the AE. In other words, the AE does not regularize the variational distribution toward a prior distribution, and there is only a point-estimate to represent the text sequence's latent feature. In practice, it has been found that learning with an AE is prone to overfitting (Bowman et al., 2015), or generating plain dialog responses (Zhao et al., 2017). Hence, it is desirable to retain meaningful posteriors in real applications. Two different schedules for β have been commonly used for a text VAE.

Constant Schedule The standard approach is to keep $\beta = 1$ fixed during the entire training procedure, as it corresponds to optimizing the true VAE objective. Unfortunately, instability on text analysis has been witnessed, in that the KL term $\mathcal{L}_R$ becomes vanishingly small during training (Bowman et al., 2015). This issue causes two undesirable outcomes: (*i*) an encoder that produces posteriors almost identical to the Gaussian prior, for all observations (rather than a more interesting posterior); and (*ii*) a decoder that completely ignores the latent variable $\boldsymbol{z}$, and a learned model that reduces to a simpler language model. This is known as the *KL vanishing* issue in text VAEs.



(a) Traditional VAE



(b) VAE with an auto-regressive decoder

Figure 1: Illustration of learning parameters $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ in the two different paradigms. Starting from the observation $\boldsymbol{x}$ in blue circle, a VAE infers its latent code $\boldsymbol{z}$ in the green circle, and further generates its reconstruction in the red circle. (a) Standard VAE learning, with only one path via $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ from $\boldsymbol{x}$ to its reconstruction; (b) VAE learning with an auto-regressive decoder. Two paths are considered from $\boldsymbol{x}$ to its reconstruction: Path A via $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ and Path B via $\boldsymbol{\theta}$.

Monotonic Annealing Schedule. A simple remedy has been proposed in (Bowman et al., 2015) to alleviate KL collapse. It sets $\beta = 0$ at the beginning of training, and gradually increases β until $\beta = 1$ is reached. In this setting, we do not optimize the proper lower bound in (2) during the early stages of training, but nonetheless improvements on the value of that bound are observed at convergence in previous work (Bowman et al., 2015; Zhao et al., 2017).

The monotonic annealing schedule has become the *de facto* standard in training text VAEs, and has been widely adopted in many NLP tasks. Though simple and often effective, this heuristic still lacks a proper justification. Further, how to best schedule β is largely unexplored.

3 Cyclical Annealing Schedule

3.1 Identifying Sources of KL Vanishing

In the traditional VAE (Kingma and Welling, 2013), $\boldsymbol{z}$ generates $\boldsymbol{x}$ directly, and the reconstruction depends only on one path of $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ passing through $\boldsymbol{z}$, as shown in Figure 1(a). Hence, $\boldsymbol{z}$ can largely determine the reconstructed $\boldsymbol{x}$. In contrast, when an auto-regressive decoder is used in a text VAE (Bowman et al., 2015), there are two paths from $\boldsymbol{x}$ to its reconstruction, as shown in Figure 1(b). Path A is the same as that in the standard VAE, where $\boldsymbol{z}$ is the global representation that controls the generation of $\boldsymbol{x}$; Path B leaks the partial ground-truth information of $\boldsymbol{x}$ at every time step of the sequential decoding. It generates x_t conditioned on $x_{<t}$. Therefore, Path B can potentially bypass Path A to generate $\boldsymbol{x}$, leading to KL vanishing.

From this perspective, we hypothesize that the model-collapse problem is related to the low quality of $\boldsymbol{z}$ at the beginning phase of decoder training. A lower quality $\boldsymbol{z}$ introduces more difficulties in reconstructing $\boldsymbol{x}$ via Path A. As a result, the model is forced to learn an easier solution to decoding: generating $\boldsymbol{x}$ via Path B only.

We argue that this phenomenon can be easily observed due to the powerful representation capability of the auto-regressive decoder. It has been shown empirically that auto-regressive decoders are able to capture highly-complex distributions, such as natural language sentences (Mikolov et al., 2010). This means that Path B alone has enough capacity to model $\boldsymbol{x}$, even though the decoder takes $\{x_{<t}, \boldsymbol{z}\}$ as input to produce x_t. Zhang et al. (2017a) has shown that flexible deep neural networks can easily fit randomly labeled training data, and here the decoder can learn to rely solely on $x_{<t}$ for generation, when $\boldsymbol{z}$ is of low quality.

We use our hypothesis to explain the learning behavior of different scheduling schemes for β as follows.

Constant Schedule The two loss terms in (2) are weighted equally in the constant schedule. At the early stage of optimization, $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ are randomly initialized and the latent codes $\boldsymbol{z}$ are of low quality. The KL term $\mathcal{L}_R$ pushes $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ close to an uninformative prior $p(\boldsymbol{z})$: the posterior becomes more like an isotropic Gaussian noise, and less representative of their corresponding observations. In other words, $\mathcal{L}_R$ blocks Path A, and thus $\boldsymbol{z}$ remains uninformative during the entire training process: it starts with random initialization and then is regularized towards a random noise. Although the reconstruction term $\mathcal{L}_E$ can be satisfied via two paths, since $\boldsymbol{z}$ is noisy, the decoder learns to discard Path A (*i.e.*, ignores $\boldsymbol{z}$), and chooses Path B to generate the sentence word-by-word.

Monotonic Annealing Schedule The monotonic schedule sets β close to 0 in the early stage of training, which effectively removes the blockage $\mathcal{L}_R$ on Path A, and the model reduces to a denoising autoencoder [1]. $\mathcal{L}_E$ becomes the only objective,

---

[1] The Gaussian sampling remains for $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$

which can be reached by both paths. Though randomly initialized, $\boldsymbol{z}$ is learned to capture useful information for reconstruction of $\boldsymbol{x}$ during training. At the time when the full VAE objective is considered ($\beta = 1$), $\boldsymbol{z}$ learned earlier can be viewed as the VAE initialization; such latent variables are much more informative than random, and thus are ready for the decoder to use.

To mitigate the KL-vanishing issue, it is key to have meaningful latent codes $\boldsymbol{z}$ at the beginning of training the decoder, so that $\boldsymbol{z}$ can be utilized. The monotonic schedule under-weights the prior regularization, and the learned $q_{\phi}(\boldsymbol{z}|\boldsymbol{x})$ tends to collapse into a point estimate (*i.e.,* the VAE reduces to an AE). This underestimate can result in sub-optimal decoder learning. A natural question concerns how one can get a better distribution estimate for $\boldsymbol{z}$ as initialization, while retaining low computational cost.

3.2 Cyclical Annealing Schedule

Our proposal is to use $\boldsymbol{z} \sim q_{\phi}(\boldsymbol{z}|\boldsymbol{x})$, which has been trained under the full VAE objective, as initialization. To learn to progressively improve latent representation $\boldsymbol{z}$, we propose a cyclic annealing schedule. We start with $\beta = 0$, increase β at a fast pace, and then stay at $\beta = 1$ for subsequent learning iterations. This encourages the model to converge towards the VAE objective, and infers its first raw full latent distribution.

Unfortunately, Path A is blocked at $\beta = 1$. The optimization is then continued at $\beta = 0$ again, which perturbs the VAE objective, dislodges it from the convergence, and reopens Path A. Importantly, the decoder is now trained with the latent code from a full distribution $\boldsymbol{z} \sim q_{\phi}(\boldsymbol{z}|\boldsymbol{x})$, and both paths are considered. We repeat this process several times to achieve better convergences.

Formally, β has the form:

$$\beta_t = \begin{cases} f(\tau), & \tau \leq R \\ 1, & \tau > R \end{cases} \quad \text{with} \tag{6}$$

$$\tau = \frac{\operatorname{mod}(t-1, \lceil T/M \rceil)}{T/M}\,, \tag{7}$$

where t is the iteration number, T is the total number of training iterations, f is a monotonically increasing function, and we introduce two new hyper-parameters associated with the cyclical annealing schedule:

- M: number of cycles (default $M = 4$);
- R: proportion used to increase β within a cycle (default $R = 0.5$).

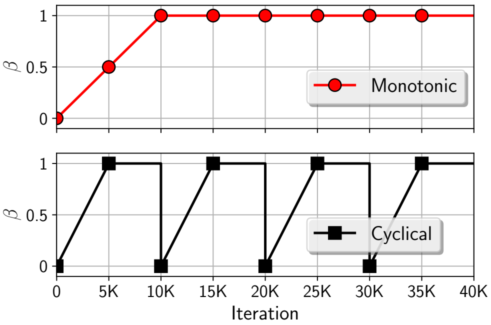


Figure 2: Comparison between (a) traditional monotonic and (b) proposed cyclical annealing schedules.In this figure, $M = 4$ cycles are illustrated, $R = 0.5$ is used for increasing within each cycle.

In other words, we split the training process into M cycles, each starting with $\beta = 0$ and ending with $\beta = 1$. We provide an example of a cyclical schedule in Figure 2(b), compared with the monotonic schedule in Figure 2(a). Within one cycle, there are two consecutive stages (divided by R):

- **Annealing**. β is annealed from 0 to 1 in the first $R\lceil T/M \rceil$ training steps over the course of a cycle. For example, the steps $[1, 5K]$ in the Figure 2(b). $\beta = f(0) = 0$ forces the model to learn representative $\boldsymbol{z}$ to reconstruct $\boldsymbol{x}$. As depicted in Figure 1(b), there is no interruption from the prior on Path A, $\boldsymbol{z}$ is forced to learn the global representation of $\boldsymbol{x}$. By gradually increasing β towards $f(R) = 1$, $q(\boldsymbol{z}|\boldsymbol{x})$ is regularized to transit from a point estimate to a distribution estimate, spreading out to match the prior.
- **Fixing**. As our ultimate goal is to learn a VAE model, we fix $\beta = 1$ for the rest of training steps within one cycle, *e.g.,* the steps $[5K, 10K]$ in Figure 2(b). This drives the model to optimize the full VAE objective until convergence.

As illustrated in Figure 2, the monotonic schedule increasingly anneals β from 0 to 1 once, and fixes $\beta = 1$ during the rest of training. The cyclical schedules alternatively repeats the annealing and fixing stages multiple times.

A Practical Recipe The existing schedules can be viewed as special cases of the proposed cyclical schedule. The cyclical schedule reduces to the constant schedule when $R = 0$, and it reduces to an monotonic schedule when $M = 1$ and R is relatively small [2]. In theory, any monotonically increasing function f can be adopted for the cyclical schedule, as long as $f(0) = 0$ and $f(R) = 1$. In practice, we suggest to build the cyclical schedule upon the success of monotonic schedules: we adopt the same f, and modify it by setting M and R (as default). Three widely used increasing functions for f are linear (Fraccaro et al., 2016; Goyal et al., 2017), Sigmoid (Bowman et al., 2015) and Consine (Lai et al., 2018). We present the comparative results using the linear function $f(\tau) = \tau/R$ in Figure 2, and show the complete comparison for other functions in Figure 7 of the Supplementary Material (SM).

3.3 On the impact of β

This section derives a bound for the training objective to rigorously study the impact of β; the proof details are included in SM. For notational convenience, we identify each data sample with a unique integer index $n \sim q(n)$, drawn from a uniform random variable on $\{1, 2, \cdots, N\}$. Further we define $q(\boldsymbol{z}|n) = q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}_n)$ and $q(\boldsymbol{z}, n) = q(\boldsymbol{z}|n)q(n) = q(\boldsymbol{z}|n)\frac{1}{N}$. Following (Makhzani et al., 2016), we refer to $q(\boldsymbol{z}) = \sum_{n=1}^{N} q(\boldsymbol{z}|n)q(n)$ as the aggregated posterior. This marginal distribution captures the aggregated $\boldsymbol{z}$ over the entire dataset. The KL term in (5) can be decomposed into two refined terms (Chen et al., 2018; Hoffman and Johnson, 2016):

$$\begin{aligned}\mathcal{F}_R &= \mathbb{E}_{q(n)}[\mathrm{KL}(q(\boldsymbol{z}|n)||p(\boldsymbol{z}))] \\ &= \underbrace{I_q(\boldsymbol{z}, n)}_{\mathcal{F}_1\text{: Mutual Info.}} + \underbrace{\mathrm{KL}(q(\boldsymbol{z})||p(\boldsymbol{z}))}_{\mathcal{F}_2\text{: Marginal KL}} \qquad (8)\end{aligned}$$

where $\mathcal{F}_1$ is the mutual information (MI) measured by q. Higher MI can lead to a higher correlation between the latent variable and data variable, and encourages a reduction in the degree of KL vanishing. The marginal KL is represented by $\mathcal{F}_2$, and it measures the fitness of the aggregated posterior to the prior distribution.

The reconstruction term in (5) provides a lower bound for MI measured by q, based on Corollary 3 in (Li et al., 2017):

$$\begin{aligned}\mathcal{F}_E &= E_{q(n),\boldsymbol{z}\sim q(\boldsymbol{z}|n)}(\log p(n|\boldsymbol{z}))] + H_q(n) \\ &\leq I_q(\boldsymbol{z}, n) \qquad (9)\end{aligned}$$

where $H(n)$ is a constant.

Analysis of β When scheduled with β, the training objective over the dataset can be written as:

$$\begin{aligned}\mathcal{F} &= -\mathcal{F}_E + \beta\mathcal{F}_R \qquad (10) \\ &\geq (\beta - 1)I_q(\boldsymbol{z}, n) + \beta\mathrm{KL}(q(\boldsymbol{z})||p(\boldsymbol{z})) \qquad (11)\end{aligned}$$

To reduce KL vanishing, we desire an increase in the MI term $I(\boldsymbol{z}, n)$, which appears in both $\mathcal{F}_E$ and $\mathcal{F}_R$, modulated by β. It shows that reducing KL vanishing is inversely proportional with β. When $\beta = 0$, the model fully focuses on maximizing the MI. As β increases, the model gradually transits towards fitting the aggregated latent codes to the given prior. When $\beta = 1$, the implementation of MI becomes implicit in $\mathrm{KL}(q(\boldsymbol{z})||p(\boldsymbol{z}))$. It is determined by the amortized inference regularization (implied by the encoder's expressivity) (Shu et al., 2018), which further affects the performance of the generative density estimator.

4 Visualization of Latent Space

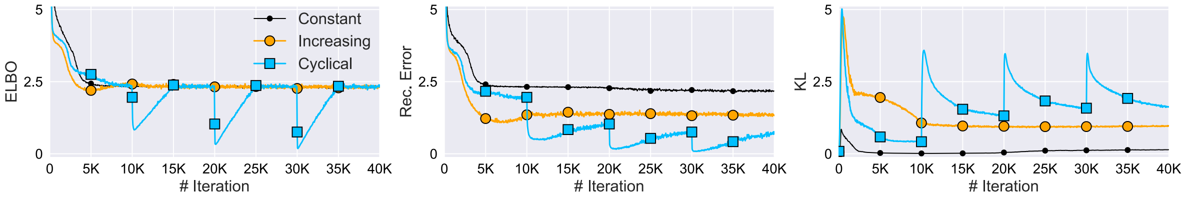
We compare different schedule methods by visualizing the learning processes on an illustrative problem. Consider a dataset consisting of 10 sequences, each of which is a 10-dimensional one-hot vector with the value 1 appearing in different positions. A 2-dimensional latent space is used for the convenience of visualization. Both the encoder and decoder are implemented using a 2-layer LSTM with 64 hidden units each. We use $T = 40$K total iterations, and the scheduling schemes in Figure 2.

The learning curves for the ELBO, reconstruction error, and KL term are shown in Figure 3. The three schedules share very similar values. However, the cyclical schedule provides substantially lower reconstruction error and higher KL divergence. Interestingly, the cyclical schedule improves the performance progressively: it becomes better than the previous cycle, and there are clear periodic patterns across different cycles. This suggests that the cyclical schedule allows the model to use the previously learned results as a warm-restart to achieve further improvement.

We visualize the resulting division of the latent space for different training steps in Figure 4, where each color corresponds to $\boldsymbol{z} \sim q(\boldsymbol{z}|n)$, for $n = 1, \cdots, 10$. We observe that the constant schedule produces heavily mixed latent codes $\boldsymbol{z}$ for different sequences throughout the entire training process. The monotonic schedule starts with a mixed $\boldsymbol{z}$, but soon divides the space into a mixture

---

[2] In practice, the monotonic schedule usually anneals in a very fast pace, thus R is small compared with the entire training procedure.



(a) ELBO (b) Reconstruction Error (c) KL term

Figure 3: Comparison of the learning curves for the three schedules on an illustrative problem.

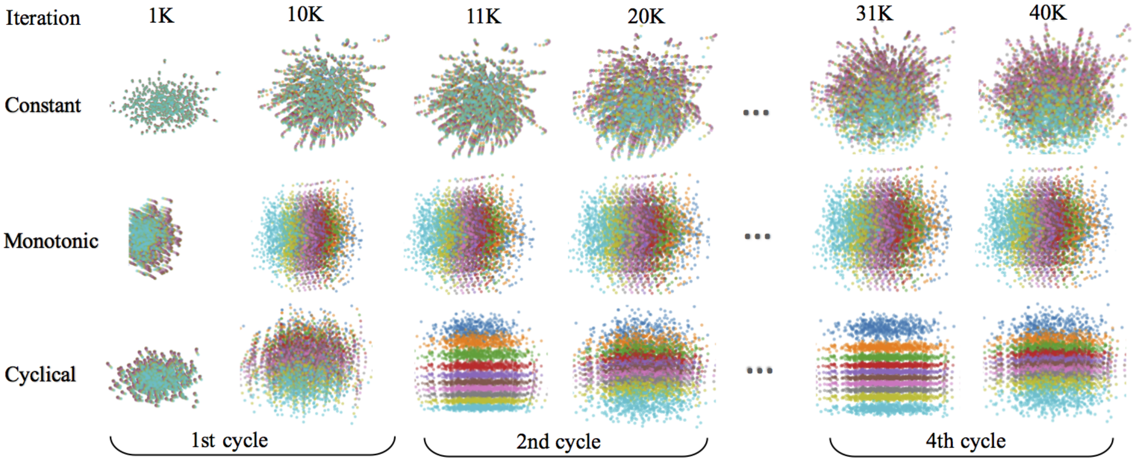


Figure 4: Visualization of the latent space along the learning dynamics on an illustrative problem.

of 10 cluttered Gaussians in the annealing process (the division remains cluttered in the rest of training). The cyclical schedule behaves similarly to the monotonic schedule in the first 10K steps (the first cycle). But, starting from the 2nd cycle, much more divided clusters are shown when learning on top of the 1st cycle results. However, $\beta < 1$ leads to some holes between different clusters, making $q(\boldsymbol{z})$ violate the constraint of $p(\boldsymbol{z})$. This is alleviated at the end of the 2nd cycle, as the model is trained with $\beta = 1$. As the process repeats, we see clearer patterns in the 4th cycle than the 2nd cycle for both $\beta < 0$ and $\beta = 1$. It shows that more structured information is captured in $\boldsymbol{z}$ using the cyclical schedule, which is beneficial in downstream applications as shown in the experiments.

5 Related Work

Solutions to KL vanishing Several techniques have been proposed to mitigate the KL vanishing issue. The proposed method is most closely related to the monotonic KL annealing technique in (Bowman et al., 2015). In addition to introducing a specific algorithm, we have comprehensively studied the impact of β and its scheduling schemes. Our explanations can be used to interpret other techniques, which can be broadly categorized into two classes.

The first category attempts to weaken Path B, and force the decoder to use Path A. Word drop decoding (Bowman et al., 2015) sets a certain percentage of the target words to zero. It has shown that it may degrade the performance when the drop rate is too high. The dilated CNN was considered in (Yang et al., 2017) as a new type of decoder to replace the LSTM. By changing the decoder's dilation architecture, one can control Path B: the effective context from $x_{<t}$.

The second category of techniques improves the dependency in Path A, so that the decoder uses latent codes more easily. Skip connections were developed in (Dieng et al., 2018) to shorten the paths from $\boldsymbol{z}$ to $\boldsymbol{x}$ in the decoder. Zhao et al. (2017) introduced an auxiliary loss that requires the decoder to predict the bag-of-words in the dialog response (Zhao et al., 2017). The decoder is thus forced to capture global information about the target response. Zhao et al. (2019) enhanced Path A via mutual information. Concurrent with our work, He et al. (2019) proposed to update encoder multiple times to achieve better latent code before updating decoder. Semi-amortized training (Kim et al., 2018) was proposed to perform stochastic variational inference (SVI) (Hoffman et al., 2013) on top of the amortized inference in VAE. It shares a similar motivation with the proposed approach, in that better latent codes can reduce KL vanishing. However, the computational cost to run SVI is high, while our monotonic schedule does not require any additional compute overhead. The KL scheduling methods are complementary to these techniques. As shown in experiments, the proposed cyclical schedule can further improve them.

β-VAE The VAE has been extended to β-regularized versions in a growing body of work (Higgins et al., 2017; Alemi et al., 2018). Perhaps the seminal work is β-VAE (Higgins et al., 2017), which was extended in (Kim and Mnih, 2018; Chen et al., 2018) to consider β on the refined terms in the KL decomposition. Their primary goal is to learn disentangled latent representations to explain the data, by setting $\beta > 1$. From an information-theoretic point of view, (Alemi et al., 2018) suggests a simple method to set $\beta < 1$ to ensure that latent-variable models with powerful stochastic decoders do not ignore their latent code. However, $\beta \neq 1$ results in an improper statistical model. Further, β is static in their work; we consider dynamically scheduled β and find it more effective.

Cyclical schedules Warm-restart techniques are common in optimization to deal with multimodal functions. The cyclical schedule has been used to train deep neural networks (Smith, 2017), warm restart stochastic gradient descent (Loshchilov and Hutter, 2017), improve convergence rates (Smith and Topin, 2017), obtain model ensembles (Huang et al., 2017) and explore multimodal distributions in MCMC sampling (Zhang et al., 2019). All these works applied cyclical schedules to the learning rate. In contrast, this paper represents the first to consider the cyclical schedule for β in VAE. Though the techniques seem simple and similar, our motivation is different: we use the cyclical schedule to re-open Path A in Figure 1(b) and provide the opportunity to train the decoder with high-quality $\boldsymbol{z}$.

6 Experiments

The source code to reproduce the experimental results will be made publicly available on GitHub[3]. For a fair comparison, we follow the practical recipe described in Section 3.2, where the monotonic schedule is treated as a special case of cyclical schedule (while keeping all other settings the same). The default hyper-parameters of the cyclical schedule are used in all cases unless stated otherwise. We study the impact of hyper-parameters in the SM, and show that larger M can provide higher performance for various R. We show the major results in this section, and put more details in the SM. The monotonic and cyclical schedules are denoted as **M** and **C**, respectively.

Schedule		**Rec**	**KL**	**ELBO**	**PPL**
VAE	**M**	101.73	0.907	-102.63	108.09
	C	**100.51**	**1.955**	-102.46	107.25
SA-VAE	**M***	100.75	1.796	-102.54	107.64
	M	101.83	1.053	-102.89	109.33
	C	**100.50**	**2.261**	-102.76	108.71
$\beta_m = 0.5$	**M**	97.36	9.605	-106.96	132.57
	C	95.22	9.484	-104.70	118.78

Table 1: Comparison of language modeling on Penn Tree Bank (PTB). The last iteration results are reported. Since SA-VAE tends to overfit, we report its best results in row M*.

6.1 Language Modeling

We first consider language modeling on the Penn Tree Bank (PTB) dataset (Marcus et al., 1993). Language modeling with VAEs has been a challenging problem, and few approaches have been shown to produce rich generative models that do not collapse to standard language models. Ideally a deep generative model trained with variational inference would pursue higher ELBO, making use of the latent space (*i.e.,* maintain a nonzero KL term) while accurately modeling the underlying distribution (*i.e.,* lower reconstruction errors). We implemented different schedules based on the code[4] published by Kim et al. (2018).

The latent variable is 32-dimensional, and 40 epochs are used. We compare the proposed cyclical annealing schedule with the monotonic schedule baseline that, following (Bowman et al., 2015), anneals linearly from 0 to 1.0 over 10 epochs. We also compare with semi-amortized (SA) training (Kim et al., 2018), which is considered as the state-of-the-art technique in preventing KL vanishing. We set SVI steps to 10.

Results are shown in Table 1. The perplexity is reported in column PPL. The cyclical schedule outperforms the monotonic schedule for both standard VAE and SA-VAE training. SA-VAE training

(a) ELBO (b) Reconstruction error (c) KL

Figure 5: Learning curves of VAE and SA-VAE on PTB. Under similar ELBO, the cyclical schedule provides lower reconstruction errors and higher KL values than the monotonic schedule.

Context `Alice`: yeah you know its interesting especially when my experience has always been at a public university.			
Topic: Choose a College	**Target** `Bob` (statement): yeah that's right		
C	1. yes 2. oh really 3. and there's a lot of <unk> there's a lot of people 4. yeah 5. and i think that's probably the biggest problem i've ever seen in the past	**M**	1. i'm not sure 2. and i'm not sure 3. and i'm not sure 4. i'm not sure 5. i'm not sure

Table 2: Generated dialog responses from the cyclical and monotonic schedules.

can effectively reduce KL vanishing, it takes 472s per epoch. However, this is significantly more expensive than the standard VAE training which takes 30s per epoch. The proposed cyclical schedule adds almost zero cost.

We show the learning curves for VAE and SA-VAE in Figure 5. Interestingly, the cyclical schedule exhibits periodical learning behaviours. The performance of the cyclical schedule gets better progressively, after each cycle. While ELBO and PPL ar similar, the cyclical schedule improves the reconstruction ability and KL values for both VAE and SA-VAE. We observe clear over-fitting issues for the SA-VAE with the monotonic schedule, while this issue is less severe for SA-VAE with the cyclical schedule.

Finally, we further investigate whether our improvements are from simply having a lower β, rather than from the cyclical schedule re-opening Path A for better learning. To test this, we use a monotonic schedule with maximum $\beta = 0.5$. We observe that the reconstruction and KL terms perform better individually, but the ELBO is substantially worse than $\beta = 1$, because $\beta = 0.5$ yields an improper model. Even so, the cyclical schedule improves its performance.

6.2 Conditional VAE for Dialog

Model	CVAE		CVAE+BoW	
Schedule	**M**	**C**	**M**	**C**
Rec-P ↓	36.16	**29.77**	18.44	**16.74**
KL Loss ↑	0.265	**4.104**	14.06	**15.55**
B4 prec	0.185	**0.234**	0.211	**0.219**
B4 recall	0.122	**0.220**	0.210	**0.219**
A-bow prec	0.957	**0.961**	0.958	**0.961**
A-bow recall	0.911	**0.941**	0.938	**0.940**
E-bow prec	0.867	0.833	0.830	0.828
E-bow recall	0.784	**0.808**	0.808	0.805

Table 3: Comparison on dialog response generation. Reconstruction perplexity (Rec-P) and BLEU (B) scores are used for evaluation.

We use a cyclical schedule to improve the latent codes in (Zhao et al., 2017), which are key to diverse dialog-response generation. Following (Zhao et al., 2017), Switchboard (SW) Corpus (Godfrey and Holliman, 1997) is used, which has 2400 two-sided telephone conversations.

Two latent variable models are considered. The first one is the Conditional VAE (CVAE), which has been shown better than the encoder-decoder neural dialog (Serban et al., 2016). The second is to augment VAE with a bag-of-word (BoW) loss to tackle the KL vanishing problem, as proposed in (Zhao et al., 2017).

Table 2 shows the sample outputs generated from the two schedules using CVAE. Caller `Alice` begins with an open-ended statement on choosing a college, and the model learns to generate responses from Caller `Bob`. The cyclical schedule generated highly diverse answers that cover multiple plausible dialog acts. On the contrary, the responses from the monotonic schedule are limited to repeat plain responses, *i.e.,* "*i'm not sure*".

Quantitative results are shown in Table 3, using the evaluation metrics from (Zhao et al., 2017). (i) Smoothed Sentence-level BLEU (Chen and Cherry, 2014): BLEU is a popular metric that measures the geometric mean of modified n-gram precision with a length penalty. We use BLEU-1 to 4 as our lexical similarity metric and normalize the score to 0 to 1 scale. (ii) Cosine Distance of Bag-of-word Embedding (Liu et al., 2016): a simple method to obtain sentence embeddings is to take the average or extreme of all the word embeddings in the sentences. We used Glove embedding and denote the average method as $A-bow$ and extreme method as $E-bow$. The score is normalized to $[0, 1]$. Higher values indicate more plausible responses.

The BoW indeed reduces the KL vanishing issue, as indicated by the increased KL and decreased reconstruction perplexity. When applying the proposed cyclical schedule to CVAE, we also see a reduced KL vanishing issue. Interestingly, it also yields the highest BLEU scores. This suggests that the cyclical schedule can generate dialog responses of higher fidelity with lower cost, as the auxiliary BoW loss is not necessary. Further, BoW can be improved when integrated with the cyclical schedule, as shown in the last column of Table 3.

6.3 Unsupervised Language Pre-training

We consider the Yelp dataset, as pre-processed in (Shen et al., 2017) for unsupervised language pre-training. Text features are extracted as the latent codes $\boldsymbol{z}$ of VAE models, pre-trained with monotonic and cyclical schedules. The AE is used as the baseline. A good VAE can learn to cluster data into meaningful groups (Kingma and Welling, 2013), indicating that well-structured $\boldsymbol{z}$ are highly informative features, which usually leads to higher classification performance. To clearly compare the quality of $\boldsymbol{z}$, we build a simple one-layer classifier on $\boldsymbol{z}$, and fine-tune the model on different proportions of labelled data (Zhang et al., 2017b).

The results are shown in Figure 6. The cyclical schedule consistently yields the highest accuracy relative to other methods. We visualize the tSNE embeddings (Maaten and Hinton, 2008) of $\boldsymbol{z}$ in Figure 9 of the SM, and observe that the cyclical schedule exhibits clearer clustered patterns.

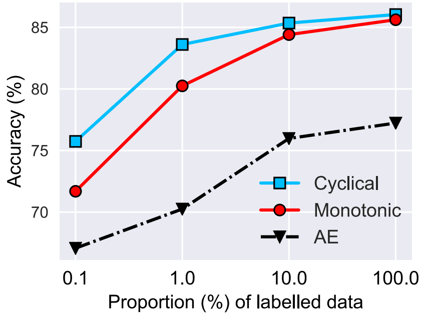

Figure 6: Accuracy of fine-tuning on the unsupervised pre-trained models on the Yelp dataset.

Schedule	Rec	KL	ELBO
Cyc β + Const η	**101.30**	**1.457**	-102.76
Mon β + Const η	101.93	0.858	-102.78
Cyc β + Cyc η	**100.61**	**1.897**	-102.51
Mon β + Cyc η	101.74	0.748	-102.49

Table 4: Comparison of cyclical schedules on β and η, tested with language modeling on PTB.

6.4 Ablation Study

To enhance the performance, we propose to apply the cyclical schedule to the learning rate η on real tasks. It ensures that the optimizer has the same length of optimization trajectory for each β cycle (so that each cycle can fully converge). To investigate the impact of cyclical on η, we perform two more ablation experiments: (i) We make only β cyclical, keep η constant. (ii) We make only η cyclical, keep β monotonic. The last epoch numbers are shown in Table 4, and the learning curves on shown in Figure 10 in SM. Compared with the baseline, we see that it is the cyclical β rather than cyclical η that contributes to the improved performance.

7 Conclusions

We provide a novel two-path interpretation to explain the KL vanishing issue, and identify its source as a lack of good latent codes at the beginning of decoder training. This provides an understanding of various β scheduling schemes, and motivates the proposed cyclical schedule. By reopening the path at $\beta = 0$, the cyclical schedule can progressively improve the performance, by leveraging good latent codes learned in the previous cycles as warm re-starts. We demonstrate the effectiveness of the proposed approach on three NLP tasks, and show that it is superior to or complementary to other techniques.

Recurrent Models and Lower Bounds for Projective Syntactic Decoding

Natalie Schluter
IT University of Copenhagen
Copenhagen, Denmark
natschluter@itu.dk

Abstract

The current state-of-the-art in neural graph-based parsing uses only approximate decoding at the training phase. In this paper aim to understand this result better. We show how recurrent models can carry out projective maximum spanning tree decoding. This result holds for both current state-of-the-art models for shift-reduce and graph-based parsers, projective or not. We also provide the first proof on the lower bounds of projective maximum spanning tree, DAG, and digraph decoding.

1 Introduction

For several years, the NLP field has seen widespread investigation into the application of Neural Networks to NLP tasks, and with this, much, rather inexplicable progress. A string of very recent work (for example, Chen et al. (2018); Weiss et al. (2018); Peng et al. (2018)), has attempted to delve into the formal properties of neural network topology choices, in attempts to both motivate, predict, and explain associated research in the field. This paper aims to further contribute along this line of research.

We present the results of our study into the ability of state-of-the-art first-order neural graph-based parsers, with seemingly simple architectures, to explicitly forego structured learning and prediction.[1] In particular, this is not due to a significantly faster, simpler, algorithm for projective maximum spanning tree (MST) decoding than Eisner (1996)'s algorithm, which we formally prove to be impossible, given the Exponential Time Hypothesis. But rather, this is due to the capacity of recurrent components of these architectures to implicitly discover a projective MST. We prove this formally by showing how these recurrent components can intrinsically simulate exact projective decoding.

The context. The current state-of-the-art for graph-based syntactic dependency parsing is a seemingly basic neural model by Dozat and Manning (2017). The parser's performance is an improvement on the first, even simpler, rather engineering-free, neural graph-based parser by Kiperwasser and Goldberg (2016). This latter parser updates with respect to an output structure: projective decoding over a matrix of arc scores coupled with hinge loss between predicted and gold arcs, reporting parser performance of, for example, 93.32% UAS and 91.2% LAS on the converted Penn Treebank.[2] Remarkably, the former parser by Dozat and Manning (2017) forgoes entirely any structural learning, employing simple cross-entropy at training time, and saving (unconstrained) maximum spanning tree decoding for test time.

We further optimised Kiperwasser and Goldberg (2016)'s parser (Varab and Schluter, 2018) and extended it for cross-entropy learning, as is done by Dozat and Manning (2017). At test time, instead of any explicit decoding algorithm over the arc score matrix, we simply take the maximum weighted incoming arc for each word; that is, the parser is highly streamlined, without any heavy neural network engineering, but now also without any structured learning, nor without any structural decoding at test time. The resulting neural parser still achieves an impressively competitive UAS of 92.61% evaluated on the converted Penn Treebank data, without recourse to any pre-trained embeddings, unlike the systems by Kiperwasser and Goldberg (2016) and Dozat and

---

[1] For the remainder of this paper, all decoding algorithms discussed are first-order.

[2] Training is on Sections 2-21, development on Section 22 and testing on Section 23), converted to dependency format following the default configuration of the Stanford Dependency Converter (version $\geq$ 3.5.2).

Minneapolis, Minnesota, June 2 - June 7, 2019.

Manning (2017). Using GloVe 100-dimensional Wikipedia and Gigaword corpus (6 billion tokens) pretrained embeddings, without updates, but linearly projected through a single linear dense layer to the same dimension, the structure-less parser achieves 93.18% UAS.[3] With this paper, we shed light on these surprising results from seemingly simple architectures. The insights we present here apply to any neural architecture that first encodes input words of a sentence using some type of recurrent neural network–i.e., all current state-of-the-art graph-based or shift reduce neural parsers.

Our contributions. This paper presents results for understanding the surprisingly superior performance of structure-free learning and prediction in syntactic (tree) dependency parsing.

1. We provide a formal proof that there will never be an algorithm that carries out projective MST decoding in sub-cubic time, unless a widely believed assumption in computational complexity theory, the *Exponential Time Hypothesis* (ETH), is false.

   Hence, computationally, we provide convincing evidence that these neural parsing architectures cannot be as simple as they appear. These results are then extended to projective maximum spanning DAG and digraph decoding.
2. In particular, we then show how to simulate Eisner's algorithm using a single recurrent neural network. This shows how, in particular, the LSTM stacked architectures for graph-based parsing by Dozat and Manning (2017), Cheng et al. (2016), Hashimoto et al. (2017), Zhang et al. (2017), and Kiperwasser and Goldberg (2016), are capable of intrinsically decoding over arc scores.

   This therefore provides one practical application where RNNs do not need supplementary approximation considerations (Chen et al., 2018).

2 Preliminaries

The Exponential Time Hypothesis (ETH) and k-Clique. The Exponential Time Hypothesis is a widely held though unproven computational hardness assumption stating that 3-SAT (or any of the several related NP-complete problems) cannot be solved in sub-exponential time in the worst case (Impagliazzo and Paturi, 1999). According to ETH, if 3-SAT were solvable in sub-exponential time, then also $P = NP$. But the ETH assumption is stronger than the assumption that $P \neq NP$, so the converse is not necessarily true. ETH can be used to show that many computational problems are equivalent in complexity, in the sense that if one of them has a subexponential time algorithm then they all do.

The k-Clique problem is the parameterised version of the NP-hard Max-Clique problem. This canonical intractable problem in parameterised complexity asks, given an input graph, whether there exists a clique of size k. A naïve algorithm for this problem running in $O(n^k)$ time checks all n^k combinations of nodes and verifies each combination in $O(k^2)$ time to see if they form a clique. However, Chen et al. (2006) showed that the problem has no $n^{o(k)}$ time algorithm–that is, the problem has no algorithm that runs in time subexponential in the exponent k assuming ETH.[4].

Recurrent neural networks. Recurrent neural networks (Rumelhart et al., 1986), as we generally use them in practise in NLP, take as input a matrix $\mathbf{x}$, containing a sequence of n vectors $\mathbf{x} = \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n}$, and apply the following set of equations recursively, with h_0 the initial state:

$$\mathbf{h_t} = g(\mathbf{b} + \mathbf{W}\mathbf{h_{(t-1)}} + \mathbf{U}\mathbf{x_t})$$

Here, g is the activation function. Typically this activation function is $\tanh$, however the computational power of the model is theoretically maintained with any so-called "squashing" function (Siegelmann, 1996).

The choice of g, on the other hand, has been shown to affect the power of the recurrent model in general, depending on the restrictions involved in the formal investigation. For the purposes of this paper, the activation function is a rectified linear unit, or `ReLU`. The general computational power of such RNNs has recently been formally explored by Chen et al. (2018) (given infinite precision) and Weiss et al. (2018) (given finite precision), and empirically investigated for practical considerations of convergence under training by Le et al. (2015).

---

[3] Our structure-less but optimised implementation of the (Kiperwasser and Goldberg, 2016) graph-based parser, with 100 dimensional generated word embeddings, 50 dimensional generated POS-tag embeddings, a stack of 3 BiLSTMs with an output dimension of 225 each (total 450 concatenated), no dropout, MLP mappings for arc nodes of 400 dimension, and for labels of 100 dimensions. We use DyNet 2.1 (Neubig et al., 2017), and the parser code is freely available at `https://github.com/natschluter/MaxDecodeParser`.

[4] The problem is said to be $W[1]$-complete (Flum and Grohe, 2006)

LSTMs (Hochreiter and Schmidhuber, 1997) are RNNs with weighted self-loops (so-called gates). The recurrence equations take the form:

$$
\begin{aligned}
\mathbf{f_t} &= g_1(\mathbf{b_f} + \mathbf{W_f}\mathbf{h_{(t-1)}} + \mathbf{U_f}\mathbf{x_t}) \\
\mathbf{i_t} &= g_1(\mathbf{b_i} + \mathbf{W_i}\mathbf{h_{(t-1)}} + \mathbf{U_i}\mathbf{x_t}) \\
\mathbf{o_t} &= g_1(\mathbf{b_o} + \mathbf{W_o}\mathbf{h_{(t-1)}} + \mathbf{U_o}\mathbf{x_t}) \\
\mathbf{c_t} &= f_t \circ c_{t-1} + i_t \circ g_1(\mathbf{b_c} + \mathbf{W_c}\mathbf{h_{(t-1)}} + \mathbf{U_c}\mathbf{x_t}) \\
\mathbf{h_t} &= \mathbf{o_t} \circ g_2(c_t)
\end{aligned}
$$

where g_1, g_2 are activation functions. Setting all $\mathbf{W_f}, \mathbf{W_i}, \mathbf{W_c}, \mathbf{U_f}, \mathbf{U_i}, \mathbf{U_c}$ to be zero matrices, b_f to be a 0 vector, b_i, b_c to be 1 vectors, and the activation function g_2 to be `ReLU` we see that, in terms of hidden states, the LSTM model includes that of the RNN. In this paper, all activation functions are `ReLU`s.

3 Related Work

State-of-the-art in neural syntactic dependency parsing. The graph-based neural architectures we refer to here have important commonalities. We focus our discussion on the key contributions by Kiperwasser and Goldberg (2016) (the simplest architecture, and the first), and by Dozat and Manning (2017) (the state-of-the-art).

The architectures can be partitioned into three general components:

1. **Word representation generation**: Both architectures generate word embeddings and POS-tag embeddings. Pretrained embeddings, if they are being used, are added to the trained embeddings, and concatenated to corresponding POS-tag embedding. The embeddings are sent through a stacked BiLSTM. Output embeddings are projected to two further vector representations: as head node or as dependent node (specialised representations).
2. **Arc scoring**: All (head, dependent) combinations are scored.
3. **Decoding**: By some decoding process, the arc score matrix yields a (possibly disconnected) graph representation of the input sentence: (n-1) arcs, where no word has more than one head, as well as their probabilities.

We show in this paper how the second and third components can be carried out implicitly within the BiLSTM layers of the first component. Since currently state-of-the-art shift-reduce parsers also encode input words of a sentence using some type of recurrent neural network, this insight also applies to these non-graph-based models.

Related computational hardness results. To date there is no known truly sub-cubic algorithm for Boolean Matrix Multiplication (BMM), nor for Context-Free Grammar (CFG) parsing. Adapting Satta (1994)'s lower bound proof for Tree Adjoining Grammar parsing, Lee (1997) proved that BMM can be reduced to finding a valid derivation a string of length $O(n^{\frac{1}{3}})$ with respect to a CFG of size $\Theta(n^2)$. Lee (1997)'s reduction shows that there can be a no $O(|G|n^{3-\epsilon})$ for some constant $\epsilon > 0$ (sub-cubic-time) algorithm for CFG-parsing without implying a significant breakthrough in BMM, which is widely believed not to be possible. However, the construction required the grammar size $|G| = \Theta(n^6)$ to be dependent on the the input size n, which, as Lee (1997) points out, is unrealistic in most applications.

Abboud et al. (2015), on the other hand, present a proof of the unlikelihood of a sub-cubic algorithm for CFG-parsing using ETH and specifically the k-Clique problem. Given an instance of the $3k$-Clique problem (i.e., an undirected graph and the parameter $3k$), they construct a string w of length n^k and a CFG, G of constant size (for any $3k$) such that if G derives w in sub-cubic time, then there is an algorithm running in time $n^{o(3k)}$ for the $3k$-Clique problem, which, as we explained in Section 2, is impossible, assuming ETH.

To date, no truly sub-cubic algorithm for projective maximum spanning tree decoding is known. In the next section, we present a proof similar in spirit to Abboud et al. (2015)'s that also shows that such an algorithm most likely cannot be found.

4 Lower Bounds for First-Order Projective Dependency Decoding

Current state-of-the-art neural graph-based parsers forego structural learning and do not even seem to require structured prediction. In this section, we provide evidence that this is indeed not because the parsers are so seemingly simple. Computationally it is unlikely that some simpler and faster decoding method alone is achieving such a competitive performance. We show this with the following theorem.

Theorem 1. *Under the assumption of ETH, there is no algorithm that carries out projective MST decoding in time significantly faster than* $O(n^3)$*; that is, there is no sub-cubic (*$O(n^{3-\epsilon})$ *for some constant* $\epsilon > 0$*) time algorithm for finding the maximally weighted projective spanning tree,* T^**, over a weighted digraph input.*

Notation and special remarks. We denote by $[n]$ the set $\{1, \ldots, n\}$. For lack of a better symbol, we use $\odot$ here to signify iterative string concatenation, which otherwise is signified by just writing symbols beside each other, or by the symbol $\cdot$. Rather than working over words of a sentence, given the formal nature of the proof, the projective MST algorithm must work over symbols of the input word w. Hence the input is a weighted digraph over the symbols of w and the output is a projective MST, T^*, over these symbols. The reduction, makes use of the weight of T^*.

Proof (of Theorem 1). Let $G = (V, E)$ be an arbitrary simple undirected graph. We place an arbitrary order on the nodes from V and fix it, so $V := \{v_1, \ldots, v_n\}$.

As in Abboud et al. (2015)'s reduction from $3k$-clique to CFG-parsing, we first generate a string of length $O(n^k)$ to represent the graph for the task at hand; we do so in $O(n^k)$ time. The string contains a representation of all of the possible k-cliques in the graph. We can create a listing of all of these k-cliques using exhaustive search in at most $O(n^k)$ time and space. Let $K := \{\{v_{i_1}, \ldots, v_{i_k}\}$ a k-clique in $G \mid i_j \in [n], v_{i_j} \in V\}$ correspond to the set of k-cliques from G, and place an arbitrary order on $K := \{k_1, \ldots, k_{|K|}\}$. So, $|K| \in O(n^k)$. We define $6 \cdot k \cdot |K|$ sets of symbols with respect to V, each with $n (= |V|)$ elements:

- **Unmarked symbols**: $A_{i,t} := \{a_{i,j,t} \mid j \in [n]\}$ for $i \in [k], t \in [|K|]$ where $a_{i,j,t}$ corresponds to node $v_j \in V$.
  Similarly for the sets $B_{i,t}$ and $C_{i,t}$.
- **Marked symbols**: $\overline{A}_{i,t} := \{\overline{a}_{i,j,t} \mid a_{i,j,t} \in A_i\}$. Similarly for the sets $\overline{B}_{i,t}$ and $\overline{C}_{i,t}$.

We let $A = \cup_{i \in [k], t \in [|K|]} (A_{i,t} \cup \overline{A}_{i,t})$ and similarly for B and C. Then the vocabulary for constructing our input word is $U := A \cup B \cup C$.

Constructing the input word w. We now construct a word w over the vocabulary U such that if the projective maximum spanning tree has weight $|w| + 2k - 2 + |K|$, then the graph G has a $3k$-clique. We do this by defining the weights of possible arcs between carefully selected pairs of symbols from the vocabulary. The entire construction of the word w takes time $O(n^k)$ (coinciding with the upper bound on the word's length).

The input word is made up of a series of gadgets. For each k-clique, we have three types of gadgets: A-, B-, and C-gadgets. A- and C-gadgets each correspond both to a particular k-clique in G, as well as all k-cliques in G. B-gadgets, on the other hand, only correspond to particular k-cliques in G. Let $k_t = \{v_{(t,1)}, \ldots, v_{(t,k)}\} \in K$ be the tth k-clique. Even if each $v_{(t,q)}$ is a node in $V(G)$ the notation for indices is useful to refer to the qth node of the tth k-clique. Also, in what follows, we use the middle index of symbols to simultaneously refer to the k-clique membership: $j_{(t,q)} \in [n]$, and simultaneously allows us to refer to the qth node in the tth k-clique from K, for $q \in [k], t \in [|K|]$.

A-gadgets:

$$\begin{aligned} A(t) :=& \odot_{i \in [k]} (\overline{a}_{i,j_{(t,1)},t} \overline{a}_{i,j_{(t,2)},t} \cdots \overline{a}_{i,j_{(t,k)},t}) \cdot \\ & \odot_{i \in [k]} (a_{i,j_{(t,1)},t} \cdot a_{i,j_{(t,2)},t} \cdots a_{i,j_{(t,k)},t}) \end{aligned}$$

C-gadgets:

$$\begin{aligned} C(t) :=& (\odot_{i \in [k]} c_{i,j_{(t,1)},t} c_{i,j_{(t,2)},t} \cdots c_{i,j_{(t,k)},t}) \\ & \cdot \overline{c}_{k,j_{(t,k)},t} \cdot \overline{c}_{k-1,j_{(t,k-1)},t} \cdots \overline{c}_{1,j_{(t,1)},t} \end{aligned}$$

and **B-gadgets:**

$$\begin{aligned} B(t) :=& L_t b_{k,j_{(t,k)},t} \cdots b_{2,j_{(t,2)},t} b_{1,j_{(t,1)},t} H_t \overline{b}_{k,j_{(t,k)},t} \\ & \cdot \overline{b}_{k-1,j_{(t,k-1)},t} \cdots \overline{b}_{2,j_{(t,2)},t} \overline{b}_{1,j_{(t,1)},t} R_t, \end{aligned}$$

We call the symbol H_t the *head of the gadget* $B(t)$, and L_t and R_t the gadget's *left and right boundary symbols* respectively.

We then set the word w to be

$$\big(\odot_{t \in [|K|]} A(t)\big) \cdot \big(\odot_{t \in [|K|]} B(t)\big) \cdot \big(\odot_{t \in [|K|]} C(t)\big)$$

consisting of an *A-gadget region* followed by a *B-gadget region*, and then a *C-gadget region*.

Idea of the proof. The idea of the proof is to allow an optimal projective MST, T^*, to be built that matches up one distinct (with respect to the k-clique) gadget from each region, each representing different k-cliques whenever there is a $3k$-clique in G. We will deduce the existence of such a clique by the weight of T^*. Essentially, a projective spanning tree of weight $|w| - 1$ will always be present, but T^* having weight superior to this will indicate a matching up of gadgets. Now, suppose we have a sub-cubic projective MST algorithm A. By our construction, if A returns a T^* with weight $|w| + 2k - 2 + |K|$, then there is a $3k$-clique. Otherwise, there is no $3k$-clique. On input of length n^k, the sub-cubic time algorithm runs in time $O((n^k)^{3-\epsilon}) = O(n^{3k-k\epsilon}) \in n^{o(3k)}$ for some constant $\epsilon > 0$. Thus A will have solved $3k$-clique in time $n^{o(3k)}$, which is impossible under the ETH assumption.

Note that by the definition of a $3k$-clique, a $3k$-clique can be partitioned arbitrarily into 3 equal sized sub-graphs over k nodes that must each form a k-clique. So, if $|K| < k$, then there trivially cannot be any $3k$-clique in G. We therefore only consider without loss of generality the argumentation for the case where $|K| \geq k$, since our algorithm can simply return a negative answer about the existence of a $3k$-clique in G after enumerating the set K and before computing any projective MST.

The projective MST algorithm takes as input the description of a weighted digraph, D, whose nodes are defined by symbols of the input word w. The digraph need not be explicitly constructed, since the algorithm can simply use the description of the digraph that follows instead to check for the existence of arcs between symbols. This description has constant length.

A description of the input weighted graph D over w. For the input digraph, arcs can (1) be missing from the fully complete digraph, (2) have weight 1, or (3) have weight 2. To construct D, weights are assigned to arcs by the following rules.

Weight 1 arcs. The following arcs of our input graph have weight 1.

1. **Region connectivity arcs.** These arcs ensure connectivity is possible within respective gadget regions.
    (a) All arcs $(\overline{a}_{1,j',t}, a_{i,j,t-1})$ and $(\overline{a}_{1,j',t}, \overline{a}_{i,j,t-1})$, i.e., the first symbol of the tth A-gadget attaches to all symbols of the previous ($t - 1$th) A-gadget.
    (b) All arcs $(\overline{c}_{1,j',t}, c_{i,j,t+1})$ and $(\overline{c}_{1,j',t}, \overline{c}_{i,j,t+1})$, i.e., the last symbol of the tth C-gadget attaches to all symbols of the next ($t + 1$th) C-gadget gadget.
    (c) All arcs $(b_{i,j,t}, b_{i+1,j',t})$ and $(\bar{b}_{i+1,j,t}, \bar{b}_{i,j',t})$ for $i \in [k-1]$.
    (d) All arcs $(b_{k,j,t}, L_t), (\bar{b}_{1,j',t}, R_t)$.
    (e) All arcs $(H_t, b_{1,j,t})$ and $(H_t, \bar{b}_{k,j',t})$ making H_t a possible head of the respective B-gadget (*B-gadget heads*) for any MST.
    (f) All arcs $(L_{t+1}, H_t), (R_t, H_{t+1})$ for all $t \in [|K| - 1]$.
    (g) All arcs $(c_{k,j_{(t,k)},t}, \overline{c}_{k,j,t})$, i.e., arcs from the last nonmarked symbol to the first marked symbol, in every C-gadget. Also, all arcs $(\overline{c}_{i+1,j,t}, \overline{c}_{i,j,t})$ for $i \in [k-1]$, i.e., together forming a path of marked symbols within each C-gadget.

        The following arcs are the reversals of (1c) through (1e).
    (h) All arcs $(b_{i+1,j,t}, b_{i,j',t})$ and $(\bar{b}_{i,j,t}, \bar{b}_{i+1,j',t})$ for $i \in [k-1]$.
    (i) All arcs $(L_t, b_{k,j,t}), (R_t, \bar{b}_{1,j',t})$.
    (j) All arcs $(b_{1,j,t}, H_t)$ and $(\bar{b}_{k,j',t}, H_t)$ making H_t the head of the respective B-gadget (*B-gadget heads*) for any MST.
2. **Boundary connectivity arcs.** These arcs ensure that the boundaries of regions are connected.
    (a) The arcs $(L_1, a_{i,j,|K|})$ and $(L_1, \overline{a}_{i,j,|K|})$, i.e., all symbols from the last of the A-gadgets attach to the first symbol of the B-gadget region.
    (b) The arcs $(R_{|K|}, c_{i,j,1})$ and $(R_{|K|}, \overline{c}_{i,j,1})$, i.e., all symbols from the first of the C-gadgets attach to the last symbol of the B-gadget region.
3. **G-induced arcs.** These arcs reflect the connections of the original graph G, and ultimately the existence of a $3k$-clique.
    (a) All arcs $(b_{i,j,t}, a_{i,j',t'})$, for each $i \in [k-1], t \neq t'$, if $v_j v_{j'} \in E(G)$ (i.e., not for $i = k$, which has a weight of 2 rather).
    (b) All arcs $(\bar{b}_{i,j,t}, c_{i,j',t'})$, for each $i \in \{2, \dots, k\}, t \neq t'$, if $v_j v_{j'} \in E(G)$ (i.e., not for $i = 1$, which has a weight of 2 rather).
    (c) All arcs $(\overline{c}_{i,j,t}, \overline{a}_{i,j',t'})$ for all $i \in [k], t \neq t'$, if $v_j v_{j'} \in E(G)$ (i.e., this time also for $i = 1$).

As we show in Lemma 1.1, with the region connectivity arcs (1a-1g) and boundary connectivity arcs (2), we ensure that the algorithm can always return a projective MST with weight at least $|w| - 1$. The G-induced arcs and region connectivity arcs (1h-1j, 4) on the other hand will be triggered to use by the algorithm's prioritisation of the following arcs.

Weight 2 arcs. We have the following arcs of weight 2.

4. **Region connectivity arcs.** (L_{t+1}, L_t) and (R_t, R_{t+1}) for $t \in [|K| - 1]$.
5. **G-induced arcs.**
    (a) All arcs $(b_{k,j,t}, a_{k,j',t'})$, for each $t \neq t'$, if $v_j v_{j'} \in E(G)$
    (b) All arcs $(\bar{b}_{1,j,t}, c_{1,j',t'})$, for each $t \neq t'$, if $v_j v_{j'} \in E(G)$

There are no other arcs in the input digraph D.

Lemma 1.1. *There always exists a projective MST in D of weight $|w| - 1$.*

Proof. The A-region, together with the symbol L_1 from the B-region can form a tree rooted in L_1

using region connectivity arcs (1a) with boundary connectivity arcs (2a)–all weight 1 arcs. Similarly for the C-region with the symbol $R_{|K|}$ from the B-region (arcs (1b) and (2b)). Moreover, these regional sub-trees are trivially projective. If we construct a projective subtree out of the B-region, in which L_1 and $R_{|K|}$ are leaf nodes, then we have the result.

The combination of weight-1 arcs from (1c), (1d), and (1e) results in each B-gadget B(t) being a projective subtree headed by its head node H_t made up of a combination of two paths $H_t, b_{1,j_1,t}, \ldots, b_{k,j_k,t}, L_t$ and $H_t, b_{k,j_k,t}, \ldots, \overline{b_{1,j_1,t}}, R_t$. To make a projective subtree out of the entire B-region, we choose some arbitrary H_t node as the root and take further weight-1 arcs described in (1f): (L_p, H_{p-1}) if $p \leq i$ and $(R_p, H_p + 1)$ otherwise, for $i \in [2, |K| - 1]$. In all these possible B-regional projective subtrees, both L_1 and $R_{|K|}$ are leaf nodes, which gives the result. □

Lemma 1.2. *Let T^* be a projective MST over D. There are at most $2k+(|K|-1)$ arcs of weight 2 in T^*: k from the B- to the A-region, k from the B- to the C-region, and the rest internal to the B-region.*

The number of arcs of weight 2, internal to or originating from the B-region, will be maximised if arcs exiting the B-region all originate from the same B-gadget (instead of 2+ distinct ones).

Moreover, suppose distinct $t_1, t_2, t_3 \in [|K|]$. If T^* includes an arc of weight 2 from gadget $B(t_2)$ to gadget $A(t_1)$ and from gadget $B(t_2)$ to gadget $C(t_3)$, then T^* must also include arcs characterised by the following

1. *all non-marked nodes in $A(t_1)$ have non-marked heads in $B(t_2)$,*
2. *all non-marked nodes in $C(t_3)$ have marked heads in $B(t_2)$, and*
3. *all marked nodes in $A(t_1)$ have marked heads in $C(t_3)$.*

Proof. There are only arcs of weight 2 in D from the B-region to both the A- and the C-regions, and internally in the B-region. We show that there are at most k weight 2 arcs connecting the A- and B-regions and C- and B-regions. Then we show that the maximal number of weight 2 edges internal to the B-region is $(|K| - 1)$.

Suppose there are more than k arcs of weight 2 from the B-region to the A-region in T^*. Then there are at least two of these arcs entering different A-gadgets: $(b_{1,j',t'}, a_{1,j,t})$ and $(b_{1,i',p'}, a_{1,i,p})$, with $p < t$. Consider the barred symbols in the tth A-gadget. There are only two possible heads: (1) the symbol following the gadget (region connectivity arcs (1a) or boundary connectivity arcs (2a)), which by projectivity is excluded because these arcs would cross $(b_{1,j',t'}, a_{1,j,t})$, or (2) symbols from the C-region, which by projectivity is also excluded because they would cross the arc $(b_{1,i',p'}, a_{1,i,p})$.

The proof that there are at most k arcs of weight 2 from the B-region to the C-region in T^* is analogous.

For the maximal number of arcs of weight 2, internal to the B-region, we first consider the maximum number of weight 2 region connectivity arcs (4). By projectivity, a B-gadget with arcs entering an A- or C-gadget cannot have any entering weight 2 region connectivity arc. Also, by projectivity, a single B-gadget can have at most 1 weight 2 region connectivity arc. Thus, the number of weight 2 arcs would be maximised by ensuring arcs exiting the B-region originate from the same B-gadget, so only one B-gadget does not have weight 2 entering arcs. Since there are $|K|$ B-gadgets in total, this means there are at most $|K| - 1$ weight 2 B-region internal arcs.

The rest of the proof follows by the similar projectivity arguments. □

Lemma 1.3. *T^* has weight $|w|+2k-1+(|K|-1)$ if and only if there is a $3k$-clique in G.*

Proof. ($\Leftarrow$) Suppose there is a $3k$-clique in G consisting of the three k-cliques k_1, k_2, and k_3, and such that $k_1 \cup k_2 \cup k_3$ is a $3k$-clique. In w, there must be corresponding gadgets in each of its gadget regions. We consider $A(1)$ the gadget for k_1 in A, by $B(2)$ the gadget for k_2 in B, and by $C(3)$ the gadget for k_3 in C. We build up a set S of arcs based on these three gadgets. The set S consists of all the possible G-induced (weight 1 and 2) arcs between these three regions–a disconnected set where no two arcs cross, by Lemma 1.2. By the same lemma, S includes exactly $2k + (|K| - 1)$ arcs of weight 2. We will add arcs to S to connect the rest of the symbols in w until we form a tree, and by Lemma 1.2 again we cannot add any further weight 2 arcs.

We must now supplement S to make a tree. We first connect the B-region. For $t < 2$, we connect B-gadgets internally by making the path from the R_t to L_t, using weight 1 region connectivity arcs. We make paths in the opposite direction, from L_t

to R_t for $t > 2$. We then add all possible weight 2 region connectivity arcs. This makes A(1) and B-region connected.

All other A-gadgets are connected as in the proof of Lemma 1.1. Similarly for the C-gadgets before and after $C(3)$.

The only nodes that still lack a head node are the marked nodes from $C(3)$. We connect these using region connectivity arcs from (1g).

We have now constructed a projective tree of weight $|w| - 1 + 2k + (|K| - 1)$. We cannot have a higher weighted projective tree by Lemma 1.2. Hence tree is an optimal T^*.

($\Rightarrow$) Suppose T^* has weight $|w| - 1 + 2k + (|K| - 1)$. By Lemma 1.2, T^* has exactly k arcs of weight 2 from the B-region to the A-region, and k from the B-region to the C-region, and that in this case all possible G-induced arcs between the three corresponding gadgets are in T^*. Moreover, internally to the B-region, there are $|K| - 1$ weight 2 edges.

Let the gadgets be w.l.o.g., A(1), B(2), and C(3). Each unmarked b symbol in B(2) corresponds to a node in V, and is the head of an unmarked symbol from A(1) corresponding to every node in k-clique k_1. This means that in G, all possible connections between nodes in k_1 and k_2 exist. The same holds for B(2) with C(3) and C(3) with A(1). Hence there is a $3k$-clique in G. □

□

With Theorem 1, we have shown that the non-structural graph-based neural parsing systems cannot be carrying out explicit exact decoding in with a significantly simpler algorithm. As we show in the next section, in fact, the LSTM stacks of these systems alone are powerful enough to simulate all components.

In our proof, the algorithm consistently makes a choice between edges of weight 1 and edges of weight 2 for the result to preserve projectivity. Possibly more edges of weight 1 may end up in a maximum spanning projective DAG or digraph, so we cannot necessarily use the weight in the same way to deduce the result. The number of edges in D is less than n^2. Hence if we replace the weights of weight 1 arcs in D by weight $1/(n^2)$, then an output maximum spanning projective digraph or DAG with weight superior to $2k + (|K| - 1)$ would indicate a $3k$-clique. By the algorithms to do this from (Schluter, 2015) in cubic time, we therefore have the same lower bound for finding a maximum spanning projective DAG or digraph.

Corollary 1.1. *Under the assumption of ETH, there is no algorithm that carries out projective maximum spanning DAG or digraph decoding in sub-cubic time.*

5 RNN Simulation of Eisner's Algorithm

Eisner (1996)'s algorithm on an input sentence of length n uses an $n \times n$ table M and dynamic programming to compute for table cell $M_{i,j}$ the highest weighted sub-trees over the span (i, j) of the input sentence. The algorithm iterates over spans of increasing length. For $M_{i,j}$, the weights of all possible combinations of sub-spans are considered as candidate sub-trees over the span, and the maximum of these is retained in $M_{i,j}$.

For our purposes, the problem with this version of the algorithm is that the RNN cannot compute the maximum of the corresponding $O(n)$ values in either constant space nor in one time-step, and the corresponding sub-tree weight is required in the computation of maximum sub-trees over the span $j - i + 1$ at the next recursive step.

In Algorithm 1, we precompute enough of the comparisons required for finding the maximum spanning sub-tree combination before the algorithm arrives in that table cell (from line 5). Thus, instead of taking the maximum across $k \in O(n)$ values, we only ever take the maximum across 2 values at a time. We now explain this algorithm.

A sub-tree over the span (i, j) is said to be *complete* if it includes some arc between i and j. Otherwise the sub-tree is called *incomplete*. We use seven weight matrices (which we extend to 25 matrices later):

- S an $n \times n$ matrix of arc scores, where $S[i, j]$ is the score of the (i, j) arc.
- I an $n \times n$ matrix of incomplete sub-tree scores, where $I[i, j, h]$ is the incomplete sub-tree for the span (i, j) with head $h \in 0, 1$. If $h = 0$, then i is the root of the sub-tree, and if $h = 1$, then j is the root.
- C is defined in the same way as I but for complete sub-trees.
- $I_r[i, j, h]$ (resp. C_r) stores the current "row"-maximum value for $I[i, j, h]$ across the span combinations $(i, k), (k + 1, j)$ for $k - i > (k + 1) - j$ (resp. $(i, k), (k, j)$ for $k - i > k - j$). These are the cases where the span (i, k) is the largest of the two sub-spans (i, j). These table values are adjusted while the algorithm visits cells (i, k).

- $I_c[i,j,h]$ (resp. C_c) stores the current "column"-maximum value for $I[i,j,h]$ across the span combinations $(i,k),(k+1,j)$ for $k-i \leq k+1-j$ (resp. $(i,k),(k,j)$ for $k-i > k-j$). These are the cases where the span $(k+1,j)$ (resp. (k,j)) is larger or equal to the other sub-span of the partitioned span (i,j). These table values are adjusted while the algorithm visits cells $(k+1,j)$ (resp. (k,j)).

The pseudocode for this algorithm, which we refer to as `streaming-max-eisner` is presented in Algorithm 1. The main difference with the original version is that the internal loop partitioning of a span is separated in Algorithm 1 over several previous iterations of the loop, so that once the algorithm visits cell (i,j), all that needs to be computed is the maximum of the two row- and column-maximum values, from I_r and I_c, or from C_r and C_c.

It is straightforward to show the correctness of this algorithm, which we state as Theorem 2. We omit the proof due to space constraints. The algorithm can also be easily adapted for backtracking.

Theorem 2. *Algorithm 1 returns the weight of* T^*.

We make a final adjustment to the algorithm before stating the simulation construction. For the simulation, we only have RNN operations at our disposal: linear combinations and a `ReLU` activation function, but no explicit max operation. In order to use only RNN operations, we replace the explicit max function.

Replacing the explicit max function. We note that to find the maximum of the two positive numbers a and b, we can use the `ReLU` function. Without loss of generality, suppose that $a > b$, then

$$\begin{aligned}\frac{(\texttt{ReLU}(a-b)+\texttt{ReLU}(b-a)+a+b)}{2} \\ = \frac{(a-b+a+b)}{2} = \frac{2a}{2} = a \\ = \max(a,b). \quad (1)\end{aligned}$$

In fact, since all weights are assumed positive, Equation 1 can be rewritten as

$$\begin{aligned}\max(a,b) = \frac{1}{2}(\texttt{ReLU}(a-b)+\texttt{ReLU}(b-a) \\ +\texttt{ReLU}(a)+\texttt{ReLU}(b)). \quad (2)\end{aligned}$$

We therefore make a final adjustment to the original Eisner algorithm, over the version Algorithm 1, replacing all max functions using Equation 2. Instead of storing only one value for each matrix I_r, I_c, C_r, C_c, I, C, we store four, denoted by the fields a, b, ab, ba corresponding the four values we need to store: $\texttt{ReLU}(a), \texttt{ReLU}(b), \texttt{ReLU}(a-b)$, and $\texttt{ReLU}(b-a)$ respectively. For instance, for the matrix I, we have I_a, I_b, I_{ab}, I_{ba}. Then, for example, line 6 becomes

$$\begin{aligned}a \leftarrow \texttt{ReLU}(\frac{1}{2} * (I_r[i,j,0].a + I_r[i,j,0].b \\ + I_r[i,j,0].ab + I_r[i,j,0].ba)) \quad (3) \\ b \leftarrow \texttt{ReLU}(\frac{1}{2} * (I_c[i,j,0].a + I_c[i,j,0].b \\ + I_c[i,j,0].ab + I_c[i,j,0].ba)) \quad (4) \\ I[i,j,0].a \leftarrow \texttt{ReLU}(a) \\ I[i,j,0].b \leftarrow \texttt{ReLU}(b) \\ I[i,j,0].ab \leftarrow \texttt{ReLU}(a-b) \\ I[i,j,0].ba \leftarrow \texttt{ReLU}(b-a)\end{aligned}$$

where Equations 3 and 4 are wrapped in an extra `ReLU` operation which yields no difference to the parameter, but which will be convenient for our simulation in Section 5.

Lines 11-14 and 16-19 are adapted in the same way. We provide the adaption of line 11 to make this precise:

$$\begin{aligned}a \leftarrow \texttt{ReLU}(\frac{1}{2} * (I[i,p,1].a + I[i,p,1].b \\ + I[i,p,1].ab + I[i,p,1].ba)) \\ b \leftarrow \texttt{ReLU}(\frac{1}{2} * (C[i,j,0].a + C[i,j,0].b \\ + C[i,j,0].ab + C[i,j,0].ba \\ + C[j+1,p,1].a + C[j+1,p,1].b \\ + C[j+1,p,1].ab + C[j+1,p,1].ba \\ + S[p,i])) \\ I_r[i,p,1].a \leftarrow \texttt{ReLU}(a) \\ I_r[i,p,1].b \leftarrow \texttt{ReLU}(b) \\ I_r[i,p,1].ab \leftarrow \texttt{ReLU}(a-b) \\ I_r[i,p,1].ba \leftarrow \texttt{ReLU}(b-a).\end{aligned}$$

Algorithm 1 therefore uses 25 matrices on input of length n–hence, still $O(n^2)$ space.

Simulating Algorithm 1. The projective dependency parsing architecture M' to be simulated first sends word embeddings $x_i, i \in [n]$ through a forward (and backward) LSTM with output word representations $\overrightarrow{o}'_i$ (and $\overleftarrow{o}'_i$) of dimension d. The concatenated result $[\overrightarrow{o}'_i; \overleftarrow{o}'_i]$ is further specialised through two unrelated nonlinear dense layers: one for dependents and one for heads. Then all resulting pairs (dependent,head) of word representations are sent through a scoring function to generate a score matrix as input to projective MST decoding (Kiperwasser and Goldberg, 2016).

10:             for $p \leftarrow j + 1$ up to $\min(j + t + 1, n)$ do     ▷ streaming-row for-loop, i.e., while $p - (j + 1) \leq t$
11:                 $I_r[i, p, 1] = \max(I[i, p, 1], C[i, j, 0] + C[j + 1, p, 1] + S[p, i])$
12:                 $I_r[i, p, 0] = \max(I[i, p, 0], C[i, j, 0] + C[j + 1, p, 1] + S[i, p])$
13:                 $C_r[i, p, 1] = \max(C[i, p, 1], C[i, j, 1] + I[j + 1, p, 1])$
14:                 $C_r[i, p, 0] = \max(C[i, p, 0], I[i, j, 0] + C[j + 1, p, 0])$
15:             for $p \leftarrow i - 1$ down to $\max(i - 1 - t, 1)$ do   ▷ streaming-column for-loop, i.e., while $(i - 1) - p \leq t$
16:                 $I_c[p, j, 1] = \max(I[p, j, 1], C[p, i - 1, 0] + C[i - 1, j, 1] + S[p, i])$
17:                 $I_c[i, p, 0] = \max(I[i, p, 0], C[i, j, 0] + C[j + 1, p, 1] + S[i, p])$
18:                 $C_c[i, p, 1] = \max(C[i, p, 1], C[i, j, 1] + I[j + 1, p, 1])$
19:                 $C_c[i, p, 0] = \max(C[i, p, 0], I[i, j, 0] + C[j + 1, p, 0])$
20:     Return $I, C$
```

The architecture M to simulate M' consists of two components, each being a recurrent layer: a BiLSTM (for contextual word representations and word specialisations) and an RNN (for scoring and to simulate Algorithm 1).

M starts by feeding word embeddings x_i into its first component, the BiLSTM. In the forward direction, at the tth time step, the contextual representation $\overrightarrow{o}'_t$ is generated, $\overrightarrow{o}'_{t-1}$ is specialised to $\overrightarrow{o}^h_{t-1}$ (head) and $\overrightarrow{o}^d_{t-1}$ (dependent), and the previously specialised word representations in $\overrightarrow{o}_t$ (i.e., corresponding to $\overrightarrow{o}'_1, \ldots, \overrightarrow{o}'_{t-2}$) are copied over. We add a single extra $(n + 1)$th time step to each direction, so M can finish specialising contextualised word representations within this first component. Similarly for the backward direction.

There is one single input to M's second component, an RNN, which also works in $n + 1$ time steps. We refer to the inputs for this component as $z_1, \ldots, z_{(n+1)}$, where $z_2 \ldots z_{(n+1)}$ are all dummy inputs. z_1 is the concatenation of the final output vectors from each direction of M's BiLSTM. In the first time step of this component, M computes the score matrix and stores it in the hidden state h_1. The hidden state has a dimension large enough to house the 25 tables ($O(n^2)$ space) required by Algorithm 1 for subtree score bookkeeping and computing the maximum of two values using linear combinations and a `ReLU`.

The outer loop (the *span for-loop* with variable t) of the algorithm corresponds to each time-step t of the RNN. For the first internal for-loop (the *diagonal for-loop* with variable i), we note that, in lines 6-9, no cells $(i, i + t)$ whose values are being computed require information from each other at this time-step t.

The *streaming-row* and *streaming-column* for loops (lines 11-14, 16-19) on the other hand sometimes requires maximal values $(i, i + t)$ from lines 6-9 to be computed. This problem is simply solved by replacing the corresponding expressions appearing as left-hand sides in lines 6-9 by the right-hand sides.

The output h_{n+1} contains the desired maximum value.

6 Concluding Remarks

Recent state-of-the art neural graph-based parsers comprising, among other components, a short stack of BiLSTMs, seem to obviate any explicit structural learning or prediction. In this paper, under the assumption of ETH, we showed that this is not due to any possible indirect discovery of a faster algorithm for finding a projective maximum spanning tree and extended the result to projective maximimum spanning DAGs and digraphs. We further showed how these architectures allow for simulating decoding, implying that they are indeed carrying out implicit structured learning and prediction.

Evaluating Composition Models for Verb Phrase Elliptical Sentence Embeddings

Abstract

Ellipsis is a natural language phenomenon where part of a sentence is missing and its information must be recovered from its surrounding context, as in “Cats chase dogs and so do foxes.”. Formal semantics has different methods for resolving ellipsis and recovering the missing information, but the problem has not been considered for distributional semantics, where words have vector embeddings and combinations thereof provide embeddings for sentences. In elliptical sentences these combinations go beyond linear as copying of elided information is necessary. In this paper, we develop different models for embedding VP-elliptical sentences. We extend existing verb disambiguation and sentence similarity datasets to ones containing elliptical phrases and evaluate our models on these datasets for a variety of non-linear combinations and their linear counterparts. We compare results of these compositional models to state of the art holistic sentence encoders. Our results show that non-linear addition and a non-linear tensor-based composition outperform the naive non-compositional baselines and the linear models, and that sentence encoders perform well on sentence similarity, but not on verb disambiguation.

1 Introduction

Compositional distributional semantics has so far relied on a tight connection between syntactic and semantic resources. Based on the assembly principle of compositionality, these models assign a sentence vector by applying a linear map to the individual word embeddings therein. The meaning of “cats chase dogs” is as follows in (1) additive, (2) multiplicative, and (3) tensor-based models:

(1) $\overrightarrow{cats} + \overrightarrow{chase} + \overrightarrow{dogs}$
(2) $\overrightarrow{cats} \odot \overrightarrow{chase} \odot \overrightarrow{dogs}$
(3) $\overrightarrow{cats}^{\top} \times (\overline{chase} \times \overrightarrow{dogs})$

Some linguistic phenomena, however, rely on copying resources while computing meaning; canonical examples thereof are anaphora and ellipsis, exemplified below:

(a) Cats clean themselves.
(b) Cats chase dogs, children do too.

More complex examples involve a structural ambiguity such as the following:

(c) Cats chase their tail, dogs too.

These lend themselves to a strict (dogs chase the cat’s tail) and a sloppy reading (dogs chase their own tail). In these examples, the meaning of at least one part of the sentence is used twice, e.g. the subject in a, the verb phrase “chase dogs” in b. Such cases can often be extended to a situation in which a meaning is used more than twice, e.g. in “Cats chase their tail, dogs too, and so do foxes”.

In order to develop distributional semantics for such sentences while respecting the principle of compositionality, one has a choice between a linear or a non-linear composition of resources. In the linear case, no information is copied, resulting in vector embeddings such as the following one (when only considering content words):

$$\overrightarrow{cats} + \overrightarrow{chase} + \overrightarrow{dogs} + \overrightarrow{children}$$

In the non-linear case, the necessary resources are copied to resolve the ellipsis, resulting in vectors embeddings such as:

$$\overrightarrow{cats} + \overrightarrow{chase} + \overrightarrow{dogs} + \overrightarrow{children} + \overrightarrow{chase} + \overrightarrow{dogs}$$

One has the same choice when dealing with multiplicative and tensor-based models. The question is which of these composition frameworks, i.e. linear versus non-linear, provides a better choice for embedding elliptical sentences. To our knowledge, this has remained an open question: although some theoretical work has been done to

Proceedings of NAACL-HLT 2019, pages 261–271
Minneapolis, Minnesota, June 2 - June 7, 2019.

model verb phrase ellipsis in compositional distributional semantics (Wijnholds and Sadrzadeh, 2018), none of the existing datasets or evaluation methods for distributional semantics focus on elliptical phenomena.

In this paper, we provide some answers. Our starting point is the lambda logical forms of sentences, e.g. those produced by the approach of Dalrymple et al. (1991), which uses a higher order unification algorithm to resolve ellipsis. We apply to these the lambdas-to-vectors mapping of Muskens and Sadrzadeh (2016, 2017) to homomorphically map the lambda terms into concrete vector embeddings resulting from a multitude of composition operators, such as addition, multiplication, and tensor-based. We work with four vector spaces (count-based, Word2Vec, GloVe, FastText) and three different verb embeddings, and contrast our compositional models with state of the art holistic sentence encoders.

We evaluate the sentence embeddings by using them in a verb disambiguation and in a sentence similarity task, created by extending previous SVO tasks from Grefenstette and Sadrzadeh (2011a) and Kartsaklis and Sadrzadeh (2013) to an elliptical setting, and obtaining new human judgements using the Amazon Mechanical Turk crowdsourcing tool. Our experiments show that in both tasks, the models that use a non-linear form of composition perform better than the models whose composition framework is linear, suggesting that resolving ellipsis contributes to the quality of the sentence embedding.

2 Background

Single-Word Embeddings: Distributional semantics on the word level relies on the embedding of word meaning in a vectorial form: by taking context words as the basis of a vector space one computes the vector components of each word by considering its distribution among corpus data. Then a similarity measure is defined on the vector space via the cosine similarity. In a count-based model, the context is taken to be a linear window and the corpus is traversed to collect raw co-occurrence counts. Then, a weighting scheme is applied to smooth the raw frequencies in the meaning representation. More discussion on count-based vector space models can be found in (Turney and Pantel, 2010), and a systematic study of the parameters of count-based word embeddings is given by (Kiela and Clark, 2014).

With the rise of deep learning techniques, much attention has been given to neural word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017), which try to predict rather than observe, the context of a word by optimising an objective function based on the probability of observing a context.

Compositional Models: The key idea of compositional models is that the meaning of elementary constituents can be combined in a structured way to obtain a representation for larger phrases. In a distributional setting, having a compositional operator is imperative: a data-driven model would not be adequate given the sparsity of full sentences in a corpus. Moreover, it is not clear that sentences follow the distributional hypothesis.

Concrete composition operators can roughly be classified as simple and tensor-based. Simple models add or multiply the word vectors to obtain a sentence vector. The work of Mitchell and Lapata (2010) experiments with these models. Tensor-based models differ in that they represent complex words as vectors of a higher order: Baroni and Zamparelli (2010) represents adjectives as matrices which, applied to a word vector produce a vector representation of the compound adjective-noun combination. The account of (Coecke et al., 2010, 2013; Clark, 2015) generalises this to higher-order tensors, e.g. cubes for transitive verbs and hypercubes for ditransitive verbs. The benefit of a type-driven approach over the simple models is that they respect the grammatical structure of sentences: the meaning of “man bites dog” is distinct from that of “dog bites man” whereas in an additive/multiplicative model they would be identical. The trade-off is that the tensors themselves have to be learnt; where Baroni and Zamparelli (2010) apply regression learning to learn the content of adjective matrices, for transitive verbs there have been several approaches using multistep regression learning (Grefenstette et al., 2013), relational learning (Grefenstette and Sadrzadeh, 2011a), or a combination of co-occurrence information with machine learning techniques (Polajnar et al., 2014a,b; Fried et al., 2015). A comparative study between count-based and neural embeddings in a compositional setting was carried out by (Milajevs et al., 2014).

Neural composition turns the problem of compositionality around by learning the composition operator instead of predicting the result. Examples are Skip-Thought Vectors (Kiros et al., 2015), the Distributed Bag of Words model (Le and Mikolov, 2014), InferSent (Conneau et al., 2017), and Universal Sentence Encoder (Cer et al., 2018).

Ellipsis, Formally: There exists many formal approaches to ellipsis and anaphora in the literature. These have generally taken either a syntactic or a semantic form[1]. Examples of the syntactic approaches are in the work of Hendriks and Dekker (1995); Morrill and Valentín (2015); Jäger (2006); Kubota and Levine (2017); these use directional extensions of categorial grammars that allow for the syntactic types at the site of ellipsis be unified with copies of the types at the antecedent of the elliptical phrase. Another approach deletes the syntactic structure at the ellipsis site and reconstruct it by copying across the antecedent structure (Fiengo and May, 1994; Merchant, 2004).

Semantic approaches (Dalrymple et al., 1991; Szabolcsi, 1987; Pulman, 1997) assume that ellipsis involves underspecification of content and resolve this by producing a predicate via a suitable abstraction from the antecedent. For instance, the elliptical phrase (b) "Cats chase dogs, children do too", will take an initial logical form (b_1); a resolution step (b_2) provides it with the lambda term in (b_3), which constitutes its final semantic form:

$$(b_1) \quad chase(cats, dogs) \wedge P(children)$$

$$(b_2) \quad P = \lambda x.chase(x, dogs)$$

$$(b_3) \quad (b_1) \rightsquigarrow_\beta chase(cats, dogs) \\ \wedge\, chase(children, dogs)$$

The ambiguous example (d) "Cats chase their tails, dogs too" is treated similarly, but can now obtain its respective strict and sloppy readings by producing predicates (d_1) and (d_2) below:

$$(d_2) \quad P = \lambda x.chase(x, tail(cats))$$

$$(d_3) \quad P = \lambda x.chase(x, tail(x))$$

Mixed syntactic/semantic approaches have also been proposed to cover wider ranges of phenomena; see Kempson et al. (2015) for an overview.

The only existing work attempting to join ellipsis analysis with vector embeddings is the proposal of (Kartsaklis et al., 2016), which is preliminary work and gives unwanted results[2]. Below, we develop a new such approach.

3 Embeddings for Elliptical Phrases

Vectors and their basic operations can be *emulated* using a lambda calculus with constants for the relevant operations, as shown in (Muskens and Sadrzadeh, 2016). They assume a type I (a finite index set) and R (modelling the real numbers) and model any vector as a term of type $V := IR$; that is, as a function from indices to real numbers. Matrices can then be represented by types $M := IIR$ and in general a tensor of rank n will have type $T^n := I_1 \ldots I_n R$. The standard operations like scalar multiplication, addition, element wise multiplication and tensor contraction can be modelled with lambda terms as follows:

$$\begin{array}{ccll}
\cdot & := & \lambda rvi.r \cdot v_i & : RVV \\
+ & := & \lambda vwi.v_i + w_i & : VVV \\
\odot & := & \lambda vwi.v_i \cdot w_i & : VVV \\
\times_1 & := & \lambda mvij.\sum\limits_j m_{ij} \cdot v_j & : MVV \\
\times_2 & := & \lambda cvijk.\sum_k c_{ijk} \cdot v_k & : T^3VM
\end{array}$$

The first three definitions above extend the arithmetic operations of addition and multiplication on real numbers in R to lists of numbers in IR and define corresponding definitions on vectors, and so $\odot$ defines the pointwise multiplication of two vectors. The operation $\times_1$ defines matrix multiplication; $\times_2$ defines the tensor contraction between a cube c (in I^3R) and a list of numbers v.

c	$\mathcal{H}(c)$	$\mathcal{T}(c)$
`cn`	**cn**	V
`adj`	$\lambda v.(\mathbf{adj} \times_1 v)$	VV
`adv`	$\lambda v.(\mathbf{adv} \times_1 v)$	VV
`itv`	$\lambda v.(\mathbf{itv} \times_1 v)$	VV
`tv`	$\lambda uv.(\mathbf{tv} \times_2 v) \times_1 u$	VVV
`coord`	$\lambda P.\lambda Q.P \nabla Q$	VVV
`quant`	$\lambda vZ.Z(\mathbf{quant} \times_1 v)$	$V(VV)V$

Table 1: Lambda Vector look up table for a tensor-based composition model. `cn`: a common noun, `adj`: adjective, `adv`: adverb, `itv`: intransitive verb, `tv`: transitive verb, `coord`: coordinator, `quant`: generalised quantifier; P, Q are variables of type V, and so are v, u, Z is a variable of type VV, ∇ is either $\odot$ or $+$.

The vector semantics of a lambda term m is computed by taking a homomorphic image over the set of its constants c. This image is computed compositionally from the vector or tensor embeddings of the constants c of m via their homomorphic images $\mathcal{H}(c)$, whose types are denoted by $\mathcal{T}(c)$.

Examples of these are given in Table 1 for a

---

[1] Although pragmatics approaches exist (Merchant, 2010), we focus here on syntactic and semantic approaches.

[2] The meaning of "Bill brought apples and John pears" coincides with that of "Bill and John brought apples and pears".

tensor-based composition model, where the boldface **c** denotes the vector/tensor embedding of c.

Using this table, we obtain homomorphic images of any lambda term over the constants. For instance, the lambda term of our exemplary resolved ellipsis phrase (b_3) $\mathit{chase}(\mathit{cats}, \mathit{dogs}) \wedge \mathit{chase}(\mathit{children}, \mathit{dogs})$ is given the following semantic, obtained by computing $\mathcal{H}(b_3)$:

$$((\mathbf{chase} \times_2 \mathbf{dogs}) \times_1 \mathbf{cats})\nabla$$
$$((\mathbf{chase} \times_2 \mathbf{dogs}) \times_1 \mathbf{children})$$

The constituents of the $\mathcal{H}(c)$ entries of Table 1 are only exemplary. Many other interpretations are possible. For instance, taking vector embeddings for all words and replacing all tensor contractions and ∇ by $+$ defines a purely additive model. The concrete models for transitive sentences that were evaluated by Milajevs et al. (2014) can all be derived by varying the $H(c)$ entries. Below are the sentences obtained by using the Copy Object (CO), Frobenius Additive (FA), Frobenius Multiplicative (FM) and Frobenius Outer (FO) instantiations of the verb, respectively:

$$\begin{aligned}
\mathbf{CO}: &\quad \lambda os.o \odot (\mathbf{verb} \times^{\top} s)\\
\mathbf{FA}: &\quad \lambda os.s \odot (\mathbf{verb} \times o) + o \odot (\mathbf{verb} \times^{\top} s)\\
\mathbf{FM}: &\quad \lambda os.s \odot (\mathbf{verb} \times o) \odot o \odot (\mathbf{verb} \times^{\top} s)\\
\mathbf{FO}: &\quad \lambda os.s \odot (\mathbf{verb} \times o) \otimes o \odot (\mathbf{verb} \times^{\top} s)
\end{aligned}$$

The vector semantics of the extensions of transitive sentences with VP elliptical phrases are obtained by taking each of the above as the semantics of each conjunct of the lambda logical form and interpreting the conjunction operation of $\wedge$ as either sum or multiplication.

4 Experimental Evaluation

For the evaluation of the model(s) in the previous section, we built two new datasets and experimented with count based and neural vector spaces, and sentence encoders.[3].

4.1 Building new datasets

In order to experiment with ellipsis, we extended the verb disambiguation dataset of Grefenstette and Sadrzadeh (2011a) and the transitive sentence similarity dataset of Kartsaklis and Sadrzadeh (2013), henceforth GS2011 and KS2013.

4.1.1 GS2011

The GS2011 verb disambiguation dataset contains 10 verbs, each with two possible interpretations. For each verb v and its two interpretations v_1 and v_2, the dataset contains human similarity judgments for 10 subject-object combinations. For instance, for the verb *meet* – ambiguous between *visit* and *satisfy* – the dataset contains the pairs ⟨*system meet requirements, system satisfy requirements*⟩ and ⟨*system meet requirements, system visit requirements*⟩. The more likely interpretation is marked as HIGH whereas the unlikely interpretation is marked LOW.

We extended this dataset as follows: for each combination of a verb triple (v, v_1, v_2) and a subject-object pair (s, o), where $\langle s\ v\ o,\ s\ v_1\ o\rangle$ is expected to have LOW similarity in the dataset and $\langle s\ v\ o,\ s\ v_2\ o\rangle$ is thus expected to have HIGH similarity, we selected a new subject s^* from the list of most frequent subjects for the verb v_2 such that it was significantly more frequent for v_2 than for v_1[4]. By doing so we strengthened the disambiguating effect of the context for each verb. The subject was selected such that the resulting elliptical phrase pairs made sense. For each combination and new subject considered, we added the two sentence pairs in the elliptical form

$$\langle s\ v\ o \text{ and } s^* \text{ does too},\ s\ v_1\ o \text{ and } s^* \text{ does too}\rangle$$
$$\langle s\ v\ o \text{ and } s^* \text{ does too},\ s\ v_2\ o \text{ and } s^* \text{ does too}\rangle$$

For example, for the verb triple (*draw, depict, attract*), and original sentence pairs

⟨*man draw sword, man depict sword* ⟩
⟨*man draw sword, man attract sword* ⟩

we selected the new subject *artist* and added two pairs, comparing *man draw sword and artist does too* with

man depict sword and artist does too
man attract sword and artist does too

We selected two new subjects for each combination, and in this way we obtained a dataset of roughly 400 entries. New human judgments were collected through Amazon Mechanical Turk, by prepending *the* to each noun and putting the phrase in the past tense. As with the original dataset, participants were asked to judge the similarity between sentence pairs using a discrete number between 1 and 7; 1 for highly dissimilar, 7 for highly similar. By inserting gold standard pairs of identical sentences we checked if participants were

---

[3] All models, the new datasets, and evaluation code are available at `github.com/gijswijnholds/compdisteval-ellipsis`

[4] As found in the combined ukWaC+WackyPedia corpus.

trustworthy. We collected 25 judgments per sentence pair but excluded participants that annotated less than 20 entries of the total dataset. We ended up with 55 different participants who ranked more than 20 entries of the total dataset, to give a final amount of ca. 9200 annotations. As an example, the verb *show* was a very hard case to disambiguate in the GS2011 dataset: *child show sign* had an average score of 2.5 with both *child picture sign* and *child express sign*. In the new dataset, with the extra subject *patient*, it got much clearer that the verb had to be interpreted as *express* with an average score of 5.869, versus 4.875 for *picture*.

4.1.2 KS2013

The KS2013 sentence similarity dataset contains 108 transitive sentence pairs annotated with human similarity judgments. As opposed to the GS2011 dataset, subjects and objects of each sentence pair are not the same, so several different contexts get compared to one another. In this sense, the KS2013 dataset aims to investigate the role of content of individual words versus the role of composition, as the similarity of sentences might be predictable from the contribution of individual words rather than the specific way of composing them.

We extend this dataset to cover VP ellipsis by following a similar procedure as for GS2011. For each transitive sentence of the form $s\ v\ o$ in the dataset, we selected a new subject s^* from a list of most frequent subjects of the verb[5] and built elliptical entries $s\ v\ o$ *and* s^* *does too* in such a way that the meaning of the original transitive sentence got changed as little as possible and that the resulting elliptical phrase made sense. We then considered every transitive sentence pair in the dataset and added the new respective subjects to both sentences. For example, for the pair

$\langle$*school encourage child, employee leave company*$\rangle$

we selected *parent* and *student* to get the new pair

$\langle$*school encourage child and parent does too,*
employee leave company and student does too$\rangle$

We chose two subjects for every original sentence, generating four possibilities for each sentence pair, and a new dataset of 432 entries. This dataset was also annotated using Amazon Mechanical Turk, after putting each verb in the past tense and prepending *the* to each noun in the dataset. Gold standard pairs of identical sentences were inserted to validate trustworthiness of participants. The final dataset contains ca. 9800 annotations by 42 different participants.

4.2 Vector Spaces

To provide a comprehensive study with robust results, we used four vector spaces: a count based vector space, and newly trained Word2Vec, GloVe, and FastText spaces, as detailed below.

Count-Based: We used the combined ukWaC and Wackypedia corpora[6] to extract raw co-occurrence counts, using as a basis the 2000 most frequently occurring tokens (after excluding the 50 most frequent ones). When extracting counts, we disregarded a list of stopwords that do not contribute to the content of the vectors. We used a context window of 5 around the focus word, and PPMI as weighting scheme. These settings were use in the original KS2013 dataset (Kartsaklis and Sadrzadeh, 2013).

Word2Vec: The Word2Vec embeddings we used were trained with the continuous bag of words model of (Mikolov et al., 2013) (CBOW). We trained this model on the combined and lemmatised ukWaC and Wackypedia corpora, using the implementation for Python available in the `gensim` package[7], with a minimum word frequency of 50, a window of 5, dimensionality 300, and 5 training iterations.

GloVe: The GloVe model (Pennington et al., 2014) considers the *ratio* of co-occurrence probabilities by minimising the least-squares objective between the dot product of two word embeddings and the log-probability of the words' co-occurrence. We trained a GloVe space on the combined and lemmatised ukWaC and Wackypedia corpora, using the code provided by the original authors[8]. Similar to the Word2Vec settings above, we trained 300 dimensional vectors with a minimum word frequency of 50 and a window of 5, but we trained with 15 iterations.

FastText: The FastText vectors are like Word2Vec, except the word vector takes into account subword information: words are represented as n-grams, for which vectors are trained. The final word vector will then be the sum of its constituent n-gram vectors (Bojanowski et al., 2017). We trained a FastText space with the same settings

[8] `nlp.stanford.edu/projects/glove`

as the Word2Vec space (CBOW, minimum word frequency 50, dimensions 300, window 5, with 5 iterations), again using `gensim`.

4.2.1 Verb Matrices

In order to work with tensor-based models we had to represent verbs as matrices rather than as vectors. We generated verb tensors using two methods that have been used previously in the literature (Grefenstette and Sadrzadeh, 2011a; Kartsaklis and Sadrzadeh, 2014).

Relational: For each verb, its corresponding matrix is obtained by summing over the tensor product of the respective subject and object vectors of the verb (subjects and objects collected from the corpus):

$$\overline{verb} = \sum_i subj_i \otimes obj_i$$

Kronecker: For each verb, its corresponding matrix is obtained by taking the tensor product of the verb vector with itself:

$$\widetilde{verb} = \overrightarrow{verb} \otimes \overrightarrow{verb}$$

In the case of the count-based space, we trained verb matrices of dimensions 2000 × 2000, for the neural word embeddings the matrices had dimensions 300 × 300. We also experimented with the skip-gram extension of Maillard and Clark (2015) and the plausibility model of Polajnar et al. (2014a) but excluded the results because the obtained verb matrices were far below par.

4.3 Concrete Models

For the experiments, we had two main goals in mind: primarily, we wanted to verify that resolving ellipsis contributes to the performance of a compositional model. For this purpose we experimented with non-linear models, i.e. models that resolve the ellipsis (and thus use the verb and object resources twice) versus linear models, which do not resolve the ellipsis (and thus only use the verb and object once). Our second goal was to investigate whether amongst the models that resolve the ellipsis, the ones that did so in a tensor-based way, i.e. using tensors instead of vectors to represent the verbs, performed better than additive and multiplicative models, and how these compare to holistic sentence encoders. Hence, we considered three classes of models: linear vector models, non-linear vector models and tensor-based models.

Linear Vector Models: These models use every resource exactly once, following the pattern $\overrightarrow{w_1} \star \overrightarrow{w_2} ... \star \overrightarrow{w_n}$ for any sequence of words $w_1 w_2 ... w_n$. For an elliptical phrase "*subj verb obj and subj* does too*" it will compute the vector

$$\overrightarrow{subj} \star \overrightarrow{verb} \star \overrightarrow{obj} \star \overrightarrow{and} \star \overrightarrow{subj^*} \star \overrightarrow{does} \star \overrightarrow{too}$$

where $\star$ denotes either addition or multiplication.

Non-Linear Vector Models: Here, the assumption is that ellipsis is resolved but models do not respect word order. The meaning of "*subj verb obj and subj* does too*" now is

$$\overrightarrow{subj} \star \overrightarrow{verb} \star \overrightarrow{obj} \star \overrightarrow{subj^*} \star \overrightarrow{verb} \star \overrightarrow{obj}$$

Tensor-Based Models: These models all are assumed to resolve ellipsis and are based on various previous models (Grefenstette and Sadrzadeh, 2011b,a; Kartsaklis et al., 2012; Kartsaklis and Sadrzadeh, 2014). Essentially, the tensor-based meaning of "*subj verb obj and subj* does too*" is

$$T(\overrightarrow{subj}, \overline{verb}, \overrightarrow{obj}) \star T(\overrightarrow{subj^*}, \overline{verb}, \overrightarrow{obj})$$

where T is a transitive model from (Milajevs et al., 2014) and $\star$ interprets the conjunction of the two subclauses. For the verb matrix we used either the relational verb or the Kronecker verb, and for $\star$ we tried both addition and multiplication. We did consider a model which simply adds or multiplies the second subject without duplicating the verb phrase, but it performed worse than non-linear addition and multiplication so we did not include it in this paper.

Sentence Encoders: To compare the mentioned compositional models with state of the art neural baselines, we carried out our experiments with a four types of holistic sentence encoders, that take arbitrary text as input and produce an embedding. To properly compare with the compositional models above, we gave three different inputs to the encoders: a baseline encoding (Base), a resolved encoding (Res), and an encoding without functional words (Abl), all as below:

Base: "*subj verb obj and subj* does too*"
Res: "*subj verb obj and subj* verb obj*"
Abl: "*subj verb obj subj**"

We used six concrete pretrained encoders, available online: 4800-dimensional embeddings from the Skip-Thought model[9], 300-dimensional embeddings from two Doc2Vec implementations

---

[9] `github.com/ryankiros/skip-thoughts`

(Lau and Baldwin, 2016)[10], 4096-dimensional embeddings from two InferSent encoders[11], and 512-dimensional embeddings from Universal Sentence Encoder[12].

5 Results

To validate the quality of the trained word spaces, we evaluate on several standard word similarity tasks: we used Rubenstein & Goodenough (RG, 1965), WordSim353 (WS353, 2001), Miller & Charles (MC, 1991), SimLex-999 (SL999, 2015), and the MEN dataset (Bruni et al., 2012). The results are displayed in Table 2, for the spaces described in the previous section.

Verb Disambiguation: Table 3 shows the results of the linear, non-linear and tensor-based models for this task, compared against a baseline in which only the verb vector or verb matrix is compared.

Our first observation is that generally, the highest performing models were tensor-based. The highest found correlation score was 0.5385 in the count based space for a tensor-based model (**CO** model above, Kronecker matrix, $\nabla = +$), with the Frobenius Additive model giving the second best result of 0.5263 (**FA** model above, Kronecker matrix, $\nabla = +$). For the neural spaces, the highest performing models were mostly tensor-based as well; they were always the Frobenius Additive (**FA**) model and the Frobenius Outer (**FO**) model, using the relational tensor and addition for the coordinator, except in the case of GloVe, where the Copy Object (**CO**) model was the second best. The only exception to this observation is the GloVe space, for which the baseline Vector Only model in fact has a higher correlation than any other model on that space.

Our second observation is that the non-linear variants of the additive and multiplicative models (which resolve ellipsis but in a naive way) show an increased performance over the linear models (which do not resolve ellipsis). All of this holds for all the four vector spaces, except for the FastText space where the linear multiplicative model achieves significantly higher correlation (0.2928) than its non-linear counterpart (0.0440).

Overall, these results suggests that a logical resolving of ellipsis and further grammatical sensitivity benefits the performance of composition.

One interesting fact about our results is that the best compositional methods across the board were those that interpret the coordinator 'and' as addition; in set-theoretic semantics one interprets this coordinator as set intersection, which corresponds to multiplication rather than addition in a vectorial setting. We suggest that the feature intersection approach using multiplication leads to sparsity in the resulting vectorial representation, which then has a negative effect on the overall result. This would explain the case of FastText, since those vectors take into account subword information one would expect them to be more fine-grained and therefore conflate more of their features under multiplication.

The choice of verb matrix was mixed: for the count-based models the Kronecker matrix worked best, for the neural embeddings it was best to use

---

[10] `github.com/jhlau/doc2vec`

[11] `github.com/facebookresearch/InferSent`

[12] `tfhub.dev/google/universal-sentence-encoder`

the relational matrix.

In comparison, the sentence encoder results of Table 4 show the same trend that suggests that resolving ellipsis improves the quality of the embeddings: with the exception of the two InferSent encoders, the resolved models gave a higher correlation than their linear baseline. However, none of the encoder models come near the results achieved using the compositional models. Since the verb disambiguation dataset contains pairs of sentence that only differ in the verb, the task becomes very much grammar-oriented, and so we argue that the tensor-based models work better since they explicitly emphasise syntactic structure.

Sentence Similarity: For the extension of the KS2013 sentence similarity dataset, the results are shown in Table 5. We again wanted to see if resolving ellipsis benefits the compositional process. This was in general true, although we observed a different pattern to the previous experiment.

In all cases, except for the FastText space, we saw that non-linear models in fact perform better than their linear counterparts. But this time the best tensor-based models only outperformed addition for the count-based space: the best models scored 0.7410 and 0.7370 (respectively for the **FO** and **FA** models above, Kronecker matrix, $\nabla = \odot$). Both Word2Vec and GloVe worked best with a non-linear additive model, with Word2Vec achieving the overall highest correlation score of 0.7617, and GloVe achieving 0.7103. For FastText, the highest score of 0.7408 was achieved by linear addition. What is more, the multiplicative model did not benefit from a non-linear approach in the case of GloVe (from 0.3666 to 0.2439), and the additive model had a similar decline in performance for the count-based space (from 0.7000 to 0.6808) and FastText (0.7408 to 0.7387). We can see that for the neural word embeddings the additive models work best, with all of them seeing a drop in performance for the tensor-based models.

Again, the best count-based models use the Kronecker matrix whereas the neural models benefit the most from using the relational matrix. However, this time the best count-based models used multiplication for coordination, the neural models preferring addition.

The sentence encoders worked a lot better in the similarity task, with all non-linear resolved models outperforming the baseline model, and the InferSent model even outperforming non-linear addition on a Word2Vec space. We argue this is the case for two reasons: first, the similarity dataset is more diffuse than the verb disambiguation dataset since sentence pairs now differ for every word in the sentence, giving more opportunity to exploit semantic similarity rather than syntactic similarity. Second, the embeddings from the sentence encoder are larger (4096), allowing them to effectively store more information to benefit the similarity score.

Table 6: Spearman ρ scores for the ellipsis similarity experiment. D2V1: Doc2Vec1, D2V2: Doc2Vec 2, ST: Skip-Thought, IS1: InferSent 1, IS2: InferSent 2, USE: Universal Sentence Encoder.

Overall we conclude again that resolving ellipsis improves the performance of composition, but this time the InferSent sentence encoder seems to work best, followed by the non-linear additive compositional model on Word2Vec, with tensor-based models only performing well in a count-based space.

6 Conclusion

In this paper we experimented with vector space semantics for VP ellipsis, working with a large variety of compositional models. We created two new datasets and compared the performance of several compositional methods, both linear and non-linear, across four vector spaces, and against state of the art holistic sentence encoders.

Our main conclusion is that resolving ellipsis improves performance: non-linear models almost always performed better than linear ones in both a verb disambiguation and a sentence similarity task. The highest performance on the verb disambiguation task was given by a grammar-driven, tensor-based model in a count-based vector space, whereas for the similarity task, the highest performance was achieved by the InferSent sentence encoder, followed by a non-linear additive model on a Word2Vec space. Although the neural word embeddings and sentence encoders were largely outperformed on the disambiguation dataset that places more emphasis on syntactic structure than on semantic similarity, they generally performed better in the sentence similarity case, where the distinction between syntactic and semantic similarity is more diffuse.

Acknowledgments

Abstract

We introduce neural finite state transducers (NFSTs), a family of string transduction models defining joint and conditional probability distributions over pairs of strings. The probability of a string pair is obtained by marginalizing over all its accepting paths in a finite state transducer. In contrast to ordinary weighted FSTs, however, each path is scored using an arbitrary function such as a recurrent neural network, which breaks the usual conditional independence assumption (Markov property). NFSTs are more powerful than previous finite-state models with neural features (Rastogi et al., 2016). We present training and inference algorithms for locally and globally normalized variants of NFSTs. In experiments on different transduction tasks, they compete favorably against seq2seq models while offering interpretable paths that correspond to hard monotonic alignments.

1 Introduction

Weighted finite state transducers (WFSTs) have been used for decades to analyze, align, and transduce strings in language and speech processing (Roche and Schabes, 1997; Mohri et al., 2008). They form a family of efficient, interpretable models with well-studied theory. A WFST describes a function that maps each string pair $(\mathbf{x}, \mathbf{y})$ to a weight—often a real number representing $p(\mathbf{x}, \mathbf{y})$ or $p(\mathbf{y} \mid \mathbf{x})$. The WFST is a labeled graph, in which each path $\mathbf{a}$ represents a sequence of operations that describes how some $\mathbf{x}$ and some $\mathbf{y}$ could be jointly generated, or how $\mathbf{x}$ could be edited into $\mathbf{y}$. Multiple paths for the same $(\mathbf{x}, \mathbf{y})$ pair correspond to different analyses (labeled alignments) of that pair.

However, WFSTs can only model certain functions, known as the rational relations (Berstel and Reutenauer, 1988).The weight of a path is simply the product of the weights on its arcs. This means that in a random path of the form $a \rightsquigarrow b \rightsquigarrow c$, the two subpaths $\rightsquigarrow$ are conditionally independent given their common state b: a Markov property.

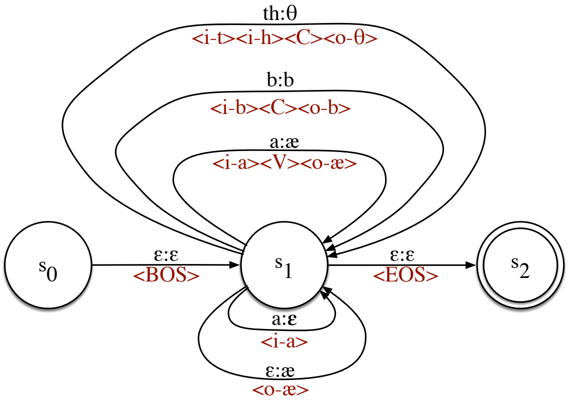

Figure 1: A marked finite-state transducer $\mathcal{T}$. Each arc in $\mathcal{T}$ is associated with input and output substrings, listed above the arcs in the figure. The arcs are not labeled with weights as in WFSTs. Rather, each arc is labeled with a sequence of *marks* (shown in brown) that featurize its qualities. The neural scoring model scores a path by scoring each mark in the context of all marks on the entire path. The example shown here is from the G2P application of §4.1; for space, only a few arcs are shown. ε represents the empty string.

In this paper, we propose neural finite state transducers (NFSTs), in which the weight of each path is instead given by some sort of neural network, such as an RNN. Thus, the weight of an arc can depend on the context in which the arc is used. By abandoning the Markov property, we lose exact dynamic programming algorithms, but we gain expressivity: the neural network can capture dependencies among the operations along a path. For example, the RNN might give higher weight to a path if it is "internally consistent": it might thus prefer to transcribe a speaker's utterance with a path that maps similar sounds in similar contexts to similar phonemes, thereby adapting to the speaker's accent.

Consider a finite-state transducer $\mathcal{T}$ as in Figure 1 (see Appendix A for background). Using the composition operator $\circ$, we can obtain a new FST, $\mathbf{x} \circ \mathcal{T}$, whose accepting paths correspond to the accepting paths of $\mathcal{T}$ that have input string $\mathbf{x}$. Similarly, the accepting paths of $\mathcal{T} \circ \mathbf{y}$ correspond to the accepting paths of $\mathcal{T}$ that have output string $\mathbf{y}$. Finally, $\mathbf{x} \circ T \circ \mathbf{y}$ extracts the paths that have both properties. We define a joint probability distribution over $(\mathbf{x}, \mathbf{y})$ pairs by marginalizing over those paths:

$$p(\mathbf{x}, \mathbf{y}) = \sum_{\mathbf{a} \in \mathbf{x} \circ \mathcal{T} \circ \mathbf{y}} p(\mathbf{a}) = \frac{1}{Z(\mathcal{T})} \sum_{\mathbf{a} \in \mathbf{x} \circ \mathcal{T} \circ \mathbf{y}} \tilde{p}(\mathbf{a}) \quad (1)$$

where $\tilde{p}(\mathbf{a})$ is the weight of path $\mathbf{a}$ and $Z(\mathcal{T}) = \sum_{\mathbf{a} \in \mathcal{T}} \tilde{p}(\mathbf{a})$ is a normalization constant.

We define $\tilde{p}(\mathbf{a}) \triangleq \exp G_{\boldsymbol{\theta}}(\mathbf{a})$ with $G_{\boldsymbol{\theta}}(\mathbf{a})$ being some parametric scoring function. In our experiments, we will adopt a fairly simple left-to-right RNN architecture (§2.2), but one could easily substitute fancier architectures. We will also consider defining $G_{\boldsymbol{\theta}}$ by a *locally normalized* RNN that ensures $Z(\mathcal{T}) = 1$.

In short, we use the finite-state transducer $\mathcal{T}$ to compactly define a set of *possible* paths $\mathbf{a}$. The number of paths may be exponential in the size of $\mathcal{T}$, or infinite if $\mathcal{T}$ is cyclic. However, in contrast to WFSTs, we abandon this combinatorial structure in favor of neural nets when defining the probability distribution over $\mathbf{a}$. In the resulting marginal distribution $p(\mathbf{x}, \mathbf{y})$ given in equation (1), the path $\mathbf{a}$ that *aligns* $\mathbf{x}$ and $\mathbf{y}$ is a latent variable. This is also true of the resulting conditional distribution $p(\mathbf{y} \mid \mathbf{x})$.

We explore training and inference algorithms for various classes of NFST models (§3). Classical WFSTs (Mohri et al., 2008) and BiRNN-WFSTs (Rastogi et al., 2016) use restricted scoring functions and so admit exact dynamic programming algorithms. For general NFSTs, however, we must resort to approximate computation of the model's training gradient, marginal probabilities, and predictions. In this paper, we will use sequential importance sampling methods (Lin and Eisner, 2018), leaving variational approximation methods to future work.

Defining models using FSTs has several benefits:

Output-sensitive encoding Currently popular models of $p(\mathbf{y} \mid \mathbf{x})$ used in machine translation and morphology include seq2seq (Sutskever et al., 2014), seq2seq with attention (Bahdanau et al., 2015; Luong et al., 2015), the Transformer (Vaswani et al., 2017). These models first encode $\mathbf{x}$ as a vector or sequence of vectors, and then condition the generation of $\mathbf{y}$ on this encoding. The vector is determined from $\mathbf{x}$ only. This is also the case in the BiRNN-WFST (Rastogi et al., 2016), a previous finite-state model to which we compare. By contrast, in our NFST, the state of the RNN as it reads and transduces the second half of $\mathbf{x}$ is influenced by the first halves of both $\mathbf{x}$ *and* $\mathbf{y}$ and their alignment.

Inductive bias Typically, a FST is constructed with domain knowledge (possibly by compiling a regular expression), so that its states reflect interpretable properties such as syllable boundaries or linguistic features. Indeed, we will show below how to make these properties explicit by "marking" the FST arcs. The NFST's path scoring function then sees these marks and can learn to take them into account. The NFST also inherits any hard constraints from the FST: if the FST omits all $(\mathbf{x}, \mathbf{y})$ paths for some "illegal" $\mathbf{x}, \mathbf{y}$, then $p(\mathbf{x}, \mathbf{y}) = 0$ for any parameter vector $\boldsymbol{\theta}$ (a "structural zero").

Interpretability Like a WFST, an NFST can "explain" why it mapped $\mathbf{x}$ to $\mathbf{y}$ in terms of a latent path $\mathbf{a}$, which specifies a hard monotonic labeled alignment. The posterior distribution $p(\mathbf{a} \mid \mathbf{x}, \mathbf{y})$ specifies which paths $\mathbf{a}$ are the best explanations (e.g., Table 5).

We conduct experiments on three tasks: grapheme-to-phoneme, phoneme-to-grapheme, and action-to-command (Bastings et al., 2018). Our results on these datasets show that our best models can improve over neural seq2seq and previously proposed hard alignment models.

2 Neuralizing Finite-State Transducers

2.1 Neuralized FSTs

An NFST is a pair $(\mathcal{T}, G_{\boldsymbol{\theta}})$, where $\mathcal{T}$ is an unweighted FST with accepting paths $\mathcal{A}$ and $G_{\boldsymbol{\theta}} : \mathcal{A} \to \mathbb{R}$ is a function that **scores** these paths. As explained earlier, we then refer to $\tilde{p}(\mathbf{a}) = \exp G_{\boldsymbol{\theta}}(\mathbf{a})$ as the **weight** of path $\mathbf{a} \in \mathcal{A}$. A **weighted relation** between input and output strings is given by $\tilde{p}(\mathbf{x}, \mathbf{y})$, which is defined to be the total weight of all paths with input string $\mathbf{x} \in \Sigma^*$ and output string $\mathbf{y} \in \Delta^*$, where where Σ and Δ are the input and output alphabets of $\mathcal{T}$. The real parameter vector $\boldsymbol{\theta}$ can be adjusted to obtain different weighted relations. We

Model	Training Algorithms	Long-Term Output-Output Dependency	Left-to-Right Factorization
WFSTs	Dynamic Programming	✗	✓
BiRNN-WFSTs	Dynamic Programming	✗	✓
Local NFSTs	Importance Sampling	✓	✓
Global NFSTs	Importance Sampling	✓	✗

Table 1: Comparison between WFSTs, BiRNN-WFSTs (Rastogi et al., 2016), and NFSTs.

can normalize $\tilde{p}$ to get a probability distribution as shown in equation (1).

2.2 A basic scoring architecture

Weighted FST. A WFST over the $(+, \times)$ semiring can be regarded as the special case in which $G_{\boldsymbol{\theta}}(\mathbf{a}) \triangleq \sum_{t=1}^{|\mathbf{a}|} g_{\boldsymbol{\theta}}(a_t)$. This is a sum of scores assigned to the arcs in $\mathbf{a} = a_1 a_2 \cdots$.

Marked FST. Our innovation is to allow the arcs' scores to depend on their context in the path. Now $\boldsymbol{\theta}$ no longer associates a fixed score with each arc. Rather, we assume that each arc a in the FST comes labeled with a sequence of **marks** from a **mark alphabet** Ω, as illustrated in Figure 1. The marks reflect the FST constructor's domain knowledge about what arc a does (see §4.2 below). We now define $G_{\boldsymbol{\theta}}(\mathbf{a}) = G_{\boldsymbol{\theta}}(\boldsymbol{\omega}(\mathbf{a}))$, where $\boldsymbol{\omega}(\mathbf{a}) = \boldsymbol{\omega}(a_1)\boldsymbol{\omega}(a_2) \cdots \in \Omega^*$ is the concatenated sequence of marks from the arcs along path $\mathbf{a}$.

It is sometimes helpful to divide marks into different classes. An arc can be regarded as a possible "edit" that aligns an input substring with an output substring in the context of transitioning from one FST state to another. The arc's **input marks** describe its input substring, its **output marks** describe its output substring, and the remaining marks may describe other properties of the arc's aligned input-output pair or the states that it connects.

Recall that an FST encodes domain knowledge. Its paths represent alignments between input and output strings, where each alignment specifies a segmentation of $\mathbf{x}$ and $\mathbf{y}$ into substrings labeled with FST states. Decorating the arcs with marks furnishes the path scoring model with domain-specific information about the alignments.

RNN scoring. If $\boldsymbol{\theta}$ merely associated a fixed score with each mark, then the marked FST would be no more powerful than the WFST. To obtain contextual mark scores as desired, one simple architecture is a recurrent neural network:

$$G_{\boldsymbol{\theta}}(\boldsymbol{\omega}) \triangleq \sum_{t=1}^{|\boldsymbol{\omega}|} g_{\boldsymbol{\theta}}(\mathbf{s}_{t-1}, \omega_t) \tag{2}$$

$$\mathbf{s}_t = f_{\boldsymbol{\theta}}(\mathbf{s}_{t-1}, \omega_t), \text{ with } \mathbf{s}_0 = \mathbf{0} \tag{3}$$

where $\mathbf{s}_{t-1} \in \mathbb{R}^d$ is the hidden state vector of the network after reading $\omega_1 \cdots \omega_{t-1}$. The $g_{\boldsymbol{\theta}}$ function defines the score of reading ω_t in this left context, and $f_{\boldsymbol{\theta}}$ defines how doing so updates the state.

In our experiments, we chose $f_{\boldsymbol{\theta}}$ to be the GRU state update function (Cho et al., 2014). We defined $g_{\boldsymbol{\theta}}(\mathbf{s}, \omega_t) \triangleq (\mathbf{W}\mathbf{s} + \mathbf{b})^\top \mathrm{emb}(\omega_t)$. The parameter vector $\boldsymbol{\theta}$ specifies the GRU parameters, $\mathbf{W}$, $\mathbf{b}$, and the mark embeddings $\mathrm{emb}(\omega)$.

One could easily substitute much fancier architectures, such as a stacked BiLSTM with attention (Tilk and Alumäe, 2016), or a Transformer (Vaswani et al., 2017).

2.3 Partitioned hidden vectors

In hopes of improving the inductive bias of the learner, we partitioned the hidden state vector into three sub-vectors: $\mathbf{s}_t = [\mathbf{s}_t^{\mathrm{a}}; \mathbf{s}_t^{\mathrm{x}}; \mathbf{s}_t^{\mathrm{y}}]$. The mark scoring function $f_{\boldsymbol{\theta}}(\mathbf{s}_{t-1}, \omega_t)$ was as before, but we restricted the form of $g_{\boldsymbol{\theta}}$, the state update function. $\mathbf{s}_t^{\mathrm{a}}$ encodes *all* past marks and depends on the *full* hidden state so far: $\mathbf{s}_t^{\mathrm{a}} = g_{\boldsymbol{\theta}}^{\mathrm{a}}(\mathbf{s}_{t-1}, \omega_t)$. However, we make $\mathbf{s}_t^{\mathrm{x}}$ encode only the sequence of past *input* marks, ignoring all others. Thus, $\mathbf{s}_t^{\mathrm{x}} = g_{\boldsymbol{\theta}}^{\mathrm{x}}(\mathbf{s}_{t-1}^{\mathrm{x}}, \omega_t)$ if ω_t is an input mark, and $\mathbf{s}_t^{\mathrm{x}} = \mathbf{s}_{t-1}^{\mathrm{x}}$ otherwise. Symmetrically, $\mathbf{s}_t^{\mathrm{y}}$ encodes only the sequence of past *output* marks. This architecture is somewhat like Dyer et al. (2016), which also uses different sub-vectors to keep track of different aspects of the history.

2.4 Local normalization

A difficulty with the general model form in equation (1) is that the normalizing constant $Z(\mathcal{T}) = \sum_{\mathbf{a} \in \mathcal{T}} \tilde{p}(\mathbf{a})$ must sum over a large set of paths—in fact, an infinite set if $\mathcal{T}$ is cyclic. This sum may diverge for some values of the parameter vector $\boldsymbol{\theta}$, which complicates training of the model (Dreyer, 2011). Even if the sum is known to converge, it is in general intractable to compute it exactly. Thus, estimating the gradient of $Z(\mathcal{T})$ during training involves approximate sampling from the typically high-entropy distribution $p(\mathbf{a})$. The resulting estimates are error-prone because the sample size tends to be too small and the approximate sampler is biased.

A standard solution in the WFST setting (e.g. Cotterell et al., 2014) is to use a locally normalized model, in which $Z(\mathcal{T})$ is guaranteed to be 1.[1] The big summation over all paths $\mathbf{a}$ is replaced by small summations—which can be computed explicitly—over just the outgoing edges from a given state.

Formally, we define the unnormalized score of arc a_i in the context of path $\mathbf{a}$ in the obvious way, by summing over the contextual scores of its marks:

$$\tilde{g}_{\boldsymbol{\theta}}(a_i) \triangleq \sum_{t=j+1}^{k} g_{\boldsymbol{\theta}}(\mathbf{s}_{t-1}, \omega_t) \tag{4}$$

where $j = |\boldsymbol{\omega}(a_1) \cdots \boldsymbol{\omega}(a_{i-1})|$ and $k = |\boldsymbol{\omega}(a_1) \cdots \boldsymbol{\omega}(a_i)|$. Its normalized score is then

$$g_{\boldsymbol{\theta},\mathcal{T}}(a_i) \triangleq \log\left(\exp \tilde{g}_{\boldsymbol{\theta}}(a_i) / \sum\nolimits_{a'} \exp \tilde{g}_{\boldsymbol{\theta}}(a')\right)$$

where a' ranges over all arcs in $\mathcal{T}$ (including a_i itself) that emerge from the same state as a_i does. We can now score the paths in $\mathcal{T}$ using

$$G_{\boldsymbol{\theta},\mathcal{T}}(\mathbf{a}) = \sum_{i=1}^{|\mathbf{a}|} g_{\boldsymbol{\theta},\mathcal{T}}(a_i) \tag{5}$$

This gives rise to a proper probability distribution $p(\mathbf{a}) \triangleq \tilde{p}(\mathbf{a}) = \exp G_{\boldsymbol{\theta},\mathcal{T}}(\mathbf{a})$ over the paths of $\mathcal{T}$. No global normalization constant is necessary. However, note that the scoring function now requires $\mathcal{T}$ as an extra subscript, because it is necessary when scoring $\mathbf{a}$ to identify the competitors in $\mathcal{T}$ of each arc a_i. Thus, when $p(\mathbf{x}, \mathbf{y})$ is found as usual by summing up the probabilities of all paths in $\mathbf{x} \circ \mathcal{T} \circ \mathbf{y}$, each path is still scored using its arcs' competitors from $\mathcal{T}$. This means that each state in $\mathbf{x} \circ \mathcal{T} \circ \mathbf{y}$ must record the state in $\mathcal{T}$ from which it was derived.

3 Sampling, Training, and Decoding

3.1 Sampling from conditioned distributions with amortized inference

Many algorithms for working with probability distributions—including our training and decoding algorithms below—rely on conditional sampling. In general, we would like to sample a path of $\mathcal{T}$ given the knowledge that its input and output strings fall into sets X and Y respectively.[2] If X and Y are regular languages, this is equivalent to defining $\mathcal{T}' = X \circ \mathcal{T} \circ Y$ and sampling from

$$p(\mathbf{a} \mid \mathcal{T}') \triangleq \frac{\tilde{p}(\mathbf{a})}{\sum_{\mathbf{a}' \in \mathcal{T}'} \tilde{p}(\mathbf{a}')}, \tag{6}$$

Due to the nonlinearity of $G_{\boldsymbol{\theta}}$, the denominator of equation (6) is generally intractable. If $\mathcal{T}'$ is cyclic, it cannot even be computed by brute-force enumeration. Thus, we fall back on normalized importance sampling, directly adopting the ideas of Lin and Eisner (2018) in our more general FST setting. We employ a proposal distribution q:

$$\begin{aligned} p(\mathbf{a} \mid \mathcal{T}') &= \mathbb{E}_{\mathbf{a} \sim q}\left[\frac{p(\mathbf{a} \mid \mathcal{T}')}{q(\mathbf{a})}\right], \qquad (7) \\ &\approx \sum_{m=1}^{M} \frac{\tilde{p}(\mathbf{a}^{(m)})}{q(\mathbf{a}^{(m)}) \cdot \hat{Z}} \cdot \mathbb{I}(\mathbf{a} = \mathbf{a}^{(m)}) \\ &= \hat{p}(\mathbf{a} \mid \mathcal{T}'), \end{aligned}$$

where $\hat{Z} = \sum_{m'=1}^{M} \frac{\tilde{p}(\mathbf{a}^{(m')})}{q(\mathbf{a}^{(m')})}$, and q is a locally normalized distribution over paths $\mathbf{a} \in \mathcal{T}'$. In this paper we further parametrize q as

$$q_{\boldsymbol{\phi}}(\mathbf{a}; \mathcal{T}') = \prod_{t=1}^{T} q_t(a_t \mid \mathbf{a}_{1 \ldots t-1}; \boldsymbol{\phi}, \mathcal{T}'), \tag{8}$$

$$q_t(a \mid \mathbf{a}_{:t-1}; \boldsymbol{\phi}, \mathcal{T}') \propto \exp(g(\mathbf{s}_{t-1}, a_t; \boldsymbol{\theta}, \mathcal{T}) + C_{\boldsymbol{\phi}}),$$

where $C_{\boldsymbol{\phi}} \triangleq C(\mathbf{s}'_t, X, Y, \boldsymbol{\phi}) \in \mathbb{R}$, $\mathbf{s}'_t \triangleq f(\mathbf{s}_{t-1}, \boldsymbol{\omega}(a))$ is a *compatibility function* that is typically modeled using a neural network. In this paper, one the following three cases are encountered:

- $X = \mathbf{x}$, is a string, and $Y = \Delta^*$: in this case $\mathcal{T}' = \mathbf{x} \circ \mathcal{T}$. We let $C_{\boldsymbol{\phi}} = C^{\mathrm{x}}(\mathbf{s}'_t, \mathrm{RNN}^{\mathrm{x}}(\mathbf{x}, i, \boldsymbol{\phi}); \boldsymbol{\phi})$, where i is the length of the input prefix in $\mathbf{a}_{1 \ldots t} . a$, $\mathrm{RNN}^{\mathrm{x}}(\mathbf{x}, i, \boldsymbol{\phi})$ is the hidden state of the i-th position after reading $\mathbf{x}$ (not $\mathbf{a}$ nor $\boldsymbol{\omega}$) backwards, and $C^{\mathrm{x}}(\cdot, \cdot)$ is a feed-forward network that takes the concatenated vector of all arguments, and outputs a real scalar. We describe the parametrization of C^{x} in Appendix C.1.

---

[1] Provided that every state in $\mathcal{T}$ is co-accessible, i.e., has a path to a final state.

[2] When X or Y is larger than a single string, it is commonly all of Σ^* or Δ^* respectively, in which case conditioning on it gives no information.

- $X = \Sigma^*$, and $Y = \mathbf{y}$ is a string: in this case $\mathcal{T}' = \mathcal{T} \circ \mathbf{y}$. We let $C_{\boldsymbol{\phi}} = C^{\mathrm{y}}(\mathbf{s}'_t, \mathrm{RNN}^{\mathrm{y}}(\mathbf{y}, j, \boldsymbol{\phi}); \boldsymbol{\phi})$, where j is the length of the output prefix in $\mathbf{a}_{1\ldots t}.a$, and $\mathrm{RNN}^{\mathrm{y}}, C^{\mathrm{y}}$ are similarly defined as in $\mathrm{RNN}^{\mathrm{x}}$ and C^{x}.
- X and Y are both strings — $X = \mathbf{x}, Y = \mathbf{y}$: in this case we let $C_{\boldsymbol{\phi}} = C^{\mathrm{xy}}(\mathbf{s}'_t, \mathrm{RNN}^{\mathrm{x}}(\mathbf{x}, i, \boldsymbol{\phi}), \mathrm{RNN}^{\mathrm{y}}(\mathbf{y}, j, \boldsymbol{\phi}); \boldsymbol{\phi})$.

Given a path prefix $\mathbf{a}_{:t-1}$, $q_t(a \mid \mathbf{a}_{:t-1}; \boldsymbol{\phi}, \mathcal{T}')$ is defined over arcs a such that $\mathbf{a}_{:t-1}.a$ is a valid path prefix in $\mathcal{T}'$. To optimize $\boldsymbol{\phi}$ with regard to $q_{\boldsymbol{\phi}}$, we follow (Lin and Eisner, 2018) and seek to find $\boldsymbol{\phi}^* = \mathrm{argmin}_{\boldsymbol{\phi}} \mathrm{KL}[\hat{p} || q_{\boldsymbol{\phi}}]$, where $\hat{p}$ is the approximate distribution defined in equation (7), which is equivalent to maximizing the log-likelihood of $q_{\boldsymbol{\phi}}(\mathbf{a})$ when $\mathbf{a}$ is distributed according to the approximation $\hat{p}$.

3.2 Training

In this paper, we consider joint training. The loss function of our model is defined as the negative log joint probability of string pair $(\mathbf{x}, \mathbf{y})$:

$$\mathcal{L}(\mathbf{x}, \mathbf{y}) = -\log p(\mathbf{x}, \mathbf{y}) = -\log \sum_{\mathbf{a} \in \mathbf{x} \circ \mathcal{T} \circ \mathbf{y}} p(\mathbf{a}). \tag{9}$$

Since p is an exponential family distribution, the gradients of $\mathcal{L}$ can be written as (Bishop, 2006)

$$\nabla \mathcal{L}(\mathbf{x}, \mathbf{y}) = -\mathbb{E}_{\mathbf{a} \sim p(\cdot \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})}[\nabla \log p(\mathbf{a})], \tag{10}$$

where $p(\cdot \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})$ is a conditioned distribution over paths. Computing equation (10) requires sampling from $p(\cdot \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})$, which, as we discuss in §3.1, is often impractical. We therefore approximate it with

$$\begin{aligned} \nabla_{\boldsymbol{\theta}} \mathcal{L}(\mathbf{x}, \mathbf{y}) &= -\mathbb{E}_{\mathbf{a} \sim p(\cdot \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})}[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{a})] \\ &\approx -\mathbb{E}_{\mathbf{a} \sim \hat{p}(\cdot \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})}[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{a})] \qquad (11) \\ &= -\sum_{m=1}^{M} w^{(m)} \nabla_{\boldsymbol{\theta}} G_{\boldsymbol{\theta}}(\mathbf{a}^{(m)}), \qquad (12) \end{aligned}$$

where q is a proposal distribution parametrized as in equation (8) (discussed in §3.1,) $\mathbf{a}^{(1)} \ldots \mathbf{a}^{(M)} \sim q$ are i.i.d. samples of paths in $\mathbf{x} \circ \mathcal{T} \circ \mathbf{y}$, and $w^{(m)}$ is the **importance weight** of the m-th sample satisfying $w^{(m)} \propto \frac{\exp G_{\boldsymbol{\theta}}(\mathbf{a}^{(m)})}{q(\mathbf{a}^{(m)})}, \sum_{m=1}^{M} w^{(m)} = 1$. Pseudocode for calculating equation (12) is listed in Algorithm 1.

Algorithm 1 Compute approximate gradient for updating $G_{\boldsymbol{\theta}}$

```
Require: $G_{\boldsymbol{\theta}} : \mathcal{A} \to \mathbb{R}$ is an NFST scoring function, $q$ is a distribution over paths, $M \in \mathbb{N}$ is the sample size
function GET-GRADIENT($G_{\boldsymbol{\theta}}$, $M$, $q$)
    for $m$ in $1 \ldots M$ do
        $\mathbf{a}^{(m)} \sim q$
        $\tilde{w}^{(m)} \leftarrow \frac{\exp G_{\boldsymbol{\theta}}(\mathbf{a}^{(m)})}{q(\mathbf{a})}$
    end for
    $\hat{Z} \leftarrow \sum_{m=1}^{M} \tilde{w}^{(m)}$
    for $m$ in $1 \ldots M$ do
        $w^{(m)} \leftarrow \frac{\tilde{w}^{(m)}}{\hat{Z}}$
    end for
    return $-\sum_{m=1}^{M} w^{(m)} \nabla_{\boldsymbol{\theta}} G_{\boldsymbol{\theta}}(\mathbf{a}^{(m)})$
end function
```

3.3 Decoding most probable strings

Besides finding good *paths* in a conditioned distribution as we discuss in §3.1, we are also often interested in finding good *output strings*, which is conventionally referred to as the *decoding* problem, which we define to be finding the best output string $\mathbf{y}^* \triangleq \mathrm{argmax}_{\mathbf{y} \in L(Y)} p_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}')$, where

$$p_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}') \triangleq \frac{\sum_{\mathbf{a} \in \mathcal{T}' \circ \mathbf{y}} \tilde{p}(\mathbf{a})}{\sum_{\mathbf{a}' \in \mathcal{T}'} \tilde{p}(\mathbf{a}')}. \tag{13}$$

$\hat{\mathbf{y}}^* \triangleq \mathrm{argmax}_{\mathbf{y}} \hat{P}_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}')$ is a consistent estimator of $\mathbf{y}^*$, which can directly be used to find the best string. However, making this estimate accurate might be expensive: it requires sampling many paths in the machine $\mathcal{T}'$, which is usually cyclic, and therefore has infinitely many more paths, than $\mathcal{T}' \circ \mathbf{y}_k$, which has finitely many paths when A is acyclic. On the other hand, for the task of finding the best string among a pool candidates, we do not need to compute (or approximate) the denominator in equation (13), since

$$\mathbf{y}^* = \underset{\mathbf{y} \in L(Y)}{\mathrm{argmax}} \sum_{\mathbf{a} \in \mathcal{T}' \circ \mathbf{y}} \tilde{p}(\mathbf{a}). \tag{14}$$

As in the case for paths, the language $L(Y)$ is usually infinitely large. However given an output candidate $\mathbf{y}_k \in L' \subseteq L(Y)$, we can approximate the summation in equation (14) using importance sampling:

$$\sum_{\mathbf{a} \in \mathcal{T}' \circ \mathbf{y}_k} \tilde{p}(\mathbf{a}) = \mathbb{E}_{\mathbf{a} \sim q(\cdot \mid \mathcal{T}' \circ \mathbf{y}_k)}\left[\frac{\tilde{p}(\mathbf{a})}{q(\mathbf{a} \mid \mathcal{T}' \circ \mathbf{y}_k)}\right], \tag{15}$$

Algorithm 2 Training procedure for $G_{\boldsymbol{\theta}}$. See Appendix C.2 for implementation details.

```
Require: $(\mathcal{T}, G_{\boldsymbol{\theta}})$ is an NFST, $\mathcal{D} = \{(\mathbf{x}_1, \mathbf{y}_1) \ldots (\mathbf{x}_{|\mathcal{D}|}, \mathbf{y}_{|\mathcal{D}|})\}$ is the training dataset, LR : $\mathbb{N} \to \mathbb{R}$ is a
    learning rate scheduler, $\boldsymbol{\theta}_0$ are the initial parameters of $G_{\boldsymbol{\theta}}$, $M$ is a given sample size, maxEpoch $\in \mathbb{N}$
    is the number of epochs to train for
procedure TRAIN($\mathcal{T}$, $G_{\boldsymbol{\theta}}$, $\mathcal{D}$, LR, $\boldsymbol{\theta}_0$, $M$, maxEpochs)
    for epoch $\in [1 \ldots \mathrm{maxEpochs}]$ do
        for $(\mathbf{x}_i, \mathbf{y}_i) \in \mathrm{shuffle}(\mathcal{D})$ do
            $\mathcal{T}' \leftarrow \mathbf{x}_i \circ \mathcal{T} \circ \mathbf{y}_i$
            Construct distribution $q(\cdot \mid \mathcal{T}')$ according to equation (8)
            $\mathbf{u} \leftarrow$ GET-GRADIENT$(G_{\boldsymbol{\theta}}, M, q)$ (listed in Algorithm 1)
            $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \mathrm{LR}(\mathrm{epoch}) \times \mathbf{u}$
            (Optional) update the parameters of $q(\cdot \mid \mathcal{T}')$.
        end for
    end for
end procedure
```

where $q(\cdot \mid \mathcal{T}' \circ \mathbf{y}_k)$ is a proposal distribution over paths in $\mathcal{T}' \circ \mathbf{y}_k$. In this paper we parametrize $q(\cdot \mid \mathcal{T}' \circ \mathbf{y}_k)$ following the definition in equation (8). When L' is finitely large, we reduce the decoding task into a reranking task.

To populate L', one possibility is to marginalize over paths in the approximate distribution $\hat{p}(\mathbf{a} \mid \mathcal{T}')$ discussed in §3.1 to obtain an estimate $\hat{p}_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}')$, and use its support as L'. Note that it's possible to populate the candidate pool in other ways, each with its advantages and drawbacks: for example, one can use a top-k path set from a weighted (Markovian) FST. This approach guarantees exact computation, and the pool quality would no longer depend on the qualities of the smoothing distribution $q_{\boldsymbol{\phi}}$. However it is also a considerably much weaker model and may yield uninspiring candidates. In the common case where the conditioned machine $\mathcal{T}' = X \circ \mathcal{T} \circ Y$ has $X = \mathbf{x} \in \Sigma^*$ as the input string, and Y is the universal acceptor that accepts Δ^*, one can obtain a candidate pool from seq2seq models: seq2seq models can capture long distance dependencies between input and output strings, and are typically fast to train and decode from. However they are not applicable in the case where $L(Y) \neq \Delta^*$. Experimental details of decoding are further discussed in §4.3.

4 Experiments

Our experiments mainly aim to: (1) show the effectiveness of NFSTs on transduction tasks; (2) illustrate that how prior knowledge can be introduced into NFSTs and improve the performance; (3) demonstrate the interpretability of our model. Throughout, we experiment on three tasks: (i) grapheme-to-phoneme, (ii) phoneme-to-grapheme, and (iii) actions-to-commands. We compare with competitive string transduction baseline models in these tasks.

4.1 Tasks and datasets

We carry out experiments on three string transduction tasks:

Grapheme-to-phoneme and phoneme-to-grapheme (G2P/P2G) refer to the transduction between words' spelling and phonemic transcription. English has a highly irregular orthography (Venezky, 2011), which necessitates the use of rich models for this task. We use a portion of the standard CMUDict dataset: the Sphinx-compatible version of CMUDict (Weide, 2005). As for metrics, we choose widely used exact match accuracy and edit distance.

Action-to-command (A2C) refers to the transduction between an action sequence and imperative commands. We use NACS (Bastings et al., 2018) in our experiment. As for metrics, we use exact match accuracy (EM). Note that the in A2C setting, a given input can yield different outputs, e.g. `I_JUMP I_WALK I_WALK` corresponds to both "jump and walk twice" and "walk twice after jump". NACS is a finite set of action-command pairs; we consider a predicted command to be correct if it is in the finite set and its corresponding actions is exactly the input. We evaluate on the *length* setting proposed by Bastings et al. (2018), where we train on shorter sequences and evaluate on longer sequences.

4.2 FST designs

NFSTs require an unweighted FST $\mathcal{T}$ which defines a scaffold for the relation it recognizes. In this paper we experiment with two versions of $\mathcal{T}$: the first is a simple 'general' design $\mathcal{T}_0$, which contains only three states $s_{\{0,1,2\}}$, where the only arc between q_0 and q_1 consumes the mark `<BOS>`; and the only arc between q_1 and q_2 consumes the mark `<EOS>`. $\mathcal{T}_0$ has exactly one accepting state, which is q_2. To ensure that $\mathcal{T}_0$ defines relation for all possible string pairs $(\mathbf{x}, \mathbf{y}) \in \Sigma^* \times \Delta^*$, we add all arcs of the form $a = (s_1, s_1, \boldsymbol{\omega}, \sigma, \delta), \forall(\sigma, \delta) \in \Sigma \times \Delta$ to $\mathcal{T}$.

To recognize transduction rules defined in the Wikipedia English IPA Help page, we define $\mathcal{T}_{\text{IPA}}$, which has all states and arcs of $\mathcal{T}_0$, and additional states and arcs to handle multi-grapheme and multi-phoneme transductions defined in the IPA Help:[3] for example, the transduction `th` → θ is encoded as two arcs $(s_1, s_3, \boldsymbol{\omega}, \mathtt{t}, \theta)$ and $(s_3, s_1, \boldsymbol{\omega}, \mathtt{h}, \varepsilon)$. Because of the lack of good prior knowledge that can be added to A2C experiments, we only use general FSTs in those experiments for such experiments. Nor do we encode special marks that we are going to introduce below.[4]

4.2.1 Design of mark sequences

As with regular WFSTs, the arcs can often be hand-engineered to incorporate prior knowledge. Recall that as we describe in §2.2, each arc is associated with a mark sequence. In this paper, we will always derive the mark sequence on an arc $a = (s', s, \boldsymbol{\omega}', \sigma, \delta)$ of the transducer $\mathcal{T}$ as $\boldsymbol{\omega} = [\sigma, \boldsymbol{\omega}', \delta, s]$, where $\boldsymbol{\omega}' \in \Omega^*$ can be engineered to reflect FST- and application-specific properties of a path, such as the IPA Help list we mentioned earlier. One way to encode such knowledge into mark sequences is to have special mark symbols in mark sequences for particular transductions. In this paper we experiment with two schemes of marks:

- **IPA Help (IPA).** We define the IPA mark $\omega_{\text{IPA}} = \{\mathtt{C} \mid \mathtt{V}\}$, where the symbol `C` indicates that this arc is part of a transduction rule listed in the consonant section of the Wikipedia English IPA Help page. Similarly, the mark `V` indicates that the transduction rule is listed in the vowel section.
- **Phoneme Classes (PHONE).** We define PHONE marks $\omega_{\text{PHONE}} = \Phi(\delta)$, where Φ is a lookup function that returns the phoneme class of δ defined by the CMUDict dataset.[5]

In this paper we experiment with the following three FST and mark configurations for G2P/P2G experiments:

- **-IPA-PHONE** in which case $\boldsymbol{\omega}' = \varnothing$ for all arcs. $\mathcal{T} = \mathcal{T}_0$.
- **+IPA-PHONE** in which case $\boldsymbol{\omega}' = [\omega_{\text{IPA}}]$ when the transduction rule is found in the IPA Help list, otherwise $\boldsymbol{\omega}' = \varnothing$. $\mathcal{T} = \mathcal{T}_{\text{IPA}}$.
- **+IPA+PHONE** in which case $\boldsymbol{\omega}' = [\omega_{\text{IPA}}\omega_{\text{PHONE}}]$ when the transduction rule is found in the IPA Help list, otherwise $\boldsymbol{\omega}' = [\omega_{\text{PHONE}}]$. $\mathcal{T} = \mathcal{T}_{\text{IPA}}$.

As we said earlier, we only use $\mathcal{T} = \mathcal{T}_0$ with no special marks for A2C experiments. Experimental results on these different configurations are in §5.3.

4.3 Decoding methods

We experiment with the following methods to decode the most probable strings:

- **Approximate Posterior (AP).** We approximate the posterior distribution over output strings $\hat{p}_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}')$, and pick $\hat{\mathbf{y}}^* = \operatorname{argmax}_{\mathbf{y}} \hat{p}_{\mathbf{Y}}(\mathbf{y} \mid \mathcal{T}')$ as the output.
- **Reranking AP.** As we discuss in §3.3, improving $\hat{\mathbf{y}}^*$ by taking more path samples in $\mathcal{T}'$ may be expensive. The reranking method uses the support of $\hat{p}_{\mathbf{Y}}$ as a candidate pool L', and for each $\mathbf{y}_k \in L'$ we estimate equation (15) using path samples in $\mathcal{T}' \circ \mathbf{y}_k$.
- **Reranking External.** This decoding method uses k-best lists from external models. In this paper, we make use of sequence-to-sequence baseline models as the candidate pool L'.
- **Reranking AP + External.** This decoding method uses the union of the support of $\hat{p}_{\mathbf{Y}}$ and k-best lists from the sequence-to-sequence baseline models as the candidate pool L'.

In this paper, we take 128 path samples per candidate for all **Reranking** methods.

---

[3] `https://en.wikipedia.org/wiki/Help:IPA/English`

[4] The NACS dataset was actually generated from a regular transducer, which we could in principle use, but doing so would make the transduction fully deterministic and probably not interesting/hard enough.

5 Results

5.1 Baselines

We compare NFSTs against the following baselines:

BiRNN-WFSTs proposed by Rastogi et al. (2016), were weighted finite-state transducers whose weights encode input string features by the use of recurrent neural networks. As we note in Table 1, they can be seen as a special case of NFSTs, where the Markov property is kept, but where exact inference is still possible.

Seq2seq models are the standard toolkit for transduction tasks. We make use of the attention mechanism proposed by Luong et al. (2015), which accomplishes 'soft alignments' that do not enforce a monotonic alignment constraint.

Neuralized IBM Model 1 is a character transduction model recently proposed by Wu et al. (2018), which marginalizes over non-monotonic hard alignments between input and output strings. Like (Luong et al., 2015), they did not enforce monotonic alignment constraints; but unlike them, they did not make use of the **input feeding** mechanism,[6] where past alignment information is fed back into the RNN decoder. This particular omission allows (Wu et al., 2018) to do exact inference with a dynamic programming algorithm.

All baseline systems are tuned on the validation sets. The seq2seq models employ GRUs, with word and RNN embedding size = 500 and a dropout rate of 0.3. They are trained with the Adam optimizer (Kingma and Ba, 2014) over 50 epochs. The Neuralized IBM Model 1 models are tuned as described in (Wu et al., 2018).

5.2 The effectiveness of NFSTs

5.2.1 Does losing the Markov property help?

Table 2 indicates that BiRNN-WFST models (Rastogi et al., 2016) perform worse than other models. Their Markovian assumption helps enable dynamic programming, but restricts their expressive power, which greatly hampers the BiRNN-WFST's performance on the P2G/G2P task. The NACS task also relies highly on output-output interactions, and BiRNN-WFST performs very poorly there.

	G2P / P2G				NACS
	EM Accuracy		Edit Distance		EM Accuracy
	Dev	Test	Dev	Test	Test
BiRNN-WFST	16.9	15.9	1.532	1.645	5.6
Seq2seq	30.7	28.9	1.373	1.426	9.0
Neuralized IBM Model 1	31.6	30.2	1.366	1.398	—
Local NFSTs	32.7	31.8	1.319	1.332	15.64

Table 2: Average exact match accuracy (%, higher the better) and edit distance (lower the better) on G2P and P2G as well as exact match accuracy on NACS. Comparison between our models with baselines. For NFST models, we make use of the **Reranking AP** decoding method described in §4.2.

5.2.2 Effectiveness of proposed decoding methods

Table 3 shows results from different decoding methods on the G2P/P2G tasks, configuration **+IPA+PHONE**. **AP** performs significantly worse than **Reranking AP**, suggesting that the estimate $\hat{\mathbf{y}}^*$ suffers from the variance problem. Interestingly, of decoding methods that employ external models, **Reranking External** performs better than **Reranking AP + External**, despite having a smaller candidate pool. We think there is some product-of-experts effect in **Reranking External** since the external model may not be biased in the same way as our model is. But such benefits vanish when candidates from **AP** are also in the pool — our learned approximation learns the bias in the model — and hence the worse performance in **Reranking AP + External**. This suggests an interesting regularization trick in practice: populating the candidate pool using external models to hide our model bias. However when we compare our method against non-NFST baseline methods we do not make use of such tricks, to ensure a more fair comparison.

	EM Accuracy		Edit Distance	
	Dev	Test	Dev	Test
AP	28.2	28.2	1.513	1.467
Reranking AP	32.7	31.8	1.319	1.332
Reranking External	33.3	32.7	1.297	1.298
Reranking AP + External	32.9	32.0	1.309	1.303

Table 3: Average exact match accuracy (%, higher the better) and edit distance (lower the better) on G2P and P2G. The effectiveness of different decoding methods.

5.3 Prior knowledge: does it help?

In Table 4 we see that combining both +IPA and +PHONE improves model generalizability over the general FST (-IPA -PHONE). We also note that using only the IPA marks leads to degraded performance

---

[6] We discuss this further in Appendix B.1.

	EM Accuracy		Edit Distance	
	Dev	Test	Dev	Test
-IPA -PHONE	31.8	29.3	1.38	1.373
+IPA -PHONE	31.3	29.2	1.367	1.431
+IPA +PHONE	32.7	31.8	1.319	1.332

Table 4: Average exact match accuracy (%, higher the better) and edit distance (lower the better) on G2P and P2G. The effectiveness of different FST designs.

compared to the general FST baseline. This is a surprising result — one explanation is the IPA marks are not defined on all paths that transduce the intended input-output pairs: NFSTs are capable of recognizing phoneme-grapheme alignments in different paths,[7] but only one such path is marked by +IPA. But we leave a more thorough analysis to future work.

6 Related Work

Recently, there has been work relating finite-state methods and neural architectures. For example, Schwartz et al. (2018) and Peng et al. (2018) have shown the equivalence between some neural models and WFSAs. The most important differences of our work is that in addition to classifying strings, NFSTs can also transduce strings. Moreover, NFSTs also allow free topology of FST design, and breaks the Markovian assumption. In addition to models we compare against in §4, we note that (Aharoni and Goldberg, 2017; Deng et al., 2018) are also similar to our work; in that they also marginalize over latent alignments, although they do not enforce the monotonicity constraint. Work that discusses globally normalized sequence models are relevant to our work. In this paper, we discuss a training strategy that bounds the partition function; other ways to train a globally normalized model (not necessarily probabilistic) include (Wiseman and Rush, 2016; Andor et al., 2016). On the other hand, our locally normalized FSTs bear resemblance to (Dyer et al., 2016), which was also locally normalized, and also employed importance sampling for training.

7 Conclusions and Future Work

Neural finite state transducers (NFSTs) are able to model string pairs, considering their monotonic alignment but also enjoying RNNs' power to handle non-finite-state phenomena. They compete favorably with state-of-the-art neural models on transduction tasks. At the same time, it is easy to inject domain knowledge into NFSTs for inductive bias, and they offer interpretable paths.

In this paper, we have used rather simple architectures for our RNNs; one could experiment with multiple layers and attention. One could also experiment with associating marks differently with arcs—the marks are able to convey useful domain information to the RNNs. For example, in a P2G or G2P task, all arcs that cross a syllable boundary might update the RNN state using a `syllable` mark. We envision using regular expressions to build the NFSTs, and embedding marks in the regular expressions as a way of sending useful features to the RNNs to help them evaluate paths.

In this paper, we have studied NFSTs as standalone systems. But as probabilistic models, they can be readily embedded in a bigger picture: it should be directly feasible to incorporate a globally/locally normalized NFST in a larger probabilistic model (Finkel and Manning, 2009; Chiang et al., 2010).

The path weights of NFSTs could be interpreted simply as scores, rather than log-probabilities. One would then decode by seeking the 1-best path with input $\mathtt{x}$, e.g., via beam search or Monte Carlo Tree Search. In this setting, one might attempt to train the NFST using methods similar to the max-violation structured perceptron or the structured SVM.

A Finite-state transducers

A.1 Rational Relations

A **relation** is a set of pairs—in this paper, a subset of $\Sigma^* \times \Delta^*$, so it relates strings over an "input" alphabet Σ to strings over an "output" alphabet Δ.

A **weighted relation** is a function R that maps any string pair $(\mathbf{x}, \mathbf{y})$ to a **weight** in $\mathbb{R}_{\geq 0}$.

We say that the relation R is **rational** if R can be defined by some weighted finite-state transducer (FST) $\mathcal{T}$. As formalized in Appendix A.3, this means that $R(\mathbf{x}, \mathbf{y})$ is the total weight of all accepting paths in $\mathcal{T}$ that are labeled with $(\mathbf{x}, \mathbf{y})$ (which is 0 if there are no such accepting paths). The weight of each accepting path in $\mathcal{T}$ is given by the product of its arc weights, which fall in $\mathbb{R}_{>0}$.

The set of pairs $\text{support}(R) \triangleq \{(\mathbf{x}, \mathbf{y}) : R(\mathbf{x}, \mathbf{y}) > 0\}$ is then said to be a **regular relation** because it is recognized by the unweighted FST obtained by dropping the weights from $\mathcal{T}$. In this paper, we are interested in defining *non-rational* weighting functions R with this same regular support set.

A.2 Finite-state transducers

We briefly review finite-state transducers (FSTs). Formally, an FST is a tuple $\mathcal{T}_0 = (\Sigma, \Delta, Q, A_0, I, F)$ where

- Σ is a finite input alphabet
- Δ is a finite output alphabet
- Q is a finite set of states
- $A_0 \subseteq Q \times Q \times (\Sigma \cup \{\epsilon\}) \times (\Delta \cup \{\epsilon\})$ is the set of weighted arcs
- $I \subseteq Q$ is the set of initial states (conventionally $|I| = 1$)
- $F \subseteq Q$ is the set of final states

Let $\mathbf{a} = a_1 \ldots a_T$ (for $T \geq 0$) be an accepting path in $\mathcal{T}_0$, that is, each $a_i = (q_{i-1}, q_i, \sigma_i, \delta_i) \in A_0$ and $q_0 \in I, q_T \in F$. We say that the input and output strings of $\mathbf{a}$ are $\sigma_1 \cdots \sigma_T$ and $\delta_1 \cdots \delta_T$.

A.3 Real-valued weighted FSTs

Weighted FSTs (WFSTs) are defined very similarly to FSTs. A WFST is formally defined as a 6-tuple, just like an (unweighted) FST: $\mathcal{T} = (\Sigma, \Delta, Q, A, I, F)$, with arcs carrying weights: $A \subseteq Q \times Q \times (\Sigma \cup \{\epsilon\}) \times (\Delta \cup \{\epsilon\}) \times \mathbb{R}$. Compared to FST arcs in Appendix A.2, a WFST arc each $a_i = (q_{i-1}, q_i, \sigma_i, \delta_i, \kappa_i) \in A$ has weight κ_i. We also define the weight of $\mathbf{a}$ to be $w(\mathbf{a}) \triangleq \bigotimes_{i=1}^{T} \kappa_i \in \mathbb{R}$.

The weight of the entire WFST $\mathcal{T}$ is defined as the total weight (under $\oplus$) of all accepting paths:

$$\mathcal{T}[\,] \triangleq \bigoplus_{\mathbf{a}} w(\mathbf{a}) \in \mathbb{R} \tag{16}$$

More interestingly, the weight $\mathcal{T}[\mathbf{x}, \mathbf{y}]$ of a string pair $\mathbf{x} \in \Sigma^*, \mathbf{y} \in \Delta^*$ is given by similarly summing $w(\mathbf{a})$ over just the accepting paths $\mathbf{a}$ whose input string is $\mathbf{x}$ and output string is $\mathbf{y}$.

B More analysis on the effectiveness of NFSTs

B.1 Does feeding alignments into the decoder help?

In particular, we attribute our models' outperforming Neuralized IBM Model 1 to the fact that a complete history of past alignments is remembered in the RNN state. (Wu et al., 2018) noted that in character transduction tasks, past alignment information seemed to barely affect decoding decisions made afterwards. However, we empirically find that there is performance gain by explicitly modeling past alignments. This also shows up in our preliminary experiments with non-input-feeding seq2seq models, which resulted in about 1% of lowered accuracy and about 0.1 longer edit distance.

B.2 Interpretability of learned paths

The model is not required to learn transduction rules that conform to our linguistic knowledge. However, we expect that a well-performing one would tend to pick up rules that resemble what we know. To verify this, we obtain samples (listed in Table 4) from $\hat{p}(\mathbf{a} \mid \mathbf{x}, \mathbf{y})$ using the importance sampling algorithm described in §3.3. We find that our NFST model has learned to align phonemes and graphemes, generating them alternately. It has no problem picking up obvious pairs in the English orthography (e.g. (ʃ, `c h`), and (ŋ, `n g`)). We also find evidence that the model has picked up how context affects alignment: for example, the model has learned that the bigram 'gh' is pronounced differently in different contexts: in 'onslau**ght**,' it is aligned with ɔ in the sequence 'augh;' in 'Willin**gh**am,' it spans over two phonemes ŋ h; and in '**gh**ezzi,' it is aligned with the phoneme ɡ. We also find that our NFST has no problem learning phoneme-grapheme alignments that span over two

arcs, which is beyond the capability of of ordinary WFSTs.

C Implementation Details

C.1 Model parametrization details

As mentioned before, the type of RNN that we use is GRU. The GRU parameterizing $G_{\boldsymbol{\theta}}$ has 500 hidden states. The embedding sizes of tokens, including the input symbol, output symbol and states, and marks are all 500. During inference we make use of proposal distributions $q_{\boldsymbol{\phi}}(\mathbf{a} \mid \mathcal{T}')$, where $\mathcal{T}' \in \{\mathbf{x} \circ \mathcal{T}, \mathcal{T} \circ \mathbf{y}, \mathbf{x} \circ \mathcal{T} \circ \mathbf{y}\}$. All RNNs used to parametrize $q_{\boldsymbol{\phi}}$ are also GRUs, with 125 hidden states. $q_{\boldsymbol{\phi}}$ makes use of input/output embeddings independent from $G_{\boldsymbol{\theta}}$, which also have size 125 in this paper. The feed-forward networks $C^{\mathrm{x},\mathrm{y},\mathrm{xy}}$ are parametrized by 3-layer networks, with ReLU as the activation function of the first two layers. The output dimension sizes of the first and second layers are $\lfloor {}^{D}/_{2} \rfloor$ and $\lfloor {}^{D}/_{4} \rfloor$, where D is the input vector dimension size.

C.2 Training procedure details

We use stochastic gradient descent (SGD) to train $G_{\boldsymbol{\theta}}$. For each example, we compute the gradient using normalized importance sampling over an ensemble of 512 particles (paths), the maximum that we could compute in parallel. By using a large ensemble, we reduce both the bias (from normalized importance sampling) and the variance of the gradient estimate; we found that smaller ensembles did not work as well. Thus, we used only one example per minibatch.

We train the 'clamped' proposal distribution $q_{\boldsymbol{\phi}}(\mathbf{a} \mid \mathbf{x} \circ \mathcal{T} \circ \mathbf{y})$ differently from the 'free' ones $q_{\boldsymbol{\phi}}(\mathbf{a} \mid \mathbf{x} \circ \mathcal{T})$ and $q_{\boldsymbol{\phi}}(\mathbf{a} \mid \mathcal{T} \circ \mathbf{y})$. The clamped distribution is trained alternately with $G_{\boldsymbol{\theta}}$, as listed in Algorithm 2. We evaluate on the development dataset at the end of each epoch using the **Reranking External** method described in §4.3. When the EM accuracy stops improving, we fix the parameters of $G_{\boldsymbol{\theta}}$ and start training $q_{\boldsymbol{\phi}}(\mathbf{x} \circ \mathcal{T})$ and $q_{\boldsymbol{\phi}}(\mathcal{T} \circ \mathbf{y})$ on the inclusive KL divergence objective function, using methods described in (Lin and Eisner, 2018). We then initialize the free distributions' RNNs using those of the clamped distributions. We train the free proposal distributions for 30 epochs, and evaluate on the development dataset at the end of each epoch. Results from the best epochs are reported in this paper.

Riemannian Normalizing Flow on Variational Wasserstein Autoencoder for Text Modeling

Abstract

Recurrent Variational Autoencoder has been widely used for language modeling and text generation tasks. These models often face a difficult optimization problem, also known as the Kullback-Leibler (KL) term vanishing issue, where the posterior easily collapses to the prior, and the model will ignore latent codes in generative tasks. To address this problem, we introduce an improved Wasserstein Variational Autoencoder (WAE) with Riemannian Normalizing Flow (RNF) for text modeling. The RNF transforms a latent variable into a space that respects the geometric characteristics of input space, which makes posterior impossible to collapse to the non-informative prior. The Wasserstein objective minimizes the distance between the marginal distribution and the prior directly, and therefore does not force the posterior to match the prior. Empirical experiments show that our model avoids KL vanishing over a range of datasets and has better performances in tasks such as language modeling, likelihood approximation, and text generation. Through a series of experiments and analysis over latent space, we show that our model learns latent distributions that respect latent space geometry and is able to generate sentences that are more diverse. [1]

1 Introduction

Variational Autocoder (VAE) (Kingma and Welling, 2013; Rezende and Mohamed, 2015) is a probabilistic generative model shown to be successful over a wide range of tasks such as image generation (Gregor et al., 2015; Yan et al., 2016), dialogue generation (Zhao et al., 2017b), transfer learning (Shen et al., 2017), and classification (Jang et al., 2017). The encoder-decoder architecture of VAE allows it to learn a continuous space of latent representations from high-dimensional data input and makes sampling procedure from such latent space very straightforward. Recent studies also show that VAE learns meaningful representations that encode non-trivial information from input (Gao et al., 2018; Zhao et al., 2017a).

Applications of VAE in tasks of Natural Language Processing (Bowman et al., 2015; Zhao et al., 2017b, 2018; Miao et al., 2016) is not as successful as those in Computer Vision. With *long-short-term-memory* network (LSTM) (Hochreiter and Schmidhuber, 1997) used as encoder-decoder model, the recurrent variational autoencoder (Bowman et al., 2015) is the first approach that applies VAE to language modeling tasks. They observe that LSTM decoder in VAE often generates texts without making use of latent representations, rendering the learned codes as useless. This phenomenon is caused by an optimization problem called KL-divergence vanishing when training VAE for text data, where the KL-divergence term in VAE objective collapses to zero. This makes the learned representations meaningless as zero KL-divergence indicates that the latent codes are independent of input texts.

Many recent studies are proposed to address this key issue. Yang et al. (2017); Semeniuta et al. (2017) use *convolutional neural network* as decoder architecture to limit the expressiveness of decoder model. Xu and Durrett (2018); Zhao et al. (2017a,b, 2018) seek to learn different latent space and modify the learning objective. And, even though not designed to tackle KL vanishing at the beginning, recent studies on *Normalizing Flows* (Rezende and Mohamed, 2015; van den Berg et al., 2018) learn meaningful latent space as it helps to transform an over-simplified latent distribution into more flexible distributions.

In this paper, we propose a new type of flow,

---

Proceedings of NAACL-HLT 2019, pages 284–294
Minneapolis, Minnesota, June 2 - June 7, 2019.

called Riemannian Normalizing Flow (RNF), together with the recently developed Wasserstein objective (Tolstikhin et al., 2018; Arjovsky et al., 2017), to ensure VAE models more robust against the KL vanishing problem. As further explained in later sections, the Wasserstein objective helps to alleviate KL vanishing as it only minimizes the distance between latent marginal distribution and the prior. Moreover, we suspect that the problem also comes from the over-simplified prior assumption about latent space. In most cases, the prior is assumed to be a standard Gaussian, and the posterior is assumed to be a diagonal Gaussian for computational efficiency. These assumptions, however, are not suitable to encode intrinsic characteristics of input into latent codes as in reality the latent space is likely to be far more complex than a diagonal Gaussian.

The RNF model we proposed in this paper thus helps the situation by encouraging the model to learn a latent space that encodes some geometric properties of input space with a well-defined geometric metric called Riemannian metric tensor. This renders the KL vanishing problem as impossible since a latent distribution that respects input space geometry would only collapse to a standard Gaussian when the input also follows a standard Gaussian, which is never the case for texts and sentences datasets. We then empirically evaluate our RNF Variational Wasserstein Autoencoder on standard language modeling datasets and show that our model has achieved state-of-the-art performances. Our major contributions can be summarized as the following:

- We propose Riemannian Normalizing Flow, a new type of flow that uses the Riemannian metric to encourage latent codes to respect geometric characteristics of input space.
- We introduce a new Wasserstein objective for text modeling, which alleviates KL divergence term vanishing issue, and makes the computation of normalizing flow easier.
- Empirical studies show that our model produces state-of-the-art results in language modeling and is able to generate meaningful text sentences that are more diverse.

2 Related Work

2.1 Variational Autoencoder

Given a set of data $\mathbf{x} = (x_1, x_2, ..., x_n)$, a Variational Autoencoder (Kingma and Welling, 2013) aims at learning a continuous latent variable that maximizes the log-likelihood $\log p(\mathbf{x}) = \log \int p_\theta(\mathbf{x}|\mathbf{z})p(\mathbf{z})d\mathbf{z}$. Since this marginal is often intractable, a variational distribution $q_\phi(\mathbf{z}|\mathbf{x})$ is used to approximate the true posterior distribution $p_\theta(\mathbf{z}|\mathbf{x})$. VAE tries to maximize the following lower bound of likelihood,

$$\mathcal{L}(\theta;\phi;\mathbf{x}) = \mathbb{E}_{q(\mathbf{x})}[\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \quad (1)$$

$$- KL(q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z}))] \quad (2)$$

where $q(\mathbf{x})$ is the empirical distribution of input, and the prior $p(\mathbf{z})$ is often assumed to be a standard Gaussian for simplicity. The first term in the objective is the reconstruction error, and the second one is KL divergence. For modeling text sentences, Bowman et al. (2015) parameterizes both the inference model $q(\mathbf{z}|\mathbf{x})$ and the generative model $p(\mathbf{x}|\mathbf{z})$ as LSTMs. The reparameterization trick proposed by Rezende and Mohamed (2015) is used to train these two models jointly.

2.2 KL Divergence Term Vanishing

Since the generative model is often an LSTM that has strong expressiveness, the reconstruction term in the objective will dominate KL divergence term. In this case, the model is able to generate texts without making effective use of latent codes as the latent variable $\mathbf{z}$ becomes independent from input when KL divergence term collapses to zero.

There are two main approaches to address this issue. One is to explore different choices of the decoder model to control the expressiveness of LSTM. Yang et al. (2017) and Semeniuta et al. (2017) use CNN as an alternative to LSTM. The dilation technique used by Yang et al. (2017) also helps to control the trade-off between decoder capacity and KL vanishing. The other approach is to change the form of latent distribution and to modify the training objective. Xu and Durrett (2018) proposes to use hyperspherical distribution and shows that the KL vanishing problem does not happen in hypersphere. The infoVAE (Zhao et al., 2017a) argues that VAE objective is anti-informatics which encourages KL divergence to be zero. They, therefore, add a mutual information term $I(\mathbf{z};\mathbf{x})$ explicitly to ensure that latent variable $\mathbf{z}$ encodes non-trivial information about $\mathbf{x}$, in which case the KL would be greater than zero as $\mathbf{z}$ is no longer independent from $\mathbf{x}$. In a similar manner, Xiao et al. (2018) introduces a Dirichlet latent variable to force latent codes to learn useful topic information given input documents. He et al. (2019) and Kim et al. (2018) achieve the current state-of-the-art in terms of sample perplexity. Moreover, the bag-of-words loss used by Zhao et al. (2017b) also dramatically alleviates KL vanishing while not sacrificing sample quality. In Section 3 and Section 4, we introduce RNF with Wasserstein objective. Our proposed model also lies in the direction which seeks to learn more flexible latent distribution, as the main advantage of RNF is to ensure a flexible latent space able to capture geometric characteristics of input space.

3 Background

In this section, we review the basic concepts of Riemannian geometry, normalizing flow, and Wasserstein Autoencoder. We then introduce our new Riemannian normalizing flow in Section 4.

3.1 Riemannian Geometry Review

Consider an input space $\mathcal{X} \subset R^D$, a d-dimensional $(d < D)$ manifold is a smooth surface of points embedded in $\mathcal{X}$. Given a manifold $\mathcal{M}$, a Riemannian manifold is a metric space $(\mathcal{M}, G)$, where G is the Riemannian metric tensor that assigns an inner product to every point on the manifold. More formally, a Riemannian metric $G : \mathcal{Z} \to R^{d\times d}$ is defined as a smooth function such that for any two vectors u, v in the tangent space $T_z M$ of each point $z \in \mathcal{M}$, it assigns the following inner product for u and v,

$$< u, v >_G = u^T G(z) v \tag{3}$$

The Riemannian metric helps us to characterize many intrinsic properties of a manifold. Consider an arbitrary smooth curve $\gamma(t) : [a, b] \to \mathcal{M}$ on a given manifold $\mathcal{M}$ with a Riemannian metric tensor G, the length of this curve is given by

$$\begin{aligned}\mathcal{L}(\gamma) &= \int_a^b ||\gamma'(t)||dt \\ &= \int_a^b \sqrt{< \gamma'_t, \gamma'_t >_G}dt \\ &= \int_a^b \sqrt{\gamma'^T_t G(\gamma_t)\gamma'_t}dt \end{aligned}\tag{4}$$

where γ'_t is the curve velocity and lies in the tangent space $T_{\gamma_t}M$ at point $\gamma(t)$. When the metric tensor G is equal to 1 everywhere on the curve, it becomes a metric tensor on Euclidean space, where the length of curve is defined as the integral of the velocity function, $\mathcal{L}(\gamma) = \int_a^b \sqrt{\gamma'^T_t \gamma'_t}dt = \int_a^b \gamma'_t dt$. Given the definition of curve length, the geodesic path between any two points can be defined as the curve that minimizes the curve length γ. Namely, if γ_t is the geodesic curve connecting $\gamma(a)$ and $\gamma(b)$, then

$$\gamma_t = \underset{\gamma}{\operatorname{argmin}}\, \mathcal{L}(\gamma) \tag{5}$$

Practically, a geodesic line is often found by optimizing the following energy function,

$$\begin{aligned} E(\gamma) &= \frac{1}{2}\int_a^b \gamma'^T_t G(\gamma_t)\gamma'_t dt \\ \gamma_t &= \underset{\gamma}{\operatorname{argmin}}\, E(\gamma) \end{aligned}\tag{6}$$

Note that the Euclidean metric is a special case of Riemannian metric. The more general metric tensor G gives us a sense of how much Riemannian geometry deviates from Euclidean geometry.

3.2 Review: Normalizing Flow

The powerful inference model of VAE can approximate the true posterior distribution through variational inference. The choice of this approximated posterior is one of the major problems. For computational efficiency, a diagonal Gaussian distribution is often chosen as the form of the posterior. As the covariance matrix is always assumed to be diagonal, the posterior fails to capture dependencies among individual dimensions of latent codes. This poses a difficult problem in variational inference. As it is unlikely that the true posterior has a diagonal form, the approximated diagonal distribution is not flexible enough to match the true posterior even in asymptotic time.

A normalizing flow, developed by (Rezende and Mohamed, 2015), is then introduced to transform a simple posterior to a more flexible distribution. Formally, a series of normalizing flows is a set of invertible, smooth transformations $f_t : R^d \to R^d$, for $t = 1, ..., T$, such that given a random variable z_0 with distribution $q(z_0)$, the resulting random variable $z^T = (f_T \circ f_{T-1} \circ ... \circ f_1)(z_0)$ has the following density function,

$$q(z_T) = q(z_0)\prod_{t=1}^{T} |det \frac{\partial f_t^{-1}}{\partial z_{t-1}}| \tag{7}$$

Since each transformation f_i for $i = 1, ..., T$ is invertible, its Jacobian determinant exists and can be computed. By optimizing the modified *evidence lower bound* objective,

$$\ln p(x) \geq \mathbb{E}_{q(z_0|x)} \left[\ln p(x|z_T) + \sum_{t=1}^{T} \ln |det \frac{\partial f_t}{\partial z_{t-1}}| \right] - KL(q(z_0|x)||p(z_T)) \quad (8)$$

the resulting latent codes z_T will have a more flexible distribution.

Based on how the Jacobian-determinant is computed, there are two main families of normalizing flow (Tomczak and Welling, 2016; Berg et al., 2018): *general normalizing flow* and *volume preserving flow*. While they both search for flexible transformation that has easy-to-compute Jacobian-determinant, the volume-preserving flow aims at finding a specific flow whose Jacobian-determinant equals 1, which simplifies the optimization problem in equation (6). Since we want a normalizing flow that not only gives flexible posterior but also able to uncover the true geometric properties of latent space, we only consider general normalizing flow whose Jacobian-determinant is not a constant as we need it to model the Riemannian metric introduced earlier.

3.3 Wasserstein Autoencoder

Wasserstien distance has been brought to generative models and is shown to be successful in many image generation tasks (Tolstikhin et al., 2018; Arjovsky et al., 2017; Bousquet et al., 2017). Instead of maximizing the *evidence lower bound* as VAE does, the Wasserstein Autoencoder (Tolstikhin et al., 2018) optimizes the optimal transport cost (Villani, 2008) between the true data distribution $P_X(x)$ and the generative distribution $P_G(x)$. This leads to the Wasserstein objective,

$$D(P_X, P_G) = \inf_{Q(Z|X) \in \mathcal{Q}} \mathbb{E}_{P_X} \mathbb{E}_{Q(Z|X)}[c(X, G(Z))] + \lambda D_Z(Q_Z, P_Z) \quad (9)$$

where $c(\cdot)$ is the optimal transport cost, $G : \mathcal{Z} \rightarrow \mathcal{X}$ is any generative function, and the coefficient λ controls the strength of regularization term D_Z. Given a positive-definite reproducing kernel $k : \mathcal{Z} \times \mathcal{Z} \rightarrow \mathcal{R}$, the regularization term D_Z can be approximated by the *Maximum Mean Discrepancy* (**MMD**) (Gretton et al., 2012) between the prior P_Z and the aggregate posterior $Q_Z(z) = \int q(z|x)p(x)dx$,

$$MMD_k(P_Z, Q_Z) = || \int_{\mathcal{Z}} k(z, \cdot)dP_Z - \int_{\mathcal{Z}} k(z, \cdot)dQ_Z|| \quad (10)$$

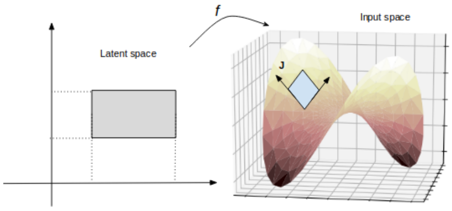

Figure 1: Parameterization of the input manifold by latent space and generative function f. J is the Jacobian tangent space at a point on the manifold, which reflects how curved the neighborhood is around that point.

4 Our Approach

In this section we propose our *Riemannian Normalizing Flow* (**RNF**). RNF is a new type of flow that makes use of the Riemannian metric tensor introduced earlier in Section 3. This metric enforces stochastic encoder to learn a richer class of approximated posterior distribution in order to follow the true geometry of latent space, which helps to avoid the local optimum in which posterior collapses to a standard prior. We then combine this with WAE and we will explain why and how WAE should be used to train with RNF.

4.1 Riemannian Normalizing Flow

In the context of VAE, learning a latent space that is homeomorphic to input space is often very challenging. Consider a manifold $\mathcal{M} \subset R^D$, a generator model $x = f(z) : \mathcal{Z} \rightarrow R^D$ serves as a low-dimensional parameterization of manifold $\mathcal{M}$ with respect to $z \in \mathcal{Z}$. For most cases, latent space $\mathcal{Z}$ is unlikely to be homeomorphic to $\mathcal{M}$, which means that there is no invertible mapping between $\mathcal{M}$ and $\mathcal{Z}$. And, since the inference model $h : \mathcal{M} \rightarrow \mathcal{Z}$ is nonlinear, the learned latent space often gives a distorted view of input space. Consider the case in Figure 2, where the leftmost graph is the input manifold, and the rightmost graph is the corresponding latent space with curvature reflected by brightness. Let us take two arbitrary points on the manifold and search for the geodesic path connecting these two points. If we consider the distorted latent space as Euclidean, then the geodesic path in latent space does not reflect the true shortest distance between these two points on the manifold, as a straight line in the latent space would

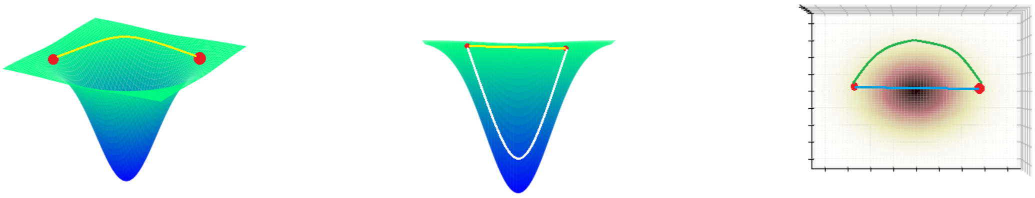

Figure 2: An example when latent space does not reflect input space. *Left:* a manifold that is highly curved in the central region. The yellow line is the geodesic (shortest) path connecting two sample points shown on the manifold. *Right:* The projection of manifold into 2D latent space, where the color brightness indicates curvature with respect to the manifold. The green line is the geodesic path if taking the curvature into account, while the blue line is the geodesic path if we regard latent space as Euclidean. *Middle:* The corresponding geodesic paths projected back from latent space to manifold. The white line corresponds to the straight geodesic path in Euclidean space. It is far longer than the true geodesic on manifold since it does not take the curvature into account in latent space.

cross the whole manifold, while the true geodesic path should circumvent this hole. This distortion is caused by the non-constant curvature of latent space. Hence, the latent space should be considered as a curved space with curvature reflected by the Riemannian metric defined locally around each point. As indicated by the brightness, we see that the central area of latent space is highly curved, and thus has higher energy. The geodesic path connecting the two latent codes minimizes the energy function $E(\gamma) = \frac{1}{2}\int \gamma'^{T}_{t} G(\gamma_t)\gamma'_t dt$, indicating that it should avoid those regions with high curvature G.

The question now becomes how to impose this intrinsic metric and curvature into latent space. In this paper, we propose a new form of normalizing flow to incorporate with this geometric characteristic. First, consider a normalizing flow $f : \mathcal{Z} \rightarrow \mathcal{Z}'$, we can compute length of a curve in the transformed latent space $\mathcal{Z}'$,

$$\begin{aligned}\mathcal{L}(f(\gamma_t)) &= \int_a^b ||\mathbf{J}_{\gamma_t}\gamma'_t||dt \\ &= \int_a^b \sqrt{\gamma'_t \mathbf{J}^T_{\gamma_t}\mathbf{J}_{\gamma_t}\gamma'_t}dt \\ &= \int_a^b \sqrt{\gamma'_t G(\gamma_t)\gamma'_t}dt \qquad (11)\end{aligned}$$

where

$$\begin{aligned}\gamma_t : [a, b] &\rightarrow \mathcal{Z}', \qquad a, b \in \mathcal{Z} \\ \mathbf{J}_{\gamma_t} &= \frac{\partial f}{\partial \mathbf{z}}\Big|_{\mathbf{z}=\gamma_t} \\ G(\gamma_t) &= \mathbf{J}^T_{\gamma_t}\mathbf{J}_{\gamma_t} \\ &= (\frac{\partial f}{\partial \mathbf{z}})^T(\frac{\partial f}{\partial \mathbf{z}})\Big|_{\mathbf{z}=\gamma_t} \qquad (12)\end{aligned}$$

$\mathbf{J}_{\gamma_\mathbf{t}}$ is the Jacobian matrix defined at γ_t. In our case, the Riemannian metric tensor G is the inner product of Jacobian $\mathbf{J}_{\gamma_t}$ and is therefore symmetric positive definite. It reflects input space curvature in low-dimensional parameterization $\mathcal{Z}'$. In a highly curved region, the metric tensor $G = \mathbf{J}^T\mathbf{J}$ is larger than those in other areas, indicating that the latent representation of input manifold has lower curvature, or area of low energy, as any geodesic connecting each pair of points on the manifold favors lower energy path. This implies that those regions outside of data manifold should have high curvature reflected in their low-dimensional parameterization $\mathcal{Z}'$.

In this paper, we introduce *Riemannian normalizing flow* (**RNF**) to model curvature. For simplicity, we build our model based on *planar flow* (Rezende and Mohamed, 2015). A planar flow is an invertible transformation that retracts and extends the support of original latent space with respect to a plane. Mathematically, a planar flow $f : \mathcal{Z} \rightarrow \mathcal{Z}'$ has the form,

$$f(\mathbf{z}) = \mathbf{z} + \mathbf{u}h(\mathbf{w^T z} + b) \qquad (13)$$

where $h : R^d \rightarrow R^d$ is any smooth non-linear function and is often chosen as $tanh(\cdot)$. The invertibiliy condition is satisfied as long as $\mathbf{u^T w} \geq -1$. Its Jacobian-determinant with respect to latent codes $\mathbf{z}$ is very each to compute,

$$\begin{aligned}|det\frac{\partial f}{\partial \mathbf{z}}| &= |1 + \mathbf{u^T}\phi(\mathbf{z})\mathbf{w}| \\ \phi(\mathbf{z}) &= h'(\mathbf{w^T}z + b) \qquad (14)\end{aligned}$$

With the Jacobian-determinant of planar flow, it is straightforward to compute the determinant of metric tensor G. To see that, note that since $\frac{\partial f}{\partial \mathbf{z}}$:

$R^d \rightarrow R^d$ is a square matrix with full column rank due to invertibility of f, we have

$$|det\ G| = \left|\frac{\partial f}{\partial \mathbf{z}}^T\right| \left|\frac{\partial f}{\partial \mathbf{z}}\right| = \left|\frac{\partial f}{\partial \mathbf{z}}\right|^2 \tag{15}$$

To ensure well-behaved geometry in a transformed latent space, we need the Jacobian-determinant $|\frac{\partial f}{\partial \mathbf{z}}|$ to be large in region with high curvature $|det\ G|$. Hence, we propose to model the metric tensor with the inverse multiquadratics kernel function $\mathcal{K}$ used by (Tolstikhin et al., 2018) and a Gaussian kernel, that is,

$$\begin{aligned} \mathcal{K}_m(\mathbf{z}, \mathbf{c_k}) &= C/(C + ||\mathbf{z} - \mathbf{c_k}||_2^2) \\ \mathbf{k} &= \text{argmin}\, ||\mathbf{z} - \mathbf{c_k}||_2^2 \\ \mathcal{K}_g(\mathbf{z}, \mathbf{c_k}) &= \exp\left(-\beta_k ||\mathbf{z} - \mathbf{z_k}||_2^2\right) \end{aligned}$$

where $\mathbf{c_k}, k = 1, 2, 3, ..., K$ are clusters of latent codes, and β_k is the bandwidth. We observe that the inverse multiquadratics kernel $\mathcal{K}_m$ generally performs better. We use the above kernels as constraints over the Jacobian-determinant, so that,

$$|det \frac{\partial f'}{\partial \mathbf{z}}| = |1 + \mathbf{u^T}(\mathbf{z})\phi(\mathbf{z})\mathbf{w}| \cdot \mathcal{K}(\mathbf{z}, \mathbf{c_k}) \tag{16}$$

As we explained earlier in this section, latent representation of region outside of input manifold should have high curvature in latent space. During training, we seek to maximize this regularized Jacobian $|det \frac{\partial f'}{\partial \mathbf{z}}|$ rather than the original one. This ensures that those latent codes within latent clusters, and therefore very likely to be on or near input manifold in input space, have much smaller curvature $|det\ G| = |\frac{\partial f}{\partial \mathbf{z}}|^2$ than those outside of latent clusters, as those outside of manifold would seek larger Jacobian in order to counter-effect the regularization term $\mathcal{K}$. The latent space $\mathcal{Z}'$ transformed by normalizing flow f is thus curved with respect to input manifold. This type of normalizing flow thus learns a latent space to respect geometric characteristics of input space. The KL vanishing problem is then unlikely to happen with a curved latent space. This is because most high-dimensional data in real life forms a curved manifold which is unlikely sampled from a multivariate standard Gaussian. Then, if the latent space reflects curvature of a curved manifold, the support of latent codes certainly does not follow a standard Gaussian either. This helps to push the posterior $q(\mathbf{z}|\mathbf{x})$ away from the standard Gaussian and never collapse to a non-informative prior.

4.2 RNF Wasserstein Autoencoder

Here we consider using the Wasserstein objective to model the latent marginal distribution of a curved latent space learned by an RNF. The Wasserstein objective with MMD is appealing in our case for two main reasons.

First, instead of minimizing the KL-divergence $KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z}))$, it minimizes distance between $q(\mathbf{z}) = \int q(\mathbf{z}|\mathbf{x})p(\mathbf{x})dx$ and $p(\mathbf{z})$, which encourages the marginal distribution of latent space to be as close as the prior while not affecting individual posterior distribution $q(\mathbf{z}|\mathbf{x})$ conditioned on each input. This makes the KL-divergence between posterior and prior, and equivalently the mutual information between latent codes and input sentences $I(\mathbf{z}, \mathbf{x}) = KL(q(\mathbf{z}, \mathbf{x})||q(\mathbf{z})p(\mathbf{x})) = \mathbb{E}_{p(\mathbf{x})}[KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z}))] - KL(q(\mathbf{z})||p(\mathbf{z}))$ impossible to be vanished as the objective does not require it to be small. Since the learned latent codes and input sentences have non-zero mutual information, the generative model will not ignore latent codes when generating texts.

Second, the MMD regularization in WAE makes it possible to optimize normalizing flow without computing the Jacobian-determinant explicitly. The use of MMD is necessary as getting a closed form KL divergence is no-longer possible after we apply RNF to the posterior. And, since the generative function G in the reconstruction term of Wasserstein objective can be any function or composition of functions (Tolstikhin et al., 2018), we can easily compose an RNF function into G such that the reconstructed texts are $\bar{X} = G(f(Z)) = G(Z'), Z' \in \mathcal{Z}'$.

Now, given a series of RNF $F = f_K \circ ... \circ f_1$, and let $\mathcal{Z}_K$ be the **curved** latent space after applying K flows over the original latent space $\mathcal{Z}$, we optimize the following RNF-Wasserstein objective,

$$\begin{aligned} D(P_X, P_G) = &\inf_{Q(Z|X) \in \mathcal{Q}} \mathbb{E}_{P_X} \mathbb{E}_{Q(Z|X)}[c(X, G(Z'))] \\ &+ \lambda MMD(Q_{Z'}, P_{Z'}) \\ &+ \alpha (KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) - \sum \log |det \frac{\partial f'}{\partial \mathbf{z}}|) \end{aligned} \tag{17}$$

where $Z \sim \mathcal{Z}$, $Z' \sim \mathcal{Z}'$, and $Z' = F(Z)$. We approximate MMD term with the Gaussian kernel $k(\mathbf{z}, \mathbf{z}') = e^{-||\mathbf{z}-\mathbf{z}'||^2}$, that is, $MMD(p, q) = \mathbb{E}_{p(\mathbf{z}), p(\mathbf{z}')}[k(\mathbf{z}, \mathbf{z}')] + \mathbb{E}_{q(\mathbf{z}), q(\mathbf{z}')}[k(\mathbf{z}, \mathbf{z}')] - 2\, \mathbb{E}_{p(\mathbf{z}), q(\mathbf{z}')}[k(\mathbf{z}, \mathbf{z}')]$.

Here we choose to minimize the MMD distance

between the prior P_Z and the marginal of non-curved latent space. This makes sampling procedure for generation tasks much easier, as it is easy to sample a latent code from a non-informative prior. We can get a sample $\mathbf{z}'$ from $\mathcal{Z}'$ indirectly by sampling: $\mathbf{z} \sim P_Z(\mathbf{z})$ and $\mathbf{z}' \sim F(\mathbf{z})$. On the other hand, it would be much more difficult to sample from a curved latent space $\mathcal{Z}'$ directly as the only prior knowledge we have about $\mathcal{Z}'$ is the curvature reflected by RNF implicitly and hence we do not know the support of $Q(Z')$.

5 Experimental Results

In this section, we investigate WAE's performance with Riemannian Normalizing Flow over language and text modeling.

5.1 Datasets

We use Penn Treebank (Marcus et al., 1993), Yelp 13 reviews (Xu et al., 2016), as in (Xu and Durrett, 2018; Bowman et al., 2015), and Yahoo Answers used in (Xu and Durrett, 2018; Yang et al., 2017) to follow and compare with prior studies. We limit the maximum length of a sample from all datasets to 200 words. The datasets statistics is shown in Table 3.

5.2 Experimental Setup

For each model, we set the maximum vocabulary size to 20K and the maximum length of input to 200 across all data sets. Following Bowman et al. (2015), we use one-layer undirectional LSTM for both encoder-decoder models with hidden size 200. Latent codes dimension is set to 32 for all models. We share Word Embeddings of size 200. For stochastic encoders, both MLP_μ and MLP_σ are two layer fully-connected networks with hidden size 200 and a batch normalizing output layer (Ioffe and Szegedy, 2015).

Data	**Train**	**Dev**	**Test**	**Vocab**
PTB	42068	3370	3761	10K
Yelp13	62522	7773	8671	15K
Yahoo	100K	10K	10K	20K

Table 3: Datasets statistics; The numbers reflect size of each dataset. Vocab is the vocabulary size.

We use Adam (Kingma and Ba, 2015) with learning rate set to 10^{-3} to train all models. Dropout is used and is set to 0.2. We train all models for 48 epochs, each of which consists of 2K steps. For models other than WAE, KL-annealing is applied and is scheduled from 0 to 1 at the 21st epoch.

For vmf-VAE (Xu and Durrett, 2018), we set the word embedding dimension to be 512 and the hidden units to 1024 for Yahoo, and set both of them to 200 for PTB and Yelp. The temperature κ is set to 80 and is kept constant during training.

For all WAE models, we add a small KL divergence term to control the posterior distribution. We found that if we only use RNF with MMD as the distance metric, then the posterior may diverge from the prior such that no reasonable samples can be generated from a standard Gaussian variable.

Hence, for all data sets, we schedule the KL divergence weight α from 0 to 0.8, and the weight of the MMD term is set as $\lambda = 10 - \alpha$. β_k of RBF is set to 10 for all models. For RNF, we use pretrained standard VAE models to gather the clusters $\mathbf{c_k}$, $k = 1, ..., K$, of latent codes, where we set the number of clusters to be 20. We use three normalizing flow for all experiments.

Hyperparameter of $\mathbf{K}_m$ When using the inverse multiquadratics kernel $\mathcal{K}_m(\mathbf{z}, \mathbf{c}_k) = C/(C + ||\mathbf{z} - \mathbf{c}_k||_2^2)$ for RNF, we follow the choice of hyperparameter in (Tolstikhin et al., 2018). We set $C = 2 \cdot d \cdot s$, where d is the dimensionality of latent codes $\mathbf{z}$, and s is ranged in $(0.1, 0.2, 0.5, 1, 2, 5, 10)$. The final kernel is computed by $\mathcal{K}_m(\mathbf{z}, \mathbf{c}_k) = \sum_s 2ds/(2ds + ||\mathbf{z} - \mathbf{c}_k||_2^2)$. As explained by (Tolstikhin et al., 2018), this strategy allows us to explore a wider range of hyperparameter in one setting.

5.3 Language Modeling Results

We show the language modeling results for PTB, Yahoo and Yelp in Table 1. We compare negative log-likelihood (NLL), KL divergence, and perplexity (PPL) with all other existing methods. The negative log-likelihood is approximated by its lower bound.

We use the negative of ELBO to approximate NLL for all VAE models. For those with normalizing flows, we use the modified ELBO, which is $\mathcal{L} = \mathbb{E}_{q(\mathbf{z}^{(0)}|\mathbf{x})}[\log p(\mathbf{x}|\mathbf{z}^{(T)}) - \log q(\mathbf{z}^{(0)}|\mathbf{x}) + \log p(\mathbf{z}^{(T)})] + \mathbb{E}_{q(\mathbf{z}^{(T)})}[\sum_{t=1}^{T} log|\frac{\partial f^{(t)}}{\partial \mathbf{z}^{(t-1)}}|]$.

The numbers show that KL-annealing and dropout used by Bowman et al. (2015) are helpful for PTB, but for complex datasets such as Yahoo and Yelp, the KL divergence still drops to zero due to the over-expressiveness of LSTM. This phenomenon is not alleviated by applying normalizing flow to make the posterior more flexible, as shown in the third row. Part of the reason may be that a simple NF such as a planar flow is not flexible enough and is still dominated by a powerful LSTM decoder.

We find that the KL vanishing is alleviated a little bit if using WAE, which should be the case as WAE objective does not require small KL. We also find that simply applying a planar flow over WAE does not improve the performance that much. On the other hand, using RNF to train WAE dramatically helps the situation which achieves the lowest text perplexity on most conditions except for YAHOO Answers, where (He et al., 2019; Yang et al., 2017; Kim et al., 2018) have the current state-of-the-art results. We want to emphasize that CNN-VAE (Yang et al., 2017) and SA-VAE (Kim et al., 2018) are not directly comparable with other current approaches. Here, we compare with models that use LSTM as encoder-decoder and have similar time complexity, while the use of CNN as decoder in CNN-VAE would dramatically change the model expressiveness, and it is known that SA-VAE's time complexity (Kim et al., 2018; He et al., 2019) is much higher than all other existing approaches.

5.4 How Good is Riemannian Latent Representation?

Mutual information between $\mathcal{Z}'$ and $\mathcal{X}$ One important question is how useful are latent variables. Since no metrics are perfect (Wang et al., 2018), we should not just look at sample perplexity to judge how good a latent code is. Hence, we also investigate how much information can be encoded into latent codes. We believe that the mutual information term $I(\mathbf{z}; \mathbf{x})$ is a better metric regarding the usefulness of latent codes than sample

Table 4: Qualitative comparison between VAE and our proposed approach. First row: PTB samples generated from prior $p(\mathbf{z})$ by VAE (*upper half*) and WAE-RNF (*lower half*). Second row: Yelp samples generated from prior $p(\mathbf{z})$ by VAE (*upper half*) and WAE-RNF (*lower half*).

perplexity, as it tells us directly how much information we can infer from $\mathbf{x}$ by looking $\mathbf{z}$.

We use Monte Carlo method (Metropolis and Ulam, 1949) to get an approximation of $I(\mathbf{z}, \mathbf{x}) = KL(q(\mathbf{z}, \mathbf{x})||q(\mathbf{z})p(\mathbf{x})) = \mathbb{E}_{p(\mathbf{x})}[KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z}))] - KL(q(\mathbf{z})||p(\mathbf{z}))$. We compared mutual information between input $\mathbf{x}$ and latent codes $\mathbf{z}$ sampled from Euclidean latent space $\mathcal{Z}$ and Riemannian latent space $\mathcal{Z}'$ respectively. We see that even though NF does not necessarily help WAE to achieve the lowest perplexity, it does make latent codes to preserve more information about the input. For WAE trained with RNF, sample perplexity and mutual information metric are both good. It is cleary that $I(\mathbf{z}', \mathbf{x}) > I(\mathbf{z}, \mathbf{x})$, where $\mathbf{z}'$ is sampled from the curved space, and $\mathbf{z}$ is the sample transformed by the normal planar flow. This further strengthens our confidence over the usefulness of the curved latent space $\mathcal{Z}'$.

Generating Texts from latent spaces Another way to explore latent space is to look at the quality of generated texts. Here we compare sentences generated from methods that do not use Wasserstein objective and RNF with those generated from curved latent space $\mathcal{Z}'$ learned by WAE.

We observe that texts generated from flat Euclidean space are not as diverse as the ones generated from curved space learned by WAE-RNF. This is largely related to the nature of Wasserstein objective. In WAE, the KL-divergence $KL(q||p))$ between the prior and the posterior $q(\mathbf{z}|\mathbf{x})$ conditioned on each input $\mathbf{x}$ does not need to be small to optimize the Wasserstein objective. This indicates that the marginal $q(\mathbf{z})$ is able to match to the prior $p(\mathbf{z})$ while allowing each posterior $q(\mathbf{z}|\mathbf{x})$ to have a much more diverse support than that of a standard Gaussian $p(\mathbf{z})$. Therefore, if we randomly generate samples from curved latent space $\mathcal{Z}'$ many times, we are likely to get samples scattered in different support of distinct posterior conditioned on different input $\mathbf{x}$. Hence, the reconstructed sentences will have a much more diverse meaning or structure.

6 Conclusion

In this paper, we introduced Riemannian Normalizing Flow to train Wasserstein Autoencoder for text modeling. This new model encourages learned latent representation of texts to respect geometric characteristics of input sentences space. Our results show that RNF WAE does significantly improve the language modeling results by modeling the Riemannian geometric space via normalizing flow.

Abstract

Developing bots demands high quality training samples, typically in the form of user utterances and their associated intents. Given the fuzzy nature of human language, such datasets ideally must cover all possible utterances of each single intent. Crowdsourcing has widely been used to collect such inclusive datasets by paraphrasing an initial utterance. However, the quality of this approach often suffers from various issues, particularly language errors produced by unqualified crowd workers. More so, since workers are tasked to write open-ended text, it is very challenging to automatically asses the quality of paraphrased utterances. In this paper, we investigate common crowdsourced paraphrasing issues, and propose an annotated dataset called *Para-Quality*, for detecting the quality issues. We also investigate existing tools and services to provide baselines for detecting each category of issues. In all, this work presents a data-driven view of incorrect paraphrases during the bot development process, and we pave the way towards automatic detection of unqualified paraphrases.

1 Introduction

With the increasing advances in deep learning as well as natural language processing, a new generation of conversational agents is attracting significant attention (Dale, 2016). Also known as *dialogue systems*, *virtual assistants*, *chatbots* or simply *bots* (Campagna et al., 2017; Su et al., 2017), some advanced bots are now designed to perform complex tasks (e.g., *flight booking*), many of which are built using machine learning techniques.

At the heart of building such *task-oriented bots* lies the challenge of accurately capturing the user's intent (e.g., *find cafes in Chicago*), and then extracting its entities to service the request (e.g *term= "cafes", location="Chicago"*). However, its success relies heavily on obtaining both, large and high quality corpora of training samples showing mappings between sample utterances and intents. This is necessary given the ambiguous nature of the human language (Wasow et al., 2005) and large variations of expressions (Wang et al., 2012; Zamanirad et al., 2017).

A lack of variations in training samples can result in incorrect intent detection and consequently execution of undesirable tasks (e.g., booking an expensive hotel instead of a cheap room) (Henderson et al., 2018). Likewise, quality issues in the training samples can lead to unmitigated disasters (Neff and Nagy, 2016) as it happened to Microsoft's *Tay* by making a huge number of offensive commentaries due to biases in the training data (Henderson et al., 2018). It is therefore not surprising that research and development into training data acquisition for bots has received significant consideration (Campagna et al., 2017; Kang et al., 2018).

Collecting training samples usually involves two primary steps: (i) firstly, obtaining an initial utterance for a given user intent (e.g., *find a cafe in Chicago*); and (ii) secondly, paraphrasing this initial expression into multiple variations (Su et al., 2017; Campagna et al., 2017). Paraphrasing is thus vital to cover the variety of ways an expression can be specified (Yang et al., 2018a). As summarized in (McCarthy et al., 2009), a quality paraphrases has three components: semantic completeness, lexical difference, and syntactic difference. To obtain lexically and syntactically diverse paraphrase, crowdsourcing paraphrases has gained popularity in recent years. However, crowdsourced paraphrases need to be checked for quality, given that they are produced by unknown workers with varied skills and motivations (Campagna et al., 2017; Daniel et al., 2018). For example, spammers, malicious and even inexperi-

Proceedings of NAACL-HLT 2019, pages 295–306
Minneapolis, Minnesota, June 2 - June 7, 2019.

enced crowd-workers may provide misleading, erroneous, and semantically invalid paraphrases (Li et al., 2016; Campagna et al., 2017). Quality issues may also stem from misunderstanding the intent or not covering important information such as values of the intent parameters (Su et al., 2017).

The common practice for quality assessment of crowdsourced paraphrases is to design another crowdsourcing task in which workers validate the output from others. However, this approach is costly having to pay for the task twice, making domain-independent automated techniques a very appealing alternative. Moreover, quality control is especially desirable if done before workers submit their paraphrases, since low quality workers can be removed early on without any payment. This can also allow crowdsourcing tasks to provide feedback to users in order to assist them in generating high quality paraphrases (Nilforoshan et al., 2017; Nilforoshan and Wu, 2018). To achieve this, it is therefore necessary to automatically recognize quality issues in crowdsourced paraphrases during the process of bot development.

In this paper, we investigate common paraphrasing errors when using crowdsourcing, and we propose an annotated dataset called *Para-Quality* in which each paraphrase is labelled with the error categories. Accordingly, this work presents a quantitative data-driven study of incorrect paraphrases in bot development process and paves the way towards *enhanced* automated detection of unqualified paraphrased utterances. More specifically, our contributions are two-folded:

- We obtained a sample set of 6000 paraphrases using crowdsourcing. To aim for a broad diversity of samples, the initial expressions were sourced from 40 expressions of highly popular APIs from various domains. Next, we examined and analyzed these samples in order to identify a taxonomy of common paraphrase errors errors (e.g., cheating, misspelling, linguistic errors). Accordingly, we constructed an annotated dataset called *Para-Quality* (using both crowdsourcing and manual verification), in which the paraphrases were labeled with a range of different categorized errors.

- We investigated existing tools and services (e.g., spell and grammar checkers, language identifiers) to detect potential errors. We formulated baselines for each category of errors to determine if they were capable to automatically detect such issues. Our experiments indicate that existing tools often have low precision and recall, and hence our results advocates the need for new approaches in effective detection of paraphrasing issues.

2 Paraphrase Dataset Collection

Various types of paraphrasing issues have been reported in the literature, namely: spelling errors (Braunger et al., 2018), grammatical errors (Jiang et al., 2017; Negri et al., 2012), and missing slot-value (happens when a worker forget to include an entity in paraphrases) (Su et al., 2017). We collected paraphrases for two main reasons: (i) to have a hands-on experience on how incorrect paraphrases are generated, and (ii) to annotate the dataset for building and evaluating paraphrasing quality control systems.

Methodology. We obtained 40 expressions from various domains (i.e. *Yelp, Skyscanner, Spotify, Scopus, Expedia, Open Weather, Amazon AWS, Gamil, Facebook, Bing Image Search*) indexed in ThingPedia (Campagna et al., 2017) and API-KG[1]. We then launched a paraphrasing task on Figure-Eight[2]. Workers were asked to provide three paraphrases for a given expression (Jiang et al., 2017), which is common practice in crowdsourced paraphrasing to reduce repetitive results (Campagna et al., 2017; Jiang et al., 2017). In the provided expression, parameter values were highlighted and crowd-workers were asked to preserve them. Each worker's paraphrases for an initial utterance are normalized by lowercasing and removing punctuation. Next, the initial utterance and the paraphrases are compared to forbid submitting empty strings or repeated paraphrases, and checked if they contain highlighted parameter values (which is also a common practice to avoid missing parameter values) (Mitchell et al., 2014). We collected paraphrases from workers in English speaking countries, and created a dataset containing 6000 paraphrases (2000 triple-paraphrases) in total[3].

3 Common Paraphrasing Issues

To characterize the types of paraphrasing issues, two authors of this paper investigated the crowd-

---

[1] http://apikg.ngrok.io

[2] https://www.figure-eight.com

[3] https://github.com/mysilver/ParaQuality

sourced paraphrases, and recognized 5 primary categories of paraphrasing issues. However, we only considered paraphrase-level issues related to the validity of a paraphrase without considering dataset-level quality issues such as lexical diversity (Negri et al., 2012) and bias (Henderson et al., 2018).

3.1 Spelling Errors

Misspelling has been reported as one of most common mistakes in paraphrasing (Inaba et al., 2015; Wang et al., 2012; Chklovski, 2005; Braunger et al., 2018). In our sample set, we also noticed misspellings were generated both intentionally (as an act of cheating to quickly generate a paraphrase such as Example 2 in Table 1) and unintentionally (due to a lack of knowledge or a simple mistake such as Example 3 in Table 1).

3.2 Linguistic Errors

Linguistic errors are also common in crowdsourced natural language collections (Jiang et al., 2017; Negri et al., 2012). Verb errors, preposition errors, vocabulary errors (improper word substitutions), and incorrect singular/plural nouns, just to name a few. Moreover, capitalization and article errors seems abundant (e.g., Example 5 in Table 1). Given that real bot users also make such errors, it is important to have linguistically incorrect utterances in the training samples (Bapat et al., 2018). However, at a very least, detecting linguistic errors can contribute to quality-aware selection of crowd workers.

3.3 Semantic Errors

This occurs when a paraphrase deviates from the meaning of the initial utterance (e.g., *find cafes in Chicago*). As reported in various studies, workers may forget to mention parameter values (also known as missing slot)(e.g., *find cafes*)[4] (Crossley et al., 2016; Su et al., 2017; Ravichander et al., 2017; Wang et al., 2012; Braunger et al., 2018), provide wrong values (e.g., *find cafes in Paris*) (Su et al., 2017; Ravichander et al., 2017; Wang et al., 2012; Negri et al., 2012; Braunger et al., 2018), or add unmentioned parameter values(Wang et al., 2012) (e.g., *find two cafes in Chicago*). Workers may also incorrectly use a singular noun instead of its plural form, and vice versa. For instance, in Example 6 of Table 1, the paraphrase only asks for the status of one specific *burglar alarm* while the expression asks for the status of all *burglar alarms*. Making mistakes in paraphrasing complementary forms of words also exists in the crowdsourced dataset. For instance, in Example 7 of Table 1, assuming that the bot answers the question only by saying "YES" or "NO", the answer for the paraphrase differs from that of the expression. However, it will make no difference if the bot's response is more descriptive (e.g., "it's working", "it isn't working".) Finally, some paraphrases significantly diverge from expressions. For instance, in Example 8 of Table 1, the intent of paraphrase is to turn off the TV; however, that of initial utterance is to query about the TV status.

3.4 Task Misunderstanding

In some cases, workers misunderstood the task and provided translations in their own native languages (referred to as *Translation* issues) (Crossley et al., 2016; Braunger et al., 2018; Bapat et al., 2018), and some mistakenly thought they should provide answers for expressions phrased as questions (referred to as *Answering* issues) such as Example 9 in Table 1. This occurred even though workers were provided with comprehensive instructions and examples. We infer that some workers did not read the instructions, ignoring the possibility of cheating.

3.5 Cheating

In crowdsourced tasks, collecting paraphrases is not immune to unqualified workers, cheaters, or spammers (Daniel et al., 2018; Crossley et al., 2016; Chklovski, 2005).

Detecting malicious behaviour is vital because even constructive feedback may not guarantee quality improvements as workers act carelessly on purpose. *Cheating* is thus considered a special case of *Semantic Error* which is done intentionally. It is difficult even for experts to detect if someone is cheating or unintentionally making mistakes. However, it becomes easier when we consider all three paraphrases written by a worker for a given expression at once. For example, in Example 10 of Table 1, the malicious worker removes words one by one to generate new paraphrases. In this example, we also notice that it is still possible that a cheater produces a valid paraphrase accidentally such as the first paraphrase in Example 10. Workers may also start providing

[4] In our task design, this type of error cannot happen since parameter values are checked using regular expressions before submission

#	Label		Sample
1	Correct	**Expression**	*Create a public playlist named new_playlist*
		Paraphrase	▷ Make a public playlist named new_playlist
2	Spelling Errors	**Expression**	*Estimate the taxi fare from the airport to home*
		Paraphrase	▷ Estimate the taxi fare from the airport to hom
3	Spelling Errors	**Expression**	*Estimate the taxi fare from the airport to home*
		Paraphrase	▷ Tell me about the far from airport to home
4	Spelling Errors	**Expression**	*Where should I try coffee near Newtown?*
		Paraphrase	▷ Find cafes near Newtown
5	Linguistic Errors	**Expression**	*Estimate the taxi fare from the airport to home*
		Paraphrase	▷ How much for taxi from airport to home
6	Semantic Errors	**Expression**	*Are the burglar alarms in the office malfunctioning?*
		Paraphrase	▷ Is the burglar alarm faulty in our work place?
7	Semantic Errors	**Expression**	*Are the burglar alarms in the office malfunctioning?*
		Paraphrase	▷ Are the office alarms working?
8	Semantic Errors	**Expression**	*Is the TV in the house off?*
		Paraphrase	▷ Can you turn off the TV in the house if it's on?
9	Task Misunderstanding	**Expression**	*Estimate the taxi fare from the airport to home?*
		Paraphrase	▷ Airport to home is $50
10	Cheating	**Expression**	*Request a taxi from airport to home*
		Paraphrases	▷ A taxi from airport to home ▷ Taxi from airport to home ▷ From airport to home
11	Cheating	**Expression**	*I want reviews for McDonald at Kensington st.*
		Paraphrases	▷ I want reviews g for McDonald at Kensington st. ▷ I want for reviews for McDonald at Kensington st. ▷ I want reviegws for McDonald at Kensington st.
12	Cheating	**Expression**	*I want reviews for McDonald at Kensington st.*
		Paraphrases	▷ I want to do reviews for McDonald's in Kensington st. ▷ I would like to do reviews for McDonald's in Kensington st. ▷ I could do reviews for McDonald's in Kensington st.
13	Cheating	**Expression**	*Create a public playlist named NewPlaylist*
		Paraphrases	▷ That song hits the public NewPlaylist this year ▷ Public really loved that NewPlaylist played on the event ▷ Public saw many NewPlaylist this year
14	Cheating	**Expression**	*Estimate the taxi fare from the airport to home*
		Paraphrases	▷ What is the fare of taxi from airport to home ▷ Tell me about fare from airport to home ▷ You have high taxi fare airport to home

Table 1: Paraphrase Samples

faulty paraphrases after generating some correct paraphrases as shown in Example 14 of Table 1. Based on our observations, the simplest mode of cheating is to add a few random characters to the source sentence as shown in Example 11. Next is adding a few words to the source sentence without much editing as shown in Example 12. Finally, there are cheaters who rewrite and change the sentences substantially in a very random way such as Example 13.

4 Dataset Annotation

Next, we designed another crowdsourcing task to annotate the collected paraphrases according to the category of issues devised above. Namely, using following labels: *Correct*, *Semantic Error*, *Misspelling*, *Linguistic Error*, *Translation*, *Answering*, and *Cheating*. We split the category of misunderstanding issues into *Translation* and *Answering* because they require different methods to detect.

Methodology. In the annotation task, crowd workers were instructed to label each paraphrase with the paraphrasing issues. Next, to further increase the quality of annotations [5], two authors of this paper manually re-annotated the paraphrases to resolve disagreements between crowd annotators. Moreover, contradictory labels (e.g., a paraphrase cannot be labeled both *Correct* and *Misspelling* simultaneously) were checked to ensure consistency. The overall Kappa test showed a high agreement coefficient between the annotators (McHugh, 2012) by Kappa being 0.85. Table 2 also shows the pair-wise inter-annotator agree-

---

[5] because of weak agreement between crowd workers

Label	**Kappa**
Correct	0.900
Misspelling	0.972
Linguistic Errors	0.879
Translation	1.000
Answering	0.855
Cheating	0.936
Semantic Errors	0.833

Table 2: Pairwise Inter-Annotator Agreement

ment (Cohen, 1960). Next, the authors discussed and revised the re-annotated labels to further increase the quality of annotations by discussing and resolving disagreements.

Statistics. Figure 1 shows the frequencies of each label in the crowdsourced paraphrases as well as their co-occurrences in an UpSet plot (Lex et al., 2014) using Intervene (Khan and Mathelier, 2017). Accordingly we infer that only 61% of paraphrases are labeled *Correct*. This plot also shows how many times two labels co-occurred. For example, all paraphrases which are labeled *Translation* (24 times), are also labeled *Cheating*[6].

5 Automatic Error Detection

Automatically detecting paraphrasing issues, especially when done during the crowd task, can minimize the cost of crowdsourcing by eliminating malicious workers, reducing the number of erroneous paraphrases, and eliminating the need for launching another crowdsourced validation task. Moreover, by detecting *Misspelling* and *Linguistic Errors*, users can be provided with proper feedback to help them improve the quality of paraphrasing by showing the source of error and suggestions to address the error (e.g., "*Spelling error detected: articl → article*"). Detecting *Semantic Errors*, such as missing parameter values, can also help crowd workers to generate high quality correct paraphrases. Automated methods can also be used to identify low quality workers, and particularly cheaters who may generate potentially large amount of invalid paraphrases intentionally. Moreover, providing suggestions to cheaters will not help and therefore early detection is of paramount.

Spell Checker	**Precision**	**Recall**	**F1**
Aspell[8]	0.249	0.618	0.354
Hunspell[9]	0.249	0.619	0.355
MySpell[10]	0.249	0.619	0.355
Norvig[11]	0.488	0.655	0.559
Ginger[12]	0.540	0.719	0.616
Yandex[13]	0.571	0.752	0.650
Bing Spell Check[14]	0.612	**0.737**	0.669
LanguageTool[15]	**0.630**	0.727	**0.674**

Table 3: Comparison of Spell Checkers

In a pre-hoc quality control approach for crowdsourced paraphrases, the most important metric seems to be the *precision* of detecting invalid paraphrases (Nilforoshan et al., 2017). That is because the main aim of using such a quality control approach is rejecting invalid paraphrases without rejecting correct ones (Burrows et al., 2013). This is essential because rejecting correct paraphrases would be unfair and unproductive. For instance, sincere and trustful crowd workers might not get paid as a result of false-positives (incorrectly detected errors). On the other hand, having a high *recall* in detecting invalid paraphrases is important to eliminate faulty paraphrases and consequently obtain robust training samples.

Moreover, such a quality control technique should ideally be domain-independent, accessible, and easily-operated to minimize the cost of customization for a special domain and requiring paid experts (e.g., an open source pre-built machine learning model). In the rest of this section, we examine current tools and approaches and discuss their effectiveness in assessing the paraphrasing issues.

5.1 Spelling Errors

We employed several spell checkers as listed in Table 3 to examine if they are effective in recognizing spelling errors. We looked up Wikipedia, Github, and ProgrammableWeb[7] to find available tools and APIs for this purpose.

---

[6] We used *Google Translate* to check whether they were proper translations or just random sentences in other languages

[15] https://languagetool.org

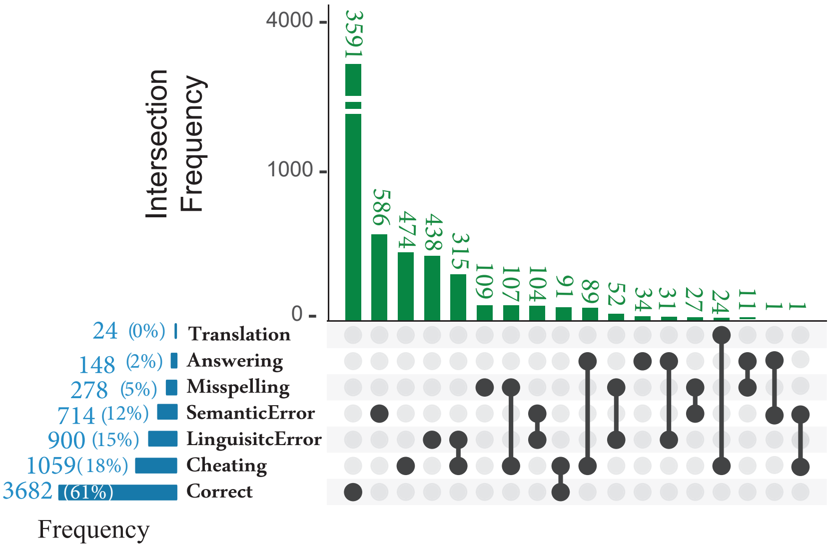

Figure 1: Dataset Label Statistics

Even though detecting misspelled words seems easy with existing automatic spellcheckers, they fall short in a few cases. This can be also concluded from Table 3 by considering the precision and recall of each spell checker in detecting only paraphrases with misspellings. For instance, spell checkers are often unable to identify homonyms (Perelman, 2016), incorrectly mark proper nouns and unusual words (Bernstein et al., 2015), and sometimes do not identify wrong words that are properly spelled (Chisholm and Henry, 2005). For instance, in Example 1 of Table 1, the "*new_playlist*" is incorrectly detected as a misspelled word by LanguageTool (the best performer as listed in Table 3). In Example 3, the word "*far*" is not detected even though the worker has misspelled the word "*fare*". In Example 4, the word "Newtown" (a suburb in Sydney) is mistakenly detected as a misspelling error. Some of these deficiencies can be addressed. For instance, in the case of spelling errors, assuming that the initial expressions given to the crowd are free of typos, we can ignore false-positives like the "Newtown" and "new_playlist".

5.2 Linguistic Errors

We investigated how well grammar checkers perform in detecting linguistic errors. We employed several grammar checkers as listed in Table 4.

Our experiments shows that spell checkers have both low precision and recall. Perelman (Perelman, 2016) also conducted several experiments with major commercial and non-commercial grammar checkers, and identified that grammar checkers are unreliable. Based on our observations, grammar checkers often fail in detecting linguistic errors as shown in Table 4. Examples include improper use of words (e.g., *"Who is the latest scientific article of machine learning?"*), random sequence of words generated by cheaters (e.g., *"Come the next sing"*), and missing articles[16] (e.g., *"I'm looking for flight for Tehran to Sydney"*). Given these examples, we believe that language models can be used to measure the likelihood of a sequence of words to detect if it is linguistically acceptable.

Grammar Checker	**Precision**	**Recall**	**F1**
AfterDeadline[17]	0.228	0.069	0.106
Ginger	0.322	**0.256**	**0.285**

LanguageTool	**0.388**	0.098	0.156

Table 4: Comparison of Grammar Checkers

5.3 Translation

We also investigated several language detectors to evaluate how well they perform when crowd workers use another language instead of English. The results of experiment in Table 5 indicate that these tools detect almost all sentences in other languages. But they produce lots of false-positives including for correct English sentences (e.g., *"play next song"*). As a result, the tools in our experi-

DetectLanguage+	**0.909**	**1.000**	**0.952**

Table 5: Language Detection

ment have low precision in detecting languages as shown in Table 5. Most of the false-positives are caused by sentences that contain unusual words such as misspellings and named entities in the sentence (e.g., Email *Phil* saying "I got you").

One possible approach to improve the precision of such tools and APIs is to check if a given paraphrase has spelling errors prior to using language detection tools. We therefore extended the *DetectLanguage* (the best performing tool) by adding a constraint: a sentence is not written in another language unless it has at least two spelling errors. This constraint is based on the assumption that spell checkers treat foreign words as spelling errors and a sentence has at least two words to be called a sentence. This approach (*DetectLanguage*+ in Table 5) significantly reduced the number of false-positives and thus improved precision.

5.4 Answering

Dialog Acts (DAs) (Jurafsky and Martin, 2018), also known as speech acts, represent general intents of an utterance. DA tagging systems label utterances with a predefined set of utterance types (*Directive, Commissive, Informative, etc* (Mezza et al., 2018).) Based on the fact that DAs must remain consistent during paraphrasing, we employed a state-of-art, domain-independent, pre-trained DA tagger proposed in (Mezza et al., 2018). For example, if an initial utterance is a *question* (e.g., *are there any cafes nearby?*) it is acceptable to paraphrase it into a *directive* sentence (e.g., *find cafes nearby.*), but its speech act cannot be *informative* (e.g., there is a cafe on the corner.). Overall, due to the lack of any other domain-independent DA tagger for the English language, we only investigated this tagger. We found that it has a precision of 2% with recall of 63%. This shows that detecting speech acts is a very challenging task especially for domain-independent environments.

Advances in speech act detection and availability of public speech act datasets can assist in detecting this category of the paraphrasing issues. Moreover, it is feasible to automatically generate pairs of questions and answers by mining datasets in the fields of Question Answering and dialog systems. Automatically building such pairs can help building a dataset which is diverse enough to be used in practice. Such a dataset can be fed into deep learning algorithms to yield better performance in detecting *Answering* issues.

5.5 Semantic Errors & Cheating

To the best our knowledge, there is not yet an approach to distinguish between categories of semantically invalid paraphrases. Paraphrase detection and textual semantic similarity (STS) methods are designed to measure how two pieces of text are semantically similar. However, they do not differentiate between different types of errors (e.g., *Cheating*, *Answering*, *Semantic Errors*) in our settings. As such, these techniques are not directly applicable. In the rest of this section, we focus on building machine learning models to detect the paraphrasing errors.

For this purpose, we used 38 established features from the literature as summarized in Table 6. Using these features and Weka (Hall et al., 2009), we built various classifiers to detect the following paraphrasing issues: *Answering*, *Semantic Errors*, and *Cheating*. We chose to test the five classification algorithms applied in paraphrasing literature as mentioned in (Burrows et al., 2013): C4.5 Decision Tree, K-Nearest Neighbor (K=50), Maximum Entropy, Naive Bayes, and Support Vector Machines (SVM) using default Weka 3.6.13 parameters for each of the classification algorithms. We also experimented with Random Forest algorithm since it is a widely-used classifier. We did not apply deep learning based classifiers directly due to the lack of expressions in the collected dataset which seems essential for developing domain independent classifiers. While our dataset is reasonably large, it contains only 40 expressions (each having 150 paraphrases). Given that deep learn-

ing techniques are data thirsty (Goodfellow et al., 2016; Yang et al., 2018a), to use these kinds of models and eliminate the burden of manual feature engineering, much more expressions are needed. Instead, we benefited from the state-of-art sentence encoders via Transfer Learning as listed in Table 6.

Table 7, 8, and 9 demonstrate the performance of various classifiers (excluding classifiers with F1 being less than 0.2) for each of paraphrasing issues using 10-fold cross validation. To keep the classifiers domain-independent, we split the dataset based on the expressions without sharing any paraphrases of a single expression between the test and train samples. It can be seen that automatically detecting these quality issues is very challenging; even the best performing classifier has a very low F1 score especially for detecting *Answering* and *Semantic Error* issues. Based on manual exploration, we also found that the classifiers fail to recognize complex cheating behaviours such as Example 13 in Table 1 as discussed in Section 3. Therefore, new approaches are required to accurately detect paraphrasing issues. Based on our explorations and a prior work (McCarthy et al., 2009), we postulate that accurately detecting linguistic errors such as grammatically incorrect paraphrases can play indispensable role in detecting cheating behaviours. Moreover, advances in measuring semantic similarity between sentences can help differentiate between semantically invalid paraphrases and correct ones.

5.6 Incorrect Paraphrases Detection

We also assessed the performance of detecting incorrect paraphrases regardless of their categories. In this setting, we labeled all incorrect sentences with a single label (*"Incorrect"*) regardless of their categories. Table 10 demonstrates the performance of various classifiers. Detecting incorrect paraphrases is useful for post-hoc quality control to remove incorrect paraphrases after crowdsourcing paraphrases and consequently eliminate the need for crowdsourced validation task.

6 Related Work

To the best of our knowledge, that our work is the first to categorize paraphrasing issues and propose

Table 10: Automatic Incorrect Paraphrase Detection

an annotated dataset for assessing quality issues of paraphrased user expressions. Nevertheless, our work is related to the areas of (i) quality control in crowdsourced natural language datasets; and (ii) semantic similarity.

Quality Control. Quality can be assessed after or before data acquisition. While *post-hoc* methods evaluate quality when all paraphrases are collected, *pre-hoc* methods can prevent submission of low quality paraphrases during crowdsourcing. The most prevalent *post-hoc* approach is launching a verification task to evaluate crowdsourced paraphrases (Negri et al., 2012; Tschirsich and Hintz, 2013). However, automatically removing misspelled paraphrases (Wang et al., 2012) and discarding submissions from workers with low/high task completion time (Ma et al., 2017) are also applied in literature. Machine learning models have also been explored in plagiarism detection systems to assure quality of crowdsourced paraphrases (Crossley et al., 2016; Burrows et al., 2013).

Pre-hoc methods, on the other hand, rely on online approaches to asses the quality of the data provided during crowdsourcing (Nilforoshan et al., 2017). Sophisticated techniques are required to avoid generation of erroneous paraphrases (e.g., automatic feedback generation was used to assist crowd workers in generating high quality paraphrases). Precog (Nilforoshan et al., 2017) is an example of such tools which is based on a supervised method for generating automatic writing feedback for multi-paragraph text– designed mostly for crowdsourced product reviews (Nilforoshan et al., 2017; Nilforoshan and Wu, 2018). This paper aims for paving the way for building automatic *pre-hoc* approaches, and providing appropriate online feedback to users to assist them in generating appropriate paraphrases. However, the provided dataset can also be used for building *post-hoc* methods to automatically omit faulty paraphrases.

Semantic Similarity. Measuring similarity between units of text plays an important role in Natural Language Processing (NLP). Several NLP tasks have been designed to cover various aspects and usages of textual similarity. Examples include textual entailment, semantic textual similarity (Yang et al., 2018b; Fakouri-Kapourchali et al., 2018), paraphrase detection (Agarwal et al., 2018; Issa et al., 2018), duplicate question detection (Mannarswamy and Chidambaram, 2018) tasks which are studied well in NLP. Moreover, recent success in sentence encoders (e.g., Sent2Vec (Pagliardini et al., 2018), InferSent (Conneau et al., 2017), Universal Sentence Encoder (Cer et al., 2018), and Concatenated Power Mean Embeddings (Rücklé et al., 2018)) can be exploited to detect paraphrasing issues with more accuracy. These techniques can be borrowed with some domain specific considerations to build automatic quality control systems for detecting low quality paraphrases.

7 Conclusion

In this paper, we employed a data-driven approach to investigate and quantitatively study various crowdsourced paraphrasing issues. We discussed how automatic techniques for detecting various quality issues can assist the manual process of crowdsourced paraphrasing. We collected an annotated dataset of crowdsourced paraphrasing in which each paraphrase is labeled with associated paraphrasing issues. We used this dataset to assess existing tools and techniques and to determine whether they are sufficient for automatically detecting such issues. Our experiments revealed that automated detection of errors in paraphrases is a challenging task. As a future work, we will be working on devising automated-assisted methods for detection of paraphrasing issues. This will be based on a two-way feedback mechanism: generating feedback for workers, while at the same time the system learns from the (data of) users to improve its machine intelligence. In time, we envision increasingly less dependence on users.

Abstract

To bridge the gap between the capabilities of the state-of-the-art in factoid question answering (QA) and what users ask, we need large datasets of real user questions that capture the various question phenomena users are interested in, and the diverse ways in which these questions are formulated. We introduce *ComQA*, a *large* dataset of *real* user questions that exhibit different *challenging aspects* such as *compositionality*, *temporal reasoning*, and *comparisons*. ComQA questions come from the WikiAnswers community QA platform, which typically contains questions that are not satisfactorily answerable by existing search engine technology. Through a large crowdsourcing effort, we clean the question dataset, group questions into *paraphrase clusters*, and annotate clusters with their answers. ComQA contains $11,214$ questions grouped into 4,834 paraphrase clusters. We detail the process of constructing ComQA, including the measures taken to ensure its high quality while making effective use of crowdsourcing. We also present an extensive analysis of the dataset and the results achieved by state-of-the-art systems on ComQA, demonstrating that our dataset can be a driver of future research on QA.

1 Introduction

Factoid QA is the task of answering natural language questions whose answer is one or a small number of entities (Voorhees and Tice, 2000). To advance research in QA in a manner consistent with the needs of end users, it is important to have access to datasets that reflect *real* user information needs by covering various *question phenomena* and the wide *lexical and syntactic variety* in expressing these information needs. The benchmarks should be large enough to facilitate the use of data-hungry machine learning methods. In this paper, we present ComQA, a large dataset of 11,214 real user questions collected from the WikiAnswers community QA website. As shown in Figure 1, the dataset contains various question phenomena. ComQA questions are grouped into 4,834 paraphrase clusters through a large-scale crowdsourcing effort, which capture lexical and syntactic variety. Crowdsourcing is also used to pair paraphrase clusters with answers to serve as a supervision signal for training and as a basis for evaluation.

Table 1 contrasts ComQA with publicly available QA datasets. The foremost issue that ComQA tackles is ensuring research is driven by information needs formulated by real users. Most large-scale datasets resort to highly-templatic synthetically generated natural language questions (Bordes et al., 2015; Cai and Yates, 2013; Su et al.,

Table 1: Comparison of ComQA with existing QA datasets over various dimensions.

2016; Talmor and Berant, 2018; Trivedi et al., 2017). Other datasets utilize search engine logs to collect their questions (Berant et al., 2013), which creates a bias towards simpler questions that search engines can already answer reasonably well. In contrast, ComQA questions come from WikiAnswers, a community QA website where users pose questions to be answered by other users. This is often a reflection of the fact that such questions are beyond the capabilities of commercial search engines and QA systems. Questions in our dataset exhibit a wide range of interesting aspects such as the need for temporal reasoning (Figure 1, cluster 1), comparison (Figure 1, cluster 2), compositionality (multiple subquestions with multiple entities and relations) (Figure 1, cluster 3), and unanswerable questions (Figure 1, cluster 4).

ComQA is the result of a carefully designed large-scale crowdsourcing effort to group questions into paraphrase clusters and pair them with answers. Past work has demonstrated the benefits of paraphrasing for QA (Abujabal et al., 2018; Berant and Liang, 2014; Dong et al., 2017; Fader et al., 2013). Motivated by this, we judiciously use crowdsourcing to obtain clean paraphrase clusters from WikiAnswers' noisy ones, resulting in ones like those shown in Figure 1, with both lexical and syntactic variations. The only other dataset to provide such clusters is that of Su et al. (2016), but that is based on synthetic information needs.

For answering, recent research has shown that combining various resources for answering significantly improves performance (Savenkov and Agichtein, 2016; Sun et al., 2018; Xu et al., 2016). Therefore, we do not pair ComQA with a specific knowledge base (KB) or text corpus for answering. We call on the research community to innovate in combining different answering sources to tackle ComQA and advance research in QA. We use crowdsourcing to pair paraphrase clusters with answers. ComQA answers are primarily Wikipedia entity URLs. This has two motivations: (i) it builds on the example of search engines that use Wikipedia entities as answers for entity-centric queries (e.g., through knowledge cards), and (ii) most modern KBs ground their entities in Wikipedia. Wherever the answers are temporal or measurable quantities, we use TIMEX3[1] and the International System of Units[2] for normalization. Providing canonical answers allows for better comparison of different systems.

We present an extensive analysis of ComQA, where we introduce the various question aspects of the dataset. We also analyze the results of running state-of-the-art QA systems on ComQA. ComQA exposes major shortcomings in these systems, mainly related to their inability to handle compositionality, time, and comparison. Our detailed error analysis provides inspiration for avenues of future work to ensure that QA systems meet the expectations of real users. To summarize, in this paper we make the following contributions:

- We present a dataset of 11,214 real user questions collected from a community QA website. The questions exhibit a range of aspects that are important for users and challenging for existing QA systems. Using crowdsourcing, questions are grouped into 4,834 paraphrase clusters that are annotated with answers. ComQA is available at: `http://qa.mpi-inf.mpg.de/comqa`.
- We present an extensive analysis and quantify the various difficulties in ComQA. We also present the results of state-of-the art QA systems on ComQA, and a detailed error analysis.

2 Related Work

There are two main variants of the factoid QA task, with the distinction tied to the underlying answering resources and the nature of answers. Traditionally, QA has been explored over large textual corpora (Cui et al., 2005; Harabagiu et al., 2001, 2003; Ravichandran and Hovy, 2002; Saquete et al., 2009) with answers being textual phrases. Recently, it has been explored over large structured resources such as KBs (Berant et al., 2013; Unger et al., 2012), with answers being semantic entities. Recent work demonstrated that the two variants are complementary, and a combination of the two results in the best performance (Sun et al., 2018; Xu et al., 2016).

QA over textual corpora. QA has a long tradition in IR and NLP, including benchmarking tasks in TREC (Voorhees and Tice, 2000; Dietz and Gamari, 2017) and CLEF (Magnini et al., 2004; Herrera et al., 2004). This has predominantly focused on retrieving answers from textual sources (Ferrucci, 2012; Harabagiu et al., 2006; Prager et al., 2004; Saquete et al., 2004; Yin et al., 2015). In IBM Watson (Ferrucci, 2012), structured data played a role, but text was the main source for answers. The TREC QA evaluation series provide hundreds of questions to be answered over documents, which have become widely adopted benchmarks for answer sentence selection (Wang and Nyberg, 2015). ComQA is orders of magnitude larger than TREC QA.

Reading comprehension (RC) is a recently introduced task, where the goal is to answer a question from a *given* textual paragraph (Kociský et al., 2017; Lai et al., 2017; Rajpurkar et al., 2016; Trischler et al., 2017; Yang et al., 2015). This setting is different from factoid QA, where the goal is to answer questions from a large repository of data (be it textual or structured), and not a single paragraph. A recent direction in RC is dealing with unanswerable questions from the underlying data (Rajpurkar et al., 2018). ComQA includes such questions to allow tackling the same problem in the context of factoid QA.

QA over KBs. Recent efforts have focused on natural language questions as an interface for KBs, where questions are translated to structured queries via semantic parsing (Bao et al., 2016; Bast and Haussmann, 2015; Fader et al., 2013; Mohammed et al., 2018; Reddy et al., 2014; Yang et al., 2014; Yao and Durme, 2014; Yahya et al., 2013). Over the past five years, many datasets were introduced for this setting. However, as Table 1 shows, they are either small in size (Free917, and ComplexQuestions), composed of synthetically generated questions (SimpleQuestions, GraphQuestions, LC-QuAD and ComplexWebQuestions), or are structurally simple (WebQuestions). ComQA addresses these shortcomings. Returning semantic entities as answers allows users to further explore these entities in various resources such as their Wikipedia pages, Freebase entries, etc. It also allows QA systems to tap into various interlinked resources for improvement (e.g., to obtain better lexicons, or train better NER systems). Because of this, ComQA provides semantically grounded reference answers in Wikipedia (without committing to Wikipedia as an answering resource). For numerical quantities and dates, ComQA adopts the International System of Units and TIMEX3 standards, respectively.

3 Overview

In this work, a factoid question is a question whose answer is one or a small number of entities or literal values (Voorhees and Tice, 2000) e.g., *"Who were the secretaries of state under Barack Obama?"* and *"When was Germany's first post-war chancellor born?"*.

3.1 Questions in ComQA

A question in our dataset can exhibit *one or more* of the following phenomena:

- **Simple:** questions about a single property of an entity (e.g., *"Where was Einstein born?"*)
- **Compositional:** A question is compositional if answering it requires answering more primitive questions and combining these. These can be *intersection* or *nested* questions. Intersection questions are ones where two or more subquestions can be answered independently, and their answers intersected (e.g., *"Which films featuring Tom Hanks did Spielberg direct?"*). In nested questions, the answer to one subquestion is necessary to answer another (*"Who were the parents of the thirteenth president of the US?"*).
- **Temporal:** These are questions that require temporal reasoning for deriving the answer, be it explicit (e.g., *'in 1998'*), implicit (e.g., *'during the WWI'*), relative (e.g., *'current'*), or latent (e.g. *'Who is the US president?'*). Temporal questions also include those *whose answer*

is an explicit temporal expression (*"When did Trenton become New Jersey's capital?"*).

- **Comparison:** We consider three types of comparison questions: *comparatives* (*"Which rivers in Europe are longer than the Rhine?"*), *superlatives* (*"What is the population of the largest city in Egypt?"*), and *ordinal* questions (*"What was the name of Elvis's first movie?"*).
- **Telegraphic** (Joshi et al., 2014): These are short questions formulated in an informal manner similar to keyword queries (*"First president India?"*). Systems that rely on linguistic analysis often fail on such questions.
- **Answer tuple**: Where an answer is a tuple of connected entities as opposed to a single entity (*"When and where did George H. Bush go to college, and what did he study?"*).

3.2 Answers in ComQA

Recent work has shown that the choice of answering resource, or the combination of resources significantly affects answering performance (Savenkov and Agichtein, 2016; Sun et al., 2018; Xu et al., 2016). Inspired by this, ComQA is not tied to a specific resource for answering. To this end, answers in ComQA are primarily Wikipedia URLs. This enables QA systems to combine different answering resources which are linked to Wikipedia (e.g., DBpedia, Freebase, YAGO, Wikidata, etc). This also allows seamless comparison across these QA systems. An answer in ComQA can be:

- **Entity:** ComQA entities are grounded in Wikipedia. However, Wikipedia is inevitably incomplete, so answers that cannot be grounded in Wikipedia are represented as plain text. For example, the answer for *"What is the name of Kristen Stewart adopted brother?"* is {Taylor Stewart, Dana Stewart}.
- **Literal value:** Temporal answers follow the TIMEX3 standard. For measurable quantities, we follow the International System of Units.
- **Empty:** In the factoid setting, some questions can be based on a false premise, and hence, are unanswerable e.g., *"Who was the first human being on Mars?"* (no human has been on Mars, yet). The correct answer to such questions is the empty set. Such questions allow systems to cope with these cases. Recent work has started looking at this problem (Rajpurkar et al., 2018).

4 Dataset Construction

Our goal is to collect factoid questions that represent real information needs and cover a range of question aspects. Moreover, we want to have different paraphrases for each question. To this end, we tap into the potential of community QA platforms. Questions posed there represent real information needs. Moreover, users of those platforms provide (noisy) annotations around questions e.g., paraphrase clusters. In this work, we exploit the annotations where users mark questions as duplicates as a basis for paraphrase clusters, and clean those. Concretely, we started with the WikiAnswers crawl by Fader et al. (2014). We obtained ComQA from this crawl primarily through a large-scale crowdsourcing effort, which we describe in what follows.

The original resource curated by Fader et al. contains 763M questions. Questions in the crawl are grouped into 30M paraphrase clusters based on feedback from WikiAnswers users. This clustering has a low accuracy (Fader et al., 2014). Extracting factoid questions and cleaning the clusters are thus essential for a high-quality dataset.

4.1 Preprocessing of WikiAnswers

To remove non-factoid questions, we filtered out questions that (i) start with *'why'*, or (ii) contain words like *(dis)similarities, differences, (dis)advantages*, etc. Questions matching these filters are out of scope as they require a narrative answer. We also removed questions with less than three or more than twenty words, as we found these to be typically noisy or non-factoid questions. This left us with about 21M questions belonging to 6.1M clusters.

To further focus on factoid questions, we automatically classified questions into one or more of the following *four classes*: (1) temporal, (2) comparison, (3) single entity, and (4) multi-entity questions. We used SUTime (Chang and Manning, 2012) to identify temporal questions and the Stanford named entity recognizer (Finkel et al., 2005) to detect named entities. We used part-of-speech patterns to identify comparatives, superlatives, and ordinals. Clusters which did not have questions belonging to any of the above classes were discarded from further consideration. Although these clusters contain false negatives e.g., *"What official position did Mendeleev hold until his death?"* due to errors by the tagging tools,

"Who was henry VII son?"
"Who was henry's vii sons?"

"Henry VII of England second son?"

"When did henry 7th oldest son die?"

"Who was Henry vii's oldest son?"
"Who is king henry VII eldest son?"
"What was the name of Henry VII first son?"
"Who was henry vII eldest son?"
"What was henry's vii oldest son?"
"Who was the oldest son of Henry VII?"

Figure 2: A WikiAnswers cluster split into four clusters by AMT Turkers.

most discarded questions are out-of-scope.

Manual inspection. We next applied the first stage of human curation to the dataset. Each WikiAnswers cluster was assigned to one of the four classes above based on the majority label of the questions within. We then randomly sampled 15K clusters from each of the four classes (60K clusters in total with 482K questions) and sampled a representative question from each of these clusters at random (60K questions). We relied on the assumption that questions within the same cluster are semantically equivalent. These 60K questions were manually examined by the authors and those with unclear or non-factoid intent were removed along with the cluster that contains them. We thus ended up with 2.1K clusters with 13.7K questions.

4.2 Curating Paraphrase Clusters

We inspected a random subset of the 2.1K WikiAnswers clusters and found that questions in the same cluster are semantically *related but not necessarily equivalent*, which is in line with observations in previous work (Fader et al., 2014). Dong et al. (2017) reported that 45% of question pairs were related rather than genuine paraphrases. For example, Figure 2 shows 10 questions in the same WikiAnswers cluster. Obtaining accurate paraphrase clusters is crucial to any systems that want to utilize them (Abujabal et al., 2018; Berant and Liang, 2014; Dong et al., 2017). We therefore utilized crowdsourcing to clean the Wikianswers paraphrase clusters. We used Amazon Mechanical Turk (AMT) to identify semantically equivalent questions within a WikiAnswers cluster, thereby obtaining cleaner clusters for ComQA. Once we had the clean clusters, we set up a second AMT task to collect answers for each ComQA cluster.

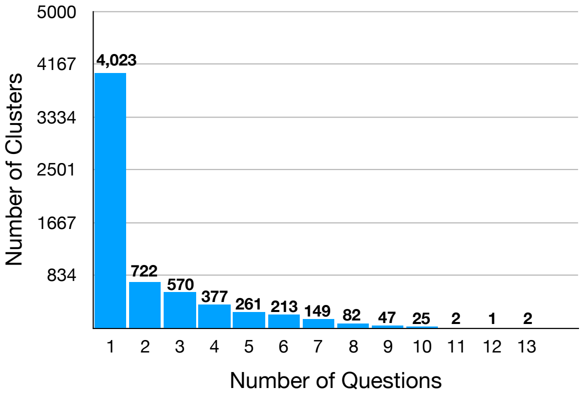

Figure 3: The distribution of questions in clusters.

Task design. We had to ensure the simplicity of the task to obtain high quality results. Therefore, rather than giving workers a WikiAnswers cluster and asking them to partition it into clusters of paraphrases, we showed them pairs of questions from a cluster and asked them to make the binary decision of whether the two questions are paraphrases. To reduce potentially redundant annotations, we utilized the transitivity of the paraphrase relationship. Given a WikiAnswers cluster $Q = \{q_1, ..., q_n\}$, we proceed in rounds to form ComQA clusters. In the first round, we collect annotations for each pair (q_i, q_{i+1}). The majority annotation among five annotators is taken. An initial clustering is formed accordingly, with clusters sharing the same question merged together (to account for transitivity). This process continues iteratively until no new clusters can be formed from Q.

Task statistics. We obtained annotations for 18,890 question pairs from 175 different workers. Each pair was shown to five different workers, with 65.7% of the pairs receiving unanimous agreement, 21.4% receiving four agreements and 12.9% receiving three agreements. By design, with five judges and binary annotations, no pair can have less three agreements. This resulted in questions being placed in paraphrase clusters, and no questions were discarded at this stage. At the end of this step, the original 2.1K WikiAnswers clusters became 6.4K ComQA clusters with a total of 13.7K questions. Figure 3 shows the distribution of questions in clusters.

To test whether relying on the transitivity of the

Property	**Example**	**Percentage%**
Compositional questions		
Conjunction	*“What is the capital of the country whose northern border is Poland and Germany?”*	17.67
Nested	*“When is Will Smith’s oldest son’s birthday?”*	14.33
Temporal questions		
Explicit time	*“Who was the winner of the World Series **in 1994?**”*	4.00
Implicit time	*“Who was Britain’s leader **during WW1?**”*	4.00
Temporal answer	*“**When** did Trenton become New Jersey’s capital?”*	15.67
Comparison questions		
Comparative	*“Who was the first US president to serve **2 terms**?”*	1.00
Superlative	*“What ocean does the **longest** river in the world flow into?”*	14.33
Ordinal	*“When was Thomas Edisons **first** wife born?”*	14.00
Question formulation		
Telegraphic	*“Neyo first album?”*	8.00
Entity distribution in questions		
Zero entity	*“What public company has the most employees in the world?”*	2.67
Single entity	*“Who is **Brad Walst**’s wife?”*	75.67
Multi-entity	*“What country in **South America** lies between **Brazil** and **Argentina**?”*	21.67
Other features		
Answer tuple	*“**Where** was Peyton Manning born and **what year was he born**?”*	2.00
Empty answer	*“Who was Calgary’s first woman mayor?”*	3.67

Table 2: Results of the manual analysis of 300 questions. Note that properties are not mutually exclusive.

paraphrase relationship is suitable to reduce the annotation effort, we asked annotators to annotate 1,100 random pairs (q_1, q_3), where we had already received positive annotations for the pairs (q_1, q_2) and (q_2, q_3) being paraphrases of each other. In 93.5% of the cases there was agreement. Additionally, as experts on the task, the authors manually assessed 600 pairs of questions, which serve as honeypots. There was 96.6% agreement with our annotations. An example result of this task is shown in Figure 2, where Turkers split the original WikiAnswers cluster into the four clusters shown.

4.3 Answering Questions

We were now in a position to obtain an answer annotation for each of the 6.4K clean clusters.

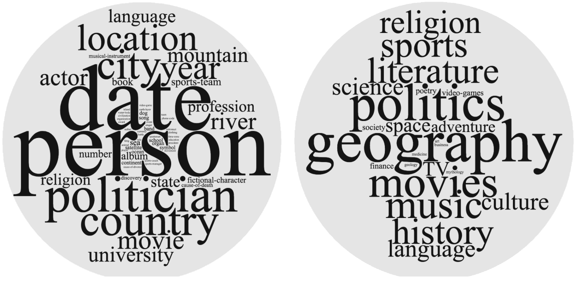
Task design. To collect answers, we designed another AMT task, where workers were shown a representative question randomly drawn from a cluster. Workers were asked to use the Web to find answers and to provide the corresponding URLs of Wikipedia entities. Due to the inevitable incompleteness of Wikipedia, workers were asked to provide the surface form of an answer entity if it does not have a Wikipedia page. If the answer is a full date, workers were asked to follow dd-mmm-yyyy format. For measurable quantities, workers were asked to provide units. We use TIMEX3 and the international system of units for normalizing temporal answers and measurable quantities e.g., *‘12th century’* to `11XX`. If no answer is found, workers were asked to type in *‘no answer’*.

Task statistics. Each representative question was shown to three different workers. An answer is deemed correct if it is common between at least two workers. This resulted in 1.6K clusters (containing 2.4K questions) with no agreed-upon answers, which were dropped. For example, *“Who was the first democratically elected president of Mexico?”* is subjective. Other questions received related answers e.g., *“Who do the people in Iraq worship?”* with `Allah`, `Islam` and `Mohamed` as answers from the three annotators. Other questions were underspecified e.g., *“Who was elected the vice president in 1796?”*. At the end of the task, we ended up with 4,834 clusters with 11,214 question-answer pairs, which form ComQA.

5 Dataset Analysis

In this section, we present a manual analysis of 300 questions sampled at random from the ComQA dataset. This analysis helps understand the different aspects of our dataset. A summary of the analysis is presented in Table 2.

Question categories. We categorized each question as either simple or complex. A question is complex if it belongs to one or more of the compositional, temporal, or comparison classes. 56.33% of the questions were complex; 32% compositional, 23.67% temporal, and 29.33% contain



(a) Answer types (b) Question topics

Figure 4: Answer types and question topics on 300 annotated examples as word clouds.

comparison conditions. A question may contain multiple conditions (*"What country has the **highest** population in the year **2008**?"* with comparison and temporal conditions).

We also identified questions of telegraphic nature e.g., *"Julia Alvarez's parents?"*, with 8% of our questions being telegraphic. Such questions pose a challenge for systems that rely on linguistic analysis of questions (Joshi et al., 2014).

We counted the number of named entities in questions: 23.67% contain two or more entities, reflecting their compositional nature, and 2.67% contain no entities e.g., *"What public company has the most employees in the world?"*. Such questions can be hard as many methods assume the existence of a pivot entity in a question.

Finally, 3.67% of the questions are unanswerable, e.g., *"Who was the first human being on Mars?"*. Such questions incentivise QA systems to return non-empty answers only when suitable. In Table 3 we compare ComQA with other current datasets based on real user information needs over different question categories.

Answer types. We annotated each question with the most fine-grained context-specific answer type (Ziegler et al., 2017). Answers in ComQA belong to a diverse set of types that range from coarse (e.g., `person`) to fine (e.g., `sports manager`). Types also include literals such as `number` and `date`. Figure 4(a) shows answer types of the 300 annotated examples as a word cloud.

Question topics. We annotated questions with topics to which they belong (e.g., geography, movies, sports). These are shown in Figure 4(b), and demonstrate the topical diversity of ComQA.

Question length. Questions in ComQA are fairly long, with a mean length of 7.73 words, indicating the compositional nature of questions.

6 Experiments

In this section we present experimental results for running ComQA through state-of-the-art QA systems. Our experiments show that these systems achieve humble performance on ComQA. Through a detailed analysis, this performance can be attributed to systematic shortcomings in handling various question aspects in ComQA.

6.1 Experimental Setup

Splits. We partition ComQA into a random train/dev/test split of 70/10/20% with 7,850, 1,121 and 2,243 questions, respectively.

Metrics. We follow the community's standard evaluation metrics: we compute average precision, recall, and F1 scores across all test questions. For unanswerable questions whose correct answer is the empty set, we define precision and recall to be 1 for a system that returns an empty set, and 0 otherwise (Rajpurkar et al., 2018).

6.2 Baselines

We evaluated two categories of QA systems that differ in the underlying answering resource: either KBs or textual extractions. We ran the following systems: (i) Abujabal et al. (2017), which automatically generates templates using question-answer pairs; (ii) Bast and Haussmann (2015), which instantiates hand-crafted query templates followed by query ranking; (iii) Berant and Liang (2015), which relies on agenda-based parsing and imitation learning; (iv) Berant et al. (2013), which uses rules to build queries from questions; and (v) Fader et al. (2013), which maps questions to queries over open vocabulary facts extracted from Web documents. Note that our intention is not to assess the quality of these systems, but to assess how challenging ComQA is.

The systems were trained with ComQA data. All systems were run over the data sources for which they were designed. The first four baselines are over Freebase. We therefore mapped ComQA answers (Wikipedia entities) to the corresponding Freebase names using the information stored with entities in Freebase. We observe that the Wikipedia answer entities have no counterpart in Freebase for 7% of the ComQA questions. This suggests an oracle F1 score of 93.0. For Fader et al. (2013), which is over web extractions, we mapped Wikipedia URLs to their titles.

Dataset	**Size**	**Compositional**	**Temporal**	**Comparison**	**Telegraphic**	**Empty Answer**
ComQA	11,214	32%	24%	30%	8%	4%
WebQuestions (Berant et al., 2013)	5,810	2%	7%	2%	0%	0%
ComplexQuestions (Bao et al., 2016)	2,100	39%	34%	9%	0%	0%

Table 3: Comparison of ComQA with existing datasets over various phenomena. We manually annotated 100 random questions from each dataset.

	Avg. Prec	**Avg. Rec**	**Avg. F1**
Abujabal et al. (2017)	21.2	38.4	22.4
Bast and Haussmann (2015)	20.7	37.6	21.6
Berant and Liang (2015)	10.7	15.4	10.6
Berant et al. (2013)	13.7	20.1	12.0
Fader et al. (2013)	7.22	6.59	6.73

Table 4: Results of baselines on ComQA test set.

	WebQuestions F1	**Free917 Accuracy**	**ComQA F1**
Abujabal et al. (2017)	51.0	78.6	22.4
Bast and Haussmann (2015)	49.4	76.4	21.6
Berant and Liang (2015)	49.7	–	10.6
Berant et al. (2013)	35.7	62.0	12.0

Table 5: Results of baselines on different datasets.

6.3 Results

Table 4 shows the performance of the baselines on the ComQA test set. Overall, the systems achieved poor performance, suggesting that current methods cannot handle the complexity of our dataset, and that new models for QA are needed. Table 5 compares the performance of the systems on different datasets (Free917 uses accuracy as a quality metric). For example, while Abujabal et al. (2017) achieved an F1 score of 51.0 on WebQuestions, it achieved 22.4 on ComQA.

The performance of Fader et al. (2013) is worse than the others due to the incompleteness of its underlying extractions and the complexity of ComQA questions that require higher-order relations and reasoning. However, the system answered some complex questions, which KB-QA systems failed to answer. For example, it answered *"What is the highest mountain in the state of Washington?"*. The answer to such a question is more readily available in Web text, compared to a KB, where more sophisticated reasoning is required to handle the superlative. However, a slightly modified question such as *"What is the* ***fourth*** *highest mountain in the state of Washington?"* is unlikely to be found in text, but be answered using KBs with the appropriate reasoning. Both examples above demonstrate the benefits of combining text and structured resources.

6.4 Error Analysis

For the two best performing systems on ComQA, QUINT (Abujabal et al., 2017) and AQQU (Bast and Haussmann, 2015), we manually inspected 100 questions on which they failed. We classified failure sources into four categories: compositionality, temporal, comparison or NER. Table 6 shows the distribution of these failure sources.

Compositionality. Neither system could handle the compositional nature of questions. For example, they returned the father of Julius Caesar as an answer for *"What did Julius Caesar's father work as?"*, while, the question requires another KB predicate that connects the father to his profession. For *"John Travolta and Jamie Lee Curtis starred in this movie?"*, both systems returned movies with Jamie Lee Curtis, ignoring the constraint that John Travolta should also appear in them. Properly answering multi-relation questions over KBs remains an open problem.

Temporal. Our analysis reveals that both systems fail to capture temporal constraints in questions, be it explicit or implicit. For *"Who won the Oscar for Best Actress in 1986?"*, they returned all winners and ignored the temporal restriction from *'in 1986'*. Implicit temporal constraints like named events (e.g., *'Vietnam war'* in *"Who was the president of the US during Vietnam war?"*) pose a challenge to current methods. Such constraints need to be detected first and normalized to a canonical time interval (November 1st, 1955 to April 30th, 1975, for the Vietnam war). Then, systems need to compare the terms of the US presidents with the above interval to account for the temporal relation of *'during'*. While detecting explicit time expressions can be done reasonably well using existing time taggers (Chang and Manning, 2012), identifying implicit ones is difficult. Furthermore, retrieving the correct temporal scopes of entities in questions (e.g., the terms of the US presidents) is hard due to the large number of temporal KB predicates associated with entities.

Comparison. Both systems perform poorly on comparison questions, which is expected since they were not designed to address those. To the best of our knowledge, no existing KB-QA system can handle comparison questions. Note that our goal is not to assess the quality the of current methods, but to highlight that these methods miss categories of questions that are important to real users. For *"What is the first film Julie Andrews made?"* and *"What is the largest city in the state of Washington?"*, both systems returned the list of Julie Andrews's films and the list of Washington's cities, for the first and the second questions, respectively. While the first question requires the attribute of `filmReleasedIn` to order by, the second needs the attribute of `hasArea`. Identifying the correct attribute to order by as well as determining the order direction (ascending for the first and descending for the second) is challenging and out of scope for current methods.

NER. NER errors come from false negatives, where entities are not detected. For example, in *"On what date did the Mexican Revolution end?"* QUINT identified *'Mexican'* rather than *'Mexican Revolution'* as an entity. For *"What is the first real movie that was produced in 1903?"*, which does not ask about a specific entity, QUINT could not generate SPARQL queries. Existing QA methods expect a pivotal entity in a question, which is not always the case.

Note that while baseline systems achieved low precision, they achieved higher recall (21.2 vs 38.4 for QUINT, respectively) (Table 4). This reflects the fact that these systems often cannot cope with the full complexity of ComQA questions, and instead end up evaluating underconstrained interpretations of the question.

To conclude, current methods can handle simple questions very well, but struggle with complex questions that involve multiple conditions on different entities or need to join the results from sub-questions. Handling such complex questions, however, is important if we are to satisfy information needs expressed by real users.

7 Conclusion

We presented ComQA, a dataset for QA that harnesses a community QA platform, reflecting questions asked by real users. ComQA contains 11,214 question-answer pairs, with questions grouped into paraphrase clusters through crowdsourcing. Questions exhibit different aspects that current QA systems struggle with. ComQA is a challenging dataset that is aimed at driving future research on QA, to match the needs of real users.

Category	**QUINT**	**AQQU**
Compositionality error	39%	43%
Missing comparison	31%	26%
Missing temporal constraint	19%	22%
NER error	11%	9%

Table 6: Distribution of failure sources on ComQA questions on which QUINT and AQQU failed.

Acknowledgments

We would like to thank Tommaso Pasini for his helpful feedback.

Abstract

In this paper, we present a new data set, named *FreebaseQA*, for open-domain factoid question answering (QA) tasks over structured knowledge bases, like Freebase. The data set is generated by matching trivia-type question-answer pairs with subject-predicate-object triples in Freebase. For each collected question-answer pair, we first tag all entities in each question and search for relevant predicates that bridge a tagged entity with the answer in Freebase. Finally, human annotation is used to remove false positives in these matched triples. Using this method, we are able to efficiently generate over 54K matches from about 28K unique questions with minimal cost. Our analysis shows that this data set is suitable for model training in factoid QA tasks since FreebaseQA provides more linguistically sophisticated questions than other existing data sets. The data set is available for free download at `http://github.com/infinitecold/FreebaseQA`.

1 Introduction

Within the field of natural language processing (NLP), there has been an increase in developments towards various real-world applications, such as factoid question answering (QA): the process of obtaining the answer(s) to a factual question - similar to trivia game settings. For this task to be successfully completed, there are several steps that need to occur. Notably, we need to interpret and parse the question, determine the domain of relevance, eliminate ambiguities if existent, and pinpoint the exact answer to the question asked. Fortunately, this task has been simplified with the emergence of large knowledge graphs, including Freebase (Bollacker et al., 2008), from where we can retrieve information. Knowledge graphs are colossal networks of data that describe concepts, entities, and their relations. In fact, Freebase is the largest publicly-available knowledge graph, consisting of 4 million nodes and approximately 3 billion edges (Google, 2017). Each node represents an entity existing in the physical world, such as a person, a location, or an organization. Each edge represents a relation between two entities, in a directed manner from a *subject* node to an *object* node. In Freebase, these edges are referred to as *predicates*, and a collection of a subject-predicate-object is referred to as a *triple*. An example triple in Freebase is the subject `Clarissa`, predicate `book.written_work.author` and object `Samuel Richardson`, explaining that the book Clarissa is written by author Samuel Richardson. Specifically, we take advantage of these relations between entities, which describe facts, to help with factoid question answering. We believe open-domain factoid QA over structured knowledge graphs like Freebase is a very interesting NLP task since it opens up many interesting real-world applications, such as natural language based query and search. Finally, once questions are formulated using a variety of rich and sophisticated representations in natural languages, such factoid QA tasks may serve as an excellent testbed to study many natural language understanding problems, e.g., examine the recently emerging research efforts to combine neural models with the traditional symbolic processing methods (Liang et al., 2017; Mou et al., 2017).

On the other hand, machine learning approaches for NLP are data hungry since they require large amounts of real-world data to train the models for the best possible performance. Existing data sets for the factoid QA task over structured knowledge bases are either too small in scale to train neural networks effectively, or contain questions

---

Proceedings of NAACL-HLT 2019, pages 318–323
Minneapolis, Minnesota, June 2 - June 7, 2019.

that are too simple in linguistic structure to amply cover real-world scenarios. In this paper, we introduce a new data set for open-domain QA over Freebase, called *FreebaseQA*, which is created by matching trivia-type question-answer pairs with Freebase triples that reflect the semantic meaning of the questions. FreebaseQA contains over 54K matches from about 28K unique questions that can be used to train machine learning (ML) models and help the development of factoid QA systems for more realistic applications. Particularly, these matches may be used to train ML models to align natural language questions with Freebase predicates to search for the correct answers in Freebase. Our analysis shows that FreebaseQA provides an advantage over all pre-existing data sets with similar objectives, which are either too small or only contain questions that are too simple in linguistic structure. These results will be explained in detail in Section 4.

2 Related Work

Factoid QA data sets involving question-answer pairs as well as their corresponding Freebase matches have been created in the past. In (Berant et al., 2013), factoid QA over knowledge graphs are formulated as semantic parsing problems, where each natural language question is first converted into a logic form to retrieve the answer with traditional symbolic approaches. In (Berant et al., 2013), a small-scale data set of several thousands of question-answer pairs, called WebQuestions, is created by human annotators. In (Yih et al., 2016), the WebQuestions set is further refined by providing human-annotated semantic parses for some questions that are answerable using Freebase, which is called WebQuestionsSP (WebQSP). Recently, deep learning approaches have become popular in the field of NLP. Neural networks require far more training data than a small data set of several thousands of samples. In (Bordes et al., 2015), a much larger QA data set of about 100K question/answer pairs, called SimpleQuestions, is created. In this work, some randomly chosen Freebase triples are shown to human annotators. For each given triple, an annotator is asked to manually compose a question to reflect the relation in the triple. The issues with SimpleQuestions lie in that most constructed questions are quite simple in linguistic structure and many questions even directly use the keywords in the Freebase predicates since human annotators may be greatly limited in composition when a particular triple is shown. According to (Petrochuk and Zettlemoyer, 2018), SimpleQuestions is nearly solved with only standard neural network methods if its linguistic ambiguity is taken into account. In (Vlad Serban et al., 2016), a large QA data set is automatically generated by neural networks but it obviously lacks rich linguistic variations. Additionally, many similar factoid QA data sets are also released for other non-English languages, e.g. WebQA in (Li et al., 2016). Meanwhile, another direction of data collection efforts involve QA in various reading comprehension tasks, e.g. SQuAD in (Rajpurkar et al., 2016), MS-MARCO in (Nguyen et al., 2016), TriviaQA in (Joshi et al., 2017). However, we believe question answering over structured knowledge graphs remains a viable NLP task for the promising research direction to combine neural computing methods with the traditional symbolic processing approaches.

3 Constructing the FreebaseQA Data Set

In this section, we outline the construction procedure of the FreebaseQA data set, which consists of about 54K matches in the form of two examples shown in Table 1.

3.1 Preparation of Question-Answer Pairs

In FreebaseQA, we have not generated any new question-answer pairs but we have instead collected pre-composed trivia-type factoid questions from a number of sources. Unlike SimpleQuestions, these questions are independently composed for human contestants in various trivia-like competitions. As a result, these questions show much richer linguistic variation and complexity than almost all existing KB-QA data sets. In particular, we use the TriviaQA (Joshi et al., 2017) data set as the primary source of our QA pairs, while also including questions scraped from the trivia websites, KnowQuiz (`http://www.knowquiz.com`), QuizBalls (`http://www.quizballs.com`), and QuizZone (`https://www.quiz-zone.co.uk`). We remove duplicate entries and the remaining pairs are consolidated into a single source.

Each question is then run through two named entity recognition (NER) systems: TAGME (Ferragina and Scaiella, 2010) and FOFE NER (Xu et al., 2017). By combining the results of both

Components	Example 1	Example 2
Question [Answer]	`Which 18th century author wrote Clarissa (or The History of a Young Lady), said to be the longest novel in the English language? [Samuel Richardson]`	`What is the correct name of the character voiced by Angela Lansbury in Beauty and The Beast? [Mrs Potts]`
Subject (Freebase ID)	`Clarissa (m.05s1st)`	`Angela Lansbury (m.0161h5)`
Predicate	`book.written-work.author`	`film.actor.dubbing-performances`
Secondary Predicate	`-`	`film.dubbing-performance.character`
Object/Answer (ID)	`Samuel Richardson (m.0hb27)`	`Mrs Potts (m.02vw823)`

Table 1: Two typical examples to illustrate the data format of all matches in FreebaseQA.

systems, we create a list of possible subjects for each question. We use confidence thresholds of 0.2 and 0.9 for the respective systems to ensure that an adequate amount of entities are produced while avoiding the production of irrelevant results.

3.2 Freebase Matching

The matching starts by searching for all Freebase nodes with a name or alias matching each subject name. For each matched Freebase node (called a subject node), we search through all object nodes that are directly linked with the subject node. Then for each object node, we search through all of its names and aliases to see if one matches the answer to the question. Once a match is found, the subject node's Freebase ID, the predicate name, and the object node's Freebase ID are saved as a triple representing the question-answer pair. Note that one question-answer pair may generate several matched triples when multiple related predicates are found since each question may contain multiple entities and each subject node may link to an object node through different predicates.

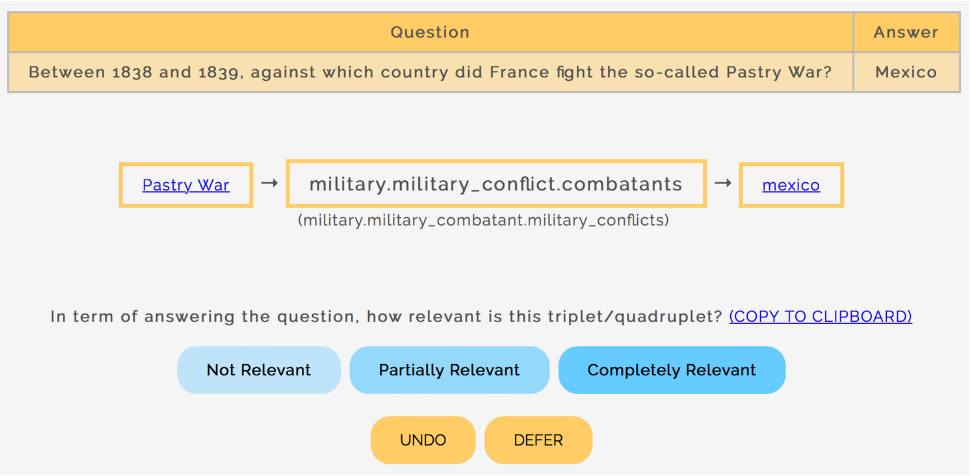
However, this procedure becomes inefficient since there is an enormous number of object nodes to process for some popular subject nodes, such as `United States (m.09c7w0)`, leading to a tremendous number of Freebase queries. Since we know the end point of the search, the answer to the question, this procedure is optimized by also starting from the answer and searching for all object nodes with a name or alias matching it. Then, the search concludes when the same object node is found from both starting points of the search. By using this two-way search method, we have accelerated the Freebase matching algorithm more than ten-fold.

3.3 Mediator Nodes

Freebase has been constructed with some special nodes called *mediator* nodes. A mediator is an intermediate node that connects a subject node with an object node. Since it itself is also considered a node, there are predicates from the subject to the mediator and from the mediator to the object. These mediator nodes are special as they do not have a name or alias associated with it, and only occurring in Freebase when there are multiple subjects and objects that are related through the mediator. When constructing the FreebaseQA data set, mediators are also accounted for. If the above search procedure reaches a mediator, a 2-hop matching strategy is conducted to search all nodes linked to this mediator. This captures a secondary predicate that bridges the subject to the answer through a mediator node. An example involving a mediator is described as Example 2 in Table 1.

3.4 Human Annotation

Since the matches found through the previously-explained algorithm are not guaranteed to be completely relevant to the question, human verification of the produced results is required to remove all possible false postitive matches. A group of 10 native English speakers are hired to label all of the collected matches. Each match is rated by the individuals as either "Completely Relevant", "Somewhat Relevant", or "Not Relevant". The choice of rating is dependent on the relevancy of the predicate to the question. If the predicate completely reflects the main idea asked by the question, the match is rated "Completely Relevant". If the predicate reflects part of the main idea of the question or is only somewhat related to it, the match is rated "Partially Relevant". Otherwise, the match is rated "Not Relevant". Compared with other



Question	Answer
Between 1838 and 1839, against which country did France fight the so-called Pastry War?	Mexico

Pastry War → military.military_conflict.combatants → mexico

(military.military_combatant.military_conflicts)

In term of answering the question, how relevant is this triplet/quadruplet? (COPY TO CLIPBOARD)

Figure 1: Human annotators use this website interface to label all automatically-generated matches, rating either Completely Relevant, Partially Relevant, or Not Relevant.

QA data collection tasks, human involvement in FreebaseQA is relatively light since each person only needs to make a one-out-of-three choice instead of composing a question or sentence from scratch. Therefore, using this method, we may significantly reduce the cost of QA data collection. As an illustration, the user interface for this data annotation procedure is shown in Figure 1.

In order to facilitate model training, the matches rated "Completely Relevant" are randomly chosen to populate the training, evaluation, and development sets of FreebaseQA. These sets are separated so that if there are multiple matches for a single question-answer pair, all of those matches will exist in only one of the sets. Moreover, the matches rated "Partially Relevant" are provided as a separate set, which may be useful for model training as well. The FreebaseQA data set is available for public use at `http://github.com/infinitecold/FreebaseQA`.

4 Results

We report the preliminary results of our statistical analysis on the collected FreebaseQA data set.

4.1 Collected Raw Question-Answer Pairs

The statistics of the originally collected question-answer pairs and the corresponding Freebase matches are summarized in Table 2. We see that with the exception of KnowQuiz, the number of matches in Freebase roughly equate the number of questions in each source. Among all the generated matches, 54,611 matches in total are kept as true positives by human annotators.

Source	Questions	Matches
TriviaQA	98,973	99,523
KnowQuiz	9,996	2,389
QuizBalls	15,370	17,856
QuizZone	7,686	7,289
Total	132,025	127,057

Table 2: A summary of the number of question-answer pairs from each source along with the number of matches generated from the above Freebase matching procedure.

4.2 FreebaseQA Statistics

The size of the FreebaseQA data set is compared to two similar QA data sets, WebQuestionsSP (WebQSP) (Yih et al., 2016) and SimpleQuestions (Bordes et al., 2015), in Table 3.

Data Set	`train`	`dev`	`eval`	Total
FreebaseQA	20,358	3,994	3,996	28,348
SimpleQuestions	75,910	10,845	21,687	108,442
WebQSP	3,098	-	1,639	4,737

Table 3: Total numbers of unique questions found in the subsets of each data set.

We see that FreebaseQA has a significantly larger size than WebQSP in number of unique questions, but it is about one quarter of SimpleQuestions in number of unique questions. Among these matches, FreebaseQA contains 28,348 unique questions in total, with 20,358, 3,994 and 3,996 in the train, dev and eval sets respectively.

However, another important factor to consider

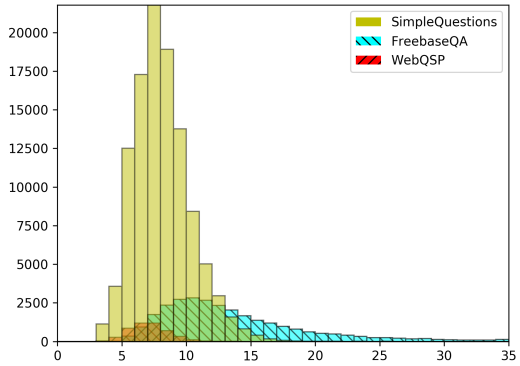


Figure 2: A histogram showing the spread of the length of the questions in each data set.

is the linguistic sophistication of the data. The sophistication of the linguistic structure of the questions in the FreebaseQA data set is compared to other similar data sets based on the average length, in number of words, of the questions. The histogram of question lengths of three data sets is shown in Figure 2. From the histogram, we see that the length of the questions in FreebaseQA extend much longer than the questions in SimpleQuestions or WebQSP (Yih et al., 2016). In fact, SimpleQuestions has an average length of 7.65 words per question and WebQSP has an average length of 6.62 words per question, while FreebaseQA has an average length of 13.35 words per question: approximately double the length of either data set.

4.3 Baseline Performance on FreebaseQA

Finally, we use FOFE-net (Zhang et al., 2015; Xu et al., 2017) to build a baseline KBQA system on FreebaseQA, which consists of subject detection, entity linking and relation detection in the pipeline. Our FOFE-net models are first compared with the popular hierarchical residual BiLSTM in (Yu et al., 2017) on two public data sets, such as SimpleQuestions and WebQSP. See (Wu et al., 2019) for more details on experimental settings and results. The comparison results are listed in Table 4.

As shown in Table 4, our baseline has achieved strong performance on the two public data sets but its final question answering accuracy has dropped significantly down to 37.0% on FreebaseQA. Obviously, FreebaseQA is a much more challenging KBQA task than both SimpleQuestions and WebQSP due to the fact that the questions in FreebaseQA are more complex in linguistic structure. Therefore, FreebaseQA may serve as an excellent testbed for more advanced KBQA techniques.

Data Set	BiLSTM (Yu et al., 2017)	FOFE-net (this work)
SimpleQuestions	77.0%	77.3%
WebQSP	63.0%	67.6%
FreebaseQA	-	**37.0%**

Table 4: Comparison of end-to-end QA accuracies on several KBQA data sets.

To facilitate the evaluation of the end-to-end question-answering pipeline on FreebaseQA, we have extracted a subset of Freebase, which contains all nodes and their corresponding predicates matching any entities in the FreebaseQA data set. This Freebase subset, also available at `http://github.com/infinitecold/FreebaseQA`, may be used to conduct end-to-end QA experiments to compare with our performance results in Table 4.

5 Conclusion

This paper presents a new data set, *FreebaseQA*, for open-domain factoid QA over structured knowledge bases. FreebaseQA has a size of over 54K matches, significantly larger than WebQSP and linguistically more sophisticated than SimpleQuestions. Our baseline QA results have also shown that FreebaseQA is a much more difficult KBQA task than either WebQSP or SimpleQuestions. Therefore, FreebaseQA may be an invaluable asset to the investigation of more advanced machine learning methods for factoid KBQA problems. Furthermore, the use of this data set is not only limited to factoid question answering, but several other applications can also be approached with this data set, including reading comprehension, natural language-based search, and the quantification of natural language understanding.

Abstract

Knowledge graph based simple question answering (KBSQA) is a major area of research within question answering. Although only dealing with *simple* questions, i.e., questions that can be answered through a single knowledge base (KB) fact, this task is neither simple nor close to being solved. Targeting on the two main steps, subgraph selection and fact selection, the research community has developed sophisticated approaches. However, the importance of subgraph ranking and leveraging the subject–relation dependency of a KB fact have not been sufficiently explored. Motivated by this, we present a unified framework to describe and analyze existing approaches. Using this framework as a starting point, we focus on two aspects: improving subgraph selection through a novel ranking method and leveraging the subject–relation dependency by proposing a joint scoring CNN model with a novel loss function that enforces the well-order of scores. Our methods achieve a new state of the art (85.44% in accuracy) on the SimpleQuestions dataset.

1 Introduction

Knowledge graph based simple question answering (KBSQA) is an important area of research within question answering, which is one of the core areas of interest in natural language processing (Yao and Van Durme, 2014; Yih et al., 2015; Dong et al., 2015; Khashabi et al., 2016; Zhang et al., 2018; Hu et al., 2018). It can be used for many applications such as virtual home assistants, customer service, and chat-bots. A *knowledge graph* is a multi-entity and multi-relation directed graph containing the information needed to answer the questions. The graph can be represented as collection of triples {(subject, relation, object)}. Each triple is called a *fact*, where a directed relational arrow points from subject node to object node. A *simple* question means that the question can be answered by extracting a single fact from the knowledge graph, i.e., the question has a single subject and a single relation, hence a single answer. For example, the question "Which Harry Potter series did Rufus Scrimgeour appear in?" can be answered by a single fact (Rufus Scrimgeour, book.book-characters.appears-in-book, Harry Potter and the Deathly Hallows). Given the simplicity of the questions, one would think this task is trivial. Yet it is far from being easy or close to being solved. The complexity lies in two aspects. One is the massive size of the knowledge graph, usually in the order of billions of facts. The other is the variability of the questions in natural language. Based on this anatomy of the problem, the solutions also consist of two steps: (1) selecting a relatively small subgraph from the knowledge graph given a question and (2) selecting the correct fact from the subgraph.

Different approaches have been studied to tackle the KBSQA problems. The common solution for the first step, subgraph selection (which is also known as entity linking), is to label the question with subject part (*mention*) and non-subject part (*pattern*) and then use the mention to retrieve related facts from the knowledge graph, constituting the subgraph. Sequence labeling models, such as a BiLSTM-CRF tagger (Huang et al., 2015), are commonly employed to label the mention and the pattern. To retrieve the subgraph, it is common to search all possible n-grams of the mention against the knowledge graph and collect the facts with matched subjects as the subgraph. The candidate facts in the subgraph may contain incorrect subjects and relations. In our running example, we first identify the

Proceedings of NAACL-HLT 2019, pages 324–334
Minneapolis, Minnesota, June 2 - June 7, 2019.

mention in the question, i.e.,"Rufus Scrimgeour", and then retrieve the subgraph which could contain the following facts: {(Rufus Scrimgeour, book.book-characters.appears-in-book, Harry Potter and the Deathly Hallows), (Rufus Wainwright, music.singer.singer-of, I Don't Know What That Is)}.

For the second step, fact selection, a common approach is to construct models to match the mention with candidate subjects and match the pattern with candidate relations in the subgraph from the first step. For example, the correct fact is identified by matching the mention "Rufus Scrimgeour" with candidate subjects {Rufus Scrimgeour, Rufus Wainwright} and matching the pattern "Which Harry Potter series did m appear in" with candidate relations {book.book-characters.appears-in-book, music.singer.singer-of}. Different neural network models can be employed (Bordes et al., 2015; Dai et al., 2016; Yin et al., 2016; Yu et al., 2017; Petrochuk and Zettlemoyer, 2018).

Effective as these existing approaches are, there are three major drawbacks. (1) First, in subgraph selection, there is no effective way to deal with inexact matches and the facts in subgraph are not ranked by relevance to the mention; however, we will later show that effective ranking can substantially improve the subgraph recall. (2) Second, the existing approaches do not leverage the dependency between mention–subjects and pattern–relations; however, mismatches of mention–subject can lead to incorrect relations and hence incorrect answers. We will later show that leveraging such dependency contributes to the overall accuracy. (3) Third, the existing approaches minimize the ranking loss (Yin et al., 2016; Lukovnikov et al., 2017; Qu et al., 2018); however, we will later show that the ranking loss is suboptimal.

Addressing these points, the contributions of this paper are three-fold: (1) We propose a subgraph ranking method with combined literal and semantic score to improve the recall of the subgraph selection. It can deal with inexact match, and achieves better performance compared to the previous state of the art. (2) We propose a low-complexity joint-scoring CNN model and a well-order loss to improve fact selection. It couples the subject matching and the relation matching by learning order-preserving scores and dynamically adjusting the weights of scores. (3) We achieve better performance (85.44% in accuracy) than the previous state of the art on the SimpleQuestions dataset, surpassing the best baseline by a large margin[1].

2 Related Work

The methods for subgraph selection fall in two schools: parsing methods (Berant et al., 2013; Yih et al., 2015; Zheng et al., 2018) and sequence tagging methods (Yin et al., 2016). The latter proves to be simpler yet effective, with the most effective model being BiLSTM-CRF (Yin et al., 2016; Dai et al., 2016; Petrochuk and Zettlemoyer, 2018).

The two categories of methods for fact selection are match-scoring models and classification models. The match-scoring models employ neural networks to score the similarity between the question and the candidate facts in the subgraph and then find the best match. For instance, Bordes et al. (2015) use a memory network to encode the questions and the facts to the same representation space and score their similarities. Yin et al. (2016) use two independent models, a character-level CNN and a word-level CNN with attentive max-pooling. Dai et al. (2016) formulate a two-step conditional probability estimation problem and use BiGRU networks. Yu et al. (2017) use two separate hierarchical residual BiLSTMs to represent questions and relations at different abstractions and granularities. Qu et al. (2018) propose an attentive recurrent neural network with similarity matrix based convolutional neural network (AR-SMCNN) to capture the semantic-level and literal-level similarities. In the classification models, Ture and Jojic (2017) employ a two-layer BiGRU model. Petrochuk and Zettlemoyer (2018) employ a BiLSTM to classify the relations and achieve the state-of-the-art performance. In addition, Mohammed et al. (2018) evaluate various strong baselines with simple neural networks (LSTMs and GRUs) or non-neural network models (CRF). Lukovnikov et al. (2017) propose an end-to-end word/character-level encoding network to rank subject–relation pairs and retrieve relevant facts.

However, the multitude of methods yield progressively smaller gains with increasing model complexity (Mohammed et al., 2018; Gupta et al.,

---

[1] Ture and Jojic (2017) reported better performance than us but neither Petrochuk and Zettlemoyer (2018) nor Mohammed et al. (2018) could replicate their result.

2018). Most approaches focus on fact matching and relation classification while assigning less emphasis to subgraph selection. They also do not sufficiently leverage the important signature of the knowledge graph—the subject–relation dependency, namely, incorrect subject matching can lead to incorrect relations. Our approach is similar to (Yin et al., 2016), but we take a different path by focusing on accurate subgraph selection and utilizing the subject–relation dependency.

3 Question Answering with Subgraph Ranking and Joint-Scoring

3.1 Unified Framework

We provide a unified description of the KBSQA framework. First, we define

Definition 1. Answerable Question *A question is answerable if and only if one of its facts is in the knowledge graph.*

Let $\mathcal{Q} := \{q \mid q \text{ is anwerable}\}$ be the set of answerable questions, and $\mathcal{G} := \{(s, r, o) \mid s \in \mathcal{S}, r \in \mathcal{R}, o \in \mathcal{O}\}$ be the knowledge graph, where $\mathcal{S}$, $\mathcal{R}$ and $\mathcal{O}$ are the set of subjects, relations and objects, respectively. The triple (s, r, o) is a *fact*. By the definition of answerable questions, the key to solving the KBSQA problem is to *find the fact in knowledge graph corresponding to the question*, i.e., we want a map $\Phi : \mathcal{Q} \to \mathcal{G}$. Ideally, we would like this map to be injective such that for each question, the corresponding fact can be uniquely determined (more precisely, the injection maps from the *equivalent class* of $\mathcal{Q}$ to $\mathcal{G}$ since similar questions may have the same answer, but we neglect such difference here for simplicity). However, in general, it is hard to find such map directly because of (1) the massive knowledge graph and (2) natural language variations in questions. Therefore, end-to-end approaches such as parsing to structured query and encoding-decoding models are difficult to achieve (Yih et al., 2015; Sukhbaatar et al., 2015; Kumar et al., 2016; He and Golub, 2016; Hao et al., 2017). Instead, related works and this work mitigate the difficulties by breaking down the problem into the aforementioned two steps, as illustrated below:

(1) Subgraph Selection:

$$\text{question} \longrightarrow \{\text{mention, pattern}\}, \quad \text{mention} \longrightarrow \text{subgraph}$$

(2) Fact Selection:

$$\text{match} \begin{cases} \text{mention} \leftrightarrow \text{subject} \\ \text{pattern} \leftrightarrow \text{relation} \end{cases} \forall (\text{subject, relation}) \in \text{subgraph}$$

$$\Rightarrow (\text{subject*, relation*}) \longrightarrow \text{object* (answer*)}$$

In the first step, the size of the knowledge graph is significantly reduced. In the second step, the variations of questions are confined to mention–subject variation and pattern–relation variation.

Formally, we denote the questions as the union of mentions and patterns $\mathcal{Q} = \mathcal{M} \bigcup \mathcal{P}$ and the knowledge graph as the subset of the Cartesian product of subjects, relations and objects $\mathcal{G} \subseteq \mathcal{S} \times \mathcal{R} \times \mathcal{O}$. In the first step, given a question $q \in \mathcal{Q}$, we find the mention via a sequence tagger $\tau : \mathcal{Q} \to \mathcal{M}$, $q \mapsto m_q$. The tagged mention consists of a sequence of words $m_q = \{w_1, \ldots, w_n\}$ and the pattern is the question excluding the mention $p_q = q \backslash m_q$. We denote the set of n-grams of m_q as $\mathcal{W}_n(m_q)$ and use $\mathcal{W}_n(m_q)$ to retrieve the subgraph as $\mathcal{S}_q \times \mathcal{R}_q \times \mathcal{O}_q \supseteq \mathcal{G}_q := \{(s, r, o) \in \mathcal{G} \mid \mathcal{W}_n(s) \bigcap \mathcal{W}_n(m_q) \neq \varnothing, n = 1, \ldots, |m_q|\}$.

Next, to select the correct fact (the answer) in the subgraph, we match the mention m_q with candidate subjects in $\mathcal{S}_q$, and match the pattern p_q with candidate relations in $\mathcal{R}_q$. Specifically, we want to maximize the log-likelihood

$$\begin{cases} \max_{s \in \mathcal{S}_q} \log \mathbb{P}(s \mid m_q) \\ \max_{r \in \mathcal{R}_q} \log \mathbb{P}(r \mid p_q). \end{cases} \tag{1}$$

The probabilities in (1) are modeled by

$$\mathbb{P}(s \mid m_q) = \frac{e^{h(f(m_q), f(s))}}{\sum_{s' \in \mathcal{S}_q} e^{h(f(m_q), f(s'))}} \tag{2}$$

$$\mathbb{P}(r \mid p_q) = \frac{e^{h(g(p_q), g(r))}}{\sum_{r' \in \mathcal{R}_q} e^{h(g(p_q), g(r'))}}, \tag{3}$$

where $f : \mathcal{M} \bigcup \mathcal{S} \to \mathbb{R}^d$ maps the mention and the subject onto a d-dimensional differentiable manifold embedded in the Hilbert space and similarly, $g : \mathcal{P} \bigcup \mathcal{R} \to \mathbb{R}^d$. Both f and g are in the form of neural networks. The map $h : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ is a metric that measures the similarity of the vector representations (e.g., the cosine similarity). Practically, directly optimizing (1) is difficult because the subgraph $\mathcal{G}_q$ is large and computing the partition functions in (2) and (3) can be intractable. Alternatively, a surrogate objective, the ranking loss (or hinge loss with negative samples) (Collobert and Weston, 2008; Dai et al., 2016) is minimized

$$\mathcal{L}_{\text{rank}} = \sum_{q \in \mathcal{Q}} \left(\sum_{s \in \mathcal{S}_q} \left[h_f(m_q, s^-) - h_f(m_q, s^+) + \lambda \right]_+ + \sum_{r \in \mathcal{R}_q} \left[h_g(p_q, r^-) - h_g(p_q, r^+) + \lambda \right]_+ \right), \quad (4)$$

where $h_f(\cdot, \cdot) = h(f(\cdot), f(\cdot))$, $h_g(\cdot, \cdot) = h(g(\cdot), g(\cdot))$; the sign $+$ and $-$ indicate correct candidate and incorrect candidate, $[\cdot]_+ = \max(\cdot, 0)$, and $\lambda > 0$ is a margin term. Other variants of the ranking loss are also studied (Cao et al., 2006; Zhao et al., 2015; Vu et al., 2016).

3.2 Subgraph Ranking

To retrieve the subgraph of candidate facts using n-gram matching (Bordes et al., 2015), one first constructs the map from n-grams $\mathcal{W}_n(s)$ to subject s for all subjects in the knowledge graph, yielding $\{\mathcal{W}_n(s) \to s \mid s \in \mathcal{S}, n = 1, \dots, |s|\}$. Next, one uses the n-grams of mention $\mathcal{W}_n(m)$ to match the n-grams of subjects $\mathcal{W}_n(s)$ and fetches those matched facts to compose the subgraph $\{(s, r, o) \in \mathcal{G} \mid \mathcal{W}_n(s) \bigcap \mathcal{W}_n(m) \neq \varnothing, n = 1, \dots |m|\}$. In our running example, for the mention "Rufus Scrimgeour", we collect the subgraph of facts with the bigrams and unigrams of subjects matching the bigram {"Rufus Scrimgeour"} and unigrams {"Rufus", "Scrimgeour"}.

One problem with this approach is that the retrieved subgraph can be fairly large. Therefore, it is desirable to rank the subgraph by relevance to the mention and only preserve the most relevant facts. To this end, different ranking methods are used, such as surface-level matching score with added heuristics (Yin et al., 2016), relation detection network (Yu et al., 2017; Hao et al., 2018), term frequency-inverse document frequency (TF-IDF) score (Ture and Jojic, 2017; Mohammed et al., 2018). However, these ranking methods only consider matching surface forms and cannot handle inexact matches, synonyms, or polysemy ("New York" , "the New York City", "Big Apple").

This motivates us to rank the subgraph not only by literal relevance but also semantic relevance. Hence, we propose a ranking score with literal closeness and semantic closeness. Specifically, the literal closeness is measured by the length of the longest common subsequence $|\sigma|(s, m)$ between a subject s and a mention m. The semantic closeness is measured by the co-occurrence probability of the subject s and the mention m

$$\begin{aligned}
\mathbb{P}(s, m) &= \mathbb{P}(s|m)\mathbb{P}(m) \\
&= \mathbb{P}(w_1, \dots w_n | \widetilde{w}_1, \dots \widetilde{w}_m) \mathbb{P}(\widetilde{w}_1, \dots \widetilde{w}_m) && (5) \\
&= \prod_{i=1}^{n} \mathbb{P}(w_i | \widetilde{w}_1, \dots \widetilde{w}_m) \mathbb{P}(\widetilde{w}_1, \dots \widetilde{w}_m) && (6) \\
&= \prod_{i=1}^{n} \left(\prod_{k=1}^{m} \mathbb{P}(w_i | \widetilde{w}_k) \right) \mathbb{P}(\widetilde{w}_1, \dots \widetilde{w}_m) && (7) \\
&= \prod_{i=1}^{n} \left(\prod_{k=1}^{m} \mathbb{P}(w_i | \widetilde{w}_k) \right) \prod_{j=1}^{m-1} \mathbb{P}(\widetilde{w}_{j+1} | \widetilde{w}_j) \mathbb{P}(\widetilde{w}_1), && (8)
\end{aligned}$$

where from (5) to (6) we assume conditional independence of the words in subject and the words in mention; from (6) to (7) and from (7) to (8) we factorize the factors using the chain rule with conditional independence assumption. The marginal term $\mathbb{P}(\widetilde{w}_1)$ is calculated by the word occurrence frequency. Each conditional term is approximated by $\mathbb{P}(w_i | w_j) \approx \exp\{\hat{w}_i^T \hat{w}_j\}$ where $\hat{w}_i$s are pretrained GloVe vectors (Pennington et al., 2014). These vectors are obtained by taking into account the word co-occurrence probability of surrounding context. Hence, the GloVe vector space encodes the semantic closeness. In practice we use the log-likelihood as the semantic score to convert multiplication in (8) to summation and normalize the GloVe embeddings into a unit ball. Then, the score for ranking the subgraph is the weighted sum of the literal score and the semantic score

$$\text{score}(s, m) = \tau |\sigma|(s, m) + (1 - \tau) \log \mathbb{P}(s, m), \quad (9)$$

where τ is a hyper-parameter whose value need to be tuned on the validation set. Consequently, for each question q, we can get the top-n ranked subgraph $\mathcal{G}_{q\downarrow}^n$ as well as the corresponding top-n ranked candidate subjects $\mathcal{S}_{q\downarrow}^n$ and relations $\mathcal{R}_{q\downarrow}^n$.

3.3 Joint-Scoring Model with Well-Order Loss

Once we have the ranked subgraph, next we need to identify the correct fact in the subgraph. One school of conventional methods (Bordes et al., 2014, 2015; Yin et al., 2016; Dai et al., 2016) is minimizing the surrogate ranking loss (4) where neural networks are used to transform the (subject, mention) and (relation, pattern) pairs into a Hilbert space and score them with inner product.

One problem with this approach is that it matches mention–subject and pattern–relation

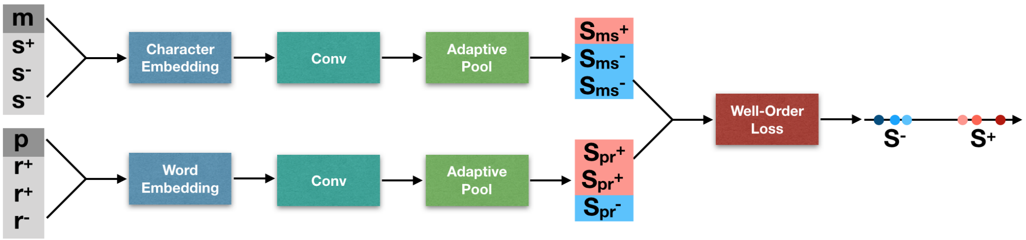

Figure 1: Model Diagram (Section 3.3) The model takes input pairs (**m**ention, **s**ubject) and (**p**attern, **r**elation) to produce the similarity scores. The loss dynamically adjusts the weights and enforces the order of positive and negative scores.

separately, neglecting the difference of their contributions to fact matching. Given that the number of subjects (order of millions) are much larger than the number of relations (order of thousands), incorrect subject matching can lead to larger error than incorrect relation matching. Therefore, matching the subjects correctly should be given more importance than matching the relations. Further, the ranking loss is suboptimal, as it does not preserve the relative order of the matching scores. We empirically find that the ranking loss tends to bring the matching scores to the neighborhood of zero (during the training the scores shrink to very small numbers), which is not functioning as intended.

To address these points, we propose a joint-scoring model with well-order loss (Figure 1). Together they learn to map from joint-input pairs to order-preserving scores supervised by a well-order loss, hence the name. The joint-scoring model takes joint-input pairs, (subject, mention) or (relation, pattern), to produce the similarity scores directly. The well-order loss then enforces the well-order in scores.

A well-order, first of all, is a total order—a binary relation on a set which is antisymmetric, transitive, and connex. In our case it is just the "$\leq$" relation. In addition, the well-order is a total order with the property that every non-empty set has a least element. The well-order restricts that the scores of correct matches are always larger or equal to the scores of incorrect matches, i.e., $\forall i : \forall j : S_i^+ \geq S_j^-$ where S_i^+ and S_i^- indicate the score of correct match and the score of incorrect match.

We derive the well-order loss in the following way. Let $S = \{S_1, \ldots, S_n\} = S^+ \bigcup S^-$ be the set of scores where S^+ and S^- are the set of scores with correct and incorrect matches. Let $I = I^+ \bigcup I^-$ be the index set of S, $|I^+| = n_1$, $|I^-| = n_2$, $n = n_1 + n_2$. Following the well-order relation

$$\begin{aligned}
&\inf S^+ \geq \sup S^- \\
\Leftrightarrow\ &\forall i^+ \in I^+ : \forall i^- \in I^- : S_{i^+}^+ - S_{i^-}^- \geq 0 \\
\Leftrightarrow\ &\sum_{i^+ \in I^+} \sum_{i^- \in I^-} (S_{i^+}^+ - S_{i^-}^-) \geq 0 \qquad (10) \\
\Leftrightarrow\ &n_2 \sum_{i^+ \in I^+} S_{i^+}^+ - n_1 \sum_{i^- \in I^-} S_{i^-}^- \geq 0, \qquad (11)
\end{aligned}$$

where from (10) to (11) we expand the sums and reorder the terms. Consequently, we obtain the well-order loss

$$\begin{aligned}
&\mathcal{L}_{\text{well-order}}(S_{ms}, S_{pr}) = \\
&\left[|I^+| \sum_{i^-} S_{ms}^{i^-} - |I^-| \sum_{i^+} S_{ms}^{i^+} + |I^+||I^-|\lambda \right]_+ + \\
&\left[|J^+| \sum_{j^-} S_{pr}^{j^-} - |J^-| \sum_{j^+} S_{pr}^{j^+} + |J^+||J^-|\lambda \right]_+, \qquad (12)
\end{aligned}$$

where S_{ms}, S_{pr} are the scores for (mention, subject), (pattern, relation) pairs for a question, I, J are the index sets for candidate subjects, relations in the ranked subgraph, $+$, $-$ indicate the correct candidate and incorrect candidate, $[\cdot]_+ = \max(\cdot, 0)$, and $\lambda > 0$ is a margin term. Then, the objective (1) becomes

$$\begin{aligned}
\min_{q \in \mathcal{Q}, (s,r) \in \mathcal{S}_{q\downarrow}^n \times \mathcal{R}_{q\downarrow}^n} &\Bigg[|I^+| \sum_{i^-} h_f(m_q, s^{i^-}) - \\
&|I^-| \sum_{i^+} h_f(m_q, s^{i^+}) + |I^+||I^-|\lambda \Bigg]_+ \\
+ &\Bigg[|J^+| \sum_{j^-} h_g(p_q, r^{j^-}) - \\
&|J^-| \sum_{j^+} h_g(p_q, r^{j^+}) + |J^+||J^-|\lambda \Bigg]_+ . \qquad (13)
\end{aligned}$$

This new objective with well-order loss differs from the ranking loss (4) in two ways, and plays a vital role in the optimization. First, instead of considering the match of mention–subjects and pattern–relations separately, (13) *jointly considers both input pairs and their dependency*. Specifically, (13) incorporates such dependency as the weight factors $|I|$ (for subjects) and $|J|$ (for relations). These factors are the controlling factors and are automatically and dynamically adjusted as they are the sizes of candidate subjects and relations. Further, the match of subjects, weighted by (I^+, I^-), will control the match of relations, weighted by (J^+, J^-). To see this, for a question and a fixed number of candidate facts in subgraph, $|I| = |J|$, the incorrect number of subjects $|I^-|$ is usually larger than the incorrect number of relations $|J^-|$, which causes larger loss for mismatching subjects. As a result, the model is forced to match subjects more correctly, and in turn, prune the relations with incorrect subjects and reduce the size of J^-, leading to smaller loss. Second, the well-order loss enforces the well-order relation of scores while the ranking loss does not have such constraint.

4 Experiments

Here, we evaluate our proposed approach for the KBSQA problem on the SimpleQuestions benchmark dataset and compare with baseline approaches.

4.1 Data

The SimpleQuestions (Bordes et al., 2015) dataset is released by the Facebook AI Research. It is the standard dataset on which almost all previous state-of-the-art literature reported their numbers (Gupta et al., 2018; Hao et al., 2018). It also represents the largest publicly available dataset for KBSQA with its size several orders of magnitude larger than other available datasets. It has $108,442$ simple questions with the corresponding facts from subsets of the Freebase (FB2M and FB5M). There are $1,837$ unique relations. We use the default train, validation and test partitions (Bordes et al., 2015) with $75,910$, $10,845$ and $21,687$ questions, respectively. We use FB2M with $2,150,604$ entities, $6,701$ relations and $14,180,937$ facts, respectively.

4.2 Models

For sequence tagging, we use the same BiLSTM-CRF model as the baseline (Dai et al., 2016) to label each word in the question as either subject or non-subject. The configurations of the model (Table 1) basically follow the baseline (Dai et al., 2016).

For subgraph selection, we use only unigrams of the tagged mention to retrieve the candidate facts (see Section 3.2) and rank them by the proposed relevance score (9) with the tuned weight $\tau = 0.9$ (hence more emphasizing on literal matching). We select the facts with top-n scores as the subgraphs and compare the corresponding recalls with the baseline method (Yin et al., 2016).

For fact selection, we employ a character-based CNN (CharCNN) model to score (mention, subject) pairs and a word-based CNN (WordCNN) model to score (pattern, relation) pairs (with model configurations shown in Table 2), which is similar to one of the state-of-the-art baselines AMPCNN (Yin et al., 2016). In fact, we first replicated the AMPCNN model and achieved comparable results, and then modified the AMPCNN model to take joint inputs and output scores directly (see Section 3.3 and Figure 1). Our CNN models have only two convolutional layers (versus six convolutional layers in the baseline) and have no attention mechanism, bearing much lower complexity than the baseline. The CharCNN and WordCNN differ only in the embedding layer, the former using character embeddings and the latter using word embeddings.

Config.	Sequence Tagging	Matching

	5	0.904
	10	0.920
	20	0.927
	50	0.945
	100	0.928

Table 4: Subgraph Selection Results

The optimizer used for training the models is Adam (Kingma and Ba, 2014). The learning configurations are shown in Table 3.

For the hyper-parameters shown in Table 1, 2 and 3, we basically follow the settings in baseline literature (Yin et al., 2016; Dai et al., 2016) to promote a fair comparison. Other hyper-parameters, such as the τ in the relevance score (9), are tuned on the validation set.

Our proposed approach and the baseline approaches are evaluated in terms of (1) the top-n subgraph selection recall (the percentage of questions that have the correct subjects in the top-n candidates) and (2) the fact selection accuracy (i.e., the overall question answering accuracy).

4.3 Results

Subgraph selection The subgraph selection results for our approach and one of the state-of-the-art baselines (Yin et al., 2016) are summarized in Table 4. Both the baseline and our approach use unigrams to retrieve candidates. The baseline ranks the candidates by the length of the longest common subsequence with heuristics while we rank the candidates by the joint relevance score defined in (9). We see that the literal score used in the baseline performs well and using the semantic score (the log-likelihood) (8) only does not outperform the baseline (except for the top-50 case). This is due to the nature of how the questions in the SimpleQuestions dataset are generated—the majority of the questions only contain mentions matching the subjects in the Freebase in the lexical level, making the literal score sufficiently effective. However, we see that combining the literal score and semantic score outperforms the baseline by a large margin. For top-1, 5, 10, 20, 50 recall our ranking approach surpasses the baseline by 11.9%, 5.4%, 4.6%, 3.9%, 4.1%, respectively. Our approach also surpasses other baselines (Lukovnikov et al., 2017; Yu et al., 2017; Qu et al., 2018; Gupta et al., 2018) under the same settings. We note that the recall is not monotonically increasing with the top-n. The reason is that, as opposed to conventional methods which rank the entire subgraph returned from unigram matching to select the top-n candidates, we choose only the first 200 candidates from the subgraph and then rank them with our proposed ranking score. This is more efficient, but at the price of potentially dropping the correct facts. One could trade efficiency for accuracy by ranking all the candidates in the subgraph.

Fact selection The fact selection results for our approach and baselines are shown in Table 5. The object accuracy is the same as the overall question answer accuracy. Recall that in Section 3.3 we explained that the weight components in the well-order loss (13) are adjusted dynamically in the training to impose a larger penalty for mention–subject mismatches and hence enforce correct matches. This can be observed by looking at the different loss components and weights as well the subject and relation matching accuracies during the training. As weights for mention–subject matches increase, the losses for mention–subject matches also increase, while both the errors for mention–subject matches and pattern–relation matches are high. To reduce the errors, the model is forced to match mention–subject more correctly. As a result, the corresponding weights and losses decrease, and both mention–subject and pattern–relation match accuracies increase.

Effectiveness of well-order loss and joint-

	Approach	Obj. (= **Overall Acc.**)	Sub.	Rel.
1	AMPCNN (Yin et al., 2016)	76.4		
2	BiLSTM (Petrochuk and Zettlemoyer, 2018)	78.1		
3	AMPCNN + wo-loss	77.69		
4	JS + wo-loss	81.10	87.44	69.22
5	JS + wo-loss + sub50	**85.44**	91.47	76.98
6	JS + wo-loss + sub1	79.34	87.97	84.12

Table 5: Fact Selection Accuracy (%). The object accuracy is the end-to-end question answer accuracy, while subject and relation accuracies refer to separately computed subject accuracy and relation accuracy.

scoring model The first and second row of Table 5 are taken from the baseline AMPCNN (Yin et al., 2016) and BiLSTM (Petrochuk and Zettlemoyer, 2018) (the state of the art prior to our work[2]). The third row shows the accuracy of the baseline with our proposed well-order loss and we see a 1.3% improvement, demonstrating the effectiveness of the well-order loss. Further, the fourth row shows the accuracy of our joint-scoring (JS) model with well-order loss and we see a 3% improvement over the best baseline[3], demonstrating the effectiveness of the joint-scoring model.

Effectiveness of subgraph ranking The fifth row of Table 5 shows the accuracy of our joint-scoring model with well-order loss and top-50 ranked subgraph and we see a further 4.3% improvement over our model without subgraph ranking (the fourth row), and a 7.3% improvement over the best baseline. In addition, the subject accuracy increases by 4.0%, which is due to the subgraph ranking. Interestingly, the relation accuracy increases by 7.8%, which supports our claim that improving subject matching can improve relation matching. This demonstrates the effectiveness of our subgraph ranking and joint-scoring approach. The sixth row shows the accuracy of our joint-scoring model with well-order loss and only the top-1 subject. In this case, the subject accuracy is limited by the top-1 recall which is 85.5%. Despite that, our approach outperforms the best baseline by 1.2%. Further, the relation accuracy increases by 7.1% over the fifth row, because restricting the subject substantially confines the choice of relations. This shows that a sufficiently high top-1 subgraph recall reduces the need for subject matching.

Incorrect Sub. only	8.67
Incorrect Rel. only	16.26
Incorrect Sub. & Rel.	34.50
Other	40.57

Table 6: Error Decomposition (%). Percentages for total of 3157 errors.

4.4 Error Analysis

In order to analyze what constitutes the errors of our approach, we select the questions in the test set for which our best model has predicted wrong answers, and analyze the source of errors (see Table 6). We observe that the errors can be categorized as follows: (1) Incorrect subject prediction; however, some subjects are actually correct, e.g., the prediction "New York" v.s. "New York City." (2) Incorrect relation prediction; however, some relations are actually correct, e.g., the prediction "fictional-universe.fictional-character.character-created-by" v.s. "book.written-work.author" in the question "Who was the writer of Dark Sun?" and "music.album.genre" v.s. "music.artist.genre." (3) Incorrect prediction of both.

However, these three reasons only make up 59.43% of the errors. The other 40.57% errors are due to: (4) Ambiguous questions, which take up the majority of the errors, e.g., "Name a species of fish." or "What movie is a short film?" These questions are too general and can have multiple correct answers. Such issues in the SimpleQuestions dataset are analyzed by Petrochuk and Zettlemoyer (2018) (see further discussion on this at the end of this Section). (5) Non-simple questions,

---

[2] As noted, Ture and Jojic (2017) reported better performance than us but neither Petrochuk and Zettlemoyer (2018) nor Mohammed et al. (2018) could replicate their result.

[3] At the time of submission we also found that Hao et al. (2018) reported 80.2% accuracy.

e.g., "Which drama film was released in 1922?" This question requires two KB facts instead of one to answer correctly. (6) Wrong fact questions where the reference fact is non-relevant, e.g., "What is an active ingredient in Pacific?" is labeled with "Triclosan 0.15 soap". (7) Out of scope questions, which have entities or relations out the scope of FB2M. (8) Spelling inconsistencies, e.g., the predicted answer "Operation Shylock: A Confession" v.s. the reference answer "Operation Shylock", and the predicted answer "Tom and Jerry: Robin Hood and His Merry Mouse" v.s. the reference answer "Tom and Jerry". For these cases, even when the models predict the subjects and relations correctly, these questions are fundamentally *unanswerable*.

Although these issues are inherited from the dataset itself, given the large size of the dataset and the small proportion of the problematic questions, it is sufficient to validate the reliability and significance of our performance improvement and conclusions.

Answerable Questions Redefined Petrochuk and Zettlemoyer (2018) set an upper bound of 83.4% for the accuracy on the SimpleQuestions dataset. However, our models are able to do better than the upper bound. Are we doing something wrong? Petrochuk and Zettlemoyer (2018) claim that a question is unanswerable if there exist multiple valid subject–relation pairs in the knowledge graph, but we claim that a question is unanswerable if and only if there is no valid fact in the knowledge graph. There is a subtle difference between these two claims.

Based on different definitions of answerable questions, we further claim that incorrect subject or incorrect relation can still lead to a correct answer. For example, for the question "What is a song from Hier Komt De Storm?" with the fact (Hier Komt De Storm: 1980-1990 live, music.release.track-list, Stephanie), our predicted subject "Hier Komt De Storm: 1980-1990 live" does not match the reference subject "Hier Komt De Storm", but our model predicts the correct answer "Stephanie" because it can deal with inexact match of the subjects. In the second example, for the question "Arkham House is the publisher behind what novel?", our predicted relation "book.book-edition.publisher" does not match the reference relation "book.publishing-company.books-published", but our model predicts the correct answer "Watchers at the Strait Gate" because it can deal with paraphrases of relations. In the third example, for the question "Who was the king of Lydia and Croesus's father?", the correct subject "Croesus" ranks second in our subject predictions and the correct relation "people.person.parents" ranks fourth in our relation predictions, but our model predicts the correct answer "Alyattes of Lydia" because it reweighs the scores with respect to the subject–relation dependency and the combined score of subject and relation ranks first.

To summarize, the reason that we are able to redefine answerable questions and achieve significant performance gain is that we take advantage of the subgraph ranking and the subject–relation dependency.

5 Conclusions

In this work, we propose a subgraph ranking method and joint-scoring approach to improve the performance of KBSQA. The ranking method combines literal and semantic scores to deal with inexact match and achieves better subgraph selection results than the state of the art. The joint-scoring model with well-order loss couples the dependency of subject matching and relation matching and enforces the order of scores. Our proposed approach achieves a new state of the art on the SimpleQuestions dataset, surpassing the best baseline by a large margin.

In the future work, one could further improve the performance on simple question answering tasks by exploring relation ranking, different embedding strategies and network structures, dealing with open questions and out-of-scope questions. One could also consider extending our approach to complex questions, e.g., multi-hop questions where more than one supporting facts is required. Potential directions may include ranking the subgraph by assigning each edge (relation) a closeness score and evaluating the length of the shortest path between any two path-connected entity nodes.

Abstract

Open-domain question answering remains a challenging task as it requires models that are capable of understanding questions and answers, collecting useful information, and reasoning over evidence. Previous work typically formulates this task as a reading comprehension or entailment problem given evidence retrieved from search engines. However, existing techniques struggle to retrieve indirectly related evidence when no directly related evidence is provided, especially for complex questions where it is hard to parse precisely what the question asks. In this paper we propose a retriever-reader model that learns to attend on essential terms during the question answering process. We build (1) an essential term selector which first identifies the most important words in a question, then reformulates the query and searches for related evidence; and (2) an enhanced reader that distinguishes between essential terms and distracting words to predict the answer. We evaluate our model on multiple open-domain multiple-choice QA datasets, notably performing at the level of the state-of-the-art on the AI2 Reasoning Challenge (ARC) dataset.

1 Introduction

Open-domain question answering (QA) has been extensively studied in recent years. Many existing works have followed the 'search-and-answer' strategy and achieved strong performance (Chen et al., 2017; Kwon et al., 2018; Wang et al., 2018b) spanning multiple QA datasets such as TriviaQA (Joshi et al., 2017), SQuAD (Rajpurkar et al., 2016), MS-Macro (Nguyen et al., 2016), ARC (Clark et al., 2018) among others.

However, open-domain QA tasks become inherently more difficult when (1) dealing with questions with little available evidence; (2) solving questions where the answer type is free-form text (e.g. multiple-choice) rather than a span among existing passages (i.e., 'answer span'); or when (3) the need arises to understand long and complex questions and reason over multiple passages, rather than simple text matching. As a result, it is essential to incorporate commonsense knowledge or to improve retrieval capability to better capture partially related evidence (Chen et al., 2017).

As shown in Table 1, the TriviaQA, SQuAD, and MS-Macro datasets all provide passages within which the correct answer is guaranteed to exist. However, this assumption ignores the difficulty of retrieving question-related evidence from a large volume of open-domain resources, especially when considering complex questions which require reasoning or commonsense knowledge. On the other hand, ARC does not provide passages known to contain the correct answer. Instead, the task of identifying relevant passages is left to the solver. However, questions in ARC have multiple answer choices that provide indirect information that can help solve the question. As such an effective model needs to account for relations among passages, questions, and answer choices. Real-world datasets such as Amazon-QA (a corpus of user queries from Amazon) (McAuley and Yang, 2016) also exhibit the same challenge, i.e., the need to surface related evidence from which to extract or summarize an answer.

Figure 1 shows an example of a question in the ARC dataset and demonstrates the difficulties in retrieval and reading comprehension. As shown for Choice 1 (C1), a simple concatenation of the

[1] For SQuAD and TriviaQA, since the questions are paired with span-type answers, it is convenient to obtain ranking supervision where retrieved passages are relevant via distant supervision; however free-form questions in ARC and Amazon-QA result in a lack of supervision which makes the problem more difficult. For MS-Macro, the dataset is designed to annotate relevant passages though it has free-form answers.

Proceedings of NAACL-HLT 2019, pages 335–344

Dataset	# of questions	Open-domain	Multiple choice	Passage retrieval	No ranking supervision[1]
ARC (Clark et al., 2018)	≈ 7K	✓	✓	✓	✓
Amazon-QA (McAuley and Yang, 2016)	≈ 1.48M	✓			✓
SQuAD (Rajpurkar et al., 2016)	≈ 100K	✓			
TriviaQA (Joshi et al., 2017)	≈ 650K	✓			
MS-Macro (Nguyen et al., 2016)	≈ 1M	✓			

Table 1: Differences among popular QA datasets.

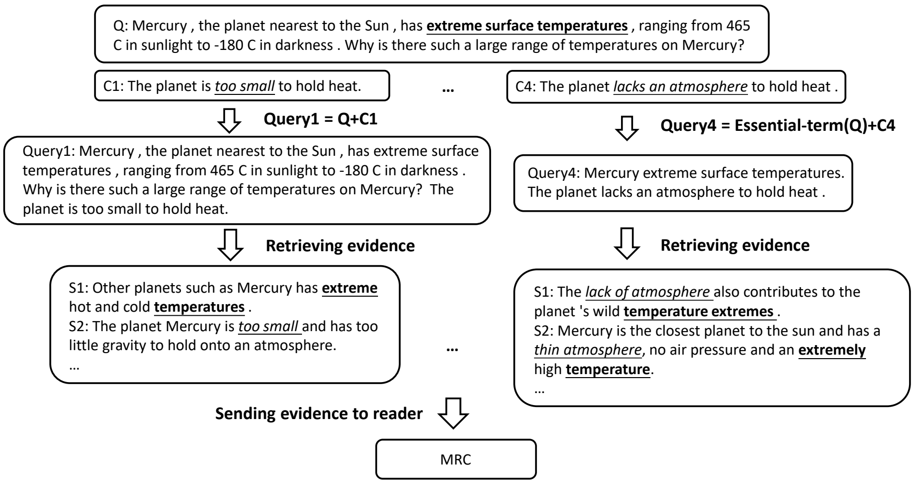

Figure 1: Example of the retrieve-and-read process to solve open-domain questions. Words related with the question are in **bold**; and words related with C1 and C4 are in *italics*.

question and the answer choice is not a reliable query and is of little help when trying to find supporting evidence to answer the question (e.g. we might retrieve sentences similar to the question or the answer choice, but would struggle to find evidence explaining *why* the answer choice is correct). On the other hand, a reformulated query consisting of essential terms in the question and Choice 4 can help retrieve evidence explaining why Choice 4 is a correct answer. To achieve this, the model needs to (1) ensure that the retrieved evidence supports the fact mentioned in both the question and the answer choices and (2) capture this information and predict the correct answer.

To address these difficulties, we propose an essential-term-aware Retriever-Reader (ET-RR) model that learns to attend on essential terms during retrieval and reading. Specifically, we develop a two-stage method with an essential term selector followed by an attention-enhanced reader.

Essential term selector. ET-Net is a recurrent neural network that seeks to understand the question and select essential terms, i.e., key words, from the question. We frame this problem as a classification task for each word in the question. These essential terms are then concatenated with each answer choice and fed into a retrieval engine to obtain related evidence.

Attention-Enhanced Reader. Our neural reader takes the triples (question, answer choice, retrieved passage) as input. The reader consists of a sequence of language understanding layers: an input layer, attention layer, sequence modeling layer, fusion layer, and an output layer. The attention and fusion layers help the model to obtain a refined representation of one text sequence based on the understanding of another, e.g. a passage representation based on an understanding of the question. We further add a choice-interaction module to handle the semantic relations and differences between answer choices. Experiments show that this can further improve the model's accuracy.

We evaluate our model on the ARC Challenge dataset, where our model achieves an accuracy of 36.61% on the test set, and outperformed all leaderboard solutions at the time of writing (Sep. 2018). To compare with other benchmark datasets, we adapt RACE (Lai et al., 2017) and MCScript (Ostermann et al., 2018) to the open domain setting by removing their supervision in the form of relevant passages. We also consider a large-scale real-world open-domain dataset, Amazon-QA, to evaluate our model's scalability and to compare against standard benchmarks designed for the open-domain setting. Experiments on these three datasets show that ET-RR outperforms baseline models by a large margin. We conduct multiple ablation studies to show the effectiveness of each component of our model. Finally, we perform in-depth error analysis to explore the model's limitations.

2 Related Work

There has recently been growing interest in building better retrievers for open-domain QA. Wang et al. (2018b) proposed a Reinforced Ranker-Reader model that ranks retrieved evidence and assigns different weights to evidence prior to processing by the reader. Min et al. (2018) demonstrated that for several popular MRC datasets (e.g. SQuAD, TriviaQA) most questions can be answered using only a few sentences rather than the entire document. Motivated by this observation, they built a sentence selector to gather this potential evidence for use by the reader model. Nishida et al. (2018) developed a multi-task learning (MTL) method for a retriever and reader in order to obtain a strong retriever that considers certain passages including the answer text as positive samples during training. The proposed MTL framework is still limited to scenarios where it is feasible to discover whether the passages contain the answer span. Although these works have achieved progress on open-domain QA by improving the ranking or selection of given evidence, few have focused on the scenario where the model needs to start by searching for the evidence itself.

Scientific Question Answering (SQA) is a representative open-domain task that requires capability in both retrieval and reading comprehension. In this paper, we study question answering on the AI2 Reasoning Challenge (ARC) scientific QA dataset (Clark et al., 2018). This dataset contains multiple-choice scientific questions from 3rd to 9th grade standardized tests and a large corpus of relevant information gathered from search engines. The dataset is partitioned into "Challenge" and "Easy" sets. The challenge set consists of questions that cannot be answered correctly by either of the solvers based on Pointwise Mutual Information (PMI) or Information Retrieval (IR). Existing models tend to achieve only slightly better and sometimes even worse performance than random guessing, which shows that existing models are not well suited to this kind of QA task.

Jansen et al. (2017) first developed a rule-based focus word extractor to identify essential terms in the question and answer candidates. The extracted terms are used to aggregate a list of potential answer justifications for each answer candidate. Experiments shown that focus words are beneficial for SQA on a subset of the ARC dataset. Khashabi et al. (2017) also worked on the problem of finding essential terms in a question for solving SQA problems. They published a dataset containing over 2,200 science questions annotated with essential terms and train multiple classifiers on it. Similarly, we leverage this dataset to build an essential term selector using a neural network-based algorithm. More recently, Boratko et al. (2018) developed a labeling interface to obtain high quality labels for the ARC dataset. One finding is that human annotators tend to retrieve better evidence after they reformulate the search queries which are originally constructed by a simple concatenation of question and answer choice. By feeding the evidence obtained by human-reformulated queries into a pre-trained MRC model (i.e., DrQA (Chen et al., 2017)) they achieved an accuracy increase of 42% on a subset of 47 questions. This shows the potential for a "human-like" retriever to boost performance on this task.

Query reformulation has been shown to be effective in information retrieval (Lavrenko and Croft, 2001). Nogueira and Cho (2017) modeled the query reformulation task as a binary term selection problem (i.e., whether to choose the term in the original query and the documents retrieved using the original query). The selected terms are then concatenated to form the new query. Instead of choosing relevant words, Buck et al. (2018) proposed a sequence-to-sequence model to generate new queries. Das et al. (2019) proposed Multi-step Retriever-Reader which explores an iterative retrieve-and-read strategy for open-domain question answering. It formulates the query reformulation problem in the embedding space where the vector representation of the question is changed to improve the performance. Since there is no supervision for training the query reformulator, all these methods using reinforcement learning to maximize the task-specific metrics (e.g. Recall for paragraph ranking, F1 and Exact Matching for span-based MRC). Different from these works, we train the query reformulator using an annotated dataset as supervision and then apply the output to a separate reader model. We leave the exploration of training our model end-to-end using reinforcement learning as future work.

3 Approach

In this section, we introduce the essential-term-aware retriever-reader model (ET-RR). As shown in Figure 2, we build a term selector to discover which terms are essential in a question. The selected terms are then used to formulate a more efficient query enabling the retriever to obtain related evidence. The retrieved evidence is then fed to the reader to predict the final answer.

For a question with q words $\mathbf{Q} = \{w_t^Q\}_{t=1}^q$ along with its N answer choices $\mathbf{C} = \{\mathbf{C}_n\}_{n=1}^N$ where $\mathbf{C}_n = \{w_t^C\}_{t=1}^c$, the essential-term selector chooses a subset of essential terms $\mathbf{E} \subset \mathbf{Q}$, which are then concatenated with each $\mathbf{C}_n$ to formulate a query. The query for each answer choice, $\mathbf{E} + \mathbf{C}_n$, is sent to the retriever (e.g. Elastic Search[2]), and the top K retrieved sentences based on the scores returned by the retriever are then concatenated into the evidence passage $\mathbf{P}_n = \{w_t^P\}_{t=1}^K$.

Next, given these text sequences $\mathbf{Q}$, $\mathbf{C}$, and $\mathbf{P} = \{\mathbf{P}_n\}_{n=1}^N$, the reader will determine a matching score for each triple $\{\mathbf{Q}, \mathbf{C}_n, \mathbf{P}_n\}$. The answer choice $\mathbf{C}_{n^*}$ with the highest score is selected.

We first introduce the reader model in Section 3.1 and then the essential term selector in Section 3.2.

3.1 Reader Model

3.1.1 Input Layer

To simplify notation, we ignore the subscript n denoting the answer choice until the final output layer. In the input layer, all text inputs—the question, answer choices, and passages, i.e., retrieved evidence—are converted into embedded representations. Similar to Wang (2018), we consider the following components for each word:

Word Embedding. Pre-trained GloVe word embedding with dimensionality $d_w = 300$.

Part-of-Speech Embedding and Named-Entity Embedding. The part-of-speech tags and named entities for each word are mapped to embeddings with dimension 16.

Relation Embedding. A relation between each word in $\mathbf{P}$ and any word in $\mathbf{Q}$ or $\mathbf{C}$ is mapped to an embedding with dimension 10. In the case that multiple relations exist, we select one uniformly at random. The relation is obtained by querying ConceptNet (Speer et al., 2017).

Feature Embeddings. Three handcrafted features are used to enhance the word representations: (1) Word Match; if a word or its lemma of $\mathbf{P}$ exists in $\mathbf{Q}$ or $\mathbf{C}$, then this feature is 1 (0 otherwise). (2) Word Frequency; a logarithmic term frequency is calculated for each word. (3) Essential Term; for the i-th word in $\mathbf{Q}$, this feature, denoted as w_{e_i}, is 1 if the word is an essential term (0 otherwise). Let $\mathbf{w}_e = [w_{e_1}, w_{e_2}, \ldots, w_{e_q}]$ denote the essential term vector.

For $\mathbf{Q}, \mathbf{C}, \mathbf{P}$, all of these components are concatenated to obtain the final word representations $\mathbf{W}_Q \in \mathbb{R}^{q \times d_Q}, \mathbf{W}_C \in \mathbb{R}^{c \times d_C}, \mathbf{W}_P \in \mathbb{R}^{p \times d_P}$, where d_Q, d_C, d_P are the final word dimensions of $\mathbf{Q}$, $\mathbf{C}$, and $\mathbf{P}$.

3.1.2 Attention Layer

As shown in Figure 2, after obtaining word-level embeddings, attention is added to enhance word representations. Given two word embedding sequences $\mathbf{W}_U, \mathbf{W}_V$, word-level attention is calculated as:

$$\begin{aligned} \mathbf{M}'_{UV} &= \mathbf{W}_U \mathbf{U} \cdot (\mathbf{W}_V \mathbf{V})^\top \\ \mathbf{M}_{UV} &= \mathrm{softmax}(\mathbf{M}'_{UV}) \\ \mathbf{W}_U^V &= \mathbf{M}_{UV} \cdot (\mathbf{W}_V \mathbf{V}), \end{aligned} \tag{1}$$

where $\mathbf{U} \in \mathbb{R}^{d_U \times d_w}$ and $\mathbf{V} \in \mathbb{R}^{d_V \times d_w}$ are two matrices that convert word embedding sequences to dimension d_w, and $\mathbf{M}'_{UV}$ contains dot products between each word in $\mathbf{W}_U$ and $\mathbf{W}_V$, and softmax is applied on $\mathbf{M}'_{UV}$ row-wise. Three types of attention are calculated using Equation (1): (1) question-aware passage representation $\mathbf{W}_P^Q \in \mathbb{R}^{p \times d_w}$; (2) question-aware choice representation $\mathbf{W}_C^Q \in \mathbb{R}^{c \times d_w}$; and (3) passage-aware choice representation $\mathbf{W}_C^P \in \mathbb{R}^{c \times d_w}$.

3.1.3 Sequence Modeling Layer

To model the contextual dependency of each text sequence, we use BiLSTMs to process the word representations obtained from the input layer and attention layer:

$$\begin{aligned} \mathbf{H}^q &= \mathbf{BiLSTM}[\mathbf{W}_Q] \\ \mathbf{H}^c &= \mathbf{BiLSTM}[\mathbf{W}_C; \mathbf{W}_C^P; \mathbf{W}_C^Q] \\ \mathbf{H}^p &= \mathbf{BiLSTM}[\mathbf{W}_P; \mathbf{W}_P^Q], \end{aligned} \tag{2}$$

---

[2] https://www.elastic.co/products/elasticsearch

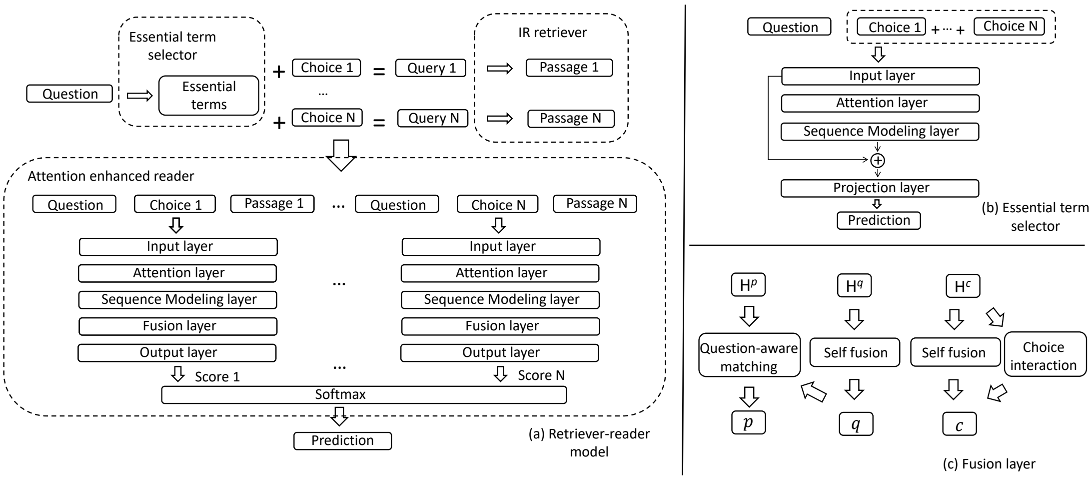

Figure 2: Model structure for our essential-term-aware retriever-reader model.

where $\mathbf{H}^q \in \mathbb{R}^{q\times l}, \mathbf{H}^c \in \mathbb{R}^{c\times l}$, and $\mathbf{H}^p \in \mathbb{R}^{p\times l}$ are the hidden states of the BiLSTMs, ';' is feature-wise concatenation, and l is the size of the hidden states.

3.1.4 Fusion Layer

We further convert each question and answer choice into a single vector: $\mathbf{q} \in \mathbb{R}^l$ and $\mathbf{c} \in \mathbb{R}^l$:

$$\begin{aligned}\boldsymbol{\alpha}_q &= \text{softmax}([\mathbf{H}^q; \mathbf{w}_e] \cdot \mathbf{w}_{sq}^\top),\ \mathbf{q} = \mathbf{H}^{q\top}\boldsymbol{\alpha}_q\\ \boldsymbol{\alpha}_c &= \text{softmax}(\mathbf{H}^c \cdot \mathbf{w}_{sc}^\top),\ \mathbf{c} = \mathbf{H}^{c\top}\boldsymbol{\alpha}_c,\end{aligned} \tag{3}$$

where the essential-term feature $\mathbf{w}_e$ from Section 3.1.1 is concatenated with $\mathbf{H}^q$, and $\mathbf{w}_{sq}$ and $\mathbf{w}_{sc}$ are learned parameters.

Finally, a bilinear sequence matching is calculated between $\mathbf{H}^p$ and $\mathbf{q}$ to obtain a question-aware passage representation, which is used as the final passage representation:

$$\boldsymbol{\alpha}_p = \text{softmax}(\mathbf{H}^p \cdot \mathbf{q}); \quad \mathbf{p} = \mathbf{H}^{p\top}\boldsymbol{\alpha}_p. \tag{4}$$

3.1.5 Choice Interaction

When a QA task provides multiple choices for selection, the relationship between the choices can provide useful information to answer the question. Therefore, we integrate a choice interaction layer to handle the semantic correlation between multiple answer choices. Given the hidden state $\mathbf{H}^{c_n}$ of choice c_n and $\mathbf{H}^{c_i}$ of other choices $c_i, \forall i \neq n$, we calculate the differences between the hidden states and apply max-pooling over the differences:

$$\mathbf{c}_{inter} = \text{Maxpool}(\mathbf{H}^{c_n} - \frac{1}{N-1}\sum_{i\neq n}\mathbf{H}^{c_i}), \tag{5}$$

where N is the total number of answer choices. Here, $\mathbf{c}_{inter}$ characterizes the differences between an answer choice c_n and other answer choices. The final representation of an answer choice is updated by concatenating the self-attentive answer choice vector and inter-choice representation as $\mathbf{c}^{final} = [\mathbf{c}; \mathbf{c}_{inter}]$.

3.1.6 Output Layer

For each tuple $\{\mathbf{q}, \mathbf{p}_n, \mathbf{c}_n\}_{n=1}^N$, two scores are calculated by matching (1) the passage and answer choice and (2) question and answer choice. We use a bilinear form for both matchings. Finally, a softmax function is applied over N answer choices to determine the best answer choice:

$$\begin{aligned} s_n^{pc} = \mathbf{p}_n\mathbf{W}^{pc}\mathbf{c}_n^{final}; \quad s_n^{qc} = \mathbf{q}\mathbf{W}^{qc}\mathbf{c}_n^{final}\\ \mathbf{s} = \text{softmax}(\mathbf{s}^{pc}) + \text{softmax}(\mathbf{s}^{qc}),\end{aligned} \tag{6}$$

where s_n^{pc}, s_n^{qc} are the scores for answer choice $1 \leq n \leq N$; $\mathbf{s}^{pc}, \mathbf{s}^{qc}$ are score vectors for all N choices; and $\mathbf{s}$ contains the final scores for each answer choice. During training, we use a cross-entropy loss.

3.2 Essential Term Selector

Essential terms are key words in a question that are crucial in helping a retriever obtain related evidence. Given a question $\mathbf{Q}$ and N answer choices $\mathbf{C}_1, \ldots, \mathbf{C}_N$, the goal is to predict a binary variable y_i for each word Q_i in the question $\mathbf{Q}$, where $y_i = 1$ if Q_i is an essential term and 0 otherwise. To address this problem, we build a neural model, ET-Net, which has the same design as the reader model for the input layer, attention layer, and sequence modeling layer to obtain the hidden state $\mathbf{H}^q$ for question $\mathbf{Q}$.

In detail, we take the question $\mathbf{Q}$ and the concatenation $\mathbf{C}$ of all N answer choices as input to

Question	If an object is attracted to a magnet, the object is most likely made of (A) wood (B) plastic (C) cardboard (D) metal
# annotators	5
Annotation	If,0; an,0; object,3; is,0; attracted,5; to,0; a,0; magnet,,5; the,0; object,1; is,0; most,0; likely,0; made,2; of,0

Table 2: Example of essential term data.

ET-Net. $\mathbf{Q}$ and $\mathbf{C}$ first go through an input layer to convert to the embedded word representation, and then word-level attention is calculated to obtain a choice-aware question representation $\mathbf{W}_Q^C$ as in Equation (1). We concatenate the word representation and word-level attention representation of the question and feed it into the sequence modeling layer:

$$\mathbf{H}^q = \mathbf{BiLSTM}[\mathbf{W}_Q; \mathbf{W}_Q^C]. \tag{7}$$

As shown in Figure 2, the hidden states obtained from the attention layer are then concatenated with the embedded representations of $\mathbf{Q}$ and fed into a projection layer to obtain the prediction vector $\mathbf{y} \in \mathbb{R}^q$ for all words in the question:

$$\mathbf{y} = [\mathbf{H}^q; \mathbf{W}_Q^f] \cdot \mathbf{w}^s, \tag{8}$$

where $\mathbf{w}^s$ contains the learned parameters, and $\mathbf{W}_Q^f$ is the concatenation of the POS embedding, NER embedding, relation embedding, and feature embedding from Section 3.1.1.

After obtaining the prediction for each word, we use a binary cross-entropy loss to train the model. During evaluation, we take words with y_i greater than 0.5 as essential terms.

4 Experiments

In this section, we first discuss the performance of the essential term selector, ET-Net, on a public dataset. We then discuss the performance of the whole retriever-reader pipeline, ET-RR, on multiple open-domain datasets.For both the ET-Net and ET-RR models, we use 96-dimensional hidden states and 1-layer BiLSTMs in the sequence modeling layer. A dropout rate of 0.4 is applied for the embedding layer and the BiLSTMs' output layer. We use adamax (Kingma and Ba, 2014) with a learning rate of 0.02 and batch size of 32. The model is trained for 100 epochs. Our code is released at `https://github.com/nijianmo/arc-etrr-code`.

Model	Precision	Recall	F1
MaxPMI	0.88	0.65	0.75
SumPMI	0.88	0.65	0.75
PropSurf	0.68	0.64	0.66
PropLem	0.76	0.64	0.69
ET Classifier	0.91	0.71	0.80
ET-Net	0.74	**0.90**	**0.81**

Table 3: Performance of different selectors.

4.1 Performance on Essential Term Selection

We use the public dataset from Khashabi et al. (2017) which contains 2,223 annotated questions, each accompanied by four answer choices. Table 2 gives an example of an annotated question. As shown, the dataset is annotated for binary classification. For each word in the question, the data measures whether the word is an "essential" term according to 5 annotators. We then split the dataset into training, development, and test sets using an 8:1:1 ratio and select the model that performs best on the development set.

Table 3 shows the performance of our essential term selector and baseline models from Khashabi et al. (2017). The second best model (ET Classifier) is an SVM-based model from Khashabi et al. (2017) requiring over 100 handcrafted features. As shown, our ET-Net achieves a comparable result with ET Classifier in terms of the F1 Score.

Table 4 shows example predictions made by ET-Net. As shown, ET-Net is capable of selecting most ground-truth essential terms. It rejects certain words such as "organisms" which have a high TF-IDF in the corpus but are not relevant to answering a particular question. This shows its ability to discover essential terms according to the context of the question.

4.2 Performance on Open-domain Multiple-choice QA

We train and evaluate our proposed pipeline method ET-RR on four open-domain multiple-choice QA datasets. All datasets are associated with a sentence-level corpus. Detailed statistics are shown in Table 5.

- ARC (Clark et al., 2018): We consider the 'Challenge' set in the ARC dataset and use the provided corpus during retrieval.
- RACE-Open: We adapted the RACE dataset (Lai et al., 2017) to the open-domain setting. Originally, each question in RACE comes

Example questions
Which **unit** of **measurement** can be used to describe the **length** of a **desk** ?
One way **animal** usually **respond** to a sudden **drop** in **temperature** is by
Organisms require energy to survive. Which of the following **processes provides energy** to the body ?

Table 4: Examples of essential term prediction (in questions) by ET-Net. True positives are marked bold and underlined while false positives are only underlined.

Dataset	Train	Dev	Test	Corpus
ARC	1,119	299	1,172	1.46M
RACE-Open	9,531	473	528	0.52M
MCScript-Open	1,036	156	319	24.2K
Amazon-Patio	36,587	4,531	4,515	2.55M
Amazon-Auto	49,643	6,205	6,206	7.32M
Amazon-Cell	40,842	5,105	5,106	1.86M

Table 5: Statistics on ARC, RACE-Open, MCScript-Open and Amazon-QA. Corpus size is the number of sentences.

Dataset	Example questions
ARC	The best way to separate salt from water is with the use of Which geologic process most likely caused the formation of the Mount St. Helens Volcano?
RACE-Open	According to the article, what does the band Four Square hope to do in the future? According to the article we know it is _ to prevent the forests from slowly disappearing.
Amazon-QA	For anyone with small ears, do these fit comfortably or do they feel like they are always going to fall out, not in correctly, etc. Does it remove easily and does it leave any sticky residue behind? thanks in advance.

Table 6: Example of predictions on ARC, RACE-Open and Amazon-QA. Predicted terms are underlined.

with a specific passage. To enable passage retrieval, we concatenate all passages into a corpus with sentence deduplication.[3]

- MCScript-Open: The MCScript (Ostermann et al., 2018) dataset is also adapted to the open-domain setting. Again we concatenate all passages to build the corpus.[4]
- Amazon-QA: The Amazon-QA dataset (McAuley and Yang, 2016) is an open-domain QA dataset covering over one million questions across multiple product categories. Each question is associated with a free-form answer. We adapt it into a 2-way multiple-choice setting by randomly sampling an answer from other questions as an answer distractor. We split all product reviews at the sentence-level to build the corpus. We consider three categories from the complete dataset in our experiments.

In the experiments, ET-RR uses ET-Net to choose essential terms in the question. Table 6 shows example predictions on these target datasets. Then it generates a query for each of the N answer choices by concatenating essential terms and the answer choice. For each query, ET-RR obtains the top K sentences returned by the retriever and considers these sentences as a passage for the reader. We set $K = 10$ for all experiments.

We compare ET-RR with existing retrieve-and-read methods on both datasets. As shown in Table 7, on the ARC dataset, ET-RR outperforms all previous models without using pre-trained models and achieves a relative 8.1% improvement over the second best BiLSTM Max-out method (Mihaylov et al., 2018). Recently, finetuning on pre-trained models has shown great improvement over a wide range of NLP tasks. Sun et al. (2019) proposed a 'Reading Strategies' method to finetune the pre-trained model OpenAI GPT, a language model trained on the BookCorpus dataset (Radford, 2018). They trained Reading Strategies on the RACE dataset to obtain more auxiliary knowledge and then finetune that model on the ARC corpus. Table 8 demonstrates the performance comparison of ET-RR and Reading Strategies on ARC. As shown, though Reading Strategies trained on both ARC and RACE dataset outperforms ET-RR, ET-RR outperforms Reading Strategies using only the ARC dataset at training time.

On the RACE-Open and MCScript-Open datasets, ET-RR achieves a relative improvement of 24.6% and 10.5% on the test set compared with the second best method IR solver respectively. We also evaluate on multiple categories of

---

[3] As short questions might not contain any words which can relate the question to any specific passage or sentence, we only keep questions with more than 15 words.

[4] We keep questions with more than 10 words rather than 15 words to ensure that there is sufficient data.

Model	ARC Test	RACE-Open Test	MCScript-Open Test

the Amazon-QA dataset. As shown in Table 9, ET-RR increases the accuracy by 10.33% on average compared to the state-of-the-art model Moqa (McAuley and Yang, 2016). We also compare ET-RR with ET-RR (Concat), which is a variant of our proposed model that concatenates the question and choice as a query for each choice. Among all datasets, ET-RR outperforms ET-RR (concat) consistently which shows the effectiveness of our essential-term-aware retriever.

4.3 Ablation study

We investigate how each component contributes to model performance.

Performance of reader. Our reader alone can be applied on MRC tasks using the given passages. Here, we evaluate our reader on the original RACE dataset to compare with other MRC models as shown in Table 10. As shown, the recently proposed Reading Strategies and OpenAI GPT models, that finetune generative pre-trained models achieve the highest scores. Among non-pre-trained models, our reader outperforms other baselines: Bi-attn (MRU) (Tay et al., 2018) and Hierarchical Co-Matching (Wang et al., 2018a) by a relative improvement of 3.8%.

Attention components. Table 11 demonstrates how the attention components contribute to the performance of ET-RR. As shown, ET-RR with all attention components performs the best on the ARC test set. The performance of ET-RR without passage-question attention drops the most significantly out of all the components. It is worth noting that the choice interaction layer gives a further 0.24% boost on test accuracy.

Essential term selection. To understand the contribution of our essential-term selector, we compare ET-RR with two variants: (1) ET-RR (Concat) and (2) ET-RR (TF-IDF). For ET-RR (TF-IDF), we calculate the TF-IDF scores and take words with the top 30% of TF-IDF scores in the question to concatenate with each answer choice as a query.[5]

Table 12 shows an ablation study comparing different query formulation methods and amounts of retrieved evidence K. As shown, with the essential term selector ET-Net, the model consistently outperforms other baselines, given different numbers of retrievals K. Performance for all models is best when $K = 10$. Furthermore, only using TF-IDF to select essential terms in a question is not effective. When $K = 10$, the ET-RR (TF-IDF)

---

[5] According to the annotated dataset, around 30% of the terms in each question are labelled as essential.

Model	ET-RR (Concat)		ET-RR (TF-IDF)		ET-RR	
Top K	Dev	Test	Dev	Test	Dev	Test
5	39.26	33.36	39.93	34.73	39.93	35.59
10	38.93	35.33	39.43	35.24	**43.96**	**36.61**
20	41.28	34.56	38.59	33.88	42.28	35.67

Table 12: Comparison of query formulation methods and amounts of retrieved evidence (i.e., top K) on the ARC dataset, in terms of percentage accuracy.

method performs even worse than ET-RR (Concat). This illustrates the challenges in understanding what is essential in a question.

Though ET-RR consistently outperforms ET-RR (TF-IDF), the improvement is relatively modest on the Test set (around 1.4%). A similar outcome has been reported in Jansen et al. (2017); Khashabi et al. (2017) where essential term extraction methods have shown around 2%-4% gain compared with TF-IDF models and struggle to obtain further improvement on SQA tasks. This consensus might show the discrepancy of essential terms between human and machine (i.e., the essential terms obtained using a human annotated dataset might not be helpful in a machine inference model). Another reason might be the current retrieval method does not effectively use these essential terms and the performance highly depends on the dataset. Note that the ET-RR outperforms ET-RR (TF-IDF) by around 4% on the Dev set. Therefore, how to develop well-formed single or even multi-hop queries using these terms are worth studying in the future.

4.4 Error Analysis

Table 13 shows two major types of error, where the correct answer choice is in **bold** and the predicted answer choice is in *italics*.

Retrieved supporting evidence but failed to reason over it. For the first question, there exists evidence that can justify the answer candidate (C). However, the model chooses (D) which has more words overlapping with its evidence. This shows that the model still lacks the reasoning capability to solve complex questions.

Failed to retrieve supporting evidence. For the second question, the retrieved evidence of both the correct answer (D) and the prediction (B) is not helpful to solve the question. Queries such as 'what determines the year of a planet' are needed to acquire the knowledge for solving this question. This poses further challenges to design a retriever that can rewrite such queries.

The elements carbon, hydrogen, and oxygen are parts of many different compounds. Which explains why these three elements can make so many different compounds?
(A) They can be solids, liquids, or gases. (B) They come in different sizes and shapes. **(C) They combine in different numbers and ratios.** * There are many different types of compounds because atoms of elements combine in many different ways (and in different whole number ratios) to form different compounds. *(D) They can be a proton, a neutron, or an electron.* * Atoms of different elements have a different number of protons, neutrons, and electrons.
Which planet in the solar system has the longest year?
(A) The planet closest to the Sun. *(B) The planet with the longest day.* * The planet with the longest day is Venus; a day on Venus takes 243 Earth days. (C) The planet with the most moons. **(D) The planet farthest from the Sun.** * The last planet discovered in our solar system is farthest away from the sun.

Table 13: Examples where ET-RR fails on ARC. The retrieved evidence for each answer candidate is marked by *.

5 Conclusion

We present a new retriever-reader model (ET-RR) for open-domain QA. Our pipeline has the following contributions: (1) we built an essential term selector (ET-Net) which helps the model understand which words are essential in a question leading to more effective search queries when retrieving related evidence; (2) we developed an attention-enhanced reader with attention and fusion among passages, questions, and candidate answers. Experimental results show that ET-RR outperforms existing QA models on open-domain multiple-choice datasets as ARC Challenge, RACE-Open, MCScript-Open and Amazon-QA. We also perform in-depth error analysis to show the limitations of current work. For future work, we plan to explore the directions of (1) constructing multi-hop query and (2) developing end-to-end retriever-reader model via reinforcement learning.

Acknowledgments

We thank Jade Huang for proofreading the paper, Liang Wang and Daniel Khashabi for sharing code and the annotated dataset with us. We thank all the reviewers for their constructive suggestions.

Abstract

In relation extraction for knowledge-based question answering, searching from one entity to another entity via a single relation is called "one hop". In related work, an exhaustive search from all one-hop relations, two-hop relations, and so on to the max-hop relations in the knowledge graph is necessary but expensive. Therefore, the number of hops is generally restricted to two or three. In this paper, we propose UHop, an unrestricted-hop framework which relaxes this restriction by use of a transition-based search framework to replace the relation-chain-based search one. We conduct experiments on conventional 1- and 2-hop questions as well as lengthy questions, including datasets such as WebQSP, PathQuestion, and Grid World. Results show that the proposed framework enables the ability to halt, works well with state-of-the-art models, achieves competitive performance without exhaustive searches, and opens the performance gap for long relation paths.

1 Introduction

A knowledge graph (KG) is a powerful graph structure that encodes knowledge to save and organize it, and to provide users with direct access to this knowledge via various applications, one of which is question answering, or knowledge-based question answering (KBQA). In the knowledge graph, beliefs are commonly represented by triples showing relations between two entities, such as LocatedIn(NewOrleans, Louisiana), where the two entities are nodes and their relation is the edge connecting them in the knowledge graph. Given a natural language question, a KBQA system returns its answer if it is included in the knowledge graph; the process of answering a question can be transformed into a traversal that starts from the question (topic) entity and searches for the appropriate path to the answer entity.

In the literature (Yu et al., 2017; Yin et al., 2016; Yih et al., 2015) KBQA is decomposed into topic entity linking, which determines the starting entity corresponding to the question, and relation extraction, which finds the path to the answer node(s). Theoretically, relation extraction finds paths of any length, that is, paths that contain any number of relation links, or hops (between two nodes), as long as it reaches the answer node. In previous work, models consider all relation paths starting from the topic entity (Yu et al., 2017; Yin et al., 2016; Yih et al., 2015); we call these relation-chain-based methods. Two main difficulties for these methods are that processing through all relations in a KG is not practical as the combination of these relations is nearly infinite, and that the number of candidate paths grows exponentially with the path length and quickly becomes intractable for large knowledge graphs. As a result, current relation-chain-based methods set the maximum length of candidate paths to 1, 2 or 3. However, under this framework we cannot find answer entities for indirect or complicated questions.

Most importantly, even given a larger maximum length, it is unrealistic to expect to know in advance the maximum number of hops for real-world applications. Thus even with exhaustive searches, if the answer entity is still too distant or lies outside of the search space, it is not reachable or answerable. In addition, setting a large maximum number of hops necessitates lengthy training instances, which is especially difficult.

In this paper, we propose UHop, an unrestricted-hop relation extraction framework to relax restrictions on candidate path length. We decompose the task of relation extraction in the knowledge graph into two subtasks: knowing where to go, and knowing when to stop (or to halt). That is, single-hop relation extraction and termination decision. Our contribution is three-

Proceedings of NAACL-HLT 2019, pages 345–356
Minneapolis, Minnesota, June 2 - June 7, 2019.

fold: (1) No predefined maximum hop number is required in UHop, as it enables models within the framework to halt; (2) UHop reduces the search space complexity from exponential to polynomial while maintaining comparable results; (3) UHop facilitates the use of different models, including state-of-the-art models.

2 Related Work

State-of-the-art KBQA methods are in general based on either semantic parsing, or on embedding (Zhou et al., 2018). Semantic parsing methods learn semantic parsers which parse natural language input queries into logical forms, and then use the logical forms to query the KG for answers (Berant et al., 2013; Yih et al., 2015, 2016; Krishnamurthy et al., 2017; Iyyer et al., 2017; Peng et al., 2017; Sorokin and Gurevych, 2018). These systems are effective and provide deep interpretation of the question, but require expensive data annotation, or require training using reinforcement learning.

Embedding-based methods first allocate candidates from the knowledge graph, represent these candidates as distributed embedding vectors, and choose or rank these vectors. Here the candidates can be either entities or relations. Some use embedding-based models to predict answers directly (Dong et al., 2015; Bast and Haussmann, 2015; Hao et al., 2017; Zhou et al., 2018; Lukovnikov et al., 2017), whereas others focus on extracting relation paths and require further procedures to select the answer entity (Bordes et al., 2015; Xu et al., 2016; Yin et al., 2016; Yu et al., 2017; Zhang et al., 2018a; Yu et al., 2018; Chen et al., 2018a; Shen et al., 2018). Our work follows the latter methods in focusing on predicting relation paths, but we seek to eliminate the need to assume in advance a maximum number of hops.

For the solution, we turn to the field of multi-hop knowledge based reasoning. Early methods include the Path-Ranking Algorithm and its variants. (Lao et al., 2011; Gardner et al., 2014, 2013; Toutanova et al., 2015) The drawback of these methods is that they use random walks independent of the type of input. DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2017) tackle this issue by framing the multi-hop reasoning problem as a Markov decision process, efficiently searching for paths using reinforcement learning; others propose an algorithm (Yang et al., 2017) for learning logical rules, a variational auto-encoder view of the knowledge graph (Chen et al., 2018b; Zhang et al., 2018b), and reward shaping technique (Lin et al., 2018) for further improvement. The major difference between UHop and these methods is that they do not utilize annotated relations and hence require REINFORCE training (Williams, 1992) for optimization. As some datasets are already annotated with relations and paths, direct learning using an intermediate reward is more reasonable. Hence UHop adopts a novel comparative termination decision module to control the search process of the relation path.

The most related approach is the IRN model (Zhou et al., 2018), composed of an input module, a memory-based reasoning module, and an answer module. At each hop, it predicts a relation path using the reasoning module, and also optimizes it using intermediate results. However, UHop has demonstrated the ability to process large-scale knowledge graphs in experiments conducted on Freebase (Bordes et al., 2015). In contrast, IRN consumes memory linearly to the size of the knowledge graph, resulting in a limited workspace, e.g., they use a subset of Freebase in their experiments. Also, IRN still uses a constraint for the number of maximum hops in the experiments, while UHop needs no such limit. Most importantly, as UHop is a framework which facilitates the use of different models, we can expect the performance of UHop to remain competitive with the state of the art over time.

3 UHop Relation Extraction

With UHop, we aim to handle unrestricted relation hops and to be compatible with existing relation extraction models. UHop breaks down unrestricted-hop relation extraction into two major subtasks: single-hop relation extraction and comparative termination decision.

Algorithm 1 illustrates how we perform these two tasks in the UHop framework. Given a question Q and the topic entity e extracted by an existing entity linking method such as S-MART (Yang and Chang, 2015), we first query the knowledge graph for the candidate outbound relations R that are connected to e. For all relations R, we extract single-hop relations in order to choose one relation to transit to the next entity e'. After transition ($e \leftarrow e'$), we decide whether to terminate, that is, we determine whether the process should proceed

Algorithm 1: Unrestricted-hop relation extraction. e denotes the extracted topic entity, ':' is the concatenation operation, and the termination decision returns *True* if the framework decides to stop.

```
Given KB, $Q$, $e$
$stop \leftarrow False$;
$P \leftarrow NULL$;
$R \leftarrow$ outbound relations of $e$;
while $stop = False$ do
    $\hat{r} \leftarrow$ single hop relation extraction;
    $P \leftarrow P : \hat{r}$;
    $e' \leftarrow$ traverse from $e$ through $\hat{r}$;
    $e \leftarrow e'$;
    $R \leftarrow$ outbound relations of $e$;
    $stop \leftarrow$ termination decision;
end
Result: $P$
```

through another iteration to extract the next relation in the relation path. If the decision to terminate is false, we search the KB again for outbound relations of the new e, after which the search process starts again. Note that starting from the second iteration, candidate relations are concatenated with the previously selected relations to remember the history and consider them as a whole. We continue this loop until the process decides to terminate. The termination decision thus enables UHop to learn when to stop searching for relations to extract: it determines the number of hops needed to reach the correct target entity. Upon termination, UHop returns the extracted relation(s).

In the UHop framework, the model is trained to favor the correct relation over incorrect relations. That is, to select the correct outbound single-hop relations from current entity e, the model prefers the correct $\hat{r}$ over the other relations $R - \hat{r}$ of e; to terminate at the current entity e, the model favors the correct relation $\hat{r}$ linked to the current entity e over the outbound R relations from e. To continue the iteration, it proceeds likewise. In UHop, we successfully utilize this preference over relations to train the same model to perform both single-hop relation extraction and termination decision. Figure 1 shows the difference between previous work and our model in the scenario of multi-hop KBQA task with an simplified knowledge graph and the question "Who published the novel adapted into A Study in Pink ?" as example.

3.1 Single Hop Relation Extraction

Single-hop relation extraction can be modeled as pairwise classification of the set of candidate relations. Given a question Q, the candidate relation set R, and a pairwise classification model F, single-hop relation extraction is illustrated as

$$r = \arg\max_{r \in R} F(Q, r). \tag{1}$$

Hinge loss, used for optimization, is defined as

$$\mathcal{L}_{RE} = \frac{\sum\limits_{r \in R - \hat{r}} \max(0, -(s^{\hat{r}} - s^{r}) + M)}{|R - \hat{r}|}, \tag{2}$$

where $s^{\hat{r}}$, s^{r} are scores of the true relation and the candidate relations respectively. The margin, M, is an arbitrary value in the range $(0, 1]$, where the goal of the loss function is to maximize the margin between the scores of the correct and the incorrect predictions. Note that this relation extraction process and those proposed in related work are compatible, which facilitates the installation of state-of-the-art models in the UHop framework.

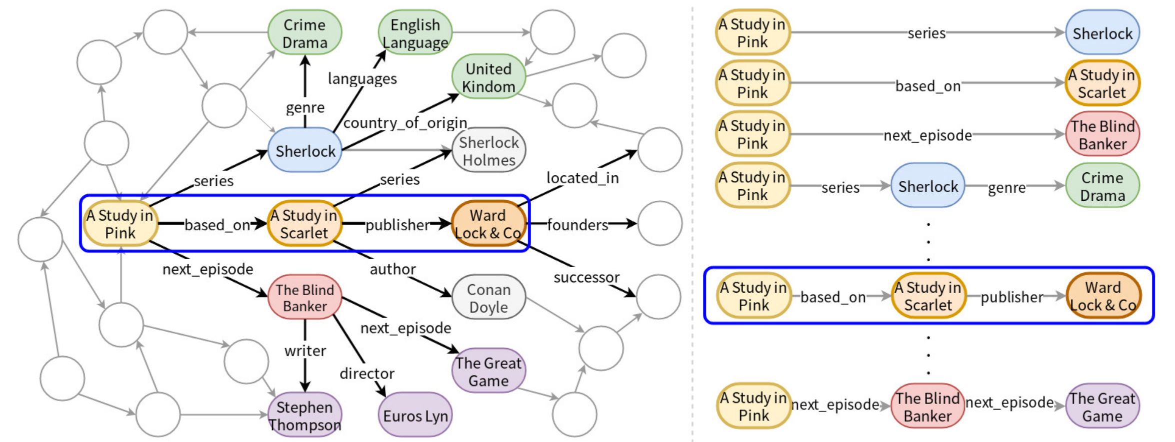
3.2 Comparative Termination Decision

In the UHop framework, as we hope to easily replace the used model by state-of-the-art models, we make the termination decision using the same model for single-hop relation extraction so that no additional model is needed. Therefore, we propose a progressive method which treats the termination decision as a comparison. That is, the model stops when it cannot extract any relation better than that from its previous hop.

What is different here is R, the relations to be compared against $\hat{r}$, are the concatenation of extracted relation and all the relation starting from the new current entity e; recall that we update $e \leftarrow e'$ before we step into termination decision. If the score $s^{\hat{r}}$ is higher than all the compared relations, the searching process terminates; otherwise, it continues.

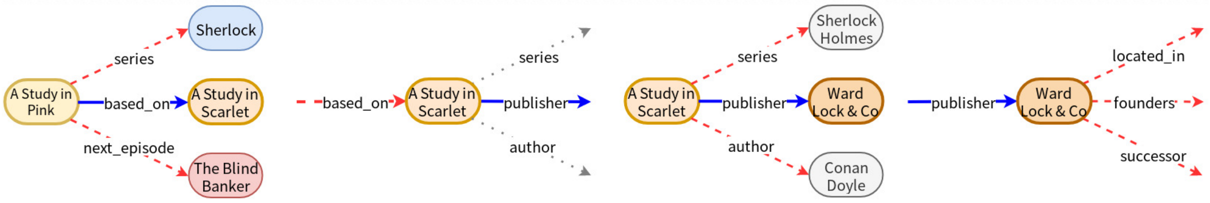
Given a question Q, an extracted relation $\hat{r}$ from the previous entity, the candidate relation set R from the new current entity e, and the same model F as in the single hop relation extraction, the procedure can be formulated as

$$stop = \begin{cases} True, & F(Q, \hat{r}) > F(Q, r) \ \forall r \in R \\ False, & F(Q, \hat{r}) < F(Q, r) \ \exists r \in R \end{cases} \tag{3}$$



(a)

(b) without UHop



(1) first hop relation extraction

(2) termination decision (stop_flag=false)

(3) second-hop relation extraction

(4) termination decision (stop_flag=true)

(c) UHop

Figure 1: (a) A snippet of knowledge graph. (b) without UHop, all the paths less than two hop are considered as candidates; (c) under UHop, the next part of relation is extracted hop by hop (step 1 and 3), then we compare the chosen relation and its outbound relations to decide to terminate or to extract the next relation: if the extracted relation has the highest score than all the outbound relations then the process is terminated (step 4), otherwise, continued (step 2). Here we use solid arrows and dash arrows to respectively represent positive/negative candidates.

Loss is defined depending on the flag *stop*. If the process should continue, i.e., *stop* is false, loss is defined as

$$\mathcal{L}_{TD} = \max(0, -(s^{r'} - s^{\hat{r}}) + \text{margin}), \quad (4)$$

where score $s^{r'}$ is the score of the question paired with the gold relation r' in the next hop and $s^{\hat{r}}$ is the score of the question paired with the extracted relation $\hat{r}$. In contrast, if the process should terminate, we optimize the model by

$$\mathcal{L}_{TD} = \frac{\sum_{r \in R} \max(0, -(s^{\hat{r}} - s^{r}) + M)}{|R|}. \quad (5)$$

The model thus learns to infer $s^{\hat{r}}$ is greater than s^{r}, resulting in the termination of relation extraction.

3.3 Dynamic Question Representation

While UHop inferences hop by hop, it is straightforward to enforce the focus at different aspects of the question. For this purpose, we update the question representation for each hop by defining a dynamic question representation generation function G. Given the previously selected relation path P and the original question Q, G generates the new question representation as $Q' = G(Q, P)$. Our assumption is that since the current relation has been selected, its related information in the question loses importance when extracting the next relation.

Inspired by both supervised attention (Mi et al., 2016; Liu et al., 2016; Kamigaito et al., 2017), which is lacking in our datasets, and the coverage loss design for summarization (See et al., 2017), we de-focus the selected relation by manipulating weights in the question representation. We propose two ways of updating the question representation, taking into account the existence of the attention layer in the model's architecture. For attentive models, we directly utilize the attention weight as part of our dynamic question representation generation function by

$$G(Q, P) = W(Q - \mathit{attention}(Q, P)) + B. \quad (6)$$

For non-attentive models, we apply a linear transformation function as G on the concatenation of the previously selected relation and the question representation to yield the new representation:

$$G(Q, P) = W[Q : P] + B, \tag{7}$$

where W and B are weight matrices to be optimized during training.

3.4 Jointly Trained Subtasks

In training, we jointly optimize the two subtasks of UHop. For each question and its candidates, the loss function is defined as

$$\mathcal{L} = \sum_{i}^{H}(\mathcal{L}_{RE}^{(i)} + \mathcal{L}_{TD}^{(i)}), \tag{8}$$

where H is the number of hops in the gold relation path; $\mathcal{L}_{RE}^{(i)}$ and $\mathcal{L}_{TD}^{(i)}$ are the loss of the two subtasks at the i-th hop respectively.

4 Experiments

In this section, we illustrate the performance UHop achieves while reducing the search space, and its relation inference power for multi-hop questions. Performances of the state of the art models are listed as the upper-bound.

4.1 Datasets

For our benchmarking evaluation materials, we selected WebQSP (WQ) (Yih et al., 2016), as it is used in most related work. WebQSP is the annotated version of WebQuestions (Berant et al., 2013), which contains questions that require a 1- or 2-hop relation path to arrive at the answer entity. More specifically, about 40% of the questions require a 2-hop relation to reach the answer. This dataset is based on the Freebase knowledge graph (Bordes et al., 2015). For questions with multiple answers, we use each answer to construct a question-answer pair. Every question is annotated with its inferential relation chain (i.e., a relation), topic entity, and answer entity. The statistics for these two datasets are shown in Table 1.

As WQ contains only questions with 1- and 2-hop answers that are still short, we also conduct experiments for path length related analysis on the PathQuestion dataset (Zhou et al., 2018), which includes questions requiring 3-hop answers. To the best of our knowledge, this is the only available general-KB dataset containing 3-hop questions. PathQuestion provides two datasets: PathQuestion (PQ) and PathQuestion-Large (PQL). These both contain 2-hop (PQ2/PQL2) and 3-hop (PQ3/PQL3) questions respectively, and both use a subset of Freebase as their knowledge graph. Note that for both PQ and PQL, questions are generated using templates, paraphrasing, and synonyms. PQL is more challenging than PQ because it utilizes a larger subset of Freebase, and provides fewer training instances. Table 1 shows statistics of these datasets.

	hops	Train	Valid	Test
WQ	1	2113	-	1,144
	2	1,285	-	647
PQ2	2	1,526	191	191
PQ3	3	4,158	520	520
PQL2	2	1,275	159	160
PQL3	3	1,649	206	207
Grid 2–4	2–4	68,046	9,742	19,298
Grid 4–6	4–6	73,092	10,362	21,037
Grid 6–8	6–8	41,473	5,844	11,789
Grid 8–10	8–10	18,386	2,667	5,326

Table 1: Number of questions in experimental datasets

The above datasets serve to show that the UHop framework yields performance competitive with state-of-the-art KBRE models. Further, we seek to demonstrate that UHop reduces the search space when required reasoning paths are even longer, i.e., longer than 3 hops, and that UHop works for different kinds of relations. For this we use Grid World (Yang et al., 2017), a synthetic dataset with questions requiring lengthy – up to 10 hops – relation paths to answer. We select it to demonstrate that UHop works for long as well as task-specific relations. In Grid World, the input is the starting node, a sequence of navigation instructions, and a 16-by-16 fully connected grid. The model must follow the instructions to arrive at the destination node. Specifically, the task is to navigate to an answer cell (answer entity) starting from a random cell (topic entity) given a sequence of instructions (questions). The KB consists of triples such as ((4, 1), South, (5, 1)), which indicates that the entity (5, 1) is south of the entity (4, 1); questions are sequences of directions such as (North, NorthEast, South). Samples in Grid World are classified into 4 buckets – [2–4], [4–6], [6–8], and [8–10] – according to their reasoning path length. Unlike relations included in general knowledge bases like Freebase, relations in Grid World are the relative directions of two nodes.

MetaQA (Zhang et al., 2018b) and sequence QA are two other multi-hop knowledge-based question-answering datasets which we do not use for experiments in this paper. MetaQA is a multi-hop dataset for end-to-end KBQA based on a movie knowledge graph with 43k entities. However, it is too simple for discussions as it contains only 6 relations and on average the number of the outbound relations for each node is 3. The Complex Sequential QA dataset (Saha et al., 2018) improves on overly simplistic KBQA datasets. Nevertheless, instead of questions requiring multi-hop relation paths, it provides a sequence of questions, each of which requires a single-hop relation to answer, resulting a different setting. Hence these two datasets are beyond the scope of this paper.

4.2 Benchmark: WQ Experiments

4.2.1 Baseline and Settings

We used two state of the art models, HR-BiLSTM (Yu et al., 2017) and ABWIM (Zhang et al., 2018a), as the models for use within the UHop framework. Another state of the art model, MVM (Yu et al., 2018), is not selected here as it requires additional information: the tail entity type. In MVM, to consider each n-th-hop relation, the model searches all related $(n+1)$-th-hop relations to collect enough information; thus further queries are necessary in MVM. This property of MVM causes the UHop to degrade to a relation-chain based model, which we are trying to avoid.

We report the results of these two models working within and independent of the UHop framework to evaluate whether relaxing the constraint on the number of hops has any impact on their performance. For comparison, we select BiCNN as baselines and list their results. As there is no predefined validation set in WQ, we randomly select 10% of the training data as the validation set. The best parameters for different models and datasets were set empirically.

In all cases we used 300-dimensional pretrained GloVe (Pennington et al., 2014) word embeddings and RMSprop optimization. In ABWIM, following the setting of (Zhang et al., 2018a), we respectively chose 1, 3, 5 as kernel sizes and 150 as the number of filters for its three CNN layers. We tune the following hyperparameters with grid search : (1) the hidden size for all LSTM ([100, 150, 256]); (2) dropout rate ([0, 0.2, 0.4]); (3) margin for Hinge loss ([0.1, 0.3, 0.5, 0.7, 1.0]); (4) learning rate ([0.01, 0.001, 0.0001]).

Method	Accuracy
BiCNN (Yih et al., 2015)	77.74
HR-BiLSTM (Yu et al., 2017)	82.53
ABWIM (Zhang et al., 2018a)	83.26[1]
HR-BiLSTM with UHop	82.60
ABWIM with UHop	82.27

Table 2: Results adopting state-of-the-art models in UHop framework vs standalone versions

4.2.2 Results and Discussion

The experimental results are shown in Table 2. As expected, the performance of models within the UHop framework is comparable to those independent of it, with the additional advantage of the unrestricted number of relation hops and a greatly reduced search space.

Table 3 lists the average number of candidates the experimental models consider for each question when working within and independent of UHop. For a dataset based on a KB with an average of n relations connected to each entity, the approximate search space without UHop is $n(n-1)^{(L-1)}$, where L is the predefined maximum hop number; with UHop the approximate search space is reduced to $n(L+1)$. The specific number depends on the actual number of outbound relations connected to the entities. Table 3 shows that UHop reduces the search space by 30% for WQ, which translates to lower processing time, less memory consumption, and sometimes slightly improved performance.

	Train	Test
Without UHop	97.2	98.8
With UHop	66.7	65.6

Table 3: Number of relation candidates in WQ

4.3 More Hops: PQ/PQL Experiments

4.3.1 Baseline and Settings

Following the original paper (Zhou et al., 2018), PQ and PQL are both partitioned into training/validation/testing sets at a ratio of 8:1:1. In addition to the original PQ/PQL dataset, we merge

---

[1] Note that the original paper reported 85.32, but we failed to reproduce such performance. Hence we report our reproduced performance which is the same model adapted in our proposed framework.

Method	PQ2	PQ3	PQ+	PQL2	PQL3	PQL+
IRN (Zhou et al., 2018)	96	87.7	53.6	72.5	71	52.9
HR-BiLSTM (Yu et al., 2017)	100	99.62	99.72	97.5	87.92	92.92
HR-BiLSTM with UHop	99.48	99.23	99.72	91.25	88.41	91.01
HR-BiLSTM with UHop + DQ	100	99.62	99.58	95	89.37	91.83
ABWIM (Zhang et al., 2018a)	98.95	99.81	99.72	94.37	89.37	92.64
ABWIM with UHop	97.38	99.62	99.02	91.25	88.89	91.01
ABWIM with UHop + DQ	100	99.62	99.44	97.5	89.37	92.37

Table 4: Accuracy on PathQuestion. PQ+ is mix of PQ2 and PQ3, and PQL+ contains PQL2 and PQL3. We use the accuracy reported in (Zhou et al., 2018) directly for PQ2, PQ3, PQ2L and PQ3L; for PQ+ and PQL+ we use the model released with the dataset. DQ stands for dynamic question representation.

PQ2 and PQ3, and then PQL2 and PQL3, to create the mixed datasets PQ+ and PQL+ to evaluate if the model terminates correctly instead of always stopping on the majority of the training data length. Again we adopt HR-BiLSTM and ABWIM in this experiment. In addition, the IRN model[2] proposed together with the PQ/PQL dataset was selected as one of the baselines for comparison. For this dataset containing questions of long relation paths, we also applied the dynamic question representations (DQ) in UHop.

4.3.2 Results and Discussion

Results[3] are shown in Table 4. Both HR-BiLSTM and ABWIM either within or independent of UHop outperform IRN and perform nearly perfectly in all datasets, which confirms that UHop is competitive even with longer relation paths. However, as shown in Table 5, the search space reduction for PQ and PQL is not obvious. We find that the knowledge graph used in PQ/PQL (a subset of Freebase) is much smaller and less complicated than the original Freebase used in WQ, i.e., the outbound degree of nodes is relatively small. Nevertheless, UHop still performs comparably with previous work. This indicates that it also works well in small and simple KBs.

As all PQ/PQL questions are multi-hop questions, we used dynamic question representations to better reflect transitions in the relation extraction process. Table 4 shows that updating the question representation dynamically (+DQ) in each iteration benefits relation extraction in most cases.

		2-hop			3-hop		
		Train	Valid	Test	Train	Valid	Test
PQ	W/o	3.53	3.65	3.90	9.77	9.63	9.61
	With	3.68	3.81	3.85	9.14	9.27	9.48
PQL	W/o	3.71	2.64	3.91	24.52	12.96	8.45
	With	3.94	3.23	4.29	10.11	9.28	6.98

Table 5: Candidates of PQ/PQL within and independent of the UHop framework

4.4 Very Long Paths: Grid World

4.4.1 Baseline and Settings

In the Grid World experiments, we used MINERVA (Das et al., 2017) and Neural LP (Yang et al., 2017) as baselines. As understanding questions is not an issue here, we randomly initialized the word embeddings and optimized them during the training process. We set the learning rate to 0.001, the hidden size to 256, the embedding size to 300, and optimized the model using the RMSprop (Hinton et al., 2014) Algorithm. In this experiment, the search space has gone too large to afford for HR-BiLSTM and ABWIM without the assistance of UHop.

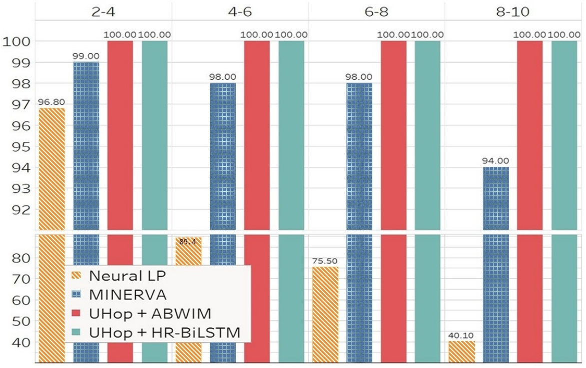


Figure 2: Grid World results of state-of-the-art knowledge-based relation extraction models

4.4.2 Results and Discussion

The results in Figure 2 show that together with the relation extraction model, UHop perfectly solves

---

[2] https://github.com/zmtkeke/IRN. We consulted the authors of the repository, who stated that this version is not the one in their paper, which they did not release publicly.

[3] Note that IRN's performance was evaluated using final answer prediction, which is slightly different from relation path prediction. However, finding the correct relation path should imply finding the correct answer entity.

this problem. In the first place, compared to Neural LP and MINERVA, UHop benefits from the more powerful natural language understanding models – HR_BiLSTM and ABWIM – equipped with sophisticated LSTM models, whereas Neural LP and MINERVA only use multi-layer neural networks as the policy network. This demonstrates UHop's merit of facilitating the use of novel models. In the second place, Figure 2 shows that error propagation leading to poor performance for long-path questions in Neural LP and MINERVA is mitigated by the relation inference power of UHop: it performs well for all four buckets of questions. Also, as Grid World includes paths of up to 10 hops, conducting experiments purely by relation-chain based models themselves like HR-BiLSTM or ABWIM independent of UHop is not feasible: the number of candidate relations in the exhaustive search space grows exponentially. In Grid World, there are 8 directions (relations), and models are allowed to go back and forth. Hence given the path length k, the approximate search space for the models working independently is 8^k, while for models working within UHop is $8 \times k$. We observe that without UHop, the required search space would preclude experiments even on the set containing the shortest paths (Grid World [2–4]), much less the longer ones.

5 Further Discussion

5.1 Dataset Characteristics

In this section we further compare the experimental multi-hop KBQA datasets WQ, PQ, and Grid World. Grid World contains questions that require the longest reasoning paths. However, they are synthetic, the relations are simply direction tokens, and the questions are just sequences of direction instructions. Therefore in this paper, it is only used to test the model's ability of making long sequential decisions instead of understanding questions. From experiments we have seen that delicate models like HR-BiLSTM and ABWIM cannot work on it without UHop, and other models such as Neural LP and MINERVA perform worse as they are rewarded only by question.

On the other hand, in WQ, questions are written in natural language and can be answered by 1-hop or 2-hop reasoning. However, for real-world questions, 2-hop reasoning is still overly simplistic. For example, although WQ questions such as "What is the name of Justin Bieber's brother?" are challenging for models, humans can easily answer these with a simple Internet search.

Noting this problem, the authors of IRN (Zhou et al., 2018) propose PQ and PQL, for which questions require at least 2-hop at most 3-hop relation paths. However, PQ/PQL also has its limitations. First, the KB used in PQ/PQL is smaller than that in WQ, and its relations are repetitive and show little variety. Figure 3 illustrates the relation distributions. Second, PQ/PQL questions are generated by extracting relation paths and filling templates, which can lead to questions with obvious, learnable patterns. This can be observed by comparing results in Tables 2 and 4. However, repeated relations could also help the model to learn better dynamic question representations with respect to these relations. Table 4 shows that updating question representations dynamically (DQ) does improve PQ/PQL performance.

Figure 3: A visualization of the KB relations that cover the dataset. The bubble's size is proportional to the relation's frequency.

5.2 Trained on 3-hop, Tested on 2-hop

To evaluate if the model halts in the search process, we conducted an experiment using PQL3 as the training/validation set and PQL2 as the testing set. The results are shown in Table 6. Within the UHop framework, both models outperform their original version by more than 7%. However, with zero 2-hop samples, it still overfits on the 3-hop length in training data, resulting in accuracies lower than 50%.

	HR-BiLSTM	ABWIM
Without UHop	32.18	32.94
With UHop	39.65	49.94

Table 6: Accuracies of models trained on PQL3 and tested on PQL2. The maximum length of relation paths for models without UHop is set to 3.

5.3 Error Analysis

The interpretability of UHop, i.e., the possibility to analyze each hop, facilitates the analysis of error distributions. We list the percentage of questions for which UHop fails to extract the correct relations by the number of hops for different

Dataset/model			1-hop		2-hop		3-hop

Table 7: Distribution of error types under UHop framework (in percentage). H stands for HR-BiLSTM, A for ABWIM, RE for 'Relation Extraction', and TD for 'Termination Decision'. * denotes the +DQ setting.

datasets. The results of HR_BiLSTM and ABWIM within the UHop framework are reported in Table 7. Our observations are offered below.

First, whether for 1-hop or 2-hop WQ questions, both models suffer in relation extraction in the first hop, whereas there are fewer errors in the second hop and for the termination decision.

Second, for the PQ/PQL datasets, as with the WQ dataset, incorrect relation extraction is the major error, and surprisingly there were no errors for termination decision except for a few on PQL3 with ABWIM. After comparing the 2-hop testing data from PQ2/PQL2 and PQ+/PQL+, we also observe that long questions help the learning of short questions. The model predicts better on 2-hop data when trained on both 2-hop and 3-hop data than when trained on 2-hop data only. Here the improvement in relation extraction in the first hop is the main contributor to this improved performance. In contrast, the performance on 3-hop data suffers when trained on 2-hop data.

Third, dynamic question representations (noted by *) significantly benefit the relation extraction (RE) for the first hop. As UHop utilizes the same model for relation selection and termination decision, relieving the attention to the previous relation in the later selection process in the training phase decreases the ambiguity in the earlier selection process in the testing phase.

Finally, in the experiments trained on 3-hop and tested on 2-hop, the model does not terminate correctly on more than 40% of the PQL2 data even though the relation extraction for 1-hop and 2-hop are both correct. We conclude that having no samples of the predicted length for training still hurts performance. In addition, there are also a few early terminations after the first relation extraction. Due to the different generation processes with different templates for the 2-hop and 3-hop questions in PQL, learning from one may not apply to the other.

6 Conclusion

In this paper, we propose the UHop framework to allow an unrestricted number of hops in knowledge-based relation extraction and to reduce the search space. Results show that running the same model in the UHop framework achieves comparable results in a reduced search space. Moreover, experiments show UHop works well for lengthy relation extraction and can be applied to small, simple KBs with task-specific relations. UHop even facilitates the use of most state-of-the-art models, and its transition-based design naturally supports the dynamic question representation for better performance. These results attest its strong power for knowledge-based relation extraction. The current framework uses a greedy search for each single hop. We expect in the future that incorporating a beam search may further improve performance.

Abstract

Multi-hop reasoning question answering requires deep comprehension of relationships between various documents and queries. We propose a Bi-directional Attention Entity Graph Convolutional Network (BAG), leveraging relationships between nodes in an entity graph and attention information between a query and the entity graph, to solve this task. Graph convolutional networks are used to obtain a relation-aware representation of nodes for entity graphs built from documents with multi-level features. Bidirectional attention is then applied on graphs and queries to generate a query-aware nodes representation, which will be used for the final prediction. Experimental evaluation shows BAG achieves state-of-the-art accuracy performance on the QAngaroo WIKIHOP dataset.

1 Introduction

Question Answering (QA) and Machine Comprehension (MC) tasks have drawn significant attention during the past years. The proposal of large-scale single-document-based QA/MC datasets, such as SQuAD (Rajpurkar et al., 2016), CNN/Daily mail (Hermann et al., 2015), makes training available for end-to-end deep neural models, such as BiDAF (Seo et al., 2016), DCN (Xiong et al., 2016) and SAN (Liu et al., 2017). However, gaps still exist between these datasets and real-world applications. For example, reasoning is constrained to a single paragraph, or even part of it. Extended work was done to meet practical demand, such as DrQA (Chen et al., 2017) answering a SQuAD question based on the whole Wikipedia instead of single paragraph. Besides, latest large-scale datasets, e.g. TriviaQA (Joshi et al., 2017) and NarrativeQA (Kočiskỳ et al., 2018), address this limitation by introducing multiple documents, ensuring reasoning cannot be done within local information. Although those datasets are fairly challenging, reasoning are within one document.

In many scenarios, we need to comprehend the relationships of entities across documents before answering questions. Therefore, reading comprehension tasks with multiple hops were proposed to make it available for machine to tackle such problems, e.g. QAngaroo task (Welbl et al., 2018). Each sample in QAngaroo contains multiple supporting documents, and the goal is selecting the correct answer from a set of candidates for a query. Most queries cannot be answered depending on a single document, and multi-step reasoning chains across documents are needed. Therefore, it is possible that understanding a part of paragraphs loses effectiveness for multi-hop inference, which posts a huge challenge for previous models. Some baseline models, e.g. BiDAF (Seo et al., 2016) and FastQA (Weissenborn et al., 2017), which are popular for single-document QA, suffer dramatical accuracy decline in this task.

In this paper, we propose a new graph-based QA model, named Bi-directional Attention Entity Graph convolutional network (BAG). Documents are transformed into a graph in which nodes are entities and edges are relationships between them. The graph is then imported into graph convolutional networks (GCNs) to learn relation-aware representation of nodes. Furthermore, we introduce a new bi-directional attention between the graph and a query with multi-level features to derive the mutual information for final prediction.

Experimental results demonstrate that BAG achieves state-of-the-art performance on the WIKIHOP dataset. Ablation test also shows BAG benefits from the bi-directional attention, multi-level features and graph convolutional networks.

Our contributions can be summarized as:

- Applying a bi-directional attention between graphs and queries to learn query-aware representation for reading comprehension.
- Multi-level features are involved to gain comprehensive relationship representation for graph nodes during processing of GCNs.

Proceedings of NAACL-HLT 2019, pages 357–362
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related Work

Recently coreference and graph-based models are studied for multi-hop QA (Dhingra et al., 2018; Santoro et al., 2017). Coref-GRU (Dhingra et al., 2018) uses coreferences among tokens in documents. However, it is still limited by the long-distance relation propagation capability of RNNs. Besides, graph is proved to be an efficient way to represent complex relationships among objects and derive relational information (Santoro et al., 2017). MHQA-GRN (Song et al., 2018) and Entity-GCN (De Cao et al., 2018) construct entity graphs based on documents to learn more compact representation for multi-hop reasoning and derive answers from graph networks. However, both of them care less about input features and the attention between queries and graph nodes.

Attention has been proven to be an essential mechanism to promote the performance of NLP tasks in previous work (Bahdanau et al., 2014; Sukhbaatar et al., 2015). In addition, bi-directional attention (Seo et al., 2016) shows its superiority to vanilla mutual attention because it provides complementary information to each other for both contexts and queries. However, little work exploits the attention between graphs and queries.

3 BAG Model

We first formally define the multiple-hop QA task, taking QAngaroo (Welbl et al., 2018) WIKIHOP data as an example, There is a set $\boldsymbol{S}$ containing N supporting documents, a query $\boldsymbol{q}$ with M tokens and a set of answer candidates $\boldsymbol{C}$. Our goal is to find the correct answer index a. Giving a triple-style query $\boldsymbol{q} = (\textit{country, kepahiang})$, it means *which country does kepahiang belongs to*. Then answer candidates are provided, e.g. $C = \{Indonesia, Malaysia\}$. There are multiple supporting documents but not all of them are related to reasoning, e.g. *Kephiang is a regency in Bengkulu*, *Bengkulu is one of provinces of Indonesia*, *Jambi is a province of Indonesia*. We can derive the correct candidate is *Indonesia*, i.e. $a = 0$, based on reasoning hops in former two documents.

We show the proposed BAG model in Figure 1. It contains five modules: (1) entity graph construction, (2) multi-level feature layer, (3) GCN layer, (4) bi-directional attention and (5) output layer.

3.1 Entity Graph Construction

We construct an entity graph based on Entity-GCN (De Cao et al., 2018), which means all mentions of candidates found out in documents are used as nodes in the graph. Undirected edges are defined according to positional properties of every node pair. There are two kinds of edges included: 1) cross-document edge, for every node pair with the same entity string located in different documents; 2) within-document edge, for every node pair located in the same document.

Nodes in an entity graph can be found out via simple string matching. This approach can simplify calculation as well as make sure all relevant entities are included in the graph. Picked out along possible reasoning chains during dataset generating (Welbl et al., 2018), answer candidates have contained all related entities for answering. Finally, We can obtain a set of T nodes $\{n_i\}, 1 \leq i \leq T$ and corresponding edges among these nodes via above procedures.

3.2 Multi-level Features

We represent both nodes and queries using multi-level features as shown in Figure 1(2). We first use pretrained word embeddings to represent tokens, such as GLoVe (Pennington et al., 2014) because nodes and queries are composed of tokens. Then contextual-level feature is used to offset the deficiency of GLoVe. Note that only part of tokens are remained during graph construction because we only extract entities as nodes. Thus contextual information around these entities in original document becomes essential for indicating relations between tokens and we use higher-level information for nodes except for token-level feature.

We use ELMo (Peters et al., 2018) as contextualized word representations, modeling both complex word characteristics and contextual linguistic conditions. It should be noted that ELMo features for nodes are calculated based on original documents, then truncated according to the position indices of nodes. Token-level and context-level features will be concatenated and encoded to make a further comprehension. Since a node may contain more than one token, we average features among tokens to generate a feature vector for each node before encoding it. It will be transformed into the encoded node feature via a 1-layer linear network.

Different from nodes, we represent a query by directly using a bidirectional LSTM (Bi-LSTM) whose output in each step is used as encoded query features. And both linear network and LSTM have the same output dimension $\hat{d}$.

In addition, we add two manual features to reflect the semantic properties of tokens, which are named-entity recognition (NER) and part-of-speech (POS). The complete feature $f_n \in \mathbb{R}^{T \times d}$, $f_q \in \mathbb{R}^{M \times d}$ for both nodes and queries will be the concatenation of corresponding encoded features, NER embedding and POS embedding, where $d = \hat{d} + d_{POS} + d_{NER}$.

3.3 GCN Layer

In order to realize multi-hop reasoning, we use a Relational Graph Convolutional Network (R-GCN) (Schlichtkrull et al., 2018) that can propagate message across different entity nodes in graphs and generate transformed representation of original ones. The R-GCN is employed to handle high-relational data characteristics and make use of different edge types. At lth layer, given the hidden state $h_i^l \in \mathbb{R}^d$ of node i, the hidden states $h_j^l \in \mathbb{R}^d, j \in \{N_i\}$ and relations R_{N_i} of all its neighbors (d is the hidden state dimension), the hidden state in the next layer can be obtained via

$$h_i^{l+1} = \sigma\Big(\sum_{r \in R_{N_i}} \sum_{j \in N_i} \frac{1}{c_{i,r}} W_r^l h_j^l + W_0^l h_i^l \Big), \quad (1)$$

where $c_{i,r}$ is a normalization constant $|N_i|$, $W_r^l \in \mathbb{R}^{d \times d}$ stands a relation-specific weight matrix and $W_0^l \in \mathbb{R}^{d \times d}$ stands a general weight.

Similar to Entity-GCN (De Cao et al., 2018), we apply a gate on update vector u_i^l and hidden state h_i^l of current node by a linear transformation f_s,

$$w_i^l = \sigma(f_s(\text{concat}(u_i^l, h_i^l))), \quad (2)$$

in which u_i^l can be obtained via (1) without sigmoid function. Then it will be used for updating weights for the hidden state h_i^{l+1} of the same node in next layer,

$$h_i^{l+1} = w_i^l \odot \tanh(u_i^l) + (1 - w_i^l) \odot h_i^l. \quad (3)$$

We stack such networks for L layers in which all parameters are shared. The information of each node will be propagated up to L-node distance away, generating L-hop-reasoning relation-aware representation of nodes. The initial input will be mutli-level nodes features $\mathbf{f_n} = \{f_{n_i}\}, 0 \leq i \leq T$ and edges $\mathbf{e} = \{e_{ij}\}$ in the graph.

3.4 Bi-directional Attention Between a Graph and a Query

Bi-directional attention is responsible for generating the mutual information between a graph and a query. In BiDAF (Seo et al., 2016), attention is applied to sequence data in QA tasks such as supporting texts. However, we also find it works well between graph nodes and queries. It generates query-aware node representations that can provide more reasoning information for prediction.

What differs in BAG is that attention is applied for graphs as shown in Figure 1(4). The similarity matrix $\mathbf{S} \in \mathbb{R}^{\mathbf{T} \times \mathbf{M}}$ is calculated via

$$\mathbf{S} = \text{avg}_{-1} f_a(\text{concat}(h_n, f_q, h_n \circ f_q)), \quad (4)$$

in which $h_n \in \mathbb{R}^{T \times d}$ is all node representations obtained from the last GCN layer, $f_q \in \mathbb{R}^{M \times d}$ is the query feature matrix after encoding, d is the dimension for both query feature and transformed node representation, f_a is a linear transformation, avg_{-1} stands for the average operation in last dimension, and $\circ$ is element-wise multiplication.

Unlike the context-to-query attention in BiDAF, we introduce a node-to-query attention $\widetilde{a}_{n2q} \in \mathbb{R}^{T \times d}$, which signifies the query tokens that have the highest relevancy for each node using

$$\widetilde{a}_{n2q} = \mathrm{softmax}_{\mathrm{col}}(\mathbf{S}) \cdot f_q, \tag{5}$$

where $\mathrm{softmax}_{\mathrm{col}}$ means performing softmax function across the column, and $\cdot$ stands for matrix multiplication.

At the same time, we also design query-to-node attention $\widetilde{a}_{q2n} \in \mathbb{R}^{M \times d}$ which signifies the nodes that are most related to each token in the query via

$$\widetilde{a}_{q2n} = \mathrm{dup}(\mathrm{softmax}(\max_{\mathrm{col}}(\mathbf{S})))^{\top} \cdot f_n\,, \tag{6}$$

in which $\max_{\mathrm{col}}$ is the maximum function applied on across column of a matrix, which will transform $\mathbf{S}$ into $\mathbb{R}^{1 \times M}$. Then function dup will duplicate it for T times into shape $\mathbb{R}^{T \times M}$. $f_n \in \mathbb{R}^{T \times d}$ is the original node feature before GCN layer.

Our bi-directional attention layer is the concatenation of the original nodes feature, nodes-to-query attention, the element-wise multiplication of nodes feature and nodes-to-query attention, and multiplication of nodes feature and query-to-nodes attention. It should be noted that the relation-aware nodes representation from GCN layer is just used to calculate the similarity matrix, and original node feature is used in rest calculation to obtain more general complementary information between graph and query. Edges are not taken in account because they are discrete and combined with nodes in GCN layer. The output is defined as

$$\widetilde{a} = \mathrm{concat}(f_n, \widetilde{a}_{n2q}, f_n \circ \widetilde{a}_{n2q}, f_n \circ \widetilde{a}_{q2n}). \tag{7}$$

3.5 Output layer

A 2-layer fully connect feed-forward network is employed to generate the final prediction, with $\tanh$ as the activation function in each layer. Softmax will be applied among the output. It uses query-aware representation of nodes from the attention layer as input, and its output is regarded as the probability of each node becoming answer. Since each candidate may appear several times in the graph, the probability of each candidate is the sum of all corresponding nodes. The loss function is defined as the cross entropy between the gold answer and its predicted probability.

4 Experiment

We used both unmasked and masked versions of the QAngaroo WIKIHOP dataset (Welbl et al., 2018) and followed its basic setting, in which masked version used specific tokens such as *__MASK1__* to replace original candidates tokens in documents. There are 43,738, 5,129 and 2,451 examples in the training set, the development set and the test set respectively, and test set is not public.

In the implementation[1], we used standard ELMo with a 1024 dimension representation. Besides, 300-dimension GLoVe pre-trained embeddings from 840B Web crawl data were used as token-level features. We used spaCy to provide additional 8-dimension NER and POS features. The dimension of the 1-layer linear network for nodes in multi-level feature module was 512 with $\tanh$ as activation function. A 2-layer Bi-LSTM was employed for queries whose hidden state size is 256. Then the feature dimension is $d = 512 + 8 + 8 = 528$. The GCN layer number L was set as 5. And the unit number of intermediate layers in output layer was 256.

In addition, the number of nodes and the query length were truncated as 500 and 25 respectively for normalized computation. Dropout with rate 0.2 was applied before GCN layer. Adam optimizer is employed with initial learning rate 2×10^{-4}, which will be halved for every 5 epochs, With batch size 32. It took about 14 hours for 50-epoch training on two GTX1080Ti GPUs using pre-built and pre-processed graph data generated from original corpus, which can significantly decrease the training time.

We consider the following baseline models: FastQA (Weissenborn et al., 2017), BiDAF (Seo et al., 2016), Coref-GRU (Dhingra et al., 2018), MHQA-GRN (Song et al., 2018), Entity-GCN (De Cao et al., 2018). Former three models are RNN-based models, while coreference relationship is involved in Coref-GRU. The last two models are graph-based models specially designed for multi-hop QA tasks.

As shown in Table 1, we collected three kinds of results. The dev and test results stand for the original validation and test sets respectively, noting that the test set is not public. In addition, we divide the original validation set of masked version into two parts evenly, one as a split validation set for tuning model and the other one as a split test set. The test[1] results are for the split test set.

Our BAG model achieves state-of-the art per-

---

[1] Source code is available on `https://github.com/caoyu1991/BAG`.

formance on both unmasked and masked data[2], with accuracy 69.0% on the test set, which is 1.4% higher in value than previous best model Entity-GCN. It is significant superior than FastQA and BiDAF due to leveraging of relationship information given by the graph and abandoning some distracting context in multiple documents. Although Coref-GRU extends GRU with coreference relationships, it is still not enough for multi-hop because hop relationships are not limited to coreference, entities with the same strings also existed across documents which can be used for reasoning. Both MHQA-GRN and Entity-GCN utilize graph networks to resolve relations among entities in documents. However, the lack of attention and complementary features limits their performance. Therefore our BAG model achieves the best performance under all data configurations. It is noticed that BAG only gets a small promotion on masked data. We argue that the reason is the attention between masks and queries generating less useful information compared to unmasked ones.

Moreover, ablation experimental results on unmasked version of the WIKIHOP dev set are given in Table 2. Once we remove the bi-directional attention and put the concatenation of nodes and queries directly into the output layer, it shows significant performance drop with more than 3%, proving the necessity of attention for reasoning in multi-hop QA. If we use linear-transformation-based single attention $a = h_n \mathbf{W_a} f_q$ given in (Luong et al., 2015) instead of our bi-directional attention, the accuracy drops with 2%, which means attention bi-directionality also contributes to the performance improvement. The similar condition will appear if we remove GCN, but use raw nodes as input for the attention layer.

In addition, if edge types are no longer considered, which makes R-GCN degraded to vanilla GCN, noticeable accuracy loss about 2% appears. The absence of multi-level features will also cause degradation. The removal of semantic-level features causes slight decline on the performance, including NER and POS features. Further removal of ELMo feature will causes a dramatical drop, which reflects the insufficiency of only using word embeddings as features for nodes and that contextual information is very important.

Models	**Unmasked**		**Masked**	
	dev	test	dev	test[1]

5 Conclusion

We propose a Bi-directional Attention entity Graph convolutional network (BAG) for multi-hop reasoning QA tasks. Regarding task characteristics, graph convolutional networks (GCNs) are efficient to handle relationships among entities in documents. We demonstrate that both bi-directional attention between nodes and queries and multi-level features are necessary for such tasks. The former one aims to obtain query-aware node representation for answering, while the latter one provides contextual comprehension of isolated nodes in graphs. Our experimental results not only demonstrate the effectiveness of two proposed modules, but also show BAG achieves state-of-the-art performance on the WIKIHOP dataset.

Our future work will be making use of more complex relations between entities and building graphs in more general way without candidates.

Abstract

In this paper, we propose a novel representation for text documents based on aggregating word embedding vectors into document embeddings. Our approach is inspired by the Vector of Locally-Aggregated Descriptors used for image representation, and it works as follows. First, the word embeddings gathered from a collection of documents are clustered by k-means in order to learn a codebook of semnatically-related word embeddings. Each word embedding is then associated to its nearest cluster centroid (codeword). The Vector of Locally-Aggregated Word Embeddings (VLAWE) representation of a document is then computed by accumulating the differences between each codeword vector and each word vector (from the document) associated to the respective codeword. We plug the VLAWE representation, which is learned in an unsupervised manner, into a classifier and show that it is useful for a diverse set of text classification tasks. We compare our approach with a broad range of recent state-of-the-art methods, demonstrating the effectiveness of our approach. Furthermore, we obtain a considerable improvement on the Movie Review data set, reporting an accuracy of 93.3%, which represents an absolute gain of 10% over the state-of-the-art approach. Our code is available at https://github.com/raduionescu/vlawe-boswe/.

1 Introduction

In recent years, word embeddings (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014) have had a huge impact in natural language processing (NLP) and related fields, being used in many tasks including sentiment analysis (Dos Santos and Gatti, 2014; Fu et al., 2018), information retrieval (Clinchant and Perronnin, 2013; Ye et al., 2016) and word sense disambiguation (Bhingardive et al., 2015; Butnaru et al., 2017; Chen et al., 2014; Iacobacci et al., 2016), among many others. Starting from word embeddings, researchers proposed various ways of aggregating word embedding vectors to obtain efficient sentence-level or document-level representations (Butnaru and Ionescu, 2017; Cheng et al., 2018; Clinchant and Perronnin, 2013; Conneau et al., 2017; Cozma et al., 2018; Fu et al., 2018; Hill et al., 2016; Kiros et al., 2015; Kusner et al., 2015; Le and Mikolov, 2014; Shen et al., 2018; Torki, 2018; Zhao et al., 2015; Zhou et al., 2016, 2018). Although the mean (or sum) of word vectors is commonly adopted because of its simplicity (Mitchell and Lapata, 2010), it seems that more complex approaches usually yield better performance (Cheng et al., 2018; Conneau et al., 2017; Cozma et al., 2018; Fu et al., 2018; Hill et al., 2016; Kiros et al., 2015; Torki, 2018; Zhao et al., 2015; Zhou et al., 2016, 2018). To this end, we propose a simple yet effective approach for aggregating word embeddings into document embeddings. Our approach is inspired by the Vector of Locally-Aggregated Descriptors (VLAD) (Jégou et al., 2010, 2012) used in computer vision to efficiently represent images for various image classification and retrieval tasks. To our knowledge, we are the first to adapt and use VLAD in the text domain.

Our document-level representation is constructed as follows. First, we apply a pre-trained word embedding model, such as *GloVe* (Pennington et al., 2014), on all the words from a set of training documents in order to obtain a set of training word vectors. The word vectors are clustered by k-means in order to learn a codebook of semnatically-related word embeddings. Each word embedding is then associated to its nearest cluster centroid (codeword). The Vector of Locally-Aggregated Word Embeddings (VLAWE) representation of a text document is then com-

Proceedings of NAACL-HLT 2019, pages 363–369
Minneapolis, Minnesota, June 2 - June 7, 2019.

puted by accumulating the differences between each codeword vector and each word vector that is both present in the document and associated to the respective codeword. Since our approach considers cluster centroids as reference for building the representation, it can easily accommodate new words, not seen during k-means training, simply by associating them to the nearest cluster centroids. Thus, VLAWE is robust to vocabulary distribution gaps between training and test, which can appear when the training set is particularly smaller or from a different domain. Certainly, the robustness holds as long as the word embeddings are pretrained on a very large set of documents, e.g. the entire Wikipedia.

We plug the VLAWE representation, which is learned in an unsupervised manner, into a classifier, namely Support Vector Machines (SVM), and show that it is useful for a diverse set of text classification tasks. We consider five benchmark data sets: Reuters-21578 (Lewis, 1997), RT-2k (Pang and Lee, 2004), MR (Pang and Lee, 2005), TREC (Li and Roth, 2002) and Subj (Pang and Lee, 2004). We compare VLAWE with recent state-of-the-art methods (Butnaru and Ionescu, 2017; Cheng et al., 2018; Fu et al., 2018; Hill et al., 2016; Iyyer et al., 2015; Kim, 2014; Kiros et al., 2015; Le and Mikolov, 2014; Liu et al., 2017; Shen et al., 2018; Torki, 2018; Xue and Zhou, 2009; Zhao et al., 2015; Zhou et al., 2016, 2018), demonstrating the effectiveness of our approach. Furthermore, we obtain a considerable improvement on the Movie Review (MR) data set, surpassing the state-of-the-art approach of Cheng et al. (2018) by almost 10%.

The rest of the paper is organized as follows. We present related works on learning document-level representations in Section 2. We describe the Vector of Locally-Aggregated Word Embeddings in Section 3. We present experiments and results on various text classification tasks in Section 4. Finally, we draw our conclusion in Section 5.

2 Related Work

There are various works (Butnaru and Ionescu, 2017; Cheng et al., 2018; Conneau et al., 2017; Fu et al., 2018; Hill et al., 2016; Iyyer et al., 2015; Kim, 2014; Kiros et al., 2015; Kusner et al., 2015; Le and Mikolov, 2014; Clinchant and Perronnin, 2013; Shen et al., 2018; Torki, 2018; Zhao et al., 2015; Zhou et al., 2018) that propose to build effective sentence-level or document-level representations based on word embeddings. While most of these approaches are based on deep learning (Cheng et al., 2018; Conneau et al., 2017; Hill et al., 2016; Iyyer et al., 2015; Kim, 2014; Kiros et al., 2015; Le and Mikolov, 2014; Zhao et al., 2015; Zhou et al., 2018), there have been some approaches that are inspired by computer vision research, namely by the bag-of-visual-words (Butnaru and Ionescu, 2017) and by Fisher Vectors (Clinchant and Perronnin, 2013). The relationship between the bag-of-visual-words, Fisher Vectors and VLAD is discussed in (Jégou et al., 2012). The discussion can be transferred to describe the relantionship of our work and the closely-related works of Butnaru and Ionescu (2017) and Clinchant and Perronnin (2013).

3 Method

The Vector of Locally-Aggregated Descriptors (VLAD) (Jégou et al., 2010, 2012) was introduced in computer vision to efficiently represent images for various image classification and retrieval tasks. We propose to adapt the VLAD representation in order to represent text documents instead of images. Our adaptation consists of replacing the Scale-Invariant Feature Transform (SIFT) image descriptors (Lowe, 2004) useful for recognizing object patterns in images with word embeddings (Mikolov et al., 2013; Pennington et al., 2014) useful for recognizing semantic patterns in text documents. We coin the term *Vector of Locally-Aggregated Word Embeddings (VLAWE)* for the resulting document representation.

The VLAWE representation is derived as follows. First, each word in the collection of training documents is represented as a word vector using a pre-trained word embeddings model. The result is a set $X = \{x_1, x_2, ..., x_n\}$ of n word vectors. As for the VLAD model, the next step is to learn a codebook $\{\mu_1, \mu_2, ..., \mu_k\}$ of representative meta-word vectors (codewords) using k-means. Each codeword μ_i is the centroid of the cluster $C_i \subset X$:

$$\mu_i = \frac{1}{|C_i|} \sum_{x_t \in C_i} x_t, \forall i \in \{1, 2, ..., k\}, \qquad (1)$$

where $|C_i|$ is the number of word vectors assigned to cluster C_i and k is the number of clusters. Since word embeddings carry semantic information by projecting semantically-related words in the same region of the embedding space, it means that the resulting clusters contain semantically-related words. The formed centroids are stored in a randomized forest of k-d trees to reduce search cost, as described in (Philbin et al., 2007; Ionescu et al., 2013; Ionescu and Popescu, 2014, 2015a). Each word embedding x_t is associated to a single cluster C_i, such that the Euclidean distance between x_t and the corresponding codeword μ_i is minimum, for all $i \in \{1, 2, ..., k\}$. For each document D and each codeword μ_i, the differences $x_t - \mu_i$ of the vectors $x_t \in C_i \cap D$ and the codeword μ_i are accumulated into column vectors:

$$v_{i,D} = \sum_{x_t \in C_i \cap D} x_t - \mu_i, \qquad (2)$$

where $D \subset X$ is the set of word embeddings in a given text document. The final VLAWE embedding for a given document D is obtained by stacking together the d-dimensional residual vectors $v_{i,D}$, where d is equal to the dimension of the word embeddings:

$$\phi_D = \begin{bmatrix} v_{1,D} \\ v_{2,D} \\ \vdots \\ v_{k,D} \end{bmatrix}. \qquad (3)$$

Therefore, the VLAWE document embedding is has $k \cdot d$ components.

The VLAWE vector ϕ_D undergoes two normalization steps. First, a power normalization is performed by applying the following operator independently on each component (element):

$$f(z) = sign(z) \cdot |z|^{\alpha}, \qquad (4)$$

where $0 \leq \alpha \leq 1$ and $|z|$ is the absolute value of z. Since words in natural language follow the Zipf's law (Powers, 1998), it seems natural to apply the power normalization in order to reduce the influence of highly frequent words, e.g. common words or stopwords, which can corrupt the representation. As Jégou et al. (2012), we empirically observed that this step consistently improves the quality of the representation. The power normalized document embeddings are then L_2-normalized. After obtaining the normalized VLAWE representations, we employ a classification method to learn a discriminative model for each specific text classification task.

4 Experiments

4.1 Data Sets

We exhibit the performance of VLAWE on five public data sets: Reuters-21578 (Lewis, 1997), RT-2k (Pang and Lee, 2004), MR (Pang and Lee, 2005), TREC (Li and Roth, 2002) and Subj (Pang and Lee, 2004).

The Reuters-21578 data set (Lewis, 1997) contains articles collected from Reuters newswire. Following Joachims (1998) and Yang and Liu (1999), we select the categories (topics) that have at least one document in the training set and one in the test set, leading to a total of 90 categories. We use the ModeApte evaluation (Xue and Zhou, 2009), in which unlabeled documents are eliminated, leaving a total of 10787 documents. The collection is already divided into 7768 documents for training and 3019 documents for testing.

The RT-2k data set (Pang and Lee, 2004) consists of 2000 movie reviews taken from the IMDB movie review archives. There are 1000 positive reviews rated with four or five stars, and 1000 negative reviews rated with one or two stars. The task is to discriminate between positive and negative reviews.

The Movie Review (MR) data set (Pang and Lee, 2005) consists of 5331 positive and 5331 negative sentences. Each sentence is selected from one movie review. The task is to discriminate between positive and negative sentiment.

TREC (Li and Roth, 2002) is a question type classification data set, where questions are divided into 6 classes. The collection is already divided into 5452 questions for training and 500 questions for testing.

The Subjectivity (Subj) (Pang and Lee, 2004) data set contains 5000 objective and 5000 subjective sentences. The task is to classify a sentence as being either subjective or objective.

4.2 Evaluation and Implementation Details

In the experiments, we used the pre-trained word embeddings computed with the *GloVe* toolkit provided by Pennington et al. (2014). The pre-trained GloVe model contains 300-dimensional vectors for 2.2 million words and phrases. Most of the steps required for building the VLAWE representation, such as the k-means clustering and the randomized forest of k-d trees, are implemented using the VLFeat library (Vedaldi and Fulkerson, 2008). We set the number of clusters (size of the codebook) to $k = 10$, leading to a VLAWE representation of $k \cdot d = 10 \cdot 300 = 3000$ components. Similar to Jégou et al. (2012), we set $\alpha = 0.5$ for the power normalization step in Equation (4), which consistently leads to near-optimal results on all data sets. In the learning stage, we employ the

DARLM (Zhou et al., 2018)	-	-	83.2	96.0	94.1
VLAWE (ours)	89.3	94.1	93.3	94.2	95.0

Table 1: Performance results (in %) of our approach (VLAWE) versus several state-of-the-art methods (Butnaru and Ionescu, 2017; Cheng et al., 2018; Fu et al., 2018; Hill et al., 2016; Iyyer et al., 2015; Kim, 2014; Kiros et al., 2015; Le and Mikolov, 2014; Liu et al., 2017; Shen et al., 2018; Torki, 2018; Xue and Zhou, 2009; Zhao et al., 2015; Zhou et al., 2016, 2018) on the Reuters-21578, RT-2k, MR, TREC and Subj data sets.

Support Vector Machines (SVM) implementation provided by LibSVM (Chang and Lin, 2011). We set the SVM regularization parameter to $C = 1$ in all our experiments. In the SVM, we use the linear kernel. For optimal results, the VLAWE representation is combined with the BOSWE representation (Butnaru and Ionescu, 2017), which is based on the PQ kernel (Ionescu and Popescu, 2013, 2015b).

We follow the same evaluation procedure as Kiros et al. (2015) and Hill et al. (2016), using 10-fold cross-validation when a train and test split is not pre-defined for a given data set. As evaluation metrics, we employ the micro-averaged F_1 measure for the Reuters-21578 data set and the standard classification accuracy for the RT-2k, the MR, the TREC and the Subj data sets, in order to fairly compare with the related art.

4.3 Results

We compare VLAWE with several state-of-the-art methods (Butnaru and Ionescu, 2017; Cheng et al., 2018; Fu et al., 2018; Hill et al., 2016; Iyyer et al., 2015; Kim, 2014; Kiros et al., 2015; Le and Mikolov, 2014; Liu et al., 2017; Shen et al., 2018; Torki, 2018; Xue and Zhou, 2009; Zhao et al., 2015; Zhou et al., 2016, 2018) as well as two baseline methods, namely the average of word embeddings and the standard bag-of-words (BOW). The corresponding results are presented in Table 1.

First, we notice that our approach outperforms both baselines on all data sets, unlike other related methods (Le and Mikolov, 2014; Hill et al., 2016). In most cases, our improvements over the baselines are higher than 5%. On the Reuters-21578 data set, we surpass the closely-related approach of Butnaru and Ionescu (2017) by around 2%. On

Method	MR
VLAWE ($k = 2$)	93.0
VALWE (PCA)	93.2
VLAWE (full, $k = 10$)	93.3

Table 2: Performance results (in %) of the full VLAWE representation (with $k = 10$) versus two compact versions of VLAWE, obtained either by setting $k = 2$ or by applying PCA.

the RT-2k data set, we surpass the related works of Fu et al. (2018) and Butnaru and Ionescu (2017) by around 4%. To our knowledge, our accuracy of 94.1% on RT-2k (Pang and Lee, 2004) surpasses all previous results reported in literature. On the MR data set, we surpass most related works by more than 10%. To our knowledge, the best accuracy on MR reported in previous literature is 83.6%, and it is obtained by Cheng et al. (2018). We surpass the accuracy of Cheng et al. (2018) by almost 10%, reaching an accuracy of 93.3% using VLAWE. On the TREC data set, we reach the third best performance, after methods such as (Cheng et al., 2018; Zhou et al., 2016, 2018). Our performance on TREC is about 2% lower than the state-of-the-art accuracy of 96.1%. On the Subj data set, we obtain an accuracy of 95.0%. There are two state-of-the-art methods (Cheng et al., 2018; Zhao et al., 2015) reporting better performance on Subj. Compared to the best one of them (Cheng et al., 2018), our accuracy is 1% lower. Overall, we consider that our results are noteworthy.

4.4 Discussion

The k-means clustering algorithm and, on some data sets, the cross-validation procedure can induce accuracy variations due to the random choices involved. We have conducted experiments to determine how large are the accuracy variations. We observed that the accuracy can decrease by up to 1%, which does not bring any significant differences to the results reported in Table 1.

Even for a small number of clusters, e.g. $k = 10$, the VLAWE document representation can grow up to thousands of features, as the number of features is $k \cdot d$, where $d = 300$ is the dimensionality of commonly used word embeddings. However, there are several document-level representations that usually have a dimensionality much smaller than $k \cdot d$. Therefore, it is desirable to obtain a more compact VLAWE representation. We hereby propose two approaches that lead to more compact representations. The first one is simply based on reducing the number of clusters. By setting $k = 2$ for instance, we obtain a 600-dimensional representation. The second one is based on applying Principal Component Analysis (PCA), to reduce the dimension of the feature vectors. Using PCA, we propose to reduce the size of the VLAWE representation to 300 components. In Table 2, the resulting compact representations are compared against the full VLAWE representation on the MR data set. Although the compact VLAWE representations provide slightly lower results compared to the VLAWE representation based on 3000 components, we note that the differences are insignificant. Furthermore, both compact VLAWE representations are far above the state-of-the-art method (Cheng et al., 2018).

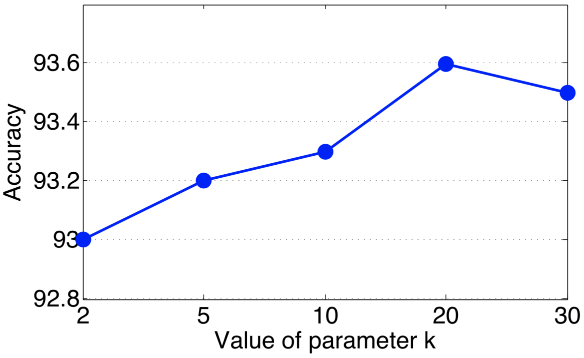

Figure 1: Accuracy on MR for different numbers of k-means clusters.

In Figure 1, we illustrate the performance variation on MR, when using different values for k. We notice that the accuracy tends to increase slightly, as we increase the number of clusters from 2 to 30. Overall, the VLAWE representation seems to be robust to the choice of k, always surpassing the state-of-the-art approach (Cheng et al., 2018).

5 Conclusion

We proposed a novel representation for text documents which is based on aggregating word embeddings using k-means and on computing the residuals between each word embedding allocated to a given cluster and the corresponding cluster centroid. Our experiments on five benchmark data sets prove that our approach yields competitive results with respect to the state-of-the-art methods.

Abstract

Related tasks often have inter-dependence on each other and perform better when solved in a joint framework. In this paper, we present a deep multi-task learning framework that jointly performs sentiment and emotion analysis both. The multi-modal inputs (i.e., *text*, *acoustic* and *visual frames*) of a video convey diverse and distinctive information, and usually do not have equal contribution in the decision making. We propose a context-level inter-modal attention framework for simultaneously predicting the sentiment and expressed emotions of an utterance. We evaluate our proposed approach on CMU-MOSEI dataset for multi-modal sentiment and emotion analysis. Evaluation results suggest that multi-task learning framework offers improvement over the single-task framework. The proposed approach reports new state-of-the-art performance for both sentiment analysis and emotion analysis.

1 Introduction

With the rapid growth of social media video platforms such as Youtube, Vimeo, users now tend to upload videos on these platforms. Such video platforms offer users an opportunity to express their opinions on any topic. Videos usually consist of *audio* and *visual* modalities, and thus can be considered as a source of multi-modal information. Although videos contain more information than text, fusing multiple modalities is a major challenge. A common practice in sentiment analysis and emotion recognition or affective computing, in general, is to analyze textual opinions. However, in recent days multi-modal affect analysis has gained a major attention (Poria et al., 2017b, 2016). In these works, in addition to the *visual frames*, other sources of information such as *acoustic* and *textual* (transcript) representation of the spoken languages are also incorporated in the analysis. Multi-modal analysis (e.g. sentiment analysis Zadeh et al. 2018c, emotion recognition Poria et al. 2016, question-answering Teney et al. 2017 etc.) is an emerging field of study, that utilizes multiple information sources for solving a problem. These sources (e.g., text, visual, acoustic, etc.) offer a diverse and often distinct piece of information that a system can leverage on. For example, *'text'* carries semantic information of the spoken sentence, whereas '*acoustic*' information reveals the emphasis (pitch, voice quality) on each word. In contrast, the '*visual*' information (image or video frame) extracts the gesture and posture of the speaker.

Traditionally, '*text*' has been the key factor in any Natural Language Processing (NLP) tasks including sentiment and emotion analysis. However, with the recent emergence of social media platforms and their available multi-modal contents, an interdisciplinary study involving *text*, *acoustic* and *visual* features have drawn significant interest among the research community. Effectively fusing this diverse information is non-trivial and poses several challenges to the underlying problem.

In our current work, we propose a multi-task model to extract both sentiment (i.e. ***positive*** or ***negative***) and emotion (i.e. ***anger***, ***disgust***, ***fear***, ***happy***, ***sad*** or ***surprise***) of a speaker in a video. In multi-task framework, we aim to leverage the inter-dependence of these two tasks to increase the confidence of individual task in prediction. For e.g., information about *anger* emotion can help in prediction of *negative* sentiment and vice-versa.

A speaker can utter multiple utterances (a unit of speech bounded by breathes or pauses) in a single video and these utterances can have different sentiments and emotions. We hypothesize that the sentiment (or, emotion) of an utterance often has inter-dependence on other contextual utterances i.e. the knowledge of sentiment (or, emo-

Proceedings of NAACL-HLT 2019, pages 370–379
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

tion) for an utterance can assist in classifying its neighbor utterances. We utilize all three modalities (i.e. *text*, *acoustic* and *visual*) for the analysis. Although all these sources of information are crucial, they are not equally beneficial for each individual instance. Few examples are presented in Table 1. In the first example, *visual frames* provide important clues than *textual* information for finding the sentiment of a sarcastic sentence "*Thanks for putting me on hold! I've all the time in the world.*". Similarly, the *textual* representation of second example "*I'm fine.*' does not reveal the exact emotion of a *sad* person. For this particular case, *acoustic* or *visual* information such as low tone voice, facial expression etc. have bigger role to play for the classification.

Utterance	Feeling	**T**	**A**	**V**
Thanks for putting me on hold! I've all the time in the world.	Sentiment (Negative)	-	-	✓
I'm fine.	Emotion (Sad)	-	✓	✓

Table 1: Contributing modalities for different scenario. Tick represents the most contributing information.

2 Problem Definition

Multi-task learning paradigm provides an efficient platform for achieving generalization. Multiple tasks can exploit the inter-relatedness for improving individual performance through a shared representation. Overall, it provides three basic advantages over the single-task learning paradigm a). it helps in achieving generalization for multiple tasks; b). each task improves its performance in association with the other participating tasks; and c). offers reduced complexity because a single system can handle multiple problems/tasks at the same time.

Sentiments (Pang et al., 2005) and emotions (Ekman, 1999) are closely related. Most of the emotional states have clear distinction of being a positive or negative situation. Emotional states e.g. '*anger*', '*fear*', '*disgust*', '*sad*' etc. belong to negative situations, whereas '*happy*' and '*surprise*' reflect the positive situations. Motivated by the association of sentiment & emotion and the advantages of the multi-task learning paradigm, we present a multi-task framework that jointly learns and classifies the sentiments and emotions in a video. As stated earlier, contextual-utterances and/or multi-modal information provide important cues for the classification. Our proposed approach applies attention over both of these sources of information simultaneously (i.e., contextual utterance and inter-modal information), and aims to reveal the most contributing features for the classification. We hypothesize that applying attention to contributing neighboring utterances and/or multi-modal representations may assist the network to learn in a better way.

Our proposed architecture employs a recurrent neural network based contextual inter-modal attention framework. In our case, unlike the previous approaches, that simply apply attention over the contextual utterance for classification, we take a different approach. Specifically, we attend over the contextual utterances by computing correlations among the modalities of the target utterance and the context utterances. This particularly helps us to distinguish which modalities of the relevant contextual utterances are more important for the classification of the target utterance. The model facilitates this modality selection process by attending over the contextual utterances and thus generates better multi-modal feature representation when these modalities from the context are combined with the modalities of the target utterance. We evaluate our proposed approach on the recent benchmark dataset of CMU-MOSEI (Zadeh et al., 2018c). It is the largest available dataset (approx. 23K utterances) for multi-modal sentiment and emotion analysis (c.f. Dataset Section). The evaluation shows that contextual inter-modal attention framework attains better performance than the state-of-the-art systems for various combinations of input modalities.

The main contributions of our proposed work are three-fold: **a)** *we leverage the interdependence of two related tasks (i.e. sentiment and emotion) in improving each others performance using an effective multi-modal framework*; **b)** *we propose contextual inter-modal attention mechanism that facilitates the model to assign weightage to the contributing contextual utterances and/or to different modalities simultaneously*. Suppose, to classify an utterance '*u1*' of 5 utterances video, visual features of '*u2*' & '*u4*', acoustic features of '*u3*' and textual features of '*u1*', '*u3*' & '*u5*' are more important than others. Our attention model is capable of highlighting such diverse contributing features; and **c)** *we present the state-of-the-arts for both sentiment and emotion predictions*.

3 Related Work

A survey of the literature suggests that multi-modal sentiment prediction is a relatively new area as compared to textual based sentiment prediction (Morency et al., 2011; Poria et al., 2017b; Zadeh et al., 2018a). A good review covering the literature from uni-modal analysis to multi-modal analysis is presented in (Poria et al., 2017a).

Zadeh et al. (2016) introduced the multi-modal dictionary to understand the interaction between facial gestures and spoken words better when expressing sentiment. In another work, Zadeh et al. (2017) proposed a Tensor Fusion Network (TFN) model to learn the intra-modality and inter-modality dynamics of the three modalities (i.e., text, visual and acoustic). Authors reported improved accuracy using multi-modality on the CMU-MOSI dataset. These works did not take contextual information into account. Poria et al. (2017b) proposed a Long Short Term Memory (LSTM) based framework for sentiment classification that leverages the contextual information to capture the inter-dependencies between the utterances. Zadeh et al. (2018a) proposed multi-attention blocks (MAB) to capture the information across the three modalities (text, visual and acoustic) for predicting the sentiments. Authors evaluated their approach on the different datasets and reported improved accuracies in the range of 2-3% over the state-of-the-art models. Blanchard et al. (2018) proposed a multi-modal fusion model that exclusively uses high-level visual and acoustic features for sentiment classification.

An application of multi-kernel learning based fusion technique was proposed in (Poria et al., 2016), where the authors employed deep convolutional neural network (CNN) for extracting the textual features and fused it with other modalities (*visual* & *acoustic*) for emotion prediction. Ranganathan et al. (2016) proposed a convolutional deep belief network (CDBN) models for multi-modal emotion recognition. The author used CDBN to learn salient multi-modal (acoustic and visual) features of low-intensity expressions of emotions. Hazarika et al. (2018) introduced a self- attention mechanism for multi-modal emotion detection by feature level fusion of text and speech. Recently, Zadeh et al. (2018c) introduced the CMU-MOSEI dataset for multi-modal sentiment analysis and emotion recognition. They effectively fused the tri-modal inputs through a dynamic fusion graph and also reported competitive performance *w.r.t.* various state-of-the-arts on MOSEI dataset for both sentiment and emotion classification.

The main difference between the proposed and existing methods is contextual inter-modal attention. Systems (Poria et al., 2016; Zadeh et al., 2016, 2017; Blanchard et al., 2018) do not consider context for the prediction. System (Poria et al., 2017b) uses contextual information for the prediction but without any attention mechanism. In contrast, (Zadeh et al., 2018a) uses multi-attention blocks but did not account for contextual information. Our proposed model is novel in the sense that our approach applies attention over multi-modal information of the contextual utterances in a single step. Thus, it ensures to reveal the contributing features across *multiple modalities* and *contextual utterances* simultaneously for sentiment and emotion analysis. Further, to the best of our knowledge, this is the first attempt at solving the problems of multi-modal sentiment and emotion analysis together in a multi-task framework.

The contextual inter-modal attention mechanism is not much explored in NLP domains as such. We found one work that accounts for bi-modal attention for visual question-answering (VQA) (Teney et al., 2017). However, its attention mechanism differs from our proposed approach in the following manner: a) VQA proposed question guided image-attention, but our attention mechanism attends multi-modalities; b) attention is applied over different positions of the image, whereas our proposed approach applies attention over multiple utterances and two-modalities at a time; c). our proposed attention mechanism attends a sequence of utterances (text, acoustic or visual), whereas VQA applies attention in the spatial domain. In another work, Ghosal et al. (2018) proposed an inter-modal attention framework for the multi-modal sentiment analysis. However, the key differences with our current work are as follows: a) Ghosal et al. (2018) addressed only sentiment analysis, whereas, in our current work, we address both the sentiment and emotion analysis; b) Ghosal et al. (2018) handles only sentiment analysis in single task learning framework, whereas our proposed approach is based on multi-task learning framework, where we solve two tasks, i.e., sentiment analysis and emotion analysis, together in a single network; c) we perform detailed comparative analysis over the single-task vs. multi-task learning; and d) we present state-of-the-art for both sentiment and emotion analysis.

4 Multi-task Multi-modal Emotion Recognition and Sentiment Analysis

In our proposed framework, we aim to leverage multi-modal and contextual information for predicting sentiment and emotion of an utterance simultaneously in a multi-task learning framework. As stated earlier, a video consists of a sequence of utterances and their semantics often have inter-dependencies on each other. We employ three bi-directional Gated Recurrent Unit (biGRU) network for capturing the contextual information (i.e., one for each modality). Subsequently, we introduce pair-wise inter-modal attention mechanism (i.e. *visual-text*, *text-acoustic* and *acoustic-visual*) to learn the joint-association between the multiple modalities & utterances. The objective is to emphasize on the contributing features by putting more attention to the respective utterance and neighboring utterances. Motivated by the residual skip connection (He et al., 2016) the outputs of pair-wise attentions along with the representations of individual modalities are concatenated. Finally, the concatenated representation is shared across the two branches of our proposed network- corresponding to two tasks, i.e., sentiment and emotion classification for prediction (one for each task in the multi-task framework). Sentiment classification branch contains a *softmax* layer for final classification (i.e. *positive* & *negative*), whereas for emotion classification we use sigmoid layer. The shared representation will receive gradients of error from both the branches (sentiment & emotion) and accordingly adjust the weights of the models. Thus, the shared representations will not be biased to any particular task, and it will assist the model in achieving generalization for the multiple tasks. Empirical evidences support our hypothesis (c.f. Table 4).

4.1 Contextual Inter-modal (CIM) Attention Framework

Our contextual inter-modal attention framework works on a pair of modalities. At first, we capture the cross-modality information by computing a pair of matching matrices $M_1, M_2 \in \mathbb{R}^{u \times u}$, where '$u$' is the number of utterances in the video. Further, to capture the contextual dependencies, we compute the probability distribution scores ($N_1, N_2 \in \mathbb{R}^{u \times u}$) over each utterance of cross-modality matrices M_1, M_2 using a softmax function. This essentially computes the attention weights for contextual utterances. Subsequently, we apply soft attention over the contextual inter-modal matrices to compute the modalitiy-wise attentive representations ($O_1 \& O_2$). Finally, a multiplicative gating mechanism (Dhingra et al., 2016) ($A_1 \& A_2$) is introduced to attend the important components of multiple modalities and utterances. The concatenated attention matrix of $A_1 \& A_2$ then acts as the output of our contextual inter-modal attention framework. The entire process is repeated for each pair-wise modalities i.e. *text-visual*, *acoustic-visual* and *text-acoustic*. We illustrate and summarize the proposed methodology in Figure 1 and Algorithm 1, respectively.

Algorithm 1 Multi-task Multi-modal Emotion and Sentiment (MTMM-ES)

```
procedure MTMM-ES($t, v, a$)
    $d \leftarrow 100$                                   ▷ GRU dimension
    $T \leftarrow biGRU_T(t, d)$
    $V \leftarrow biGRU_V(v, d)$
    $A \leftarrow biGRU_A(a, d)$
    $Atn_{TV} \leftarrow CIM\text{-}Attention(T, V)$
    $Atn_{AV} \leftarrow CIM\text{-}Attention(A, V)$
    $Atn_{TA} \leftarrow CIM\text{-}Attention(T, A)$
    $Rep \leftarrow [Atn_{TV}, Atn_{AV}, Atn_{TA}, T, V, A]$
    $polarity \leftarrow Sentiment(Rep)$
    $emotion \leftarrow Emotion(Rep)$
    return $polarity, emotion$

procedure CIM-ATTENTION($X, Y$)
    /*Cross-modality information*/
    $M_1 \leftarrow X.Y^T$
    $M_2 \leftarrow Y.X^T$
    /*Contextual Inter-modal attention*/
    for $i, j \in 1, ..., u$ do                          ▷ $u = \#utterances$
        $N_1(i,j) \leftarrow \frac{e^{M_1(i,j)}}{\sum_{k=1}^{u} e^{M_1(i,k)}}$
        $N_2(i,j) \leftarrow \frac{e^{M_2(i,j)}}{\sum_{k=1}^{u} e^{M_2(i,k)}}$
    $O_1 \leftarrow N_1.Y$
    $O_2 \leftarrow N_2.X$
    /*Multiplicative gating*/
    $A_1 \leftarrow O_1 \odot X$                          ▷ Element-wise mult.
    $A_2 \leftarrow O_2 \odot Y$
    return $[A_1, A_2]$
```

5 Datasets, Experiments, and Analysis

In this section, we describe the datasets used for our experiments and report the results along with necessary analysis.

5.1 Datasets

We evaluate our proposed approach on the benchmark datasets of sentiment and emotion analysis, namely CMU Multi-modal Opinion Sentiment and Emotion Intensity (CMU-MOSEI) dataset (Zadeh et al., 2018c). CMU-MOSEI dataset consists of 3,229 videos spanning over 23,000 utterances from more than 1,000 online YouTube speakers. The training, validation & test set comprises of 16216, 1835 & 4625 utterances, respectively.

Each utterance has six emotion values associated with it, representing the degree of emotion for *anger*, *disgust*, *fear*, *happy*, *sad* and *surprise*. Emotion labels for an utterance are identified as all non-zero intensity values, i.e. if an utterance has three emotions with non-zero values, we take all three emotions as multi-labels. Further, an utterance that has no emotion label represents the absence of emotion. For experiments, we adopt 7-classes (6 *emotions* + 1 *no emotion*) and pose it as multi-label classification problem, where we try to optimize the binary-cross entropy for each of the class. A brief statistics for multi-label emotions is presented in Table 3. In contrast, the sentiment values for each utterance are disjoint, i.e. *value* < 0 and *value* ≥ 0 represent the negative and positive sentiments, respectively. A detailed statistics of the CMU-MOSEI dataset is shown in Table 2.

Statistics	Train	Dev	Test
#Videos	2250	300	679
#Utterance	16216	1835	4625
#Positive	11499	1333	3281
#Negative	4717	502	1344
#Anger	3506	334	1063
#Disgust	2946	280	802
#Fear	1306	163	381
#Happy	8673	978	2484
#Sad	4233	511	1112
#Surprise	1631	194	437
#Speakers		1000

Table 4: Single-task learning (STL) and Multi-task (MTL) learning frameworks for the proposed approach. T: Text, V: Visual, A: *Acoustic*. Weighted accuracy as a metric is chosen due to unbalanced samples across various emotions and it is also in line with the other existing works (Zadeh et al., 2018c).

5.2 Feature extraction

We use the CMU-Multi-modal Data SDK[1] for downloading and feature extraction. The dataset was pre-tokenized and a feature vector was provided for each word in an utterance. The *textual*, *visual* and *acoustic* features were extracted by *GloVe* (Pennington et al., 2014), *Facets*[2] & *CovaRep* (Degottex et al., 2014), respectively. Thereafter, we compute the average of *word-level* features to obtain the *utterance-level* features.

Parameters	Values
Bi-GRU	2×200 *neurons*, *dropout=0.3*
Dense layer	100 *neurons*, *dropout=0.3*
Activations	*ReLu*
Optimizer	*Adam* (*lr=0.001*)
Output	*Softmax* (Sent) & *Sigmoid* (Emo)
Loss	*Categorical cross-entropy* (Sent) *Binary cross-entropy* (Emo)
Threshold	0.4 (F1) & 0.2 (W-Acc) for multi-label
Batch	*16*
Epochs	*50*

Table 5: Model configurations

5.3 Experiments

We evaluate our proposed approach on the datasets of CMU-MOSEI. We use the Python based Keras library for the implementation. We compute *F1-score* and *accuracy values* for sentiment classification and *F1-score* and *weighted accuracy* (Tong et al., 2017) for emotion classification. Weighted accuracy as a metric is chosen due to unbalanced samples across various emotions and it is also in line with the other existing works (Zadeh et al., 2018c). To obtain multi-labels for emotion classification, we use 7 sigmoid neurons (corresponds to 6 emotions + 1 no-emotion) with binary cross-entropy loss function. Finally, we take all the emotions whose respective values are above a $threshold$. We optimize and cross-validate both the evaluation metrics (i.e. F1- score and weighted accuracy) and set the *threshold* as 0.4 & 0.2 for F1-score and weighted accuracy, respectively. We show our model configurations in Table 5.

As stated earlier, our proposed approach requires at least two modalities to compute bi-modal attention. Hence, we experiment with bi-modal and tri-modal input combinations for the proposed approach i.e. taking *text-visual*, *text-acoustic*, *acoustic-visual* and *text-visual-acoustic* at a time. For completeness (i.e., uni-modal inputs), we also experiment with a variant of the proposed approach where we apply self-attention on the utterances of each modality separately. The self-attention unit utilizes the contextual information of the utterances (i.e., it receives $u \times d$ hidden representations), applies attention and forward it to the output layer for classification. We report the experimental results of both single-task (STL) and multi-task (MTL) learning framework in Table 4. In the single-task framework, we build separate systems for sentiment and emotion analysis, whereas in multi-task framework a joint-model is learned for both of these problems. For sentiment classification, our single-task framework reports an F1-score of 77.67% and accuracy value of 79.8% for the tri-modal inputs. Similarly, we obtain 77.71% F1-score and 60.88% weighted accuracy for emotion classification.

Comparatively, when both the problems are learned and evaluated in a multi-task learning framework, we observe performance enhancement for both sentiments as well as emotion classification. MTL reports 78.86% F1-score and 80.47% accuracy value in comparison to 77.67% and 79.8% of STL with tri-modal inputs, respectively. For emotion classification, we also observe an improved F-score (78.6 (MTL) vs. 77.7 (STL)) and weighted accuracy (62.8 (MTL) vs. 60.8 (STL))

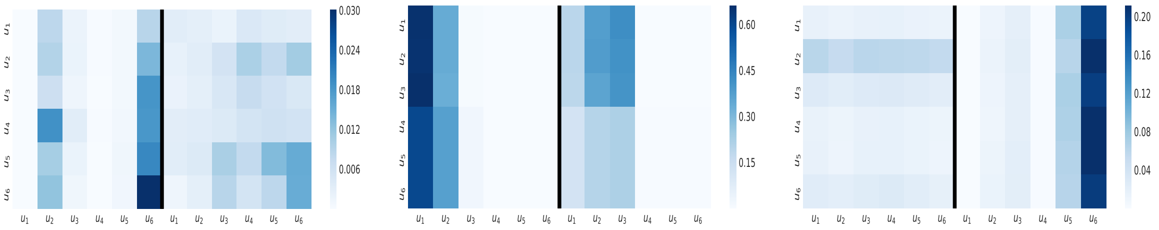
Table 6: Example video for heatmap analysis of the contextual inter-modal (CIM) attention mechanism of the proposed MTMM-ES framework. Figure 3 depicts the heatmaps for the above video.



(a) *Softmax attention weights N_1 & N_2 for TV.* (b) *Softmax attention weights N_1 & N_2 for AV.* (c) *Softmax attention weights N_1 & N_2 for TA.*

Figure 3: (a), (b) & (c): Pair-wise softmax attention weights N_1 & N_2 of *visual-text*, *acoustic-visual* & *text-acoustic* for multi-task learning framework. Solid line at the center represents boundary of N_1 & N_2. The heatmaps represent attention weights of a particular utterance with respect to other utterances in N_1 & N_2. Each cell (i, j) of the heatmap signifies the weights of utterance 'j' for the classification of utterance 'i' of the pair-wise modality matrices, hence, assists in predicting the labels concisely by incorporating contextual inter-modal information.

in the multi-task framework. It is evident from Figure 2 that multi-task learning framework successfully leverages the inter-dependence of both the tasks in improving the overall performance in comparison to single-task learning. The improvements of MTL over STL framework is also statistically significant with *p*-value < 0.05 (c.f. Table 7).

We also present attention heatmaps of the multi-task learning framework in Figure 3. For illustration, we take the video of the first utterance of Table 6. It has total six utterances. We depict three pair-wise attention matrices of $2 \times (6 \times 6)$ dimension-one each for *text-visual*, *text-acoustics* and *acoustics-visual*. Solid lines in between represent the boundary of the two modalities, e.g. left

Table 7: Comparative results: Proposed multi-task framework attains better performance as compared to the state-of-the-art (SOTA) systems in both the tasks i.e. emotion recognition (average) and sentiment analysis. *Values are taken from Zadeh et al. (2018c). †Six-class average. Significance T-test (< 0.05). STL: Single-task learning.

side of Figure 3a represents *text* modality and right side represents the *visual* modality. The heatmaps represent the contributing features for the classification of utterances. Each cell (*i,j*) of Figure 3 signifies the weights of utterance '*j*' for the classification of utterance '*i*' of the pair-wise modality matrices. For example, for the classification of utterance '*u4*' in Figure 3a, model puts more focus on the textual features of '*u2*' and '*u6*' than others and more-or-less equal focus on the visual features of all the utterances.

5.4 Comparative Analysis

We compare our proposed approach against various existing systems (Nojavanasghari et al., 2016; Rajagopalan et al., 2016; Zadeh et al., 2017, 2018a,b,c; Blanchard et al., 2018) that made use of the same datasets. A comparative study is shown in Table 7. We report the results of the top three existing systems (as reported in Zadeh et al. 2018c) for each case. In emotion classification, the proposed multi-task learning framework reports the best F1-score of 78.6% as compared to the 76.3% and Weighted Accuracy of 62.8% as compared to the 62.3% of the state-of-the-art. Similarly, for sentiment classification, the state-of-the-art system reports 77.0% F1-score and 76.9% accuracy value in the multi-task framework. In comparison, we obtain the best F1-score and accuracy value of 78.8% and 80.4%, respectively, i.e., an improvement of 1.8% and 3.5% over the state-of-the-art systems.

During analysis, we make an important observation. Small improvements in performance do not reveal the exact improvement in the number of instances. Since there are more than 4.6K test samples, even the improvement by one point reflects that the system improves its predictions for 46 samples.

We also perform test-of-significance (T-test) and observe that the obtained results are statistically significant *w.r.t.* the state-of-the-art and proposed single-task results with p-values< 0.05.

5.5 STL v/s MTL framework

In this section, we present our analysis *w.r.t.* single-task and multi-task frameworks. Table 8 lists a few example cases where the proposed multi-task learning framework shows how it yields better performance for both sentiment and emotion, while the single-task framework finds it non-trivial for the classification. For example, first utterance has gold sentiment label as negative which was misclassified by STL framework. However, the MTL framework improves this by correctly predicting '*positive*'. Similarly, in emotion analysis STL predicts three emotions i.e. *disgust*, *happy* and *sad*, out of which only one emotion (*disgust*) matches the gold emotions of *anger* and *disgust*. In comparison, MTL predicts four emotions (i.e. *anger*, *disgust*, *happy* and *sad*) for the same utterance. The precision (2/4) and recall (2/2) for MTL framework is better than the precision (1/3) and recall (1/2) for the STL framework. These analyses suggest that the MTL framework, indeed, captures better evidences than the STL framework.

In the second example, knowledge of sentiment helps in identifying the correct emotion label in the MTL framework. For the gold sentiment (*positive*) and emotion (*happy* and *sad*) labels, STL correctly classifies one emotion (i.e. *sad*), but fails to predict the other emotion (i.e. *happy*). In addition, it misclassifies another emotion (i.e. *anger*). Since, gold label *happy* corresponds to the *posi-*

	Utterances	**Sentiment**			**Emotion**		
		Actual	**STL**	**MTL**	**Actual**	**STL**	**MTL**
1	*richard gere and susan umm you i really didn't enjoy this movie at all it kinda boring for*	Neg	Pos	Neg	Anger, Disgust	Disgust, Happy, Sad	Anger, Disgust, Happy, Sad
2	*we look forward to cooperating with the new government as it works to make progress on a wide range of issues including further democratic reforms promotion of human rights economic development and national reconciliation*	Pos	Pos	Pos	Happy, Sad	Anger, Sad	Happy, Sad
3	*laughter and applause still there though..*	Pos	Neg	Pos	Happy	Happy, Surprise	Happy
4	*is in love with some other person so you know the story*	Neg	Pos	Neg	Anger, Disgust, Sad	Disgust, Happy, Sad	Anger, Disgust, Sad
5	*i can say unfortunately i don't think it's a serious program*	Neg	Pos	Neg	Disgust, Sad, Surprise	Anger, Happy, Sad	Anger, Disgust, Happy, Sad
6	*the last administration bought into just as much as this one does unfortunately*	Neg	Pos	Neg	Anger, Disgust, Sad	Anger, Happy	Anger, Disgust, Happy, Sad
7	*it's just too great of a risk and it is socially unacceptable*	Neg	Pos	Neg	Anger, Disgust, Happy	Anger, Happy	Anger, Disgust, Happy
8	*had a robot here at hopkins since the year longer than most institutions in this country and around the world we*	Pos	Pos	Pos	Happy	Happy, Sad, No class	Happy
9	*in total we spent hundreds of hours on the ground on site watching these leaders in action*	Pos	Pos	Pos	No class	Happy	No class

Table 8: Comparison with multi-task learning and single-task learning frameworks. Few error cases where multi-task learning framework performs better than the single-task framework. *First utterance*: Improved MTL (*Pre: 0.5, Rec: 1.0*) performance over STL (*Pre: 0.3, Rec: 0.5*). *Second utterance:* Sentiment (i.e. *Pos*) assists in emotion classification (i.e. *Happy*). Red color represents error in classification.

tive scenario and predicted label *anger* is related to negative, knowledge of sentiment is a crucial piece of information. Our MTL framework identifies this relation and leverage the predicted sentiment for the classification of emotion i.e. *positive* sentiment assists in predicting *happy* emotion. This is an example of inter-dependence between the two related tasks and the MTL framework successfully exploits it for the performance improvement.

We also observe that the system puts comparatively more focus on some classes in MTL framework than the STL framework. As an instance, MTL predicts '*anger*' class for 1173 utterances, whereas STL predicts it for 951 utterances (1063 anger utterances in the gold dataset). Further, we observe contrasting behavior for the '*sad*' class, where MTL predicts 1618 utterances as '*sad*' compared to the 2126 utterances of STL. For '*disgust*' and '*happy*' classes, both STL and MTL frameworks predict the approximately equal number of utterances.

Further, we observe that MTL performs poorly for the '*fear*' and '*surprise*' classes, where it could not predict a significant number of utterances. A possible reason would be the under-representation of these instances in the given dataset.

6 Conclusion

In this paper, we have proposed a deep multi-task framework that aims to leverage the inter-dependence of two related tasks, i.e., multi-modal sentiment and emotion analysis. Our proposed approach learns a joint-representation for both the tasks as an application of GRU based inter-modal attention framework. We have evaluated our proposed approach on the recently released benchmark dataset on multi-modal sentiment and emotion analysis (MOSEI). Experimental results suggest that sentiment and emotion assist each other when learned in a multitask framework. We have compared our proposed approach against the various existing systems and observed that multi-task framework attains higher performance for all the cases.

In the future, we would like to explore the other dimensions to our multi-task framework, e.g., Sentiment classification & intensity prediction, Emotion classification & intensity prediction and all the four tasks together.

Abstract

Aspect-based sentiment analysis (ABSA), which aims to identify fine-grained opinion polarity towards a specific aspect, is a challenging subtask of sentiment analysis (SA). In this paper, we construct an auxiliary sentence from the aspect and convert ABSA to a sentence-pair classification task, such as question answering (QA) and natural language inference (NLI). We fine-tune the pre-trained model from BERT and achieve new state-of-the-art results on SentiHood and SemEval-2014 Task 4 datasets. The source codes are available at https://github.com/HSLCY/ABSA-BERT-pair.

1 Introduction

Sentiment analysis (SA) is an important task in natural language processing. It solves the computational processing of opinions, emotions, and subjectivity - sentiment is collected, analyzed and summarized. It has received much attention not only in academia but also in industry, providing real-time feedback through online reviews on websites such as Amazon, which can take advantage of customers' opinions on specific products or services. The underlying assumption of this task is that the entire text has an overall polarity.

However, the users' comments may contain different aspects, such as: "This book is a hardcover version, but the price is a bit high." The polarity in 'appearance' is positive, and the polarity regarding 'price' is negative. Aspect-based sentiment analysis (ABSA) (Jo and Oh, 2011; Pontiki et al., 2014, 2015, 2016) aims to identify fine-grained polarity towards a specific aspect. This task allows users to evaluate aggregated sentiments for each aspect of a given product or service and gain a more granular understanding of their quality.

Both SA and ABSA are sentence-level or document-level tasks, but one comment may refer to more than one object, and sentence-level tasks cannot handle sentences with multiple targets. Therefore, Saeidi et al. (2016) introduce the task of targeted aspect-based sentiment analysis (TABSA), which aims to identify fine-grained opinion polarity towards a specific aspect associated with a given target. The task can be divided into two steps: (1) the first step is to determine the aspects associated with each target; (2) the second step is to resolve the polarity of aspects to a given target.

The earliest work on (T)ABSA relied heavily on feature engineering (Wagner et al., 2014; Kiritchenko et al., 2014), and subsequent neural network-based methods (Nguyen and Shirai, 2015; Wang et al., 2016; Tang et al., 2015, 2016; Wang et al., 2017) achieved higher accuracy. Recently, Ma et al. (2018) incorporate useful commonsense knowledge into a deep neural network to further enhance the result of the model. Liu et al. (2018) optimize the memory network and apply it to their model to better capture linguistic structure.

More recently, the pre-trained language models, such as ELMo (Peters et al., 2018), OpenAI GPT (Radford et al., 2018), and BERT (Devlin et al., 2018), have shown their effectiveness to alleviate the effort of feature engineering. Especially, BERT has achieved excellent results in QA and NLI. However, there is not much improvement in (T)ABSA task with the direct use of the pretrained BERT model (see Table 3). We think this is due to the inappropriate use of the pre-trained BERT model.

Since the input representation of BERT can represent both a single text sentence and a pair of text sentences, we can convert (T)ABSA into a sentence-pair classification task and fine-tune the

Minneapolis, Minnesota, June 2 - June 7, 2019.

pre-trained BERT.

In this paper, we investigate several methods of constructing an auxiliary sentence and transform (T)ABSA into a sentence-pair classification task. We fine-tune the pre-trained model from BERT and achieve new state-of-the-art results on (T)ABSA task. We also conduct a comparative experiment to verify that the classification based on a sentence-pair is better than the single-sentence classification with fine-tuned BERT, which means that the improvement is not only from BERT but also from our method. In particular, our contribution is two-fold:

1. We propose a new solution of (T)ABSA by converting it to a sentence-pair classification task.
2. We fine-tune the pre-trained BERT model and achieve new state-of-the-art results on SentiHood and SemEval-2014 Task 4 datasets.

2 Methodology

In this section, we describe our method in detail.

2.1 Task description

TABSA In TABSA, a sentence s usually consists of a series of words: $\{w_1, \cdots, w_m\}$, and some of the words $\{w_{i_1}, \cdots, w_{i_k}\}$ are pre-identified targets $\{t_1, \cdots, t_k\}$, following Saeidi et al. (2016), we set the task as a 3-class classification problem: given the sentence s, a set of target entities T and a fixed aspect set $A = \{general, price, transit\text{-}location, safety\}$, predict the sentiment polarity $y \in \{positive, negative, none\}$ over the full set of the target-aspect pairs $\{(t, a) : t \in T, a \in A\}$. As we can see in Table 1, the gold standard polarity of (LOCATION2, price) is negative, while the polarity of (LOCATION1, price) is none.

ABSA In ABSA, the target-aspect pairs $\{(t, a)\}$ become only aspects a. This setting is equivalent to learning subtask 3 (Aspect Category Detection) and subtask 4 (Aspect Category Polarity) of SemEval-2014 Task 4[1] at the same time.

2.2 Construction of the auxiliary sentence

For simplicity, we mainly describe our method with TABSA as an example.

We consider the following four methods to convert the TABSA task into a sentence pair classification task:

Example:
LOCATION2 is central London so extremely expensive, LOCATION1 is often considered the coolest area of London.

Target	Aspect	Sentiment
LOC1	general	Positive
LOC1	price	None
LOC1	safety	None
LOC1	transit-location	None
LOC2	general	None
LOC2	price	Negative
LOC2	safety	None
LOC2	transit-location	Positive

Table 1: An example of SentiHood dataset.

Methods	Output	Auxiliary Sentence
QA-M	S.P.	Question w/o S.P.
NLI-M	S.P.	Pseudo w/o S.P.
QA-B	{yes,no}	Question w/ S.P.
NLI-B	{yes,no}	Pseudo w/ S.P.

Table 2: The construction methods. Due to limited space, we use the following abbreviations: *S.P.* for *sentiment polarity*, *w/o* for *without*, and *w/* for *with*.

Sentences for QA-M The sentence we want to generate from the target-aspect pair is a question, and the format needs to be the same. For example, for the set of a target-aspect pair (LOCATION1, safety), the sentence we generate is “what do you think of the safety of location - 1 ?”

Sentences for NLI-M For the NLI task, the conditions we set when generating sentences are less strict, and the form is much simpler. The sentence created at this time is not a standard sentence, but a simple pseudo-sentence, with (LOCATION1, safety) pair as an example: the auxiliary sentence is: “location - 1 - safety”.

Sentences for QA-B For QA-B, we add the label information and temporarily convert TABSA into a binary classification problem ($label \in \{yes, no\}$) to obtain the probability distribution. At this time, each target-aspect pair will generate three sequences such as “the polarity of the aspect safety of location - 1 is positive”, “the polarity of the aspect safety of location - 1 is negative”, “the polarity of the aspect safety of location - 1 is none”. We use the probabil-

---

[1] http://alt.qcri.org/semeval2014/task4/

ity value of yes as the matching score. For a target-aspect pair which generates three sequences ($positive, negative, none$), we take the class of the sequence with the highest matching score for the predicted category.

Sentences for NLI-B The difference between NLI-B and QA-B is that the auxiliary sentence changes from a question to a pseudo-sentence. The auxiliary sentences are: "location - 1 - safety - positive", "location - 1 - safety - negative", and "location - 1 - safety - none".

After we construct the auxiliary sentence, we can transform the TABSA task from a single sentence classification task to a sentence pair classification task. As shown in Table 3, this is a necessary operation that can significantly improve the experimental results of the TABSA task.

2.3 Fine-tuning pre-trained BERT

BERT (Devlin et al., 2018) is a new language representation model, which uses bidirectional transformers to pre-train a large corpus, and fine-tunes the pre-trained model on other tasks. We fine-tune the pre-trained BERT model on TABSA task. Let's take a brief look at the input representation and the fine-tuning procedure.

2.3.1 Input representation

The input representation of the BERT can explicitly represent a pair of text sentences in a sequence of tokens. For a given token, its input representation is constructed by summing the corresponding token, segment, and position embeddings. For classification tasks, the first word of each sequence is a unique classification embedding ([CLS]).

2.3.2 Fine-tuning procedure

BERT fine-tuning is straightforward. To obtain a fixed-dimensional pooled representation of the input sequence, we use the final hidden state (i.e., the output of the transformer) of the first token as the input. We denote the vector as $C \in \mathbb{R}^H$. Then we add a classification layer whose parameter matrix is $W \in \mathbb{R}^{K \times H}$, where K is the number of categories. Finally, the probability of each category P is calculated by the softmax function $P = \mathbf{softmax}(CW^{\mathrm{T}})$.

2.3.3 BERT-single and BERT-pair

BERT-single for (T)ABSA BERT for single sentence classification tasks. Suppose the number of target categories are n_t and aspect categories are n_a. We consider TABSA as a combination of $n_t \cdot n_a$ target-aspect-related sentiment classification problems, first classifying each sentiment classification problem, and then summarizing the results obtained. For ABSA, We fine-tune pre-trained BERT model to train n_a classifiers for all aspects and then summarize the results.

BERT-pair for (T)ABSA BERT for sentence pair classification tasks. Based on the auxiliary sentence constructed in Section 2.2, we use the sentence-pair classification approach to solve (T)ABSA. Corresponding to the four ways of constructing sentences, we name the models: BERT-pair-QA-M, BERT-pair-NLI-M, BERT-pair-QA-B, and BERT-pair-NLI-B.

3 Experiments

3.1 Datasets

We evaluate our method on the SentiHood (Saeidi et al., 2016) dataset[2], which consists of 5,215 sentences, 3,862 of which contain a single target, and the remainder multiple targets. Each sentence contains a list of target-aspect pairs $\{t, a\}$ with the sentiment polarity y. Ultimately, given a sentence s and the target t in the sentence, we need to:

(1) detect the mention of an aspect a for the target t;

(2) determine the positive or negative sentiment polarity y for detected target-aspect pairs.

We also evaluate our method on SemEval-2014 Task 4 (Pontiki et al., 2014) dataset[3] for aspect-based sentiment analysis. The only difference from the SentiHood is that the target-aspect pairs $\{t, a\}$ become only aspects a. This setting allows us to jointly evaluate subtask 3 (Aspect Category Detection) and subtask 4 (Aspect Category Polarity).

3.2 Hyperparameters

We use the pre-trained uncased BERT-base model[4] for fine-tuning. The number of Transformer blocks is 12, the hidden layer size is 768, the number of self-attention heads is 12, and the total number of parameters for the pre-trained model is 110M. When fine-tuning, we keep the dropout probability at 0.1, set the number of

BERT-pair-NLI-B	**79.8**	87.5	96.6	92.8	96.9

Table 3: Performance on SentiHood dataset. We boldface the score with the best performance across all models. We use the results reported in Saeidi et al. (2016), Ma et al. (2018) and Liu et al. (2018). "-" means not reported.

epochs to 4. The initial learning rate is 2e-5, and the batch size is 24.

3.3 Exp-I: TABSA

We compare our model with the following models:

- LR (Saeidi et al., 2016): a logistic regression classifier with n-gram and pos-tag features.
- LSTM-Final (Saeidi et al., 2016): a biLSTM model with the final state as a representation.
- LSTM-Loc (Saeidi et al., 2016): a biLSTM model with the state associated with the target position as a representation.
- LSTM+TA+SA (Ma et al., 2018): a biLSTM model which introduces complex target-level and sentence-level attention mechanisms.
- SenticLSTM (Ma et al., 2018): an upgraded version of the LSTM+TA+SA model which introduces external information from SenticNet (Cambria et al., 2016).
- Dmu-Entnet (Liu et al., 2018): a bidirectional EntNet (Henaff et al., 2016) with external "memory chains" with a delayed memory update mechanism to track entities.

During the evaluation of SentiHood, following Saeidi et al. (2016), we only consider the four most frequently seen aspects (general, price, transit-location, safety). When evaluating the aspect detection, following Ma et al. (2018), we use strict accuracy and Macro-F1, and we also report AUC. In sentiment classification, we use accuracy and macro-average AUC as the evaluation indices.

3.3.1 Results

Results on SentiHood are presented in Table 3. The results of the BERT-single model on aspect detection are better than Dmu-Entnet, but the accuracy of sentiment classification is much lower than that of both SenticLstm and Dmu-Entnet, with a difference of 3.8 and 5.5 respectively.

However, BERT-pair outperforms other models on aspect detection and sentiment analysis by a substantial margin, obtaining 9.4 macro-average F1 and 2.6 accuracies improvement over Dmu-Entnet. Overall, the performance of the four BERT-pair models is close. It is worth noting that BERT-pair-NLI models perform relatively better on aspect detection, while BERT-pair-QA models perform better on sentiment classification. Also, the BERT-pair-QA-B and BERT-pair-NLI-B models can achieve better AUC values on sentiment classification than the other models.

3.4 Exp-II: ABSA

The benchmarks for SemEval-2014 Task 4 are the two best performing systems in Pontiki et al. (2014) and ATAE-LSTM (Wang et al., 2016). When evaluating SemEval-2014 Task 4 subtask 3 and subtask 4, following Pontiki et al. (2014), we use Micro-F1 and accuracy respectively.

3.4.1 Results

Results on SemEval-2014 are presented in Table 4 and Table 5. We find that BERT-single

BERT-pair-QA-M	85.2	89.3	95.4
BERT-pair-NLI-M	85.1	88.7	94.4
BERT-pair-QA-B	**85.9**	**89.9**	**95.6**
BERT-pair-NLI-B	84.6	88.7	95.1

Table 5: Test set accuracy (%) for Semeval-2014 task 4 Subtask 4: Aspect Category Polarity. We use the results reported in XRCE (Brun et al., 2014), NRC-Canada (Kiritchenko et al., 2014) and ATAE-LSTM (Wang et al., 2016). "-" means not reported.

has achieved better results on these two subtasks, and BERT-pair has achieved further improvements over BERT-single. The BERT-pair-NLI-B model achieves the best performance for aspect category detection. For aspect category polarity, BERT-pair-QA-B performs best on all 4-way, 3-way, and binary settings.

4 Discussion

Why is the experimental result of the BERT-pair model so much better? On the one hand, we convert the target and aspect information into an auxiliary sentence, which is equivalent to exponentially expanding the corpus. A sentence s_i in the original data set will be expanded into $(s_i, t_1, a_1), \cdots, (s_i, t_1, a_{n_a}), \cdots, (s_i, t_{n_t}, a_{n_a})$ in the sentence pair classification task. On the other hand, it can be seen from the amazing improvement of the BERT model on the QA and NLI tasks (Devlin et al., 2018) that the BERT model has an advantage in dealing with sentence pair classification tasks. This advantage comes from both unsupervised masked language model and next sentence prediction tasks.

TABSA is more complicated than SA due to additional target and aspect information. Directly fine-tuning the pre-trained BERT on TABSA does not achieve performance growth. However, when we separate the target and the aspect to form an auxiliary sentence and transform the TABSA into a sentence pair classification task, the scenario is similar to QA and NLI, and then the advantage of the pre-trained BERT model can be fully utilized. Our approach is not limited to TABSA, and this construction method can be used for other similar tasks. For ABSA, we can use the same approach to construct the auxiliary sentence with only aspects.

In BERT-pair models, BERT-pair-QA-B and BERT-pair-NLI-B achieve better AUC values on sentiment classification, probably because of the modeling of label information.

5 Conclusion

In this paper, we constructed an auxiliary sentence to transform (T)ABSA from a single sentence classification task to a sentence pair classification task. We fine-tuned the pre-trained BERT model on the sentence pair classification task and obtained the new state-of-the-art results. We compared the experimental results of single sentence classification and sentence pair classification based on BERT fine-tuning, analyzed the advantages of sentence pair classification, and verified the validity of our conversion method. In the future, we will apply this conversion method to other similar tasks.

Abstract

In this paper, we propose a variational approach to weakly supervised document-level multi-aspect sentiment classification. Instead of using user-generated ratings or annotations provided by domain experts, we use target-opinion word pairs as "supervision." These word pairs can be extracted by using dependency parsers and simple rules. Our objective is to predict an opinion word given a target word while our ultimate goal is to learn a sentiment polarity classifier to predict the sentiment polarity of each aspect given a document. By introducing a latent variable, i.e., the sentiment polarity, to the objective function, we can inject the sentiment polarity classifier to the objective via the variational lower bound. We can learn a sentiment polarity classifier by optimizing the lower bound. We show that our method can outperform weakly supervised baselines on TripAdvisor and BeerAdvocate datasets and can be comparable to the state-of-the-art supervised method with hundreds of labels per aspect.

1 Introduction

Document-level multi-aspect sentiment classification (DMSC) aims to predict the sentiment polarity of each aspect given a document which consists of several sentences describing one or more aspects (Wang et al., 2010, 2011; Yin et al., 2017). Solving the DMSC task is useful for providing both recommendations for users and suggestions for business owners on customer review platforms.

Aspect based sentiment classification (Tang et al., 2016a,b; Wang et al., 2016b; Chen et al., 2017; Ma et al., 2017; Wang et al., 2018) was usually done by supervised learning, where aspect-level annotations should be provided. Aspect-level annotations are not easy to obtain. Even when the platform provides the function to rate for different aspects, users are less likely to submit all of them. For example, about 37% of the aspect ratings are missing on TripAdvisor. If we can solve DMSC task without using aspect-level annotations, it can save human effort to annotate data or collect user-generated annotations on the platform.

Existing weakly supervised approaches (Wang et al., 2010, 2011) use overall polarities instead of aspect polarities as "supervision." Compared with the polarity of each aspect, it is relatively easy to obtain overall polarities. Specifically, they minimize the square loss between the overall polarity and the weighted sum of all aspect polarities. However, when users only care about a particular rare aspect, e.g., childcare services, these approaches cannot estimate parameters of the rare aspect incrementally. They have to re-collect documents which mentioned this rare aspect and estimate parameters of all aspects based on the new corpus. In addition, these approaches assume the document is a bag-of-words, which neglects the order of the words and fails to capture the similarity between words.

In this paper, we propose to use target-opinion word pairs as "supervision." Target-opinion word pairs can be helpful with our ultimate goal which is to learn a classifier to predict the sentiment polarity of each aspect given a document. For example, in a document "The bedroom is very spacious," if we can extract the target-opinion pair "bedroom-spacious," the sentiment polarity of the aspect *room* is likely to be *positive*. Hence, we propose to achieve the polarity classification goal by accomplishing another relevant objective: to predict an opinion word given a target word.

We can decompose the opinion word prediction objective into two sub-tasks. The first sub-task is to predict the sentiment polarity based on a document. For example, given a document "The bedroom is very spacious," it predicts the sentiment polarity of the aspect *room* to be *positive*. The sec-

Proceedings of NAACL-HLT 2019, pages 386–396
Minneapolis, Minnesota, June 2 - June 7, 2019.

ond sub-task is to predict the opinion word given a target word and a sentiment polarity predicted by the first sub-task. For example, knowing the fact that the sentiment polarity of the aspect *room* is *positive*, it predicts the opinion word associated with the target word "room" to be "spacious." By introducing a latent variable, i.e., the sentiment polarity of an aspect, to the opinion word prediction objective, we can inject the polarity classification goal (the first sub-task) into the objective via the variational lower bound which also incorporates the second sub-task. In this sense, our training objective is only based on the target-opinion word pairs which can be extracted by using dependency parsers and some manually designed rules. We consider our approach as weakly supervised learning because there is no direct supervision from polarity of each aspect.

In other words, our model includes two classifiers: a sentiment polarity classifier and an opinion word classifier. In the sentiment polarity classifier, it predicts the sentiment polarity given a document. In the opinion word classifier, it predicts an opinion word based on a target word and a sentiment polarity. Compared with previous approaches (Wang et al., 2010, 2011), our approach can get rid of the assumption that the overall polarity should be observed and it is a weighted sum of all aspect polarities. Moreover, our approach can estimate parameters of a new aspect incrementally. In addition, our sentiment polarity classifier can be more flexible to capture dependencies among words beyond the bag-of-words representation if we use a deep neural network architecture to extract features to represent a document. We conducted experiments on two datasets, TripAdvisor (Wang et al., 2010) and BeerAdvocate (McAuley et al., 2012), to illustrate the effectiveness of our approach.

Our contributions are summarized as follows,

- We propose to solve DMSC task in a nearly unsupervised way.
- We propose to learn a classifier by injecting it into another relevant objective via the variational lower bound. This framework is flexible to incorporate different kinds of document representations and relevant objectives.
- We show promising results on two real datasets and we can produce comparable results to the supervised method with hundreds of labels per aspect.

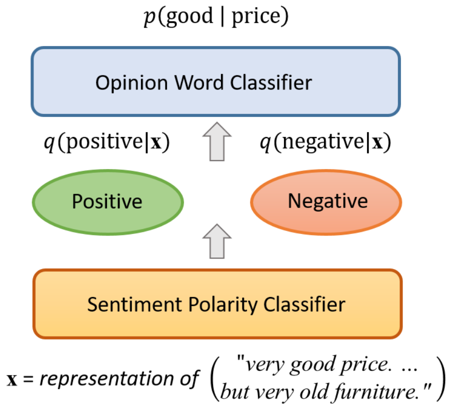

Figure 1: A sentiment polarity classifier and an opinion word classifier associated with the aspect *price*.

Code and data for this paper are available on https://github.com/HKUST-KnowComp/VWS-DMSC.

2 VWS-DMSC Approach

In this section, we describe our variational approach to weakly supervised DMSC (VWS-DMSC). In the next section, we present how we obtain target-opinion word pairs by using a rule-based extraction approach.

2.1 Overview

Our model consists of a sentiment polarity classifier and an opinion word classifier. Our task is document-level multi-aspect sentiment classification. For each aspect, we train a sentiment polarity classifier and an opinion word classifier. The input of the sentiment polarity classifier of each aspect is the same, i.e., a representation of a document. The target-opinion word pairs used in opinion word classifiers are different for different aspects.

Figure 1 shows the relation between two classifiers (on the aspect *price*). The input $\mathbf{x}$ of the sentiment polarity classifier is a representation of a document, e.g., bag-of-words or a representation learned by recurrent neural networks. The sentiment polarity classifier takes $\mathbf{x}$ as input and produces a distribution of sentiment polarity R_a of an aspect a, denoted as $q(R_a|\mathbf{x})$. If R_a only has two possible values, i.e., positive and negative, then outputs of the classifier are $q(positive|\mathbf{x})$ and $q(negative|\mathbf{x})$ respectively. The opinion word classifier takes a target word ("price") and a possible value of the sentiment polarity r_a as input, and estimates $p(\text{“good”}|r_a, \text{“price”})$. Our training objective is to maximize the log-likelihood of an opinion word given a target word, e.g., p(“good”|“price”). The likelihood is estimated based on the sentiment polarity classifier and the opinion word classifier.

2.2 Sentiment Polarity Classifier

The sentiment polarity classifier aims to estimate a distribution of sentiment polarity $q(R_a|\mathbf{x})$, where R_a is a discrete random variable representing the sentiment polarity and $\mathbf{x}$ is a feature representation of a document. We use a simple Softmax classifier here. We denote r_a as a possible value of the random variable R_a, representing a possible sentiment polarity. The model estimates the probability of class r_a as

$$q(R_a = r_a|\mathbf{x}) = \frac{\exp\left(\mathbf{w}_{r_a}^T \mathbf{x}\right)}{\sum_{r'_a} \exp\left(\mathbf{w}_{r'_a}^T \mathbf{x}\right)} , \quad (1)$$

where $\mathbf{w}_{r_a}$ is a vector associated with sentiment class r_a for aspect a.

Document Representation The representation of a document $\mathbf{x}$ can be different using different feature extraction approaches. Traditional document representations of sentiment classification would be bag-of-words, n-gram, or averaged word embeddings. Recently, end-to-end recurrent neural network based models demonstrate a powerful capacity to extract features of a document. The state-of-the-art model in DMSC task is (Yin et al., 2017). We use it as the document representation in our model.

2.3 Opinion Word Classifier

The opinion word classifier aims to estimate the probability of an opinion word w_o given a target word w_t and a sentiment polarity r_a:

$$p(w_o|r_a, w_t) = \frac{\exp\left(\varphi(w_o, w_t, r_a)\right)}{\sum_{w'_o} \exp\left(\varphi(w'_o, w_t, r_a)\right)} , \quad (2)$$

where φ is a scoring function related to opinion word w_o, target word w_t, and sentiment polarity r_a. Here we use the dot product as the scoring function:

$$\varphi(w_o, w_t, r_a) = I\big((w_t, w_o) \in \mathcal{P}, w_t \in \mathcal{K}_a\big) \cdot \mathbf{c}_{r_a}^T \mathbf{w}_o , \quad (3)$$

where $\mathbf{w}_o$ is the word embedding of opinion word w_o, $\mathbf{c}_{r_a}$ is a vector associated with r_a, $\mathcal{P}$ is the set of pairs extracted from the document, $\mathcal{K}_a$ is the set of target words associated with aspect a, and $I(\cdot)$ is an indicator function where $I(true) = 1$ and $I(false) = 0$.

Given a target word w_t and a sentiment polarity r_a, we aim to maximize the probability of opinion words highly related to them. For example, opinion word “good” is usually related to target word “price” for aspect *value* with sentiment polarity *positive*, and opinion word “terrible” is usually related to target word “traffic” for aspect *location* with sentiment polarity *negative*.

2.4 Training Objective

The objective function is to maximize the log-likelihood of an opinion word w_o given a target word w_t. As we mentioned before, the objective function can be decomposed into two sub-tasks. The first one corresponds to the sentiment polarity classifier. The second one corresponds to the opinion word classifier. After introducing a latent variable, i.e., the sentiment polarity, to the objective function, we can derive a variational lower bound of the log-likelihood which can incorporate two classifiers:

$$\begin{aligned}
\mathcal{L} &= \log p(w_o|w_t) \\
&= \log \sum_{r_a} p(w_o, r_a|w_t) \\
&= \log \sum_{r_a} q(r_a|\mathbf{x}) \left[\frac{p(w_o, r_a|w_t)}{q(r_a|\mathbf{x})}\right] \\
&\geq \sum_{r_a} q(r_a|\mathbf{x}) \left[\log \frac{p(w_o, r_a|w_t)}{q(r_a|\mathbf{x})}\right] \\
&= \mathbb{E}_{q(R_a|\mathbf{x})} \left[\log p(w_o|r_a, w_t) p(r_a|w_t)\right] \\
&\quad + H(q(R_a|\mathbf{x})) \\
&= \mathbb{E}_{q(R_a|\mathbf{x})} \left[\log p(w_o|r_a, w_t) p(r_a)\right] \\
&\quad + H(q(R_a|\mathbf{x})) , \qquad (4)
\end{aligned}$$

where $H(\cdot)$ refers to the Shannon entropy. By applying Jensen’s inequality, the log-likelihood is lower-bounded by Eq. (4). The equality holds if and only if the KL-divergence of two distributions, $q(R_a|\mathbf{x})$ and $p(R_a|w_t, w_o)$, equals to zero. Maximizing the variational lower bound is equivalent to minimizing the KL-divergence. Hence, we can learn a sentiment polarity classifier which can produce a similar distribution to the true posterior $p(R_a|w_t, w_o)$. Compared with $p(R_a|w_t, w_o)$, $q(R_a|\mathbf{x})$ is more flexible since it can take any kind of feature representations as input. We assume that a target word w_t and a sentiment polarity r_a are independent since the polarity assignment is not influenced by the target word. We also assume that the sentiment polarity R_a follows a uniform distribution, which means $p(r_a)$ is a constant. We remove it in Eq. (4) to get a new objective function as follows:

$$\mathbb{E}_{q(R_a|\mathbf{x})}\left[\log p(w_o|r_a, w_t)\right] + H(q(R_a|\mathbf{x})) \,. \quad (5)$$

2.4.1 Approximation

The partition function of Eq. (2) requires the summation over all opinion words in the vocabulary. However, the size of opinion word vocabulary is large, so we use the negative sampling technique (Mikolov et al., 2013) to approximate Eq. (2). Specifically, we substitute $\log p(w_o|r_a, w_t)$ in the objective (5) with the following objective function:

$$\log\sigma\big(\varphi(w_o, w_t, r_a)\big) + \sum_{w_o' \in \mathcal{N}} \log\sigma\big(-\varphi(w_o', w_t, r_a)\big) \,, \quad (6)$$

where w_o' is a negative sample of opinion words in the vocabulary, $\mathcal{N}$ is the set of negative samples and σ is the sigmoid function. Then our final objective function is rewritten as:

$$\mathbb{E}_{q(R_a|\mathbf{x})}\Big[\log\sigma\big(\varphi(w_o, w_t, r_a)\big) + \sum_{w_o' \in \mathcal{N}} \log\sigma\big(-\varphi(w_o', w_t, r_a)\big)\Big] + \alpha H(q(R_a|\mathbf{x})) \,, \quad (7)$$

where α is a hyper-parameter which can adjust the expectation and entropy terms into the same scale (Marcheggiani and Titov, 2016).

3 Target Opinion Word Pairs Extraction

Target-opinion word pairs extraction is a well studied problem (Hu and Liu, 2004; Popescu and Etzioni, 2005; Bloom et al., 2007; Qiu et al., 2011). We designed five rules to extract potential target-opinion word pairs. Our method relies on Stanford Dependency Parser (Chen and Manning, 2014). We describe our rules as follows.

Rule 1: We extract pairs satisfying the grammatical relation *amod* (adjectival modifier) (De Marneffe and Manning, 2008). For example, in phrase "very good price," we extract "price" and "good" as a target-opinion pair.

Rule 2: We extract pairs satisfying the grammatical relation *nsubj* (nominal subject), and the head word is an adjective and the tail word is a noun. For example, in a sentence "The room is small," we can extract "room" and "small" as a target-opinion pair.

Dataset	TripAdvisor	BeerAdvocate
# docs	28,543	27,583
# target words	3,737	3,088
# opinion words	12,406	9,166
# pairs from R1	208,676	249,264
# pairs from R2	82,944	28,505
# pairs from R3	2,241	1,092
# pairs from R4	2,699	6,812
# pairs from R5	16,537	55,825

Table 1: Statistics of extracted target-opinion pairs .

Rule 3: Some verbs are also opinion words and they are informative. We extract pairs satisfying the grammatical relation *dobj* (direct object) when the head word is one of the following four words: "like", "dislike", "love", and "hate". For example, in the sentence "I like the smell," we can extract "smell" and "like" as a target-opinion pair.

Rule 4: We extract pairs satisfying the grammatical relation *xcomp* (open clausal complement), and the head word is one of the following word: "seem","look", "feel", "smell", and "taste". For example, in the sentence "This beer tastes spicy," we can extract "taste" and "spicy" as a target-opinion pair.

Rule 5: If the sentence contains some adjectives that can implicitly indicate aspects, we manually assign them to the corresponding aspects. According to (Lakkaraju et al., 2014), some adjectives serve both as target words and opinion words. For example, in the sentence "very tasty, and drinkable," the previous rules fail to extract any pair. But we know it contains a target-opinion pair, i.e., "taste-tasty." Most of these adjectives have the same root form with the aspects they indicated, e.g., "clean" (cleanliness), and "overpriced" (price). This kind of adjective can be extracted first and then we can obtain more similar adjectives using word similarities. For example, given "tasty," we could get "flavorful" by retrieving similar words.

Table 1 shows the statistics of the rule-based extraction on our two datasets. The first four rules can be applied to any dataset while the last one is domain dependent which requires human effort to identify these special adjectives. In practice, rule

5 can be removed to save human effort. The effect of removing rule 5 is shown in experiments.

After extracting potential target-opinion word pairs, we need to assign them to different aspects as supervision signals. We select some seed words to describe each aspect, and then calculate similarities between the extracted target (or opinion) word and seed words, and assign the pair to the aspect where one of its seed words has the highest similarity. The similarity we used is the cosine similarity between two word embeddings trained by word2vec (Mikolov et al., 2013). For example, suppose seed words {"room", "bed"} and {"business", "Internet"} are used to describe the aspect *room* and *business* respectively, and the candidate pair "pillow - soft" will be assigned to the aspect *room* if the similarity between "pillow" and "bed" is highest among all combinations.

4 Experiment

In this section, we report average sentiment classification accuracies over all aspects on binary DMSC task.

4.1 Datasets

We evaluate our model on TripAdvisor (Wang et al., 2010) and BeerAdvocate (McAuley et al., 2012; Lei et al., 2016; Yin et al., 2017) datasets, which contain seven aspects (value, room, location, cleanliness, check in/front desk, service, and business) and four aspects (feel, look, smell, and taste) respectively. We run the same preprocessing steps as (Yin et al., 2017). Both datasets are split into train/development/test sets with proportions 8:1:1. All methods can use development set to tune their hyper-parameters. Ratings of TripAdvisor and BeerAdvocate datasets are on scales of 1 to 5 and 0 to 5 respectively. But in BeerAdvocate, 0 star is rare, so we treat the scale as 1 to 5. We convert original scales to binary scales as follows: 1 and 2 stars are treated as negative, 3 is ignored, and 4 and 5 stars are treated as positive. In BeerAdvocate, most reviews have positive polarities, so to avoid the unbalanced issue, we perform data selection according to overall polarities. After data selection, the number of reviews with negative overall polarities and that with positive overall polarities are equal.

4.2 Compared Methods

To demonstrate the effectiveness of our method, we compare our model with following baselines:

Majority uses the majority of sentiment polarities in training sets as predictions.

Lexicon means using an opinion lexicon to assign sentiment polarity to an aspect (Read and Carroll, 2009; Pablos et al., 2015). We combine two popular opinion lexicons used by Hu and Liu (2004) and Wilson et al. (2005) to get a new one. If an opinion word from extracted pairs is in positive (negative) lexicon, it votes for positive (negative). When the opinion word is with a negation word, its polarity will be flipped. Then, the polarity of an aspect is determined by using majority voting among all opinion words associated with the aspect. When the number of positive and negative words is equal, we adopt two different ways to resolve it. For **Lexicon-R**, it randomly assigns a polarity. For **Lexicon-O**, it uses the overall polarity as the prediction. Since overall polarities can also be missing, for both Lexicon-R and Lexicon-O, we randomly assign a polarity in uncertain cases and report both mean and std based on five trials of random assignments.

Assign-O means directly using the overall polarity of a review in the development/test sets as the prediction for each aspect.

LRR assumes the overall polarity is a weighted sum of the polarity of each aspect (Wang et al., 2010). LRR can be regarded as the only existing weakly supervised baseline where both algorithm and source code are available.

BoW-DMSC-A is a simple softmax classifier using all annotated training data where the input is a bag-of-words feature vector of a document.

N-DMSC-A is the state-of-the-art neural network based model (Yin et al., 2017) (**N-DMSC**) in DMSC task using all annotated training data, which serves an upper bound to our method.

N-DMSC-O is to use overall polarities as "supervision" to train an N-DMSC and apply it to the classification task of each aspect at the test time.

N-DMSC-{50,100,200,500,1000} is the N-DMSC algorithm using partial data. In order to see our method is comparable to supervised methods using how many labeled data, we use $\{50, 100, 200, 500, 1000\}$ annotations of each aspect to train N-DMSC and compare them to our method. In addition to annotated data for training, there are extra 20% annotated data for validation.

Table 2: Averaged accuracies on DMSC of unsupervised, weakly supervised, and supervised methods on TripAdvisor and BeerAdvocate. Methods involve randomness also report standard deviation.

Since the sampled labeled data may vary for different trials, we perform five trials of random sampling and report both mean and std of the results.

For our method, denoted as **VWS-DMSC**, the document representation we used is obtained from N-DMSC (Yin et al., 2017). They proposed a novel hierarchical iterative attention model in which documents and pseudo aspect related questions are interleaved at both word and sentence-level to learn an aspect-aware document representation. The pseudo aspect related questions are represented by aspect related keywords. In order to benefit from their aspect-aware representation scheme, we train an N-DMSC to extract the document representation using only overall polarities. In the iterative attention module, we use the pseudo aspect related keywords of all aspects released by Yin et al. (2017). One can also use document-to-document autoencoders (Li et al., 2015) to generate the document representation. In this way, our method can get rid of using overall polarities to generate the document representation. Hence, unlike LRR, it is not necessary for our method to use overall polarities. Here, to have a fair comparison with LRR, we use the overall polarities to generate document representation. For our method, we do not know which state is positive and which one is negative at training time, so the Hungarian algorithm (Kuhn, 1955) is used to resolve the assignment problem at the test time.

4.3 Results and Analysis

We show all results in Table 2, which consists of three blocks, namely, unsupervised, weakly supervised, and supervised methods.

For unsupervised methods, our method can outperform majority on both datasets consistently. But other weakly supervised methods cannot outperform majority on BeerAdvocate dataset, which shows these baselines cannot handle unbalanced data well since BeerAdvocate is more unbalanced than TripAdvisor. Our method outperforms Lexicon-R and Lexicon-O, which shows that predicting an opinion word based on a target word may be a better way to use target-opinion pairs, compared with performing a lexicon lookup using opinion words from extract pairs. Good performance of Lexicon-O and Assign-O demonstrates the usefulness of overall polarities in development/test sets. N-DMSC-O trained with the overall polarities cannot outperform Assign-O since N-DMSC-O can only see overall polarities in training set while Assign-O can see overall polarities for both development and test sets and does not involve learning and generalization.

For weakly supervised methods, LRR is the only open-source baseline in the literature on weakly supervised DMSC, and our method outperforms LRR by **6%** and **16%** on TripAdvisor and BeerAdvocate datasets. N-DMSC-O can also be considered as a weakly supervised method be-

Dataset	TripAdvisor		BeerAdvocate	
Rule	DEV	TEST	DEV	TEST
R1	0.7215	0.7174	0.7220	0.7216
R2	0.7172	0.7180	0.6864	0.6936
R3	0.6263	0.6187	0.6731	0.6725
R4	0.6248	0.6279	0.6724	0.6717
R5	0.5902	0.5856	0.7095	0.7066

All	0.7577	0.7561	0.7502	0.7538

Table 3: Averaged accuracies on DMSC. "R1 – R5" means only using a rule while "-R1 – -R5" means removing a rule from all the rules.

cause it only uses overall polarities as "supervision," and we still outperform it significantly. It is interesting that LRR is worse than N-DMSC-O. We guess that assuming that the overall polarity is a weighted sum of all aspect polarities may not be a good strategy to train each aspect's polarity or the document representation learned by N-DMSC is better than the bag-of-words representation.

For supervised block methods, BoW-DMSC-A and N-DMSC-A are both supervised methods using all annotated data, which can be seen as the upper bound of our algorithm. N-DMSC-A outperforms BoW-DMSC-A, which shows that the document representation based on neural network is better than the bag-of-words representation. Hence, we use the neural networks based document representation as input of the sentiment polarity classifier. Our results are comparable to N-DMSC-200 on TripAdvisor and N-DMSC-100 on BeerAdvocate.

4.4 Ablation Study

To evaluate effects of extracted rules, we performed an ablation study. We run our algorithm VWS-DMS with each rule kept or removed over two datasets. If no pairs extracted for one aspect in training set, the accuracy of this aspect will be 0.5, which is a random guess. From the Table 3 we can see that, the rule R1 is the most effective rule for both datasets. Rules R3/R4/R5 are less effective on their own. However, as a whole, they can still improve the overall performance. When considering removing each of rules, we found that our algorithm is quite robust, which indicates missing one of the rules may not hurt the performance much. Hence, if human labor is a major concern, rule 5 can be discarded. We found that sometimes removing one rule may even result in better accuracy (e.g., "-R3" for BeerAdvocate dataset). This means this rule may introduce some noises into the objective function. However, "-R3" can result in worse accuracy for TripAdvisor, which means it is still complementary to the other rules for this dataset.

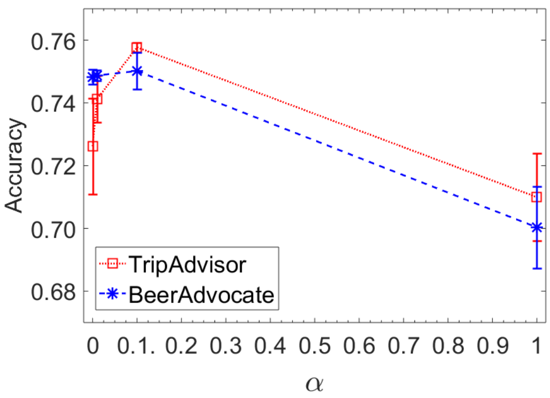

Figure 2: Parameter sensitivity analysis.

4.5 Parameter Sensitivity

We also conduct parameter sensitivity analysis of our approach. The parameter α in Equation (7) adjusts the expectation and entropy terms on the same scale. We test $\alpha = \{0, 0.01, 0.1, 1\}$ for both of the datasets. As we can see from Figure 2, $\alpha = 0.1$ is a good choice for both datasets.

4.6 Implementation Details

We implemented our models using TensorFlow (Abadi et al., 2016). For N-DMSC and LRR, we used code released by Yin et al. (2017) and Wang et al. (2010) respectively and followed their preprocessing steps and optimal settings.

Parameters are updated by using ADADELTA (Zeiler, 2012), an adaptive learning rate method. To avoid overfitting, we impose weight decay and drop out on both classifiers. The regularization coefficient and drop out rate are set to 10^{-3} and 0.3 respectively. The number of negative samples and α in our model are set to 10 and 0.1 respectively. For each document and each aspect, multiple target-opinion pairs are extracted. The opinion word classifier associated with an aspect will predict five target-opinion pairs at a time. These five target-opinion pairs are selected with bias. The probability of a pair being selected is proportional to the frequency of the opinion word to the power of -0.25. In this way, opinion words with low frequency are more likely to be selected compared to the uniform sampling. In order to initialize both classifiers better, the word embeddings are retrofitted (Faruqui et al., 2015) using PPDB (Ganitkevitch et al., 2013) semantic lexicons.

5 Related Work

In this section, we review the related work on document-level multi-aspect sentiment classification, target-opinion word pairs extraction, and variational methods.

Document-level Multi-Aspect Sentiment Classification. Wang et al. (2010) proposed a LRR model to solve this problem. LRR assumes the overall polarity is a weighted sum of all aspect polarities which are represented by word frequency features. LRR needs to use aspect keywords to perform sentence segmentation to generate the representation of each aspect. To address the limitation of using aspect keywords, LARAM (Wang et al., 2011) assumes that the text content describing a particular aspect is generated by sampling words from a topic model corresponding to the latent aspect. Both LRR and LARAM can only access to overall polarities in the training data, but not gold standards of aspect polarities. Meng et al. (2018) proposed a weakly supervised text classification method which can take label surface names, class-related keywords, or a few labeled documents as supervision. Ramesh et al. (2015) developed a weakly supervised joint model to identify aspects and the corresponding sentiment polarities in online courses. They treat aspect (sentiment) related seed words as weak supervision. In the DMSC task which is a fine-grained text classification task, the label surface names or keywords for some aspects would be very similar. Given that the inputs are the same and the supervisions are similar, weakly supervised models cannot distinguish them. So we do not consider them as our baselines. Yin et al. (2017) modeled this problem as a machine comprehension problem under a multi-task learning framework. It also needs aspect keywords to generate aspect-aware document representations. Moreover, it can access gold standards of aspect polarities and achieved state-of-the-art performance on this task. Hence, it can serve as an upper bound. Some sentence-level aspect based sentiment classification methods (Wang et al., 2016b, 2018) can be directly applied to the DMSC task, because they can solve aspect category sentiment classification task. For example, given a sentence "the restaurant is expensive," the aspect category sentiment classification task aims to classify the polarity of the aspect category "price" to be *negative*. The aspect categories are predefined which are the same as the DMSC task. Some of them (Tang et al., 2016a,b; Chen et al., 2017; Ma et al., 2017) cannot because they are originally designed for aspect term sentiment classification task. For example, given a sentence "I loved their fajitas," the aspect term sentiment classification task aims to classify the polarity of the aspect term "fajitas" to be *positive*. The aspect terms appearing in the sentence should be provided as inputs.

Target Opinion Word Pairs Extraction. There are two kinds of methods, namely, rule based methods and learning based methods to solve this task. Rule based methods extract target-opinion word pairs by mining the dependency tree paths between target words and opinion words. Learning based methods treat this task as a sequence labeling problem, mapping each word to one of the following categories: target, opinion, and other.

(Hu and Liu, 2004) is one of earliest rule based methods to extract target-opinion pairs. An opinion word is restricted to be an adjective. Target words are extracted first, and then an opinion word is linked to its nearest target word to form a pair. Popescu and Etzioni (2005) and Bloom et al. (2007) manually designed dependency tree path templates to extract target-opinion pairs. If the path between a target word candidate and an opinion word candidate belongs to the set of path templates, the pair will be extracted. Qiu et al. (2011) identified dependency paths that link opinion words and targets via a bootstrapping process. This method only needs an initial opinion lexicon to start the bootstrapping process. Zhuang et al. (2006) adopted a supervised learning algorithm to learn valid dependency tree path templates, but it requires target-opinion pairs annotations.

Learning based methods require lots of target-opinion pairs annotations. They trained conditional random fields (CRF) (Lafferty et al., 2001) based models (Jakob and Gurevych, 2010; Yang and Cardie, 2012; Wang et al., 2016a) or deep neural networks (Liu et al., 2015; Wang et al., 2017; Li and Lam, 2017) to predict the label (target, opinion or other) of each word. Jakob and Gurevych (2010) and Li et al. (2012) extracted target-opinion pairs without using using any labeled data in the domain of interest, but it needs lots of labeled data in another related domain.

In this paper, we only use very simple rules to extract target-opinion pairs to validate the effectiveness of our approach. If better pairs can be extracted, we can further improve our results.

Variational Methods. Variational autoencoders (Kingma and Welling, 2014; Rezende et al., 2014) (VAEs) use a neural network to parameterize a probability distribution. VAEs consists of an encoder which parameterizes posterior probabilities and a decoder which parameterizes the reconstruction likelihood given a latent variable. VAEs inspire many interesting works (Titov and Khoddam, 2015; Marcheggiani and Titov, 2016; Šuster et al., 2016; Zhang et al., 2018; Chen et al., 2018) which are slightly different from VAEs. Their encoders produce a discrete distribution while the encoder in VAEs yields a continuous latent variable. Titov and Khoddam (2015) aimed to solve semantic role labeling problem. The encoder is essentially a semantic role labeling model which predicts roles given a rich set of syntactic and lexical features. The decoder reconstructs argument fillers given predicted roles. Marcheggiani and Titov (2016) aimed to solve unsupervised open domain relation discovery. The encoder is a feature-rich relation extractor, which predicts a semantic relation between two entities. The decoder reconstructs entities relying on the predicted relation. Šuster et al. (2016) tried to learn multi-sense word embeddings. The encoder uses bilingual context to choose a sense for a given word. The decoder predicts context words based on the chosen sense and the given word. Zhang et al. (2018) aimed to solve knowledge graph powered question answering. Three neural networks are used to parameterize probabilities of a topic entity given a query and an answer, an answer based on a query and a predicted topic, and the topic given the query. Chen et al. (2018) aimed to infer missing links in a knowledge graph. Three neural networks are used to parameterize probabilities of a latent path given two entities and a relation, a relation based on two entities and the chosen latent path, and the relation given the latent path. Our method also uses neural networks to parameterize two discrete distributions but aims to solve the DMSC task.

6 Conclusion

In this paper, we propose a variational approach to weakly supervised DMSC. We extract many target-opinion word pairs from dependency parsers using simple rules. These pairs can be "supervision" signals to predict sentiment polarity. Our objective function is to predict an opinion word given a target word. After introducing the sentiment polarity as a latent variable, we can learn a sentiment polarity classifier by optimizing the variational lower bound. We show that we can outperform weakly supervised baselines by a large margin and achieve comparable results to the supervised method with hundreds of labels per aspect, which can reduce a lot of labor work in practice. In the future, we plan to explore better target-opinion word extraction approaches to find better "supervision" signals.

Abstract

In this paper, we address three challenges in utterance-level emotion recognition in dialogue systems: (1) the same word can deliver different emotions in different contexts; (2) some emotions are rarely seen in general dialogues; (3) long-range contextual information is hard to be effectively captured. We therefore propose a hierarchical Gated Recurrent Unit (HiGRU) framework with a lower-level GRU to model the word-level inputs and an upper-level GRU to capture the contexts of utterance-level embeddings. Moreover, we promote the framework to two variants, HiGRU with individual features fusion (HiGRU-f) and HiGRU with self-attention and features fusion (HiGRU-sf), so that the word/utterance-level individual inputs and the long-range contextual information can be sufficiently utilized. Experiments on three dialogue emotion datasets, IEMOCAP, Friends, and EmotionPush demonstrate that our proposed HiGRU models attain at least 8.7%, 7.5%, 6.0% improvement over the state-of-the-art methods on each dataset, respectively. Particularly, by utilizing only the textual feature in IEMOCAP, our HiGRU models gain at least 3.8% improvement over the state-of-the-art conversational memory network (CMN) with the trimodal features of text, video, and audio.

1 Introduction

Emotion recognition is a significant artificial intelligence research topic due to the promising potential of developing empathetic machines for people. Emotion is a universal phenomena across different cultures and mainly consists of six basic types: anger, disgust, fear, happiness, sadness, and surprise (Ekman, 1971, 1992).

In this paper, we focus on textual dialogue systems because textual feature dominates the performance over audio and video features (Poria et al., 2015, 2017). In utterance-level emotion recognition, an utterance (Olson, 1977) is a unit of speech bounded by breathes or pauses and its goal is to tag each utterance in a dialogue with the indicated emotion.

Role	Utterance	Emotion
Rachel	Oh okay, I'll fix that to. What's her e-mail address?	Neutral
Ross	Rachel!	Anger
Rachel	All right, I promise. I'll fix this. I swear. I'll-I'll- I'll-I'll talk to her.	Non-neutral
Ross	***Okay!***	***Anger***
Rachel	***Okay.***	***Neutral***
Nurse	This room's available.	Neutral
Rachel	***Okay!***	***Joy***
Rachel	Okay wait!	Non-neutral
Rachel	You listen to me!	Anger

Figure 1: The word "okay" exhibits different emotions in the American television sitcom, Friends.

In this task, we address three challenges: First, the same word can deliver different emotions in different contexts. For example, in Figure 1, the word "okay" can deliver three different emotions, anger, neutral, and joy, respectively. Strong emotions like joy and anger may be indicated by the symbols "!" or "?" along the word. To identify a speaker's emotion precisely, we need to explore the dialogue context sufficiently. Second, some emotions are rarely seen in general dialogues. For example, people are usually calm and present a neutral emotion while only in some particular situations, they express strong emotions, like anger or fear. Thus we need to be sensitive to the minority emotions while relieving the effect of the majority emotions. Third, the long-range contextual information is hard to be effectively captured in an utterance/dialogue, especially when the length of an utterance/dialogue in the testing set is longer than those in the training set.

To tackle these challenges, we propose a hierarchical Gated Recurrent Unit (HiGRU) framework for the utterance-level emotion recognition

Proceedings of NAACL-HLT 2019, pages 397–406
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

in dialogue systems. More specifically, HiGRU is composed by two levels of bidirectional GRUs, a lower-level GRU to model the word sequences of each utterance to produce individual utterance embeddings, and an upper-level GRU to capture the sequential and contextual relationship of utterances. We further promote the proposed HiGRU to two variants, HiGRU with individual features fusion (HiGRU-f), and HiGRU with self-attention and features fusion (HiGRU-sf). In HiGRU-f, the individual inputs, i.e., the word embeddings in the lower-level GRU and the individual utterance embeddings in the upper-level GRU, are concatenated with the hidden states to generate the contextual word/utterance embeddings, respectively. In HiGRU-sf, a self-attention layer is placed on the hidden states from the GRU to learn long-range contextual embeddings, which are concatenated with the original individual embeddings and the hidden states to generate the contextual word/utterance embeddings. Finally, the contextual utterance embedding is sent to a fully-connected (FC) layer to determine the corresponding emotion. To alleviate the effect of data imbalance issue, we follow (Khosla, 2018) to train our models by minimizing a weighted categorical cross-entropy.

We summarize our contributions as follows:

- We propose a HiGRU framework to better learn both the individual utterance embeddings and the contextual information of utterances, so as to recognize the emotions more precisely.
- We propose two progressive HiGRU variants, HiGRU-f and HiGRU-sf, to sufficiently incorporate the individual word/utterance-level information and the long-range contextual information respectively.
- We conduct extensive experiments on three textual dialogue emotion datasets, IEMOCAP, Friends, and EmotionPush. The results demonstrate that our proposed HiGRU models achieve at least 8.7%, 7.5%, 6.0% improvement over state-of-the-art methods on each dataset, respectively. Particularly, by utilizing only the textual feature in IEMOCAP, our proposed HiGRU models gain at least 3.8% improvement over the existing best model, conversational memory network (CMN) with not only the text feature, but also the visual, and audio features.

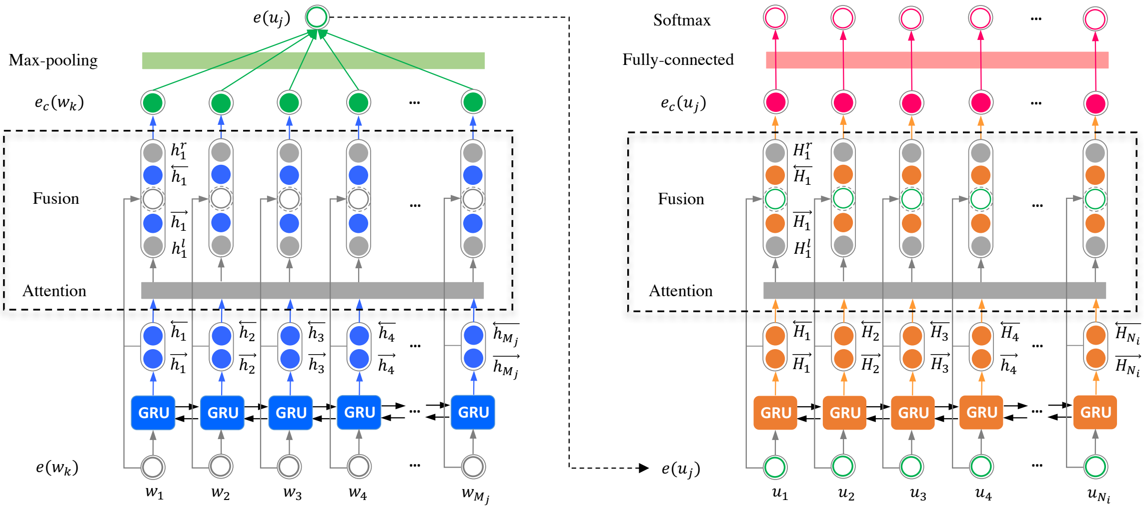
2 Related Work

Text-based emotion recognition is a long-standing research topic (Wilson et al., 2004; Yang et al., 2007; Medhat et al., 2014). Nowadays, deep learning technologies have become dominant methods due to the outstanding performance. Some prominent models include recursive autoencoders (RAEs) (Socher et al., 2011), convolutional neural networks (CNNs) (Kim, 2014), and recurrent neural networks (RNNs) (Abdul-Mageed and Ungar, 2017). However, these models treat texts independently thus cannot capture the inter-dependence of utterances in dialogues (Kim, 2014; Lai et al., 2015; Grave et al., 2017; Chen et al., 2016; Yang et al., 2016). To exploit the contextual information of utterances, researchers mainly explore in two directions: (1) extracting contextual information among utterances, or (2) enriching the information embedded in the representations of words and utterances.

Contextual Information Extraction. The RNN architecture is a standard way to capture the sequential relationship of data. Poria et al. propose a bidirectional contextual long short-term memory (LSTM) network, termed bcLSTM, to model the context of textual features extracted by CNNs. Hazarika et al. improve bcLSTM by a conversational memory network (CMN) to capture the self and inter-speaker emotional influence, where GRU is utilized to model the self-influence and the attention mechanism is employed to excavate the inter-speaker emotional influence. Though CMN is reported to attain better performance than bcLSTM on IEMOCAP (Hazarika et al., 2018), the memory network is too complicated for small-size dialogue datasets.

Representation Enrichment. Multimodal features have been utilized to enrich the representation of utterances (Poria et al., 2015, 2017). Previous work indicate that textual features dominate the performance of recognizing emotions in contrast to visual or audio features (Poria et al., 2015, 2017). Recently, the textual features are mainly extracted by CNNs to learn individual utterance embeddings (Poria et al., 2015, 2017; Zahiri and Choi, 2018; Hazarika et al., 2018). However, CNNs do not capture the contextual information within each utterance well.

On the other hand, hierarchical RNNs have been proposed and demonstrated good performance in



Individual Utterance Embedding **Contextual Utterance Embedding**

Figure 2: The architecture of our proposed HiGRU-sf. "Attention" denotes self-attention. By removing the "Attention" layer, we attain HiGRU-f, and by further removing the "Fusion" layer, we can recover the vanilla HiGRU.

conventional text classification task (Tang et al., 2015), dialogue act classification (Liu et al., 2017; Kumar et al., 2018), and speaker change detection (Meng et al., 2017). But they are not well explored in the task of utterance-level emotion recognition in dialogue systems.

3 Approach

The task of utterance-level emotion recognition is defined as follows:

Definition 1 (Utterance-level Emotion Recognition). *Suppose we are given a set of dialogues,* $\mathcal{D} = \{D_i\}_{i=1}^{L}$, *where* L *is the number of dialogues. In each dialogue,* $D_i = \{(u_j, s_j, c_j)\}_{j=1}^{N_i}$, *is a sequence of* N_i *utterances, where the utterance* u_j *is spoken by the speaker* $s_j \in \mathcal{S}$ *with a certain emotion* $c_j \in \mathcal{C}$. *All speakers compose the set* $\mathcal{S}$ *and the set* $\mathcal{C}$ *consists of all emotions, such as anger, joy, sadness, and neutral. Our goal is to train a model* $\mathcal{M}$ *to tag each new utterance with an emotion label from* $\mathcal{C}$ *as accurately as possible.*

To solve this task, we propose a hierarchical Gated Recurrent Units (HiGRU) framework and extend two progressive variants, HiGRU with individual features fusion (HiGRU-f) and HiGRU with self-attention and features fusion (HiGRU-sf) (illustrated in Figure 2).

3.1 HiGRU: Hierarchical GRU

The vanilla HiGRU consists of two-level GRUs: the lower-level bidirectional GRU is to learn the individual utterance embedding by modeling the word sequence within an utterance and the upper-level bidirectional GRU is to learn the contextual utterance embedding by modeling the utterance sequence within a dialogue.

Individual Utterance Embedding. For the j^{th} utterance in D_i, $u_j = \{w_k\}_{k=1}^{M_j}$, where M_j is the number of words in the utterance u_j. The corresponding sequence of individual word embeddings $\{e(w_k)\}_{k=1}^{M_j}$ are fed into the lower-level bidirectional GRU (Cho et al., 2014) to learn the individual utterance embedding in two opposite directions:

$$\overrightarrow{h_k} = \mathrm{GRU}(e(w_k), \overrightarrow{h_{k-1}}), \quad (1)$$

$$\overleftarrow{h_k} = \mathrm{GRU}(e(w_k), \overleftarrow{h_{k+1}}). \quad (2)$$

The two hidden states $\overrightarrow{h_k}$ and $\overleftarrow{h_k}$ are concatenated into $hs = [\overrightarrow{h_k}; \overleftarrow{h_k}]$ to produce the *contextual word embedding* for w_k via the tanh activation function on a linear transformation:

$$e_c(w_k) = \tanh(W_w \cdot hs + b_w), \quad (3)$$

where $W_w \in \mathbb{R}^{d_1 \times 2d_1}$ and $b_w \in \mathbb{R}^{d_1}$ are the model parameters, d_0 and d_1 are the dimensions of word embeddings and the hidden states of the lower-level GRU, respectively.

The individual utterance embedding is then obtained by max-pooling on the contextual word embeddings within the utterance:

$$e(u_j) = \mathrm{maxpool}\left(\{e_c(w_k)\}_{k=1}^{M_j}\right). \quad (4)$$

Contextual Utterance Embedding. For the i^{th} dialogue, $D_i = \{(u_j, s_j, c_j)\}_{j=1}^{N_i}$, the learned individual utterance embeddings, $\{e(u_j)\}_{j=1}^{N_i}$, are fed into the upper-level bidirectional GRU to capture the sequential and contextual relationship of utterances in a dialogue:

$$\overrightarrow{H_j} = \text{GRU}(e(u_j), \overrightarrow{H_{j-1}}), \tag{5}$$

$$\overleftarrow{H_j} = \text{GRU}(e(u_j), \overleftarrow{H_{j+1}}). \tag{6}$$

Here, the hidden states of the upper-level GRU are represented by $H_j \in \mathbb{R}^{d_2}$, to distinguish from those learned in the lower-level GRU denoted by h_k. Accordingly, we can obtain the *contextual utterance embedding* by

$$e_c(u_j) = \tanh(W_u \cdot Hs + b_u), \tag{7}$$

where $Hs = [\overrightarrow{H_j}; \overleftarrow{H_j}]$, $W_u \in \mathbb{R}^{d_2 \times 2d_2}$ and $b_u \in \mathbb{R}^{d_2}$ are the model parameters, d_2 is the dimension of the hidden states in the upper-level GRU. Since the emotions are recognized at utterance-level, the learned contextual utterance embedding $e_c(u_j)$ is directly fed to a FC layer followed by a softmax function to determine the corresponding emotion label:

$$\hat{y}_j = \text{softmax}(W_{fc} \cdot e_c(u_j) + b_{fc}), \tag{8}$$

where $\hat{y}_j$ is the predicted vector over all emotions, and $W_{fc} \in \mathbb{R}^{|\mathcal{C}| \times d_2}$, $b_{fc} \in \mathbb{R}^{|\mathcal{C}|}$.

3.2 HiGRU-f: HiGRU + Individual Features Fusion

The vanilla HiGRU contains two main issues: (1) the individual word/utterance embeddings are diluted with the stacking of layers; (2) the upper-level GRU tends to gather more contextual information from the majority emotions, which deteriorates the overall model performance.

To resolve these two problems, we propose to fuse individual word/utterance embeddings with the hidden states from GRUs so as to strengthen the information of each word/utterance in its contextual embedding. This variant is named as HiGRU-f, representing HiGRU with individual features fusion. Hence, the lower-level GRU can maintain individual word embeddings and the upper-level GRU can relieve the effect of majority emotions and attain a more precise utterance representation for different emotions. Specifically, the contextual embeddings are updated as:

$$e_c(w_k) = \tanh(W_w \cdot hs^f + b_w), \tag{9}$$

$$e_c(u_j) = \tanh(W_u \cdot Hs^f + b_u), \tag{10}$$

where $W_w \in \mathbb{R}^{d_1 \times (d_0 + 2d_1)}$, $W_u \in \mathbb{R}^{d_2 \times (d_1 + 2d_2)}$, $hs^f = [\overrightarrow{h_k}; e(w_k); \overleftarrow{h_k}]$, and $Hs^f = [\overrightarrow{H_j}; e(u_j); \overleftarrow{H_j}]$.

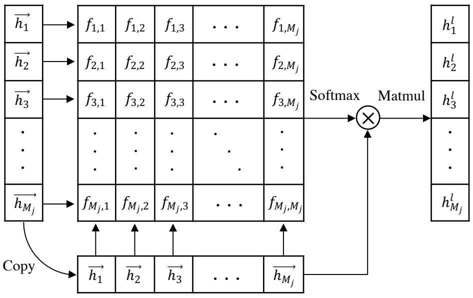


Figure 3: Self-attention over the forward hidden states of GRU.

3.3 HiGRU-sf: HiGRU + Self-Attention and Feature Fusion

Another challenging issue is to extract the contextual information of long sequences, especially the sequences in the testing set that are longer than those in the training set (Bahdanau et al., 2014). To fully utilize the global contextual information, we place a self-attention layer upon the hidden states of HiGRU and fuse the attention outputs with the individual word/utterance embeddings and the hidden states to learn the contextual word/utterance embeddings. Hence, this variant is termed HiGRU-sf, representing HiGRU with self-attention and features fusion.

Particularly, we apply self-attention upon the forward and backward hidden states separately to produce the left context embedding, h_k^l (H_j^l), and the right context embedding, h_k^r (H_j^r), respectively. This allows us to gather the unique global contextual information at the current step in two opposite directions and yield the corresponding contextual embeddings computed as follows:

$$e_c(w_k) = \tanh(W_w \cdot hs^{sf} + b_w), \tag{11}$$

$$e_c(u_j) = \tanh(W_u \cdot Hs^{sf} + b_u), \tag{12}$$

where $W_w \in \mathbb{R}^{d_1 \times (d_0 + 4d_1)}$, $W_u \in \mathbb{R}^{d_2 \times (d_1 + 4d_2)}$, $hs^{sf} = [h_k^l; \overrightarrow{h_k}; e(w_k); \overleftarrow{h_k}; h_k^r]$, and $Hs^{sf} = [H_j^l; \overrightarrow{H_j}; e(u_j); \overleftarrow{H_j}; H_j^r]$.

Self-Attention (SA). The self-attention mechanism is an effective non-recurrent architecture to compute the relation between one input to all other inputs and has been successfully applied in various natural language processing applications such as reading comprehension (Hu et al., 2018), and neural machine translation (Vaswani et al., 2017). Figure 3 shows the dot-product SA over the forward hidden states of GRU to learn the left context h_k^l. Each element in the attention matrix is computed by

$$f(\overrightarrow{h_k}, \overrightarrow{h_p}) = \begin{cases} \overrightarrow{h_k}^\top \overrightarrow{h_p}, & \text{if } k, p \le M_j, \\ -\infty, & \text{otherwise.} \end{cases} \tag{13}$$

An attention mask is then applied to waive the inner attention between the sequence inputs and paddings. At each step, the corresponding left context h_k^l is then computed by the weighted sum of all the forward hidden states:

$$h_k^l = \sum_{p=1}^{M_j} a_{kp} \overrightarrow{h_p}, \; a_{kp} = \frac{\exp(f(\overrightarrow{h_k}, \overrightarrow{h_p}))}{\sum_{p'=1}^{M_j} \exp\big(f(\overrightarrow{h_k}, \overrightarrow{h_{p'}})\big)}, \tag{14}$$

where a_{kp} is the weight of $\overrightarrow{h_p}$ to be included in h_k^l. The right context h_k^r can be computed similarly.

3.4 Model Training

Following (Khosla, 2018) which attains the best performance in the EmotionX shared task (Hsu and Ku, 2018), we minimize a weighted categorical cross-entropy on each utterance of all dialogues to optimize the model parameters:

$$loss = -\frac{1}{\sum_{i=1}^{L} N_i} \sum_{i=1}^{L} \sum_{j=1}^{N_i} \omega(c_j) \sum_{c=1}^{|\mathcal{C}|} y_j^c \log_2(\hat{y}_j^c), \tag{15}$$

where y_j is the original one-hot vector of the emotion labels, and y_j^c and $\hat{y}_j^c$ are the elements of y_j and $\hat{y}_j$ corresponding to the class c.

Similar to (Khosla, 2018), we assign the loss weight $\omega(c_j)$ inversely proportional to the number of training utterances in the class c_j, denoted by I_c, i.e., assigning larger loss weights for the minority classes to relieve the data imbalance issue. The difference is that we add a constant α to adjust the smoothness of the distribution. Then, we have:

$$\frac{1}{\omega(c)} = \frac{I_c^\alpha}{\sum_{c'=1}^{|\mathcal{C}|} I_{c'}^\alpha}. \tag{16}$$

4 Experiments

We conduct systematical experiments to demonstrate the advantages of our proposed HiGRU models.

4.1 Datasets

The experiments are carried out on three textual dialogue emotion datasets (see the statistics in Table 1):

IEMOCAP[1]**.** It contains approximately 12 hours of audiovisual data, including video, speech, motion capture of face, text transcriptions. Following (Poria et al., 2017; Hazarika et al., 2018): (1) We apply the first four sessions for training and the last session for test; (2) The validation set is extracted from the shuffled training set with the ratio of 80:20; (3) We only evaluate the performance on four emotions: anger, happiness, sadness, neutral, and remove the rest utterances.

Friends[2]**.** The dataset is annotated from the Friends TV Scripts (Hsu and Ku, 2018), where each dialogue in the dataset consists of a scene of multiple speakers. Totally, there are 1,000 dialogues, which are split into 720, 80, and 200 dialogues for training, validation, and testing, respectively. Each utterance in a dialogue is labeled by one of the eight emotions: anger, joy, sadness, neutral, surprise, disgust, fear, and non-neutral.

EmotionPush[3]**.** The dataset consists of private conversations between friends on the Facebook messenger collected by an App called EmotionPush, which is released for the EmotionX shared task (Hsu and Ku, 2018). Totally, there are 1,000 dialogues, which are split into 720, 80, 200 dialogue for training, validation, and testing, respectively. All the utterances are categorized into one of the eight emotions as in the Friends dataset.

Following the setup of (Hsu and Ku, 2018), in Friends and EmotionPush, we only evaluate the model performance on four emotions: anger, joy, sadness, and neutral, and we exclude the contribution of the rest emotion classes during training by setting their loss weights to zero.

Data Preprocessing. We preprocess the datasets by the following steps: (1) The utterances are split into tokens with each word being made into the lowercase; (2) All non-alphanumerics except "?" and "!" are removed because these two symbols usually exhibit strong emotions, such as surprise,

[3] `http://doraemon.iis.sinica.edu.tw/emotionlines`

Dataset	#Dialogue (#Utterance)			#Emotion				
	Train	Val	Test	Ang	Hap/Joy	Sad	Neu	Others
IEMOCAP	96 (3,569)	24 (721)	31 (1,208)	1,090	1,627	1,077	1,704	0
Friends	720 (10,561)	80 (1,178)	200 (2,764)	759	1,710	498	6,530	5,006
EmotionPush	720 (10,733)	80 (1,202)	200 (2,807)	140	2,100	514	9,855	2,133

Table 1: Statistics of the textual dialogue datasets.

joy and anger; (3) We build a dictionary based on the words and symbols extracted, and follow (Poria et al., 2017) to represent the tokens by the publicly available 300-dimensional word2vec[4] vectors trained on 100 billion words from Google News. The tokens not included in the word2vec dictionary are initialized by randomly-generated vectors.

4.2 Evaluation Metrics

To conduct fair comparison, we adopt two metrics as (Hsu and Ku, 2018), the weighted accuracy (WA) and unweighted accuracy (UWA):

$$\mathrm{WA} = \sum_{c=1}^{|\mathcal{C}|} p_c \cdot a_c, \quad \mathrm{UWA} = \frac{1}{|\mathcal{C}|} \sum_{c=1}^{|\mathcal{C}|} a_c, \quad (17)$$

where p_c is the percentage of the class c in the testing set, and a_c is the corresponding accuracy.

Generally, recognizing strong emotions may provide more value than detecting the neutral emotion (Hsu and Ku, 2018). Thus, in Friends and EmotionPush, UWA is a more favorite evaluation metric because WA is heavily compromised with the large proportion of the neutral emotion.

4.3 Compared Methods

Our proposed vanilla HiGRU, HiGRU-f, and HiGRU-sf[5] are compared with the following state-of-the-art baselines:

bcLSTM (Poria et al., 2017): a bidirectional contextual LSTM with multimodal features extracted by CNNs;

CMN (Hazarika et al., 2018): a conversational memory network with multimodal features extracted by CNNs;

SA-BiLSTM (Luo et al., 2018): a self-attentive bidirectional LSTM model, a neat model achieving the second place of EmotionX Challenge (Hsu and Ku, 2018);

CNN-DCNN (Khosla, 2018): a convolutional-deconvolutional autoencoder with more handmade features, the winner of EmotionX Challenge (Hsu and Ku, 2018);

bcLSTM$_*$ and **bcGRU**: our implemented bcLSTM and bcGRU with the weighted loss on the textual feature extracted from CNNs.

4.4 Training Procedure

All our implementations are coded on the Pytorch framework. To prevent the models fitting the order of data, we randomly shuffle the training set at the beginning of every epoch.

Parameters. For **bcLSTM$_*$** and **bcGRU**, the CNN layer follows the setup of (Kim, 2014), i.e., consisting of the kernels of 3, 4, and 5 with 100 feature maps each. The convolution results of each kernel are fed to a max-over-time pooling operation. The dimension of the hidden states of the upper-level bidirectional LSTM or GRU is set to 300. For HiGRU, HiGRU-f, and HiGRU-sf, the dimensions of hidden states are set to 300 for both levels. The final FC layer contains two sub-layers with 100 neurons each.

Training. We adopt Adam (Kingma and Ba, 2014) as the optimizer and set an initial learning rate, 1×10^{-4} for IEMOCAP and 2.5×10^{-4} for Friends and EmotionPush, respectively. An annealing strategy is utilized by decaying the learning rate by half every 20 epochs. Early stopping with a patience of 10 is adopted to terminate training based on the accuracy of the validation set. Specifically, following the best models on each dataset, the parameters are tuned to optimize WA on the validation set of IEMOCAP and to optimize UWA on the validation set of Friends and EmotionPush, respectively. Gradient clipping with a norm of 5 is applied to model parameters. To prevent overfitting, dropout with a rate of 0.5 is applied after the contextual word/utterance embeddings, and the FC layer.

Loss weights. For Friends and EmotionPush, as mentioned in Section 4.1, the loss weights are set to zero except the four considered emotions, to ignore the others during training. Besides, the power rate α of loss weights is tested from 0 to 1.5 with

Table 2: Experimental results on IEMOCAP. "(Feat)" represents the features used in the models, where T, V, and A denote the textual, visual, and audio features, respectively. The results of bcLSTM and CMN are from (Poria et al., 2017) and (Hazarika et al., 2018), respectively. The underlined results are derived by us accordingly, while "-" means the results are unavailable from the original paper.

a step of 0.25, and we use the best one for each model and dataset.

4.5 Main Results

Table 2 and Table 3 report the average results of 10 trials each on the three datasets, where the standard deviations of WA and UWA are recorded by the subscripts in round brackets. The results of bcLSTM, CMN, SA-BiLSTM, and CNN-DCNN are copied directly from the original papers for a fair comparison because we follow the same configuration for the corresponding datasets. From the results, we have the following observations:

(1) Baselines. Our implemented bcLSTM$_*$ and bcGRU, attain comparable performance with the state-of-the-art methods on all three datasets.

From the results on IEMOCAP in Table 2, we observe that: **(a)** By utilizing the textual feature only, bcGRU outperforms bcLSTM and CMN trained on the textual feature significantly, attaining +3.3 and +2.8 gain in terms of WA, respectively. bcLSTM$_*$ performs better than bcGRU, and even beats bcLSTM and CMN with the trimodal features in terms of WA. In terms of UWA, CMN performs better than bcLSTM$_*$ only when it is equipped with multimodal features. **(b)** By examining the detailed accuracy in each emotion, bcLSTM$_*$ and bcGRU with the textual feature attain much higher accuracy on the neutral emotion than bcLSTM with the only textual feature while maintaining good performance on the other three emotions. The results show that the weighted loss function benefits the training of models.

From the results on Friends and EmotionPush in Table 3, we observe that bcLSTM$_*$ and bcGRU trained on the same dataset (F+E) of CNN-DCNN perform better than CNN-DCNN on EmotionPush while attaining comparable performance with CNN-DCNN on Friends. The results show that by utilizing the contextual information with the weighted loss function, bcLSTM$_*$ and bcGRU can beat the state-of-the-art method.

(2) HiGRUs vs. Baselines. Our proposed HiGRUs outperform the state-of-the-art methods with significant margins on all the datasets.

From Table 2, we observe that: **(a)** CMN with the trimodal features attains the best performance on the anger emotion while our vanilla HiGRU achieves the best performance on the happiness emotion and gains further improvement on sadness and neutral emotions over CMN. Overall, the vanilla HiGRU achieves at least 8.7% and 3.8% improvement over CMN with the textual feature and the trimodal features in terms of WA, respectively. The results, including those of bcLSTM$_*$ and bcGRU, indicate that GRU learns better representations of utterances than CNN in this task. **(b)** The two variants, HiGRU-f and HiGRU-sf, can further attain +0.9 and +1.5 improvement over HiGRU in terms of WA and +1.0 and +1.2 improvement over HiGRU in terms of UWA, respectively. The results demonstrate that the included individual word/utterance-level features and long-range contextual information in HiGRU-f and HiGRU-sf, are indeed capable of boosting the performance of the vanilla HiGRU.

From Table 3, we can see that: **(a)** In terms of UWA, HiGRU trained and tested on individual sets of Friends and EmotionPush gains at least 7.5% and 6.0% improvement over CNN-DCNN, respectively. Overall, our proposed HiGRU achieves well-balanced performance for the four tested emotions, especially attaining significant better performance on the minority emotions of anger and sadness. **(b)** Moreover, HiGRU-f and HiGRU-sf further improve HiGRU +1.2 accuracy and +1.7 accuracy on Friends and +0.6 accuracy and +1.8 accuracy on EmotionPush in terms of UWA, respectively. The results again demonstrate the superior power of HiGRU-f and HiGRU-sf.

(3) Mixing Training Sets. By examining the results from the last ten rows in Table 3, we conclude that it does not necessarily improve the performance by mixing the two sets of training data.

Though the best performance of SA-BiLSTM

300	-	67.2(0.6)	68.4(1.0)	68.9(1.5)
200	-	67.6(2.0)	**68.9**(0.9)	69.1(1.3)
150	-	**67.6**(1.5)	68.5(1.3)	68.9(1.2)
100	-	67.5(1.7)	68.4(1.3)	**69.6**(1.0)

Table 4: Experimental results of UWA on Friends by our proposed models with different scales of utterance encoder.

and CNN-DCNN is obtained by training on the mixed dataset, the testing results show that our implemented bcLSTM$_*$, bcGRU and our proposed HiGRU models can attain better performance on EmotionPush but yield worse performance on Friends in terms of UWA.

By examining the detailed emotions, we speculate that: EmotionPush is a highly imbalanced dataset with over 60% of utterances in the neutral emotion. Introducing EmotionPush into a more balanced dataset, Friends, is equivalent to down-sampling the minority emotions in Friends. This hurts the performance on the minority emotions, anger and sadness. Meanwhile, introducing Friends into EmotionPush corresponds to up-sampling the minority emotions in EmotionPush. The performance of the sadness emotion is significantly boosted and that on the anger emotion is at least unaffected.

4.6 Discussions

Model Size. We study how the scale of the utterance encoder affects the performance of our proposed models, especially when our models contain a similar number of parameters as the baseline, say bcGRU. Such a fair condition can be made between our HiGRU-sf and bcGRU if we set d_1 to 150. From the testing results on Friends in Table 4, we can observe that: (1) Under the fair condition, the performance of our HiGRU-sf is not degraded compared to that when $d_1 = 300$. HiGRU-sf still outperforms bcGRU by a significant margin. (2) Overall, no matter d_1 is larger or smaller than 150, HiGRU-sf maintains consistently good performance and the difference between HiGRU-sf and HiGRU-f or HiGRU keeps noticeable. These results further demonstrate the superiority of our proposed models over the baseline bcGRU and the motivation of developing the two variants based on the vanilla HiGRU.

Successful Cases. We investigate three scenes related to the word "okay" that expresses three distinct emotions. The first two scenes come from the testing set of Friends and the third one from that of IEMOCAP. We report the predictions made by bcGUR and our HiGRU-sf, respectively, in Table 5. In **Scene-1**, "okay" with period usually exhibits little emotion and both bcGRU and HiGRU-sf correctly classify it as "Neu". In **Scene-2**, "okay" with "!" expresses strong emotion. However, bcGRU misclassifies it to "Ang" while HiGRU-sf successfully recognizes it as "Joy". Actually, the mistake can be traced back to the first utterance of this scene which is also misclassified as "Ang". This indicates that bcGRU tends to capture the wrong atmosphere within the dialogue. As for **Scene-3**, "okay" with period now indicates "Sad" and is correctly recognized by HiGRU-sf but misclassified as "Neu" by bcGRU. Note that HiGRU-sf also classifies the third utterance in **Scene-3** as "Sad" which seems to be conflicting

Role	Utterance	Truth	bcGRU	HiGRU-sf
Scene-1				
Phoebe	Okay. Oh but don't tell them Monica's pregnant because they frown on that.	Neu	Neu	Neu
Rachel	Okay.	Neu	Neu	Neu
Phoebe	Okay.	Neu	Neu	Neu
Scene-2				
Phoebe	Yeah! Sure! Yep! Oh, y'know what? If I heard a shot right now, I'd throw my body on you.	Joy	Ang	Joy
Gary	Oh yeah? Well maybe you and I should take a walk through a bad neighborhood.	Other	/	/
Phoebe	Okay!	Joy	Ang	Joy
Gary	All right.	Neu	Neu	Neu
Scene-3				
Female	Can I send you, like videos and stuff? What about when they start walking.	Other	/	/
Male	Yeah yeah yeah.	Sad	Hap	Sad
Male	You you record every second. You record every second because I want to see it all. Okay?	Hap	Hap	Sad
Male	If I don't get to see it now, I get to see it later at least, you know? You've got to keep it all for me; all right?	Other	/	/
Female	Okay.	Sad	Neu	Sad

Table 5: "Okay" expresses distinct emotions in three different scenes.

Role	Utterance	Truth	bcGRU	HiGRU-sf

Speaker-1	Sorry for keeping you up	Sad	Sad	Sad
Speaker-2	Lol don't be	Joy	Joy	Joy
Speaker-2	I didn't have to get up today	Neu	Sad	Sad
Speaker-1	:p	Joy	Joy	Joy
Speaker-2	It's actually been a really lax day	Joy	Neu	Sad

Table 6: Wrong predictions made by both bcGRU and our HiGRU-sf in two scenes.

to the ground truth. In fact, our HiGRU-sf captures the blues of this parting situation, where the true label "Hap" may not be that suitable. These results show that our HiGRU-sf learns from both each utterance and the context, and can make correct predictions of the emotion of each utterance.

Failed Cases. At last, we show some examples that both bcGRU and our HiGRU-sf fail in recognizing the right emotions in Table 6, i.e., **Scene-4** from Friends and **Scene-5** from EmotionPush. In **Scene-4**, both bcGRU and HiGRU-sf make wrong predictions for the fifth and the sixth utterances. It should be good news that Ross has his paper published and Rachel is glad to see related reports about it. However, the transcripts do not reveal very strong emotions compared to what the characters might act in the TV show. This kind of scenes may be addressed by incorporating some other features like audio and video. As for **Scene-5**, the third and the fifth utterances are classified into wrong emotions. Notice that the emotions indicated from the two utterances are very subtle even for humans. The Speaker-2 did not plan to get up today, but Speaker-1 kept him/her up and it ended up with a really lax day. So, the Speaker-2 feels joyful now. This indicates that even taking into the context into account, the models' capability of understanding subtle emotions is still limited and more exploration is required.

5 Conclusion

We propose a hierarchical Gated Recurrent Unit (HiGRU) framework to tackle the utterance-level emotion recognition in dialogue systems, where the individual utterance embeddings are learned by the lower-level GRU and the contexts of utterances are captured by the upper-level GRU. We promote the HiGRU framework to two variants, HiGRU-f, and HiGRU-sf, and effectively capture the word/utterance-level inputs and the long-range contextual information, respectively. Experimental results demonstrate that our proposed HiGRU models can well handle the data imbalance issue and sufficiently capture the available text information, yielding significant performance boosting on all three tested datasets. In the future, we plan to explore semi-supervised learning methods to address the problem of data scarcity in this task.

Abstract

Negation scope detection is widely performed as a supervised learning task which relies upon negation labels at word level. This suffers from two key drawbacks: (1) such granular annotations are costly and (2) highly subjective, since, due to the absence of explicit linguistic resolution rules, human annotators often disagree in the perceived negation scopes. To the best of our knowledge, our work presents the first approach that eliminates the need for word-level *negation* labels, replacing it instead with document-level *sentiment* annotations. For this, we present a novel strategy for learning fully interpretable negation rules via weak supervision: we apply reinforcement learning to find a policy that reconstructs negation rules from sentiment predictions at document level. Our experiments demonstrate that our approach for weak supervision can effectively learn negation rules. Furthermore, an out-of-sample evaluation via sentiment analysis reveals consistent improvements (of up to 4.66 %) over both a sentiment analysis with (i) no negation handling and (ii) the use of word-level annotations from humans. Moreover, the inferred negation rules are fully interpretable.

1 Introduction

Negations are a frequently utilized linguistic tool for expressing disapproval or framing negative content with positive words. Neglecting negations can lead to false attributions (Morante et al., 2008) and, moreover, impair accuracy when analyzing natural language; e. g., in information retrieval (Cruz Díaz et al., 2012; Rokach et al., 2008) and especially in sentiment analysis (Cruz et al., 2015; Wiegand et al., 2010). Hence, even simple heuristics for identifying negation scopes can yield substantial improvements in such cases (Jia et al., 2009).

Negation scope detection is sometimes implemented as unsupervised learning (e. g., Pröllochs et al., 2016), while a better performance is commonly achieved via supervised learning (see our supplements for a detailed overview): the resulting models thus learn to identify negation scopes from word-level annotations (e. g., Li and Lu, 2018; Reitan et al., 2015). We argue that this approach suffers from inherent drawbacks. (1) Such granular annotations are costly and, especially at word level, a considerable number of them is needed. (2) Negation scope detection is highly subjective (Councill et al., 2010). Due to the absence of explicit linguistic rules for resolutions, existing corpora often come with annotation guidelines (Morante and Blanco, 2012; Morante and Daelemans, 2012). Yet there are considerable differences: some corpora were labeled in a way that negation scopes consist of single text spans, while others allowed disjoint spans (Fancellu et al., 2017). More importantly, given the absence of universal rules, human annotators largely disagree in their perception of what words should be labeled as negated.

Motivational experiment. Since prevalent corpora were labeled only by a single rater, we now establish the severity of between-rater discrepancies. For this, we carried out an initial analysis of 500 sentences from movie reviews.[1] Each sentence contained at least one explicit negation phrase from the list of Jia et al. (2009), such as *"not"* or *"no."* Two human raters were then asked

---

[1] Details are reported in our supplementary materials.

Proceedings of NAACL-HLT 2019, pages 407–413
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

to annotate negation scopes. They could choose an arbitrary selection of words and were not restricted to a single subspan, as recommended by Fancellu et al. (2017). The annotations resulted in large differences: only 50.20 % of the words were simultaneously labeled as “negated” by both raters. Based on this experimental evidence, we showcase there is no universal definition of negation scopes (rather, human annotations are likely to be noisy or even error-prone) and thus highlight the need for further research.

Contributions. To the best of our knowledge, our work presents the first approach that eliminates the need for *word-level* annotations of *negation labels*. Instead, we perform negation scope detection merely by utilizing shallow annotations at *document level* in the form of *sentiment labels* (e. g., from user reviews). Our novel strategy learns interpretable negation rules via weak supervision: we apply reinforcement learning to find a policy that reconstructs negation rules based on sentiment prediction at document level (as opposed to conventional word-level annotations).

In our approach, a single document d comes with a sentiment label y_d. The document consists of N_d words, $w_{d,1}, \ldots, w_{d,N_d}$, where the number of words can easily surpass several hundreds. Based on the sentiment value, we then need to make a decision (especially out-of-sample) for each of the N_d words, whether or not it should be negated. In this case, a *single* sentiment value is outnumbered by potentially *hundreds* of negation decisions, thus pinpointing to the difficulty of this task. Formally, the goal is to learn individual labels $a_{d,i} \in \{\text{Negated}, \neg\text{Negated}\}$ for each word $w_{d,i}$. Rewards are the errors in sentiment prediction at document level.

Strengths. Our approach exhibits several favorable features that overcome shortcomings found in prior works. Among them, it eliminates the need for manual word-level labels. It thus avoids the detrimental influence of subjectivity and misinterpretation. Instead, our model is solely trained on a document-level variable and can thus learn domain-specific particularities of the given prose. The inferred negation rules are fully interpretable while documents can contain multiple instances of negations with arbitrary complexity, sometimes nested or consisting out of disjoint text spans. Despite facing several times more negation decisions than sentiment labels, our experiments demonstrate that this problem can be effectively learned through reinforcement learning.

Evaluation. Given the considerable inconsistencies in human annotations of negation scopes and the lack of universal rules, we regard the “true” negation scopes as unobservable. Hence, we later compare the identified negation scopes with those from rater 1 and 2 only as a sensitivity check because of the fact that both raters have only 50.2 % overlap. Instead, we choose the following evaluation strategy. We concentrate on the performance of negation scope detection as a supporting tool in natural language processing where its primary role is to facilitate more complex learning tasks such as sentiment analysis. Therefore, we report the performance improvements in sentiment analysis resulting from our approach. For a fair comparison, we use baselines that only rely upon the same information as our weak supervision (and thus have no access to word-level negation labels). Our performance is even on par with a supervised classifier that can exploit richer labels during training.

2 Learning Negation Scope Detection via Weak Supervision

Intuition. The choice of reinforcement learning for weak supervision might not be obvious at first, but, in fact, it is informed by theory: it imitates the human reading process as stipulated by cognitive reading theory (Just and Carpenter, 1980), where readers iteratively process information word-by-word.

States and actions. In each learning iteration, the reinforcement learning agent observes the current state $s_i = (w_i, a_{i-1})$ that we engineer as the combination of the i-th word w_i in a document and the previous action a_{i-1}. This specification establishes a *recurrent* architecture whereby the previous negation can pass on to the next word. At the same time, this allows for nested negations, as a word can first introduce a negation scope and another subsequent negation can potentially revert it.

After observing the current state, the agent chooses an action a_t from of two possibilities: (1) it can set the current word to *negated* or (2) it can mark it as *not negated*. Hence, we obtain the following set of possible actions $A = \{\text{Negated}, \neg\text{Negated}\}$. Based on the selected action, the agent receives a reward, r_i which updates the knowledge in the state-action function

$Q(s_i, a_i)$. This state-action function is then used to infer the best possible action a_i in each state s_i, i. e., the optimal policy $\pi^*(s_i, a_i)$.

Reward function. The reward r_i depends upon the correlation between a given a document-level label (e. g., a rating in movie reviews) and the sentiment of a document. We predict the sentiment S_d of document d using a widely-used sentiment routine based on the occurrences of positively- and negatively-opinionated terms (see Taboada et al., 2011). If a term is negated by the policy, the polarity of the corresponding term is inverted, i. e., positively opinionated terms are counted as negative and vice versa. In the following, S_d^0 denotes the document sentiment without considering negations; S_d^π the sentiment when incorporating negations based on policy π.

When processing a document, we cannot actually compute the reward until we have processed all words. Therefore, we set the reward before the last word to $c \approx 0$, i. e., $r_i = c$ for $i = 1, \ldots, N_d - 1$. For the final word, the agent compares its performance in predicting the document label based on sentiment without considering negations S_d^0 to the sentiment when incorporating negations based on the current policy π^*. The former is defined by the absolute difference between the document label y_d and the predicted sentiment without negations S_d^0, whereas the latter is defined by the absolute difference between y_d and the adjusted sentiment using the current policy S_d^π. Then the difference between these values returns the terminal reward r_{N_d}. Thus the reward is

$$r_i = \begin{cases} 0, & \text{if } a_i = \text{Neg and } i < N_d, \\ c, & \text{if } a_i = \neg\text{Neg and } i < N_d, \\ \left|y_d - S_d^0\right| - \left|y_d - S_d^\pi\right|, & \text{if } i = N_d, \end{cases}$$

with a constant c (we use $c = 0.005$) that adds a small reward for default (i. e., non-negating) actions to avoid overfitting.

***Q*-learning.** During the learning process[2], the agent then successively observes a sequence of words in which it can select between exploring new actions or taking the current optimal one. This choice is made by ε-greedy selection according to which the agent explores the environment by selecting a random action with probability ε or, alternatively, exploits the current knowledge with probability $1 - \varepsilon$.

3 Experiments

Datasets. We use the following benchmark datasets with document-level annotations from the literature (cf. Hogenboom et al., 2011; Pröllochs et al., 2016; Wiegand et al., 2010):

IMDb: movie reviews from the Internet Movie Database archive, each annotated with an overall rating at document level (Pang and Lee, 2005).

Airport: user reviews of airports from Skytrax, each annotated with an overall rating at document level (Pérezgonzález and Gilbey, 2011).

Ad hoc: financial announcements with complex, domain-specific language (Pröllochs et al., 2016), labeled with the daily abnormal return of the corresponding stock.

Learning parameters. We perform 4000 learning iterations with a higher exploration rate as given by the following parameters[3]: exploration $\varepsilon = 0.001$, discount factor $\gamma = 0$ and learning rate $\alpha = 0.005$. In a second phase, we run 1000 iterations for fine-tuning with exploration $\varepsilon = 0.0001$, discount factor $\gamma = 0$ and learning rate $\alpha = 0.001$.

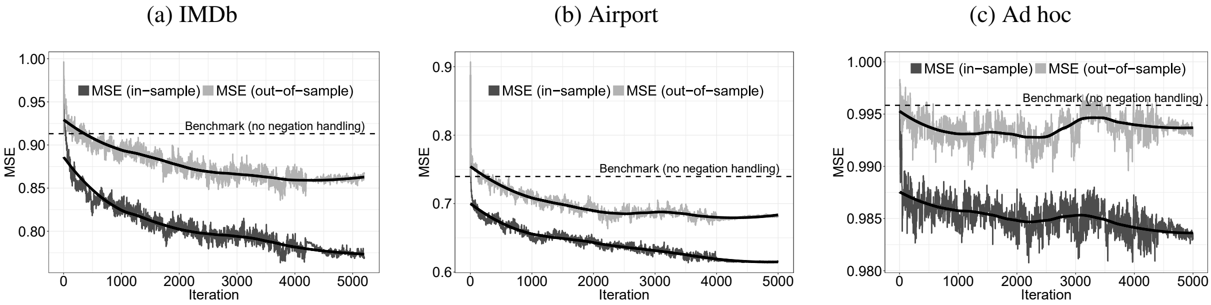
Policy learning. For each dataset, the reinforcement learning process converges to a stationary policy that shows reward fluctuations below 0.05 %. As part of a benchmark, we study the mean squared error (MSE) between y_d and the predicted sentiment S_d^0 when leaving negations untreated as our benchmark. For all datasets, the in-sample MSE decreases substantially (see Figure 1), demonstrating the effectiveness of our learning approach. The reductions number to 14.93 % (IMDb), 16.77 % (airport), and 0.91 % (ad hoc). The latter is a result of the considerably more complex language in financial statements.

Performance in Sentiment Analysis. We use 10-fold cross validation to compare the out-of-sample performance in sentiment analysis of reinforcement learning to benchmarks without word-level labels from previous works. The benchmarks consists of rules (Hogenboom et al., 2011; Taboada et al., 2011), which search for the occurrence of specific cues based on pre-defined lists and then invert the meaning of a fixed number of surrounding words. Table 1 compares the out-of-sample MSE between predicted sentiment and the

---

[2] We use Watkin's $Q(\lambda)$ with eligibility traces; see Sutton and Barto (1998) for details. At the beginning, we initialize the action-value function $Q(s, a)$ to zero for all states and actions. This also controls our default action when encountering unknown states or out-of-vocabulary (OOV) words. In such cases, the non-negated action is preferred.

[3] Further details regarding the learning parameters are provided in the supplementary materials.



(a) IMDb (b) Airport (c) Ad hoc

Figure 1: MSE between the document label and predicted sentiment across different learning iterations using 10-fold cross validation. Additional lines in black from smoothing.

document-level label:[4]

IMDb: Negating a fixed window of the next 4 words achieves the lowest error among all rules, similar to Dadvar et al. (2011). This rule reduces the MSE of the benchmark with no negation handling by 1.05 %. Our approach works even more accurately, and dominates all of the rules, reducing the out-of-sample MSE by at least 4.60 %.

Airport: Our method decreases the MSE by 4.66 % compared to the best-performing rule (negating a fixed window of the next 4 words).

Ad hoc: Even for complex financial language, reinforcement learning exceeds this benchmark method by 0.19 % in terms of out-of-sample MSE.

Altogether, our weak supervision improves sentiment analysis consistently across all datasets.[5]

Approach	IMDb	Airport	Ad hoc
Benchmark: no negation handling	0.9133	0.7415	0.9958
Negating all subsequent words	0.9160	0.7312	0.9949
Negating the whole sentence	0.9339	0.7811	0.9961
Fixed window of 1 word	0.9082	0.7212	0.9950
Fixed window of 2 words	0.9052	0.7130	0.9943
Fixed window of 3 words	0.9047	0.7146	0.9943
Fixed window of 4 words	0.9038	0.7134	0.9942
Fixed window of 5 words	0.9039	0.7136	0.9942
Proposed reinforcement learning for weak supervision	**0.8622**	**0.6798**	**0.9923**

Table 1: Out-of-sample MSE between sentiment S_d^π and the document label y_d. Lowest error in bold.

Comparison to human raters. For reasons of completeness, our supplements report the overlap with both human raters from our motivational experiment, which is in the range of 18.8 % to 25.2 %. However, these numbers should be treated with caution, as we remind that there is no universal definition of negation scopes and even the two human annotations reveal on 50.2 %. Moreover, our approach was not learned towards reconstructing these human annotations, since we focused on rules that achieve the greatest benefit in sentiment analysis.

Comparison to word-level classifiers. We also compared weak supervision against a supervised HMM classifier from Pröllochs et al. (2016) that draws upon granular word-level negation labels. Here we report the sentiment analysis on IMDb in order to be able to use the domain-specific negation labels from IMDb text snippets of our initial experiment. In comparison to our reinforcement learning, the supervised classifier results in a 5.79 % higher (and thus inferior) MSE. Yet our weak supervision circumvents costly word-level annotations.

Interpretability. Our method yields negation rules that are fully interpretable: one simply has to assess the state-action function $Q(s_i, a_i)$. Table 2 provides an example excerpt for the document *"this beautiful movie isn't good but fantastic."* The agent the starts by observing the first state given by the combination of the first word w_1 and the previous action a_0, i. e. $s_1 = (\textit{this}, \neg\text{Negated})$. According to the state-action table, the best action for the agent is to set this state to not negated ($a_1 = \neg\text{Negated}$). This pattern continues until it observes state $s_4 = (\textit{isn't}, \neg\text{Negated})$ in which the policy implies to initiate a negation scope ($a_4 = \text{Negated}$). Subsequently, the negation scope is forwarded until the agent observes $s_6 = (\textit{but}, \text{Negated})$ in which it terminates the negation scope ($a_6 = \neg\text{Negated}$). Finally, the agent observes $s_7 = (\textit{fantastic}, \neg\text{Negated})$ in which it takes action $a_7 = \neg\text{Negated}$.

---

[4] We also experimented with performance comparisons in a classification task, yet our approach also yields consistent improvements in this evaluation.

[5] We also investigated the relationship between prediction performance and text length, finding only minor effects.

State=(w_i, a_{i-1})	Negated	¬Negated	$\pi^*(s_i, a_i)$
(*this*, ¬Negated)	0.0114	0.0502	¬Negated
(*beautiful*, ¬Negated)	0.0081	0.0779	¬Negated
(*movie*, ¬Negated)	0.0039	0.0506	¬Negated
(*isn't*, ¬Negated)	0.0700	0.0456	Negated
(*good*, Negated)	0.0578	0.0322	Negated
(*but*, Negated)	0.0120	0.0365	¬Negated
(*fantastic*, ¬Negated)	–0.0181	0.1708	¬Negated

Table 2: Excerpt of state-action function $Q(s_i, a_i)$ actions $A = \{\text{Negated}, \neg\text{Negated}\}$ and the learned policy π^* for IMDb reviews.

4 Related Work

State-of-the-art methods for detecting, handling and interpreting negations can be grouped into different categories (cf. Pröllochs et al., 2015, 2016; Rokach et al., 2008).

Rule-based approaches are among the most common due to their ease of implementation and solid out-of-the-box performance. These usually suppose a forward influence of negation cues based on which they invert the meaning of the whole sentence or a fixed number of subsequent words (Hogenboom et al., 2011). Furthermore, they can also incorporate syntactic information in order to imitate subject and object (Padmaja et al., 2014; Chowdhury and Lavelli, 2013). Negation rules have been found to work effectively across different domains and rarely need fine-tuning (Taboada et al., 2011). However, rule-based approaches entail several drawbacks, as the list of negations must be pre-defined and the selection criterion according to which rule a rule is chosen is usually random or determined via cross validation. In addition, rules cannot effectively cope with implicit expressions or particular, domain-specific characteristics.

Generative probabilistic models (e. g., hidden Markov models or conditional random fields) can partially overcome these shortcomings (Li and Lu, 2018; Reitan et al., 2015; Rokach et al., 2008), such as the difficulty of recognizing implicit negations. These process narrative language word-by-word and move between hidden states representing negated and non-negated parts. Such models can adapt to domain-specific language, but require more computational resources and rely upon ex ante transition probabilities. Although variants based on unsupervised learning avoid the need for any labels, practical applications reveal inferior performance compared to supervised approaches (Pröllochs et al., 2015). The latter usually depend on manual labels at a granular level, which are not only costly but suffer from subjective interpretations (Fancellu et al., 2017).

A third category of methods links the polarity shift effect of negations more closely to sentiment analysis tasks at sentence or document level. For example, text parts can be classified into a polarity-unshifted part and a polarity-shifted part according to certain rules (Li and Huang, 2009). Sentiment classification models are then trained using both parts (Li et al., 2010). Alternatively, rule-based algorithms can extract sentences with inconsistent sentiment and omit them from standard sentiment analysis procedures (Orimaye et al., 2012). Reversely, antonym dictionaries have been used to generate sentiment-inverted texts to classify polarity in pairs (Xia et al., 2016). Although such data expansion techniques usually enhance the performance of sentiment analysis, they require either complex linguistic knowledge or extra human annotations (Xia et al., 2015).

Research gap. In contrast to these methods, we propose a novel strategy for learning negation rules via weak supervision. Our model uses reinforcement learning to reconstruct negation rules based on an document-level variable and does not require any kind of manual word-level labeling or precoded linguistic patterns. It is able to recognize explicit as well as implicit negations, while avoiding the influence of subjective interpretations.

5 Conclusion

This paper proposes the first approach for negation scope detection based on weak supervision. Our proposed reinforcement learning strategy circumvents the need for word-level annotations with negation scopes, as it reconstructs negation rules based on a document-level sentiment labels. Our experiments show that our weak supervision is effective in negation scope detection; it yields consistent improvements (of up to 4.66 %) over a sentiment analysis without negation handling.

Our works suggests important implications. We are in line with growing literature (e. g., Fancellu et al., 2017) that reports challenges in resolving negation scopes through humans. Beyond prior works, our experiment reveals between-rater inconsistencies. While negation scope detection is widely studied as an isolated task, it could be beneficial when linking its evaluation more closely to context-specific uses such as sentiment analysis.

Abstract

Unsupervised domain adaptation (UDA) is the task of modifying a statistical model trained on labeled data from a source domain to achieve better performance on data from a target domain, with access to only unlabeled data in the target domain. Existing state-of-the-art UDA approaches use neural networks to learn representations that can predict the values of subset of important features called "pivot features." In this work, we show that it is possible to improve on these methods by jointly training the representation learner with the task learner, and examine the importance of existing pivot selection methods.

1 Introduction

Unsupervised domain adaptation (UDA) is the task of modifying a statistical model trained on labeled data from a source domain to achieve better performance on data from a target domain, without access to any labeled data in the target domain. Supervised domain adaptation methods can obtain excellent performance from a small number of labeled examples in the target domain (Daumé III, 2007), but UDA is attractive in cases where annotation requires specialized expertise or the number of meaningfully different sub-domains is large (e.g., both are true for clinical NLP).

Structural correspondence learning (Blitzer et al., 2006) (SCL) is one widely-used method for UDA in natural language processing. The key idea in SCL is that a subset of features, believed to be predictive across domains, are selected as *pivot features*. For each selected pivot feature, SCL creates an auxiliary classification task of predicting the value of that feature in an instance, given the values of all the non-pivot features for that instance. The auxiliary classifiers therefore learn important cross-domain information about the structure of the feature space, which the SCL algorithm uses to create an augmented representation that aligns features from different domains (further details in Section 2).

Meanwhile, recent advances in neural network learning have shown that training regimens that jointly consider evidence from multiple sources can improve performance – both multi-task learning (Søgaard and Goldberg, 2016) and fine tuning (Howard and Ruder, 2018; Devlin et al., 2018). However, existing SCL-based methods treat the representation learning and task learning as separate tasks, so the parameters of the representation learning machinery are fixed before training for the downstream task. Jointly learning the representation- and task-specific parameters can potentially allow a learning algorithm to find representations that are better suited for the task.

In this work, we describe a new UDA algorithm that is trained to jointly maximize two objectives: the primary supervised task in the source domain, and a pivot feature reconstruction task that can be trained on unlabeled data. We also explore the importance of pivot feature selection to this algorithm, in experiments that quantitatively and qualitatively examine the quality of existing pivot selection methods. We find that our joint neural approach to SCL improves unsupervised domain adaptation substantially on a standard sentiment classification task. Our results also show that while existing pivot selection methods perform well, they are below an oracle-provided ceiling for many source-target pairs for the sentiment classification task we examine.

2 Background

This work builds off of existing work in unsupervised domain adaptation, starting with Blitzer's work on structural correspondence learning (SCL) (Blitzer et al., 2006, 2007). In the UDA

Proceedings of NAACL-HLT 2019, pages 414–419
Minneapolis, Minnesota, June 2 - June 7, 2019.

task setup, one is given two datasets, the source $D_S = \{X_s, y_s\}$, with labels for each instance, and the target $D_T = \{X_t\}$, with unlabeled instances only. The goal of UDA is to learn a function $f_u(X_s, y_s, X_t)$ that improves on the classification performance over a function $f_l(X_s, y_s)$ when applied to new data drawn from the target distribution.

SCL is essentially a representation learning algorithm that works by creating a number of auxiliary classification tasks from the unlabeled source and target training instances (inspired by Ando and Zhang 2005). First, a set of p *pivot features* are selected, intended (in Blitzer's words) to be "features which behave in the same way for discriminative learning in both domains." Then, SCL creates p auxiliary tasks of predicting the value of pivot features in an instance given the non-pivot features in the instance. The weights of these linear classifiers are then aligned as columns in a matrix W, and the k left singular vectors are chosen from the singular value decomposition $W = U\Sigma V^\top$ to reduce its dimensionality, leading to a projection matrix $\theta \in R^{n\times k}$ that maps instances from the original feature space into the learned space. Most practical implementations find the best performance of SCL is obtained when projected features are concatenated with the original feature space; for some tasks and datasets other combinations have been tested and proved superior (Sapkota et al., 2016).

Recently, neural-network-based domain adaptation algorithms have been successful, including domain adversarial methods (Ganin et al., 2016) and auto-encoder-based methods (Glorot et al., 2011; Chen et al., 2014). However, a neural version of SCL still obtains near state-of-the-art performance (Ziser and Reichart, 2017). In that work, the AE-SCL system uses a multi-layer perceptron to replace the SVD for learning the feature projection. This network takes non-pivot features as input, has one hidden layer, and predicts the value of the pivot features at the output layer. Since it obtains supervision from the values of features, it can be trained on unlabeled instances from the source and target domains. To train for the downstream sentiment classification task, the source instances are first passed into the trained representation learning network, and the values of the hidden layer are considered an additional set of features. These features are combined with all the original features, and the authors use a logistic regression classifier for the final sentiment classifier.

One standard corpus used to develop new domain adaptation algorithms is the Amazon sentiment analysis dataset.[1] This corpus was created by Blitzer et al. (2007), but we use the version included in the software release from Ziser and Reichart (2017)[2], along with their pre-processing steps, for ease of comparison with their results. This dataset contains reviews from four product categories on Amazon.com – books, DVDs, electronics, and kitchen appliances. Reviews are mapped to binary categories: *positive* if the review assigns the product >3 stars (out of 5) and *negative* if it assigns the product <3 stars. This dataset also contains additional unlabeled instances for each category, used for training the pivot predictor.

3 Methods

The current work has two motivating factors. First, we would like to improve the performance of SCL using joint training. Existing SCL-based methods are successful in treating pivot prediction as a pre-training phase, but joint training may improve UDA by allowing the network to find representations that are equally good at pivot reconstruction but better for downstream task performance. Second, we would like to evaluate the quality of pivot selection methods and explore whether this step might be eliminated to simplify SCL.

We focus on feature-based UDA methods, as opposed to approaches that rely on embeddings (e.g., Barnes et al., 2018; Ziser and Reichart, 2018), since our primary interest is in improving existing models developed with a feature engineering approach. Such methods allow us to quickly adapt a number of different models to new datasets (e.g., for already-existing NLP pipeline software), rather than engineering new neural models from scratch for each of the pipeline tasks. For that reason, we compare to the AE-SCL model of Ziser and Reichart, rather than their subsequent models that take embeddings as input. In any case, we show that with some tuning the AE-SCL model can obtain state-of-the-art performance for many pairs.

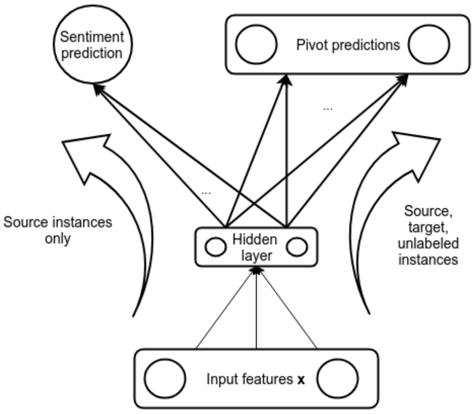

Figure 1: Network architecture for unsupervised domain adaptation.

3.1 Joint Neural Structural Correspondence Learning

Figure 1 graphically depicts our proposed joint model. The input to the model $\mathbf{x} \in \mathcal{R}^n$ is the set of all features extracted from the text – to compare with Ziser and Reichart (2017) we use unigrams and bigrams, extracted using scikit-learn (Pedregosa et al., 2011). We experimented with a few different hidden layer sizes, and settled on $d = 2000$ – this balances the need of the representation to predict more output variables than the AE-SCL method with run-time constraints. The representation is generated with $h(\mathbf{x}) = ReLU(W_h\mathbf{x})$, for $W_h \in \mathcal{R}^{d\times n}$. The task prediction is $f_{task}(\mathbf{x}) = Sigmoid(W_t h(\mathbf{x}))$ ($W_t \in \mathcal{R}^{1\times d}$) and the pivot prediction is $f_{pivot}(\mathbf{x}) = Sigmoid(W_p h(\mathbf{x}))$ ($W_p \in \mathcal{R}^{p\times d}$).

The joint loss function for labeled source data D_l, all data D_a, and model parameters θ is:

$$\begin{aligned}\mathcal{L}(D;\theta) = & \sum_{\mathbf{x},y\in D_l} BCE(f_{task}(\mathbf{x}), y) + \\ & \lambda \sum_{\mathbf{x}\in D_a} BCE(f_{pivot}(\mathbf{x}), pivots(\mathbf{x})) + \\ & \rho\mathcal{R}(\theta)\end{aligned} \tag{1}$$

where BCE is the binary cross-entropy loss, λ controls the weight of pivot prediction loss, $pivots$ is a function that selects the indices from an instance that are the pivot features to be predicted, and ρ is the weight of the regularization term $\mathcal{R}$.

To train this model, we alternate passing labeled source data and unlabeled data from the source and target domains into the network. For the labeled data, the error term is the sum of task- and pivot-prediction tasks, while for the unlabeled data only the pivot-prediction loss is computed.

Training proceeds for 30 epochs, with mini-batch size of 50 instances, using the Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001. For the loss function weight, we used $\rho = 0.1$ and $\lambda = 100$. We used held-out source data to compute validation loss after each epoch and selected the trained model with the lowest validation loss.

3.2 Pivot Selection for Neural Systems

One standard way of choosing pivot features is by calculating mutual information (MI) between the source features and labels, and selecting the features with the highest MI. It is far from clear, however, that this technique is always optimal. Earlier experiments with the POS tagging task (Blitzer et al., 2006) used feature frequency instead, and the extent of the correlation between frequency and MI for that task is not established.

Here, we attempt to provide some evidence about the quality of MI for the task of sentiment classification, using the classification pair of books to electronics. First, we wanted to rule out the null hypothesis that prediction of MI pivots is essentially a generic representation learning algorithm – in other words, that a network learning structure between any sets of sufficiently common features may improve adaptation performance. We modified Ziser et al.'s code to simply select random feature indices from the subset of those that occurred frequently enough to be pivot candidates. With this setup, adaptation performance averaged 0.724 across ten runs, well below their reported 0.744, casting doubt on the null hypothesis.

Next, we want to examine the contention that features with high MI relative to source labels are general. To do this, we simply compare the list of MI features used when the source is *books* to those when the source is *electronics*. We find that, out of the 100 pivot features selected by MI in either cases, there is overlap of 26 features, some examples of which are shown in Table 1 (left). Table 1 also shows a number of MI-selected pivots from the *books* domain that are not general (middle), and then a set of features MI-correlated with the target domain that seem general (right). These latter two columns are essentially precision and recall errors of the MI pivot selection algorithm.

Shared features	Book (spec)	Elec (gen)

Table 2: Summary of results. B=Books, D=Dvd, E=Electronics,K=Kitchen. AE-SCL=Reported results from Ziser and Reichart (2017). AE-SCL$_R$=Replicated results from the same. $Joint_{MI}$=results from the joint model in Section 3.1. $Joint_O$=results from the joint model using oracle MI pivot selection. Bold indicates a significant difference ($p < 0.05$) between AE-SCL$_R$ and $Joint_{MI}$ using Welch's one-tailed t-test.

Finally, we perform an oracle-based adaptation experiment, where we select the pivot feature indices using MI against the gold labels of the *target* domain, but then proceed with training looking only at source labels, with results in Table 2 discussed below.

4 Evaluation

We follow the standard setup for the Amazon sentiment task, splitting each source dataset into 1600 training and 400 validation instances, and evaluating on the entire labeled target dataset for each pair. We compare against two baselines: First, the reported results of Ziser and Reichart, and second, our replication of their results using their code. Our replication changed their code by replacing the stochastic gradient descent optimizer with Adam (Kingma and Ba, 2014), and increasing the training batch size from 1 to 50. These changes were made to speed training runs during development; we found they produced better-than-reported results and include these superior results as an even stronger baseline. We report results of two configurations of our joint learner. The first configuration ($Joint_{MI}$) uses the MI between source labels and features to select 100 pivot features. The second configuration ($Joint_{Oracle}$) is an oracle-informed system where we use the MI between *target* labels and features to select pivot features, but only use source labels while training the network. Both the AE-SCL$_R$ model and our $Joint_{MI}$ model were run for 10 iterations to minimize differences due to random initialization and to calculate significance statistics.

Table 2 shows the results of our experiments. First, we note that our replication of AE-SCL improves upon their reported results in 8 of 12 pairs, often by substantial margins, and is only worse in one pair (Kitchen→Books). Our $Joint_{MI}$ method is superior to the reported AE-SCL results in all pairs, 1.7 points (absolute) on average, and significantly better than the AE-SCL$_R$ in 9 of 12 pairs, using Welch's one-tailed t-test. This is, to our knowledge, the best result on this task using a feature-based approach (i.e., excluding systems that use embeddings). Despite constraining our system to adapting feature-based models, this result is competitive with the best-known result using a pure neural approach with embeddings as input, as Ziser and Reichart (2018) report an average accuracy of 0.804. The $Joint_{Oracle}$ configuration shows that, despite the large gains of joint training, there is still significant improvement available with better pivot selection.

5 Discussion and Conclusion

Our results show that by jointly learning representations and task networks, UDA can be greatly improved over existing neural UDA methods. We note that there are existing domain adaptation methods that use joint training with auxiliary tasks. Yu and Jiang (2016) use an auxiliary task of predicting whether a masked pivot word in a sentence is positive or negative sentiment, where they introduce a new technique to select pivots that still is based on correlations with source labels. Our work is unique in showing that the standard task of mutual-information-selected pivot prediction is a high quality auxiliary task, though future work should explore whether their pivot selection algorithm is superior to MI in our joint model. We also showed that existing neural UDA methods can be improved significantly with minor changes to the training regimen. Finally, we show that mutual information pivot selection is quite far from the performance ceiling provided by oracle-based pivot selection.

This work evaluated on the widely-used Amazon sentiment dataset from Blitzer et al. (2007). However, we believe that future work on domain adaptation should phase out the use of this dataset.[3] The test set for this setup is flawed in two important ways: first, it is artificially balanced with positive and negative reviews, when the problem is not actually balanced; it also has 3-star reviews removed, which is not a realistic test set setup without looking at labels. For these reasons, we recommend that future work use different domain adaptation datasets.

The Pytorch implementation used to produce these results is publicly available. [4]

Learning Bilingual Sentiment-Specific Word Embeddings without Cross-lingual Supervision

Yanlin Feng and **Xiaojun Wan**
Institute of Computer Science and Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
{fengyanlin,wanxiaojun}@pku.edu.cn

Abstract

Word embeddings learned in two languages can be mapped to a common space to produce Bilingual Word Embeddings (BWE). Unsupervised BWE methods learn such a mapping without any parallel data. However, these methods are mainly evaluated on tasks of word translation or word similarity. We show that these methods fail to capture the sentiment information and do not perform well enough on cross-lingual sentiment analysis. In this work, we propose UBiSE (Unsupervised Bilingual Sentiment Embeddings), which learns sentiment-specific word representations for two languages in a common space without any cross-lingual supervision. Our method only requires a sentiment corpus in the source language and pretrained monolingual embeddings of both languages. We evaluate our method on three language pairs for cross-lingual sentiment analysis. Experimental results show that our method outperforms previous unsupervised BWE methods and even supervised BWE methods. Our method succeeds for a distant language pair English-Basque.

1 Introduction

Lack of annotated corpora degrades the quality of sentiment analysis in low-resource languages. Cross-lingual sentiment analysis tackles this problem by adapting the sentiment resource in a resource-rich language (the source language) to a resource-poor language (the target language).

Bilingual Word Embeddings (BWE) provide a way to transfer the sentiment information from the source language to the target language. There has been an increasing interest in BWE methods in recent years, including both supervised methods and unsupervised methods. Supervised BWE methods map the word vectors of the two languages in a common space by exploiting either a bilingual seed dictionary or other parallel data, while unsupervised BWE methods do not utilize any form of bilingual supervision. Yet, these methods are mostly evaluated on tasks of word translation or word similarity, and do not perform well enough on cross-lingual sentiment analysis as shown in Section 4.

Consider the case where we want to perform sentiment analysis on the target language with merely an annotated sentiment corpus in the source language. We assume pretrained monolingual embeddings of both languages are available to us. One solution is to first align the embeddings of both languages in a common space using unsupervised BWE methods, then train a classifier based on the source sentiment corpus. In this solution, no sentiment information is utilized to learn the alignment.

In this paper, we propose to exploit the sentiment information and learn sentiment-specific alignment. The sentiment information is gradually incorporated into the BWE through an iterative constraint relaxation procedure. Unlike previous work which performed alignment in a single direction by linearly mapping the source vectors to the target vector space, we propose an alignment model that maps the vectors of the two languages to a new shared space with two non-linear transformations. Our model is able to separate positive vectors from negative vectors in the bilingual space and allow such sentiment information to be transferred to the target language. Our main contributions are as follows:

1. We propose a novel approach to learn bilingual sentiment-specific word embeddings without any cross-lingual supervision and perform cross-lingual sentiment analysis with minimum resource requirement. We propose an iterative constraint relaxation pro-

Proceedings of NAACL-HLT 2019, pages 420–429
Minneapolis, Minnesota, June 2 - June 7, 2019.

cedure that gradually incorporates the sentiment information into the BWE. Our proposed approach achieves state-of-the-art results.

2. We introduce a novel sentiment-specific objective without having to explicitly build a classifier. Our approach is more explainable and better balances sentimental similarity and semantic similarity compared to previous approaches.

3. We introduce an alignment-specific objective and a simple re-normalization trick. Unlike previous BWE methods that learn orthogonal mappings, we introduce non-orthogonal mappings which enable the transfer of sentiment information from the source language to the target language.

2 Related Work

Cross-Lingual Sentiment Analysis Existing approaches for cross-lingual sentiment analysis can be mainly divided into two categories: (i) approaches that rely on machines translation (MT) systems (ii) approaches that rely on cross-lingual word embeddings.

Standard MT-based approaches perform cross-lingual sentiment analysis by translating the sentiment data into a selected language (e.g. English). More sophisticated algorithms including co-training (Wan, 2009; Demirtas and Pechenizkiy, 2013) and multi-view learning (Xiao and Guo, 2012) have been shown to improve performance.

Zhou et al. (2015, 2016b,a) performed cross-lingual sentiment analysis by learning bilingual document representations. These methods translate each document into the other language and enforce a bilingual constraint between the original document and the translated version.

Bilingual Word Embeddings Word embeddings trained separately on two languages can be aligned in a shared space to produce Bilingual Word Embeddings (BWE), which support many NLP tasks including machine translation (Lample et al., 2017), cross-lingual sentiment analysis (Barnes et al., 2018; Zhou et al., 2015) and cross-lingual dependency parsing (Guo et al., 2015). BWE can be obtained in a supervised way using a seed dictionary (Joulin et al., 2018; Artetxe et al., 2016), or in an unsupervised way without any bilingual data. Adversarial training was the first successful attempt to learn unsupervised BWE (Zhang et al., 2017; Conneau et al., 2017). Self-learning was proposed by (Artetxe et al., 2017)to learn BWE with minimum bilingual resources, which was later extended into a fully unsupervised framework by adding an unsupervised dictionary initialization step (Artetxe et al., 2018).

Multilingual Word Embeddings BWE methods can be extended to the case of multiple languages by simply mapping all the languages to the vector space of a selected language. However, directly learning multilingual word embeddings (MWE) in a shared space has been shown to improve performance (Ammar et al., 2016; Duong et al., 2017; Chen and Cardie, 2018; Alaux et al., 2018). Yet, all these approaches are mainly evaluated on word translation and their effectiveness on cross-lingual sentiment analysis have not been empirically compared.

Sentimental Embeddings Continuous word representations encode the syntactic context of a word but often ignore the information of sentiment polarity. This drawback makes them hard to distinguish words with similar syntactic context but opposite sentiment polarity (e.g. *good* and *bad*), resulting in unsatisfactory performance on sentiment analysis. Tang et al. (2014) learned word representations that encode both syntactic context and sentiment polarity by adding an objective to classify the polarity of an n-gram. This method can be generalized to the cross-lingual setting by training monolingual sentimental embeddings on both languages then aligning them in a common space. However, it requires sentiment resources in the target language thus is impractical for low-resource languages.

There are also approaches to learn sentimental embeddings in the bilingual space without any sentiment resources in the target language. Barnes et al. (2018) jointly minimized an alignment objective based on a seed dictionary, and a classification objective based on the sentiment corpus. Its performance is compared to our method in Section 4. Xu and Wan (2017) learned multilingual sentimental embeddings by extending the BiSkip model (Luong et al., 2015). However, their method does not apply to pretrained embeddings and requires large-scale parallel corpora thus is not included in our experiments.

3 Proposed Method

3.1 The Overall Framework

This subsection first introduces the proposed mappings for aligning the monolingual embeddings in the bilingual space, then describes the general self-learning algorithm used to learn these bilingual mappings. The details of our algorithm are explained in Section 3.2 - Section 3.6.

3.1.1 The Alignment Model

We assume we have normalized monolingual embeddings $\mathbf{S} \in \mathbb{R}^{v \times d}$ and $\mathbf{T} \in \mathbb{R}^{v \times d}$, where the i-th row of $\mathbf{S}$ is the vector representation of word i in the source language. The normalization procedure is as follows: (i) l_2-normalize each vector (ii) center the vectors (iii) l_2-normalize each vector again (Artetxe et al., 2018).

Given these monolingual embeddings, existing BWE methods typically learn a projection matrix $\mathbf{W} \in \mathbb{R}^{d \times d}$ from the source vector space to the target vector space. However, these methods are unsuitable in our setting for two reasons: (i) most methods constrain $\mathbf{W}$ to be orthogonal or near-orthogonal, thus preserving distances between word vectors; (ii) word vectors in the target language space remain unchanged. These two properties prevent us from separating words with opposite sentiment polarity in the bilingual space. In this work, we propose to align the monolingual embeddings with two non-linear mappings:

$$f_s(\mathbf{x}) = \frac{\mathbf{W}_s\mathbf{x}}{\|\mathbf{W}_s\mathbf{x}\|} \qquad f_t(\mathbf{x}) = \frac{\mathbf{W}_t\mathbf{x}}{\|\mathbf{W}_t\mathbf{x}\|}$$

where $\|\cdot\|$ denotes the l_2-norm, $\mathbf{W}_s$ ($\mathbf{W}_t$) is the projection matrix for the source (target) embeddings, and $\mathbf{x}$ is a d-dimension word vector. Each mapping can be seen as a linear projection followed by a re-normalization step.

We propose the following convex domain $\mathcal{D} = \{\mathbf{W} \in \mathbb{R}^{d \times d} \mid \|\mathbf{W}\|_2 \leq r\}$ as an alternative for the orthogonal constraint, where $\|\cdot\|_2$ denotes the spectral norm and r is a hyperparameter that determines to what extent we want to preserve word distances. This is inspired by the unit spectral norm constraint proposed by (Joulin et al., 2018).

3.1.2 The Self-learning Procedure

Given a bilingual seed dictionary, we can learn the projection matrices $\mathbf{W}_s$ and $\mathbf{W}_t$ by forcing the word pairs in the dictionary to have similar representations in the bilingual space. In the unsupervised case, such a dictionary can be induced from the monolingual embeddings $\mathbf{S}$ and $\mathbf{T}$ (Artetxe et al., 2018). However, the quality of this dictionary is usually not good, which in turn degrades the quality of the projection matrices learned from this dictionary. Previous work (Artetxe et al., 2017, 2018) showed that an iterative self-learning procedure can induce a good bilingual dictionary and hence good projection matrices. Given an initial dictionary D_{bi}, this procedure iterates over two steps: (i) it aligns the monolingual embeddings in a common space based on D_{bi}, yielding $\mathbf{S}'$ and $\mathbf{T}'$; (ii) it computes a new dictionary D_{bi} using nearest neighbour retrieval over the approximately aligned embeddings $\mathbf{S}'$ and $\mathbf{T}'$.

In our method, there are three objects $\mathbf{W}_s$, $\mathbf{W}_t$ and D_{bi} to update through the self-learning procedure. Thus we iterates over the following three steps:

1. Solve $\mathbf{W}_s$ by minimizing a sentiment-specific objective $\mathcal{L}_s$ over $\mathcal{D}$, as described in Section 3.3;
2. Solve $\mathbf{W}_t$ by minimizing an alignment-specific objective $\mathcal{L}_t$ over $\mathcal{D}$, as described in Section 3.4;
3. Derive a new bilingual dictionary D_{bi} based on $\mathbf{S}' = \mathbf{S}\mathbf{W}_s^\top$ and $\mathbf{T}' = \mathbf{T}\mathbf{W}_t^\top$, as described in Section 3.5.

Re-normalization is applied as a final step after we have obtained $\mathbf{W}_s$ and $\mathbf{W}_t$.

3.2 Preliminaries

3.2.1 Unsupervised Bilingual Dictionary Initialization

The normalized embeddings $\mathbf{S}$ and $\mathbf{T}$ are not aligned along the first axis, i.e., the i-th row of $\mathbf{S}$ does not correspond to the i-th row of $\mathbf{T}$. Therefore, an initial bilingual dictionary is required in order to access the correspondence between the two languages. Following (Artetxe et al., 2018), we first compute the similarity matrices $\mathbf{M}_s = \sqrt{\mathbf{S}\mathbf{S}^\top}$ and $\mathbf{M}_t = \sqrt{\mathbf{T}\mathbf{T}^\top}$, sort them along the second axis and normalize the rows, yielding $\mathbf{M}'_s$ and $\mathbf{M}'_t$. For each row in $\mathbf{M}'_s$, we apply nearest neighbour retrieval over the rows of $\mathbf{M}'_t$ to find its corresponding translation, yielding a dictionary $D_{s \to t} =$

$\{(1, T_{s\to t}(1)), (2, T_{s\to t}(2)), \ldots, (v, T_{s\to t}(v))\}$, where $T_{s\to t}(i)$ is the translation of the source word i. The same procedure is repeated in the other direction, yielding $D_{t\to s}$. The two dictionaries are then concatenated to produce the initial bilingual dictionary $D_{bi} = D_{s\to t} \cup D_{t\to s}$.

3.2.2 Learning Sentiment-Specific Vectors

In order to incorporate the sentiment information into the bilingual word embeddings, we need a set of d-dimension vectors with known sentiment polarity. We propose a neural network based approach to learn these sentiment-specific vectors. Let the training corpus in the source language be $\mathcal{C} = \{(z_1, y_1), (z_2, y_2), \ldots, (z_{|\mathcal{C}|}, y_{|\mathcal{C}|})\}$, where z_i is a text and y_i is its corresponding label. A d-dimension vector with sentiment polarity y_i can be obtained by calculating the weighted average of the word vectors in z_i:

$$\mathbf{h}_i = \frac{\sum_{j\in z_i} \exp(\alpha_j)\mathbf{S}_{j\cdot}}{\sum_{j\in z_i} \exp(\alpha_j)} \tag{1}$$

where $\mathbf{S}_{j\cdot}$ is the vector representation of the word j in the source language (corresponding to the j-th row of $\mathbf{S}$) and α_j is a scalar that scores the importance of word j on the sentiment polarity. α_j is computed by $\alpha_j = \max(\mathbf{A}\mathbf{S}_{j\cdot} + \mathbf{b})$, where $\mathbf{A} \in \mathbb{R}^{h\times d}$ and $\mathbf{b} \in \mathbb{R}^h$ are the parameters to learn. This function can be seen as a convolution layer with h filters followed by a max pooling layer. The number of filters h is set to 4. Each $\mathbf{h}_i$ is then forwarded to a linear classifier to predict the sentiment label y_i.

Once we have trained the model by minimizing the cross-entropy loss, we re-compute $\mathbf{h}_i$ for each training example z_i. We denote the set of vectors (i.e., $\mathbf{h}_i$) with positive labels as $\mathcal{P} = \{\mathbf{h}^p_1, \mathbf{h}^p_2, \ldots, \mathbf{h}^p_{|\mathcal{P}|}\}$ and the set of vectors with negative labels as $\mathcal{N} = \{\mathbf{h}^n_1, \mathbf{h}^n_2, \ldots, \mathbf{h}^n_{|\mathcal{N}|}\}$. In the 4-class setup, we have four sets: $\mathcal{P}$, $\mathcal{N}$, $\mathcal{SP}$ (the set of strongly positive vectors), $\mathcal{SN}$ (the set of strongly negative vectors).

3.3 Solving $\mathbf{W}_s$

Given a set of positive d-dimension vectors $\mathcal{P} = \{\mathbf{h}^p_1, \mathbf{h}^p_2, \ldots, \mathbf{h}^p_{|\mathcal{P}|}\}$ and a set of negative d-dimension vectors $\mathcal{N} = \{\mathbf{h}^n_1, \mathbf{h}^n_2, \ldots, \mathbf{h}^n_{|\mathcal{N}|}\}$ (or four sets in the 4-class setup), our goal is to distinguish the positive vectors from the negative vectors in the bilingual space, i.e., to separate $\mathbf{W}_s\mathbf{h}^p_i$ from $\mathbf{W}_s\mathbf{h}^n_j$ for any pair of i, j.

We introduce a new d-dimension vector $\mathbf{a}^p \in \mathcal{O} = \{\mathbf{x} \in \mathbb{R}^d \mid \|\mathbf{x}\| \leq 1\}$ to represent the "positive direction", which is to be learned. In order to separate positive vectors from negative vectors in the bilingual space, we try to make $\mathbf{W}_s\mathbf{h}^p_i$ $(i = 1, \ldots, |\mathcal{P}|)$ to be close to $\mathbf{a}^p$ and $\mathbf{W}_s\mathbf{h}^n_i$ $(i = 1, \ldots, |\mathcal{N}|)$ to be distant from $\mathbf{a}^p$.

For a given $\mathbf{a}^p$, we first compute ${\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^p_i$ for $i = 1, 2, \ldots, |\mathcal{P}|$ and denote the set of i with $\lambda|\mathcal{P}|$ smallest values as $\mathcal{Q}^p_+$, where $\lambda \in [0, 1]$ is a hyperparameter[1]. These $\mathbf{W}_s\mathbf{h}^p_i$ are least similar with $\mathbf{a}^p$ (dot product is used as the similarity metric), hence we maximize the average of ${\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^p_i$ over $\mathcal{Q}^p_+$. Likewise, we denote the set of $i \in \{1, 2, \ldots, |\mathcal{N}|\}$ with $\lambda|\mathcal{N}|$ largest values of ${\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^n_i$ as $\mathcal{Q}^p_-$. These $\mathbf{W}_s\mathbf{h}^n_i$ are most similar to $\mathbf{a}^p$, hence we minimize the average of ${\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^n_i$ over $\mathcal{Q}^p_-$. The overall objective is as follows:

$$\begin{aligned}\min_{\substack{\mathbf{W}_s\in\mathcal{D}\\ \mathbf{a}^p\in\mathcal{O}}} \mathcal{L}_s(\mathbf{W}_s, \mathbf{a}^p) &= \mathcal{L}'(\mathbf{W}_s, \mathbf{a}^p, \mathcal{P}, \mathcal{N})\\ &\triangleq -\frac{1}{\lambda|\mathcal{P}|}\sum_{i\in\mathcal{Q}^p_+} {\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^p_i\\ &\quad+\frac{1}{\lambda|\mathcal{N}|}\sum_{i\in\mathcal{Q}^p_-} {\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^n_i\end{aligned} \tag{2}$$

where $\mathcal{D}$ is the convex set defined in Section 3.1.1. The rationale for this objective is that, instead of forcing every $\mathbf{W}_s\mathbf{h}^p_i$ to be close to $\mathbf{a}^p$, we only focus on a fraction of positive vectors that are most distant from $\mathbf{a}^p$, and vice versa for those negative vectors. We observe that this objective can be rewritten as:

$$\begin{aligned}\min_{\substack{\mathbf{W}_s\in\mathcal{D}\\ \mathbf{a}^p\in\mathcal{O}}} &\mathcal{L}_s(\mathbf{W}_s, \mathbf{a}^p)\\ &= \frac{1}{\lambda|\mathcal{P}|}\max_{\mathcal{Q}\in\mathcal{S}_{\lambda|\mathcal{P}|}(|\mathcal{P}|)} -\sum_{i\in\mathcal{Q}} {\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^p_i\\ &\quad+\frac{1}{\lambda|\mathcal{N}|}\max_{\mathcal{Q}\in\mathcal{S}_{\lambda|\mathcal{N}|}(|\mathcal{N}|)}\sum_{i\in\mathcal{Q}} {\mathbf{a}^p}^\top\mathbf{W}_s\mathbf{h}^n_i\end{aligned} \tag{3}$$

where $\mathcal{S}_{\lambda|\mathcal{P}|}(|\mathcal{P}|)$ represents all subsets of $\{1, 2, \ldots, |\mathcal{P}|\}$ of size $\lambda|\mathcal{P}|$, and $\mathcal{S}_{\lambda|\mathcal{N}|}(|\mathcal{N}|)$ is similarly defined. [2] This formulation shows that

---

[1] For simplicity, we assume $\lambda|\mathcal{P}|$ is already rounded to an integer.

[2] There is no need to introduce a new vector $\mathbf{a}^n$ to represent the "negative direction" and introduce a new objective, since the new objective is exactly the same after replacing $\mathbf{a}^p$ with $-\mathbf{a}^n$.

both terms of this objective can be seen as a maximum of linear functions of either $\mathbf{W}_s$ or $\mathbf{a}^p$. Therefore, our objective is convex with respect to either $\mathbf{W}_s$ or $\mathbf{a}^p$, thus can be efficiently minimized by using the projected gradient descent algorithm. We first minimize this objective with respect to $\mathbf{a}^p$ over $\mathcal{O}$, then minimize it with respect to $\mathbf{W}_s$ over $\mathcal{D}$.

While this objective is useful in the binary setup, it does not separate a strongly positive vector in $\mathcal{SP}$ from a weakly positive vector in $\mathcal{P}$ (similarly for $\mathcal{SN}$ and $\mathcal{N}$). In order to achieve better performance in the 4-class setup, we adopt the one-versus-rest strategy to write $\mathcal{L}_s$ as the sum of four terms:

$$\begin{aligned}
&\min_{\substack{\mathbf{W}_s \in \mathcal{D} \\ \mathbf{a}^p \in \mathcal{O} \\ \mathbf{a}^{sp} \in \mathcal{O} \\ \mathbf{a}^n \in \mathcal{O} \\ \mathbf{a}^{sn} \in \mathcal{O}}} \mathcal{L}_s(\mathbf{W}_s, \mathbf{a}^p, \mathbf{a}^{sp}, \mathbf{a}^n, \mathbf{a}^{sn}) \\
&\quad = \mathcal{L}'(\mathbf{W}_s, \mathbf{a}^p, \mathcal{P}, \mathcal{N} \cup \mathcal{SP} \cup \mathcal{SN}) \\
&\quad + \mathcal{L}'(\mathbf{W}_s, \mathbf{a}^{sp}, \mathcal{SP}, \mathcal{P} \cup \mathcal{N} \cup \mathcal{SN}) \\
&\quad + \mathcal{L}'(\mathbf{W}_s, \mathbf{a}^n, \mathcal{N}, \mathcal{P} \cup \mathcal{SP} \cup \mathcal{SN}) \\
&\quad + \mathcal{L}'(\mathbf{W}_s, \mathbf{a}^{sn}, \mathcal{SN}, \mathcal{P} \cup \mathcal{SP} \cup \mathcal{N}) \quad (4)
\end{aligned}$$

where $\mathcal{L}'$ is defined in Eq.(2) and $\mathbf{a}^c$ is a d-dimension vector representing the "direction" of class c.

3.4 Solving $\mathbf{W}_t$

Based on the current bilingual dictionary D_{bi}, we construct two sets of vectors $\{\mathbf{x}_1^s, \mathbf{x}_2^s, \ldots, \mathbf{x}_{2v}^s\}$ and $\{\mathbf{x}_1^t, \mathbf{x}_2^t, \ldots, \mathbf{x}_{2v}^t\}$, where $\mathbf{x}_i^s$ and $\mathbf{x}_i^t$ are the vector representations of the i-th word pair in D_{bi}. With $\mathbf{W}_s$ fixed, we can solve $\mathbf{W}_t$ by minimizing:

$$\min_{\mathbf{W}_t \in \mathcal{D}} \mathcal{L}_t(\mathbf{W}_t) = \sum_{i=1}^{2v} \|\mathbf{W}_s \mathbf{x}_i^s - \mathbf{W}_t \mathbf{x}_i^t\|^2 \quad (5)$$

where $\mathcal{D}$ is the convex set defined in Section 3.1.1. This objective is convex with respect to $\mathbf{W}_t$, thus can be minimized efficiently by using the projected gradient descent algorithm.

3.5 Bilingual Dictionary Induction

Once we have computed $\mathbf{W}_s$ and $\mathbf{W}_t$, we can obtain the aligned embeddings $\mathbf{S}' = \mathbf{S}\mathbf{W}_s^\top$ and $\mathbf{T}' = \mathbf{T}\mathbf{W}_t^\top$. Then we induce a new dictionary D_{bi} using nearest neighbour retrieval over the rows of $\mathbf{S}'$ and $\mathbf{T}'$. We perform the induction in two directions to produce $D_{s \to t}$ and $D_{t \to s}$, then concatenate them to produce D_{bi}.

In this work, we propose a modified version of CSLS(Conneau et al., 2017) to be used as the similarity metric to preform nearest neighbour retrieval:

$$\begin{aligned}
&\mathrm{CSLS}'(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\top \mathbf{y} \\
&\quad - \frac{1}{k} \sum_{\mathbf{y}' \in \mathcal{N}_Y(\mathbf{x})} \mathbf{x}^\top \mathbf{y}' - \frac{1}{k} \sum_{\mathbf{x}' \in \mathcal{N}_X(\mathbf{y})} \mathbf{x}'^\top \mathbf{y} \quad (6)
\end{aligned}$$

where $\mathcal{N}_Y(\mathbf{x})$ is the set of k nearest neighbours of $\mathbf{x}$ in the set of vectors Y (in our case Y is the set of rows of $\mathbf{T}'$). We set k to 10 following the original paper.

3.6 Iterative Constraint Relaxation

As mentioned in Section 3.1.1, we introduce a hyperparameter r to define the convex domain $\mathcal{D}$. There is a trade-off to make for r: a large r better incorporates sentimental similarity but significantly harms the quality of the alignment, while a small r constrains $\mathbf{W}_s$ to be near-orthogonal thus prevents it to capture the sentimental similarity.

In order to address this problem, we propose to first set r to 1, letting the the monolingual embeddings to be properly aligned. Then r is iteratively increased by Δr, causing the positive vectors in the bilingual space to be gradually moved further away from the negative vectors. The training process stops when r reaches a maximum value r_{max}, where r_{max} is a hyperparameter [3].

The pseudo code of UBiSE in the binary setup is shown in Algorithm 1. For the 4-class UBiSE, lines 3,6,7 are replaced by their counterparts in the 4-class setup.

4 Experiments

4.1 Datasets

We use the multilingual sentiment dataset provided by (Barnes et al., 2018). It contains annotated hotel reviews in English (EN), Spanish (ES), Catalan (CA) and Basque (EU). In our experiment, we use EN as the source language and ES, CA, EU as the target languages. For each target language, the dataset is divided into a target development set and a target test set. We also combine the strong and weak labels to produce a binary setup.

---

[3] Although having the number of iterations be implicitly defined by r_{max} and Δr makes choosing a small r_{max} impractical, it allows us to tune r_{max} in a single training process.

Algorithm 1 binary UBiSE

```
Input: $\lambda, r_{max}, \Delta r, \mathbf{S}, \mathbf{T}, \mathcal{C}$
Output: $\mathbf{S}', \mathbf{T}', \mathbf{W}_s, \mathbf{W}_t$

$r \leftarrow 1$
Initialize $\mathbf{W}_s$ and $\mathbf{W}_t$ to identity matrices
Learn $\mathcal{P}, \mathcal{N}$ from $\mathbf{S}$ and $\mathcal{C}$, according to Section 3.2.2
Compute the initial bilingual dictionary $D_{bi}$ from $\mathbf{S}$ and $\mathbf{T}$, according to Section 3.2.1
while $r \leq r_{max}$ do
    $\mathbf{a}^p \leftarrow \mathrm{argmin}_{\mathbf{a}^p \in \mathcal{O}} \mathcal{L}_s(\mathbf{a}^p, \mathbf{W}_s)$
    $\mathbf{W}_s \leftarrow \mathrm{argmin}_{\mathbf{W}_s \in \mathcal{D}} \mathcal{L}_s(\mathbf{a}^p, \mathbf{W}_s)$
    $\mathbf{W}_t \leftarrow \mathrm{argmin}_{\mathbf{W}_t \in \mathcal{D}} \mathcal{L}_t(\mathbf{W}_t)$
    $\mathbf{S}' \leftarrow \mathbf{S}\mathbf{W}_s^\top$
    $\mathbf{T}' \leftarrow \mathbf{T}\mathbf{W}_t^\top$
    Derive a new bilingual dictionary $D_{bi}$ from $\mathbf{S}'$ and $\mathbf{T}'$, according to Section 3.5
    $r \leftarrow r + \Delta r$
end while
Normalize the rows of $\mathbf{S}'$, $\mathbf{T}'$ to unit length
return $\mathbf{S}', \mathbf{T}', \mathbf{W}_s, \mathbf{W}_t$
```

The normalized 300-dimension fastText vectors (Bojanowski et al., 2017) are used by all methods. The MUSE dataset(Conneau et al., 2017) is used by approaches that require bilingual supervision [4]. Each dictionary contains 5000 unique source words.

4.2 Implementation details

We empirically set $\Delta r = 0.01$ and $v = 10000$. The vocabulary of each language is limited to the v most frequent words so that the embedding matrix has shape $v \times d$. Hyper parameters λ and r_{max} are tuned on the target development set via a grid search. We apply stochastic dictionary induction by randomly setting the elements of the similarity matrix used for nearest neighbour retrieval to zero with probability $1 - p$, as described in (Artetxe et al., 2018). p is initialized to 0.1 and increased by 0.005 at each iteration. We empirically stop updating the dictionary when r exceeds 3.

4.3 Baselines

We compare our method with the following baselines, including state-of-the-art BWE methods that are originally evaluated on the word translation task, as well as bilingual sentimental embeddings methods that are optimized for cross-lingual sentiment analysis. The bilingual word embeddings learned by each method are later evaluated on cross-lingual sentiment analysis using the same classifier for fairness.

4.3.1 Unsupervised BWE Methods

ADVERSARIAL Conneau et al. (2017) proposed an unsupervised BWE method based on adversarial training. After a near-orthogonal projection matrix is learned through adversarial training, a refinement procedure is applied to improve the quality of the alignment.

VECMAP Artetxe et al. (2018) proposed an unsupervised BWE learning framework. It consists of an unsupervised dictionary initialization step and the self-learning procedure mentioned in Section 3.1.2.

4.3.2 Supervised BWE Methods

PROCRUSTES Artetxe et al. (2016) proposed a simple and effective supervised BWE method that requires a seed dictionary. It computes the optimal projection matrix by taking singular value decomposition (SVD).

RCSLS Joulin et al. (2018) proposed an supervised BWE method that also requires a seed dictionary. They proposed a training objective that is consistent with the retieval criterion that can be minimized by using gradient descent. It achieves state-of-the-art results on the word translation task.

4.3.3 Bilingual Sentimental Embedding Methods

BLSE Barnes et al. (2018) exploited both bilingual supervision and the sentiment corpus to learn bilingual sentimental embeddings. They jointly minimize an alignment-specific objective and a classification objective to learn the projection matrices. The trade-off between the two objectives is controlled by a hyperparameter $\alpha \in [0, 1]$. We tune α on the target development set as described in the original paper. Once the projection matrices have been learned, the classifier in this model is abandoned. The quality of the resulting BWE is evaluated using the classifier mentioned in Section 4.4.

4.4 Evaluation

We use DAN (Iyyer et al., 2015) as the classifier to preform cross-lingual sentiment analysis. The loss

---

[4] This dataset does not contain a dictionary for EN-EU, thus we translate the EN-ES dictionary into EN-EU

of each instance is weighted by its inverse class frequency to address the class imbalance problem. For each method, the dropout rate is fixed at 0.3 and the l_2-regularization strength is tuned on the target development set[5]. We train five classifiers for each method and report the average macro-F1 on the target test set.

4.5 Results and Analysis

Table 1 presents the results of different BWE methods. UBISE outperforms all unsupervised methods on all six tasks and outperforms all baselines on four out of six tasks.

All methods, especially unsupervised methods, suffer from distant language pairs, which is consistent with the observation of (Søgaard et al., 2018). VECMAP and ADVERSARIAL perform significantly worse on EN-EU compared to supervised methods. Yet, UBISE outperforms the strongest baseline by 2.1% on EN-EU, indicating that incorporating sentiment is vital for cross-lingual sentiment analysis on distant languages.

Despite the similar performance across different BWE methods in the binary setup, UBISE outperform all baselines in the 4-class setup by a large margin (average of $+2.2\%$). This may indicate that the original monolingual embeddings are able to distinguish positive words from negative words(e.g., *good* and *bad*), but bad at distinguishing strongly positive words from weakly positive words (e.g., *good* and *perfect*).

The performance of BLSE is merely comparative with other baselines.[6] We suspect that this is due to the classifier we use to perform cross-lingual sentiment analysis. The original paper used SVM or logistic regression to perform classification, in which case BLSE achieved better performance due to the utilization of sentiment information. But if we use a deeper neural network to perform cross-lingual sentiment analysis, preserving the original semantic similarity is more important. A qualitative comparison between BLSE and UBISE is presented in Section 4.8.

4.6 Effect of the Sentiment Information

We perform an ablation test to demonstrate the effect of the sentiment information provided by $\mathcal{L}_s$. We create a new model UBISE_MIN that does not utilize the sentiment information by eliminating lines 6,7,12 in Algorithm 1. UBISE_MIN runs 500 iterations for every language pairs.

The comparative results in Table 2 show that utilizing the sentiment information leads to an average improvement of $+3.1\%$ in the binary setup or $+4.1\%$ in the 4-class setup.

4.7 Effect of Re-Normalization

Re-normalization is useful in the sense that it leads to better alignment by constraining all the bilingual vectors to be on the unit sphere. While this property does not matter for word translation as long as cosine-similarity is used as the retrieval criterion, it matters for cross-lingual sentiment analysis. Another effect of re-normalization is that it introduces non-linearity between the linear projection and the classifier, which is vital for separating words with opposite sentiment polarity. Without non-linearity the linear projection and the first layer of the classifier would collapse into a single linear projection, thus eliminating the effect of $\mathbf{W}_s$. Figure 2 illustrates how this non-linearity helps separating positive words from negative words in the bilingual space. This effect is demonstrated in Section 4.8.

4.8 Visualization of the Bilingual Space

To illustrate how UBISE transfers sentiment information from the source language to the target language, we visualize six categories of words in the bilingual space of UBISE and BLSE using t-SNE (Maaten and Hinton, 2008). As shown in Figure 1, both methods manage to separate positive words from negative words without any annotated data in Spanish. However, Barnes et al. (2018) abandon the original semantic similarity, which degrades its performance as shown in Section 4.5. In contrast, our method preserves semantic similarity by limiting the largest singular values of $\mathbf{W}_s$ and $\mathbf{W}_t$ to be smaller than r_{max}. The trade-off between semantic similarity and sentimental similarity is made by choosing an appropriate r_{max}.

5 Conclusion

This paper presents a method to learn bilingual sentiment-specific word embeddings without any cross-lingual supervision. We propose a novel sentiment-specific objective that separates words

---

[5] The optimal regularization strength depends on the BWE method. Stronger regularization is favourable to BLSE and UBISE.

[6] We already obtain significantly better results after replacing the original classifier with DAN, compared with the original reported results.

with opposite sentiment polarity in the bilingual space, and an alignment objective that enables the transfer of sentiment information from the source language to the target language. An iterative constraint relaxation procedure is applied to gradually incorporate the sentiment information into the bilingual word embeddings. We empirically evaluate our method on three language pairs for cross-lingual sentiment analysis and demonstrate its effectiveness. Experimental results show that incorporating sentiment information significantly improves the performance on fine-grained cross-lingual sentiment analysis.

Abstract

Regularization of neural machine translation is still a significant problem, especially in low-resource settings. To mollify this problem, we propose regressing word embeddings (ReWE) as a new regularization technique in a system that is jointly trained to predict the next word in the translation (categorical value) and its word embedding (continuous value). Such a joint training allows the proposed system to learn the distributional properties represented by the word embeddings, empirically improving the generalization to unseen sentences. Experiments over three translation datasets have showed a consistent improvement over a strong baseline, ranging between 0.91 and 2.54 BLEU points, and also a marked improvement over a state-of-the-art system.

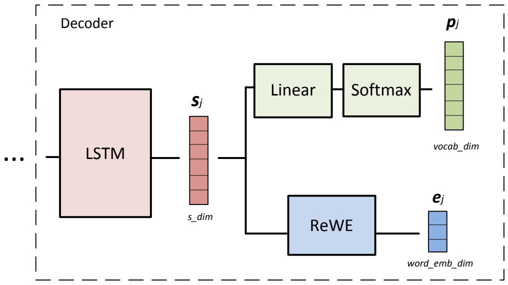

Figure 1: The proposed regularizer: the hidden vector in the decoder, s_j, transits through two paths: 1) a linear and a softmax layers that output vector v_j (vocab_dim) which is used for predicting the target word as usual, and 2) a two-layer network (ReWE) that outputs a vector, e_j, of word embedding size (word_emb_dim). During training, e_j is used in a regressive loss with the ground-truth embedding.

1 Introduction

The last few years have witnessed remarkable improvements in the performance of machine translation (MT) systems. These improvements are strongly linked to the development of neural machine translation (NMT): based on encoder-decoder architectures (also known as seq2seq), NMT can use recurrent neural networks (RNNs) (Sutskever et al., 2014; Cho et al., 2014; Wu et al., 2016), convolutional neural networks (CNNs) (Gehring et al., 2017) or transformers (Vaswani et al., 2017) to learn how to map a sentence from the source language to an adequate translation in the target language. In addition, attention mechanisms (Bahdanau et al., 2015; Luong et al., 2015) help soft-align the encoded source words with the predictions, further improving the translation.

NMT systems are usually trained via maximum likelihood estimation (MLE). However, as pointed out by (Elbayad et al., 2018), MLE suffers from two obvious limitations: the first is that it treats all the predictions other than the ground truth as equally incorrect. As a consequence, synonyms and semantically-similar words — which are often regarded as highly interchangeable with the ground truth — are completely ignored during training. The second limitation is that MLE-trained systems suffer from "exposure bias" (Bengio et al., 2015; Ranzato et al., 2015) and do not generalize well over the large output space of translations. Owing to these limitations, NMT systems still struggle to outperform other traditional MT approaches when the amount of supervised data is limited (Koehn and Knowles, 2017).

In this paper, we propose a novel regularization technique for NMT aimed to influence model learning with contextual properties. The technique — nicknamed ReWE from "regressing word embedding" — consists of modifying a conventional seq2seq decoder to jointly learn to a) predict the next word in the translation (categorical value), as

---

Minneapolis, Minnesota, June 2 - June 7, 2019.

usual, and b) regress its word embedding (numerical value). Figure 1 shows the modified decoder. Both predictions are incorporated in the training objective, combining standard MLE with a continuous loss function based on word embeddings. The rationale is to encourage the system to learn to co-predict the next word together with its context (by means of the word embedding representation), in the hope of achieving improved generalization. At inference time, the system operates as a standard NMT system, retaining the categorical prediction and ignoring the predicted embedding. We qualify our proposal as a regularization technique since, like any other regularizers, it only aims to influence the model's training, while leaving the inference unchanged. We have evaluated the proposed system over three translation datasets of different size, namely English-French (en-fr), Czech-English (cs-en), and Basque-English (eu-en). In each case, ReWE has significantly outperformed its baseline, with a marked improvement of up to 2.54 BLEU points for eu-en, and consistently outperformed a state-of-the-art system (Denkowski and Neubig, 2017).

2 Related work

A substantial literature has been devoted to improving the generalization of NMT systems. Fadaee et al. (2017) have proposed a data augmentation approach for low-resource settings that generates synthetic sentence pairs by replacing words in the original training sentences with rare words. Kudo (2018) has trained an NMT model with different subword segmentations to enhance its robustness, achieving consistent improvements over low-resource and out-of-domain settings. Zhang et al. (2018) have presented a novel regularization method that encourages target-bidirectional agreement. Other work has proposed improvements over the use of a single ground truth for training: Ma et al. (2018) have augmented the conventional seq2seq model with a bag-of-words loss under the assumption that the space of correct translations share similar bag-of-words vectors, achieving promising results on a Chinese-English translation dataset; Elbayad et al. (2018) have used sentence-level and token-level reward distributions to "smooth" the single ground truth. Chousa et al. (2018) have similarly leveraged a token-level smoother.

In a recent paper, Denkowski and Neubig (2017) have achieved state-of-the-art translation accuracy by leveraging a variety of techniques which include: dropout (Srivastava et al., 2014), lexicon bias (Arthur et al., 2016), pre-translation (Niehues et al., 2016), data bootstrapping (Chen et al., 2016), byte-pair encoding (Sennrich et al., 2016) and ensembles of independent models (Rokach, 2010).

However, to our knowledge none of the mentioned approaches have explicitly attempted to leverage the embeddings of the ground-truth tokens as targets. For this reason, in this paper we explore regressing toward pre-trained word embeddings as an attempt to capture contextual properties and achieve improved model regularization.

3 Model

3.1 Seq2seq baseline

The model is a standard NMT model with attention in which we use RNNs for the encoder and decoder. Following the notation of (Bahdanau et al., 2015), the RNN in the decoder generates a sequence of hidden vectors, $\{\mathbf{s}_1, \ldots, \mathbf{s}_m\}$, given the context vector, the previous hidden state $\mathbf{s}_{j-1}$ and the previous predicted word $\mathbf{y}_{j-1}$:

$$\mathbf{s}_j = dec_{rnn}(\mathbf{s}_{j-1}, \mathbf{y}_{j-1}, \mathbf{c}_j) \quad j = 1, \ldots, m \quad (1)$$

where y_0 and s_0 are initializations for the state and label chains. Each hidden vector $\mathbf{s}_j$ (of parameter size S) is then linearly transformed into a vector of vocabulary size, V, and a softmax layer converts it into a vector of probabilities (Eq. 2), where W (a matrix of size $V \times S$) and b (a vector of size $V \times 1$) are learnable parameters. The predicted conditional probability distribution over the words in the target vocabulary, $\mathbf{p}_j$, is given as:

$$\mathbf{p}_j = softmax(\mathbf{W}\mathbf{s}_j + \mathbf{b}) \quad (2)$$

As usual, training attempts to minimize the negative log-likelihood (NLL), defined as:

$$NLL_{loss} = -\sum_{j=1}^{m} \log(\mathbf{p}_j(\mathbf{y}_j)) \quad (3)$$

where $\mathbf{p}_j(\mathbf{y}_j)$ notes the probability of ground-truth word $\mathbf{y}_j$. The NLL loss is minimized when the probability of the ground truth is one and that of all other words is zero, treating all predictions different from the ground truth as equally incorrect.

3.2 ReWE

Pre-trained word embeddings (Pennington et al., 2014; Bojanowski et al., 2017; Mikolov et al., 2013) capture the contextual similarities of words, typically by maximizing the probability of word w_{t+k} to occur in the context of center word w_t. This probability can be expressed as:

$$\begin{gathered} p(w_{t+k}|w_t), \quad -c \leq k \leq c, k \neq 0 \\ t = 1, \ldots, T \end{gathered} \tag{4}$$

where c is the size of the context and T is the total number of words in the training set. Traditionally, word embeddings have only been used as input representations. In this paper, we instead propose using them in output as part of the training objective, in the hope of achieving regularization and improving prediction accuracy. Building upon the baseline model presented in Section 3.1, we have designed a new "joint learning" setting: our decoder still predicts the probability distribution over the vocabulary, $\mathbf{p}_j$ (Eq. 2), while simultaneously regressing the same shared $\mathbf{s}_j$ to the ground-truth word embedding, $e(\mathbf{y}_j)$. The ReWE module consists of two linear layers with a Rectified Linear Unit (ReLU) in between, outputting a vector $\mathbf{e}_j$ of word embedding size (Eq. 5). Please note that adding this extra module adds negligible computational costs and training time. Full details of this module are given in the supplementary material.

$$\begin{aligned} \mathbf{e}_j &= ReWE(\mathbf{s}_j) \\ &= \mathbf{W}_2(ReLU(\mathbf{W}_1\mathbf{s}_j + \mathbf{b}_1)) + \mathbf{b}_2 \end{aligned} \tag{5}$$

The training objective is a numerical loss, l (Eq. 6), computed between the output vector, $\mathbf{e}_j$, and the ground-truth embedding, $e(\mathbf{y}_j)$:

$$ReWE_{loss} = l(\mathbf{e}_j, e(\mathbf{y}_j)) \tag{6}$$

In the experiment, we have explored two cases for the $ReWE_{loss}$: the minimum square error (MSE)[1] and the cosine embedding loss (CEL)[2]. Finally, the NLL_{loss} and the $ReWE_{loss}$ are combined to form the training objective using a positive trade-off coefficient, λ:

$$Loss = NLL_{loss} + \lambda ReWE_{loss} \tag{7}$$

As mentioned in the Introduction, at inference time we ignore the ReWE output, $\mathbf{e}_j$, and the model operates as a standard NMT system.

4 Experiments

We have developed our models building upon the OpenNMT toolkit (Klein et al., 2017)[3]. For training, we have used the same settings as (Denkowski and Neubig, 2017). We have also explored the use of sub-word units learned with byte pair encoding (BPE) (Sennrich et al., 2016). All the preprocessing steps, hyperparameter values and training parameters are described in detail in the supplementary material to ease reproducibility of our results.

We have evaluated these systems over three publicly-available datasets from the 2016 ACL Conference on Machine Translation (WMT16)[4] and the 2016 International Workshop on Spoken Language Translation (IWSLT16)[5]. Table 1 lists the datasets and their main features. Despite having nearly 90,000 parallel sentences, the eu-en dataset only contains 2,000 human-translated sentences; the others are translations of Wikipedia page titles and localization files. Therefore, we regard the eu-en dataset as very low-resource.

In addition to the seq2seq baseline, we have compared our results with those recently reported by Denkowski and Neubig for non-ensemble models (2017). For all models, we report the BLEU scores (Papineni et al., 2002), with the addition of selected comparative examples. Two contrastive experiments are also added in supplementary notes.

4.1 Results

As a preliminary experiment, we have carried out a sensitivity analysis to determine the optimal value of the trade-off coefficient, λ (Eq. 6), using the en-fr validation set. The results are shown in Figure 2, where each point is the average of three runs trained with different seeds. The figure shows that

Baseline + ReWE:	Select the Control Panel → Default Program , and change it .

Table 3: Translation example from the eu-en test set.

the MSE loss has outperformed slightly the baseline for small values of λ (< 1), but the BLEU score has dropped drastically for larger values. Conversely, the CEL loss has increased steadily with λ, reaching 38.23 BLEU points for $\lambda = 20$, with a marked improvement of 1.53 points over the baseline. This result has been encouraging and therefore for the rest of the experiments we have used CEL as the $ReWE_{loss}$ and kept the value of λ to 20. In Section 4.3, we further discuss the behavior of CEL and MSE.

Table 2 reports the results of the main experiment for all datasets. The values of our experiments are for blind runs over the test sets, averaged over 10 independent runs with different seeds. The results show that adding ReWE has significantly improved the baseline in all cases, with an average of 1.46 BLEU points. In the case of the eu-en dataset, the improvement has reached 2.54 BLEU points. We have also run unpaired t-tests between our baseline and ReWE, and the differences have proved statistically significant (p-values < 0.05) in all cases. Using BPE has proved beneficial for the cs-en and eu-en pairs, but not for the en-fr pair. We speculate that English and French may be closer to each other at word level and, therefore, less likely to benefit from the use of sub-word units. Conversely, Czech and Basque are morphologically very rich, justifying the improvements with BPE.

Table 2 also shows that our model has outperformed almost all the state-of-the-art results reported in (Denkowski and Neubig, 2017) (dropout, lexicon bias, pre-translation, and bootstrapping), with the only exception of the pre-translation case for the cs-en pair with BPE. This shows that the proposed model is competitive with contemporary NMT techniques.

4.2 Qualitative comparison

To further explore the improvements obtained with ReWE, we have qualitatively compared several translations provided by the baseline and the baseline + ReWE (CEL), trained with identical seeds. Overall, we have noted a number of instances where ReWE has provided translations with more information from the source (higher adequacy). For reasons of space, we report only one example in Table 3, but more examples are available in the supplementary material. In the example, the baseline has chosen a generic word, “program”, while ReWE has been capable of correctly predicting “Default Program” and being specific about the object, “it”.

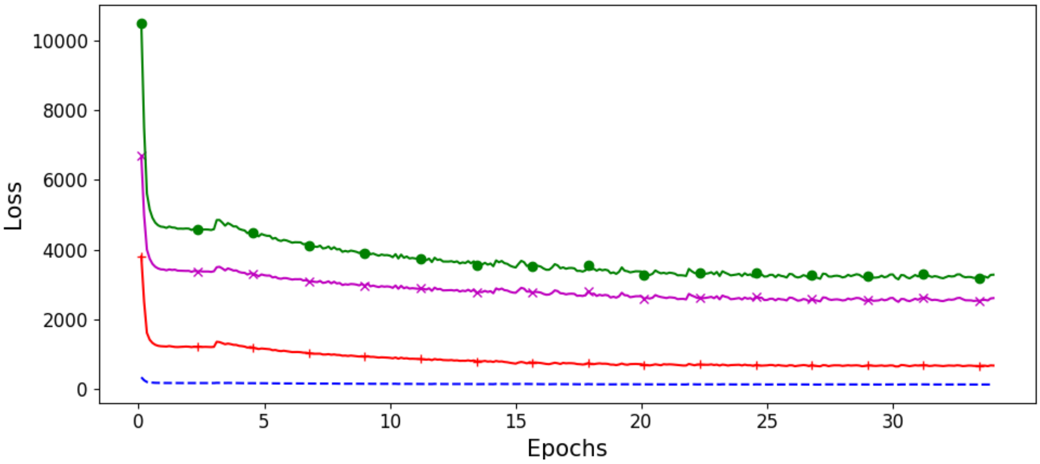

Figure 3: Plot of the values of various loss functions during training of our model over the en-fr training set: green, ●: training loss (NLL + ($\lambda = 20$) ReWE (CEL); Eq.7); red, +: NLL loss; blue, dashed: ReWE (CEL) loss; magenta, ×: ReWE (CEL) loss scaled by $\lambda = 20$. Each point in the graph is an average value of the corresponding loss over 25,000 sentences.

4.3 Discussion

To further explore the behaviour of the ReWE loss, Figure 3 plots the values of the NLL and ReWE (CEL) losses during training of our model over the en-fr training set. The natural values of the ReWE (CEL) loss (blue, dashed) are much lower than those of the NLL loss (red, +), and thus its contribution to the gradient is likely to be limited. However, when scaled up by a factor of $\lambda = 20$ (magenta, ×), its influence on the gradient becomes more marked. Empirically, both the NLL and ReWE (CEL) losses decrease as the training progresses and the total loss (green, ●) decreases. As shown in the results, this combined training objective has been able to lead to improved translation results.

Conversely, the MSE loss has not exhibited a similarly smooth behaviour (supplementary material). Even when brought to scale with the NLL loss, it shows much larger fluctuations as the training progresses. In particular, it shows major increases at the re-starts of the optimizer for the simulated annealing that are not compensated for by the rest of the training. It is easy to speculate that the MSE loss is much more sensitive than the cosine distance to the changes in the weights caused by dropout and the re-starts. As such, it seems less suited for use as training objective.

5 Conclusion

In this paper, we have proposed a new regularization technique for NMT (ReWE) based on a joint learning setting in which a seq2seq model simultaneously learns to a) predict the next word in the translation and b) regress toward its word embedding. The results over three parallel corpora have shown that ReWE has consistently improved over both its baseline and recent state-of-the-art results from the literature. As future work, we plan to extend our experiments to better understand the potential of the proposed regularizer, in particular for unsupervised NMT (Artetxe et al., 2018; Lample et al., 2018).

Acknowledgments

We would like to acknowledge the financial support received from the Capital Markets Cooperative Research Centre (CMCRC), an industry-led research initiative of the Australian Government. We would also like to thank Ben Hachey, Michael Nolan and Nadia Shnier for their careful reading of our paper and their insightful comments. Finally, we are grateful to the anonymous reviewers for all their comments and suggestions.

Lost in Machine Translation: A Method to Reduce Meaning Loss

Reuben Cohn-Gordon

reubencg@stanford.edu

Noah D. Goodman
Stanford
ngoodman@stanford.edu

Abstract

A desideratum of high-quality translation systems is that they preserve meaning, in the sense that two sentences with different meanings should not translate to one and the same sentence in another language. However, state-of-the-art systems often fail in this regard, particularly in cases where the source and target languages partition the "meaning space" in different ways. For instance, "I cut my finger." and "I cut my finger off." describe different states of the world but are translated to French (by both *Fairseq* and *Google Translate*) as "Je me suis coupé le doigt.", which is ambiguous as to whether the finger is detached. More generally, translation systems are typically many-to-one (non-injective) functions from source to target language, which in many cases results in important distinctions in meaning being lost in translation. Building on Bayesian models of informative utterance production, we present a method to define a less ambiguous translation system in terms of an underlying pre-trained neural sequence-to-sequence model. This method increases injectivity, resulting in greater preservation of meaning as measured by improvement in cycle-consistency, without impeding translation quality (measured by BLEU score).

1 Many-to-One Translations

Languages differ in what meaning distinctions they must mark explicitly. As such, translations risk mapping from a form in one language to a more ambiguous form in another. For example, the definite (1) and indefinite (2) both translate (under *Fairseq* and *Google Translate*) to (3) in French, which is ambiguous in definiteness.

The animals run fast. (1)

Animals run fast. (2)

Les animaux courent vite (3)

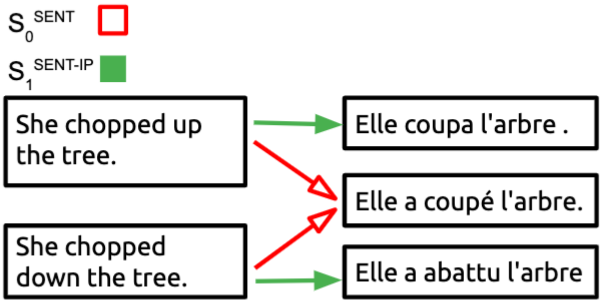

Figure 1: State-of-the-art neural image captioner S_0^{SNT} loses a meaning distinction which *informative* model $S_1^{\text{SNT-IP}}$ preserves.

Survey To evaluate the nature of this problem, we explored a corpus[1] of 500 pairs of distinct English sentences which map to a single German one (the evaluation language in section 2.3). We identify a number of common causes for the many-to-one maps. Two frequent types of verbal distinction lost when translating to German are tense (54 pairs, e.g. "...others {were, have been} introduced .") and modality (16 pairs, e.g. "...prospects for this year {*could*, *might*} be better."), where German "können" can express both epistemic and ability modality, distinguished in English with "might" and "could" respectively. Owing to English's large vocabulary, lexical difference in verb (31 pairs, e.g. "arise" vs. "emerge"), noun (56 pairs, e.g. "mystery" vs. "secret"), adjective (47 pairs, e.g. "unaffected" vs. "untouched") or deictic/pronoun (32 pairs, usually "this" vs "that") are also common. A large number of the pairs differ instead either orthographically, or in other ways that do not correspond to a clear semantic distinc-

---

[1] Generated by selecting short sentences from the Brown corpus (Kučera and Francis, 1967), translating them to German, and taking the best two candidate translations back into English, if these two themselves translate to a single German sentence. Translation in both directions was done with Fairseq.

Proceedings of NAACL-HLT 2019, pages 437–441
Minneapolis, Minnesota, June 2 - June 7, 2019.

A	He is wearing glasses.
B	He wears glasses.
$S_0^{\text{SNT}}(A)$	Er trägt eine Brille.
$S_0^{\text{SNT}}(B)$	Er trägt eine Brille .
$S_1^{\text{SNT-IP}}(A)$	Er trägt jetzt eine Brille.
$S_1^{\text{SNT-IP}}(B)$	Er hat eine Brille.

Figure 2: Similar to Figure 1, S_0^{SNT} collapses two English sentences into a single German one, whereas $S_1^{\text{SNT-IP}}$ distinguishes the two in German.

tion (e.g. "She had {*taken*, *made*} a decision.").

Our approach While languages differ in what distinctions they are *required* to express, all are usually capable of expressing any given distinction when desired. As such, meaning loss of the kind discussed above is, in theory, avoidable. To this end, we propose a method to reduce meaning loss by applying the Rational Speech Acts (RSA) model of an informative speaker to translation. RSA has been used to model natural language *pragmatics* (Goodman and Frank, 2016), and recent work has shown its applicability to image captioning (Andreas and Klein, 2016; Vedantam et al., 2017; Mao et al., 2016), another sequence-generation NLP task. Here we use RSA to define a translator which reduces many-to-one mappings and consequently meaning loss, in terms of a pretrained neural translation model. We introduce a strategy for performing inference efficiently with this model in the setting of translation, and show gains in *cycle-consistency*[2] as a result. Moreover, we obtain improvements in translation quality (BLEU score), demonstrating that the goal of meaning preservation directly yields improved translations.

2 Meaning Preservation as Informativity

In the RSA framework, speakers and listeners, modeled as Bayesian agents, reason about each other in a nested fashion. We refer to listeners and speakers which do not reason about another agent as L_0 and S_0 respectively, and an agent which reasons about another agent as L_1 or S_1. For instance, an informative speaker model S_1 is given a state $w \in W$, and chooses an utterance $u \in U$ to convey w to S_1's model of a listener. By contrast, S_0 chooses utterances without a listener model in mind — its behavior might be determined by a semantics, or in our case, by a pretrained neural model.

For translation, the state space W is a set of source language sentences (sequences of words in the language), while U is a set of target language sentences. S_1's goal is to choose a translation u which allows a listener to pick out the source sentence w from among the set of distractors. This informative behavior discourages many-to-one maps that a non-informative translation model S_0 might allow.

$\mathbf{S_0}$ Model BiLSTMs with attention (Bahdanau et al., 2014), and more recently CNNs (Gehring et al., 2016) and entirely attention based models (Vaswani et al., 2017) constitute the state-of-the-art architectures in neural machine translation . All of these systems, once trained end-to-end on aligned data, can be viewed as a conditional distribution[3] $S_0^{\text{WD}}(wd|w, c)$, for a word *wd* in the target language, a source language sentence w, and a partial sentence c in the target language. S_0^{WD} yields a distribution S_0^{SNT} over full sentences[4]:

$$S_0^{\text{SNT}}(u|w, c) = \prod_t S_0^{\text{WD}}(u[t]|w, c + u[: t]) \quad (4)$$

S_0^{SNT} returns a distribution over continuations of c into full target language sentences[5]. To obtain a sentence from S_0^{SNT} given a source language sentence s, one can greedily choose the highest probability word from S_0^{WD} at each timestep, or explore a beam of possible candidates. We implement S_0^{WD} (in terms of which all our other models are defined) using *Fairseq*'s publicly available[6] pretrained Transformer models for English-German, and for German-English train a CNN using *Fairseq*.

2.1 Explicit Distractors

We first describe a sentence level, *globally pragmatic* model $S_1^{\text{SNT-GP}}$ for the simple case where

---

[2] Formally, say that a pair of functions $f : A \to B$, $g : B \to A$ is cycle-consistent if $g \cdot f = id$, the identity function. If f is *not* one-to-one, then (f, g) is not cycle-consistent. (Note however that when A and B are infinite, the converse does not hold: even if f and g are both one-to-one, (f, g) need not be cycle-consistent, since many-to-one maps between infinite sets are not necessarily bijective.)

[3] We use $S_{0/1}^{WD}$ and $S_{0/1}^{SNT}$ respectively to distinguish word and sentence level speaker models

[4] Python list indexing conventions are used, "+" means concatenation of list to element or list

[5] In what follows, we omit c when it is empty, so that $S_0^{\text{SNT}}(u|w)$ is the probability of sentence u given w

[6] `https://github.com/pytorch/fairseq`

a source language sentence needs to be distinguished from a presupplied distractor[7] (as in the pairs shown in figures (2) and (1)). We use this model as a stepping stone to one which requires an input sentence in the source language only, and no distractors. We begin by defining a listener L_1^{SNT}, which receives a target language sentence u and infers which sentence $w \in W$ (a presupplied set such as the pair (1) and (2)) would have resulted in the pretrained neural model S_0^{SNT} producing u:

$$L_1^{\text{SNT}}(w|u) \propto \frac{S_0^{\text{SNT}}(u|w)}{\sum_{w' \in W} S_0^{\text{SNT}}(u|w')} \tag{5}$$

This allows $S_1^{\text{SNT-GP}}$ to be defined in terms of L_1^{SNT}, where U is the set of all possible target language sentences[8]:

$$S_1^{\text{SNT-GP}}(u|w) = \frac{S_0^{\text{SNT}}(u|w) L_1^{\text{SNT}}(w|u)^{\alpha}}{\sum_{u' \in U} S_0^{\text{SNT}}(u'|w) L_1^{\text{SNT}}(w|u')^{\alpha}} \tag{6}$$

The key property of this model is that, for $W = \{A, B\}$, when translating A, $S_1^{\text{SNT-GP}}$ prefers translations of A that are unlikely to be good translations of B. So for pairs like (1) and (2), $S_1^{\text{SNT-GP}}$ is compelled to produce a translation for the former that reflects its difference from the latter, and vice versa.

Inference Since U is an infinite set, exactly computing the most probable utterance under $S_1^{\text{SNT-GP}}(\cdot|w)$ is intractable. Andreas and Klein (2016) and Mao et al. (2016) perform approximate inference by sampling the subset of U produced by a beam search from S_0^{SNT}. Vedantam et al. (2017) and Cohn-Gordon et al. (2018) employ a different method, using an *incremental* model $S_1^{\text{SNT-IP}}$ as an approximation of $S_1^{\text{SNT-GP}}$ on which inference can be tractably performed.

$S_1^{\text{SNT-IP}}$ considers informativity not over the whole set of utterances, but instead at each decision of the next word in the target language sentence. For this reason, the incremental method avoids the problem of lack of beam diversity encountered when subsampling from S_0^{SNT}, which becomes especially bad when producing long sequences, as is often the case in translation. $S_1^{\text{SNT-IP}}$ is defined as the product of informative decisions, specified by S_1^{WD} (itself defined in terms of L_1^{WD}), which are defined analogously to (6) and (5).

$$L_1^{\text{WD}}(w|wd, c) \propto S_0^{\text{WD}}(wd|w, c) \tag{7}$$

$$S_1^{\text{WD}}(wd|w, c) \propto S_0^{\text{WD}}(wd|w, c) * L_1^{\text{WD}}(w|wd, c)^{\alpha} \tag{8}$$

$$S_1^{\text{SNT-IP}}(u|w, c) = \prod_t S_1^{\text{WD}}(u[t]|w, c + u[:t]) \tag{9}$$

Examples $S_1^{\text{SNT-IP}}$ is able to avoid many-to-one mappings by choosing more informative translations. For instance, its translation of (1) is "Ces animaux courent vite" (*These* animals run fast.). See figures (1) and (2) for other examples of many-to-one mappings under S_0^{SNT} avoided by $S_1^{\text{SNT-IP}}$.

2.2 Avoiding Explicit Distractors

While $S_1^{\text{SNT-IP}}$ can disambiguate between pairs of sentences, it has two shortcomings. First, it requires one (or more) distractors to be provided, so translation is no longer fully automatic. Second, because the distractor set W consists of only a pair (or finite set) of sentences, $S_1^{\text{SNT-IP}}$ only cares about being informative up to the goal of distinguishing between these sentences. Intuitively, total meaning preservation is achieved by a translation which distinguishes the source sentence w from every other sentence in the source language which differs in meaning.

Both of these problems can be addressed by introducing a new "cyclic" globally pragmatic model $S_1^{\text{SNT-CGP}}$ which reasons not about L_1^{SNT} but about a pretrained translation model from target language to source language, which we term L_0^{SNT}.

$$S_1^{\text{SNT-CGP}}(u|w) \propto S_0^{\text{SNT}}(u|w) L_0^{\text{SNT}}(w|u)^{\alpha} \tag{10}$$

$S_1^{\text{SNT-CGP}}$ is like $S_1^{\text{SNT-GP}}$, but its goal is to produce a translation which allows a listener model (now L_0^{SNT}) to infer the original sentence, not among a small set of presupplied possibilities, but among *all source language sentences*. As such, an optimal translation u of w under $S_1^{\text{SNT-CGP}}$ has high probability of being generated by S_0^{SNT} and

---

[7] Implementations for all models are available to `https://github.com/reubenharry/pragmatic-translation`

[8] α is a hyperparameter of $S_1^{\text{SNT-GP}}$; as it increases, the model cares more about being informative and less about producing a reasonable translation.

high probability of being back-translated to w by L_0^{SNT}. $S_1^{\text{SNT-CGP}}$ is very closely related to reconstruction methods, e.g. (Tu et al., 2017).

Incremental Model Exact inference is again intractable, though as with $S_1^{\text{SNT-GP}}$, it is possible to approximate by subsampling from S_0^{SNT}. This is very close to the approach taken by (Li et al., 2016), who find that reranking a set of outputs by probability of recovering input "dramatically decreases the rate of dull and generic responses." in a question-answering task. However, because the subsample is small relative to U, they use this method in conjunction with a diversity increasing decoding algorithm.

As in the case with explicit distractors, we instead opt for an incremental model, now $S_1^{\text{SNT-CIP}}$ which approximates $S_1^{\text{SNT-CGP}}$. The definition of $S_1^{\text{SNT-CIP}}$ (12) is more complex than the incremental model with explicit distractors ($S_1^{\text{SNT-IP}}$) since L_0^{WD} must receive complete sentences, rather than partial ones like L_1^{WD}. As such, we need to marginalize over continuations k of partial sentences in the target language:

$$S_1^{\text{WD-C}}(wd|w,c) \propto S_0^{\text{WD}}(wd|w,c)* \\ \sum_k (L_0^{\text{SNT}}(w|c+wd+k) S_0^{\text{SNT}}(k|w,c+wd)) \tag{11}$$

$$S_1^{\text{SNT-CIP}}(u|w,c) = \prod_t S_1^{\text{WD-C}}(u[t]|w,c+u[:t]) \tag{12}$$

Since the sum over continuations of c in (11) is intractable to compute exactly, we approximate it by a single continuation, obtained by greedily unrolling S_0^{SNT}. The whole process of generating a new word wd of the translation from a sequence c and a source language sentence w is as follows: first use S_0^{WD} to generate a set of candidates for the next word (in practice, we only consider two, for efficiency). For each of these, use S_0^{SNT} to greedily unroll a full target language sentence from $c+wd$, namely $c+wd+k$, and rank each wd by the probability $L_0^{\text{SNT}}(w|c+wd+k)$.

2.3 Evaluating the Informative Translator

Our objective is to improve meaning preservation without detracting from translation quality in other regards (e.g. grammaticality). We conduct our evaluations on English to German translation, making use of publicly available pre-trained English-German and German-English Fairseq models. The pragmatic model we evaluate is $S_1^{\text{SNT-CIP}}$ since, unlike $S_1^{\text{SNT-IP}}$, it is not necessary to hand-supply a distractor set of source language sentences.

An example of the behavior of $S_1^{\text{SNT-CIP}}$ and S_0^{SNT} on of our test sentences is shown below; S_0^{SNT} is able to preserve the phrase "world's eyes", which S_0^{SNT} translates merely as "world":

- Source sentence: Isolation keeps the world's eyes off Papua.
- Reference translation: Isolation hält die Augen der Welt fern von Papua.
- S_0^{SNT}: Die Isolation hält die Welt von Papua fern.
- $S_1^{\text{SNT-CIP}}$: Die Isolation hält die Augen der Welt von Papua fern.

We use cycle-consistency as a measure of meaning preservation, since the ability to recover the original sentence requires meaning distinctions not to be collapsed. In evaluating cycle-consistency, it is important to use a separate target-source translation mechanism than the one used to define $S_1^{\text{SNT-CIP}}$. Otherwise, the system has access to the model which evaluates it and may improve cycle-consistency without producing meaningful target language sentences. For this reason, we translate German sentences (produced by S_0^{SNT} or $S_1^{\text{SNT-CIP}}$) back to English with *Google Translate*. To measure cycle-consistency, we use the BLEU metric (implemented with sacreBLEU (Post, 2018)), with the original sentence as the reference.

However, this improvement of cycle consistency, especially with a high value of α, may come at the cost of translation quality. Moreover, it is unclear whether BLEU serves as a good metric for evaluating sentences of a single language. To further ensure that translation quality is not compromised by $S_1^{\text{SNT-CIP}}$, we evaluate BLEU scores of the German sentences it produces. This requires evaluation on a corpus of aligned sentences, unlike the sentences collected from the Brown corpus in section 1[9].

---

[9] While we find that $S_1^{\text{SNT-CIP}}$ improves cycle-consistency for the Brown corpus over S_0^{SNT}, we have no way to establish whether this comes at the cost of translation quality.

Model	Cycle	Translate
S_0^{SNT}	43.35	37.42
$S_1^{\text{SNT-CIP}}$	**47.34**	**38.29**

Table 1: BLEU score on cycle-consistency and translation for WMT, across baseline and informative models. Greedy unrolling and $\alpha = 0.1$

We perform both evaluations (cycle-consistency and translation) on 750 sentences[10] of the 2018 English-German WMT News test-set.[11] We use greedy unrolling in all models (using beam search is a goal for future work). For α (which represents the trade-off between informativity and translation quality) we use 0.1, obtained by tuning on validation data.

Results As shown in table (1), $S_1^{\text{SNT-CIP}}$ improves over S_0^{SNT} not only in cycle-consistency, but in translation quality as well. This suggests that the goal of preserving information, in the sense defined by $S_1^{\text{SNT-CGP}}$ and approximated by $S_1^{\text{SNT-CIP}}$, is important for translation quality.

3 Conclusions

We identify a shortcoming of state-of-the-art translation systems and show that a version of the RSA framework's informative speaker S_1, adapted to the domain of translation, alleviates this problem in a way which improves not only cycle-consistency but translation quality as well. The success of $S_1^{\text{SNT-CIP}}$ on two fairly similar languages raises the question of whether improvements will increase for more distant language pairs, in which larger scale differences exist in what information is obligatorily represented - this is a direction for future work.

Acknowledgements

Thanks to the reviewers for their substantive comments, and to Daniel Fried and Jacob Andreas for many helpful discussions during the development of this project.

---

[10] Our implementation of $S_1^{\text{SNT-CIP}}$ was not efficient, and we could not evaluate on more sentences for reasons of time.

Abstract

We aim to better exploit the limited amounts of parallel text available in low-resource settings by introducing a differentiable reconstruction loss for neural machine translation (NMT). This loss compares original inputs to reconstructed inputs, obtained by back-translating translation hypotheses into the input language. We leverage differentiable sampling and bi-directional NMT to train models end-to-end, without introducing additional parameters. This approach achieves small but consistent BLEU improvements on four language pairs in both translation directions, and outperforms an alternative differentiable reconstruction strategy based on hidden states.

1 Introduction

Neural Machine Translation (NMT) performance degrades sharply when parallel training data is limited (Koehn and Knowles, 2017). Past work has addressed this problem by leveraging monolingual data (Sennrich et al., 2016a; Ramachandran et al., 2017) or multilingual parallel data (Zoph et al., 2016; Johnson et al., 2017; Gu et al., 2018a). We hypothesize that the traditional training can be complemented by better leveraging limited training data. To this end, we propose a new training objective for this model by augmenting the standard translation cross-entropy loss with a **differentiable input reconstruction loss** to further exploit the source side of parallel samples.

Input reconstruction is motivated by the idea of round-trip translation. Suppose sentence $\boldsymbol{f}$ is translated forward to $\boldsymbol{e}$ using model $\boldsymbol{\theta}_{fe}$ and then translated back to $\hat{\boldsymbol{f}}$ using model $\boldsymbol{\theta}_{ef}$, then $\boldsymbol{e}$ is more likely to be a good translation if the distance between $\hat{\boldsymbol{f}}$ and $\boldsymbol{f}$ is small (Brislin, 1970). Prior work applied round-trip translation to monolingual examples and sampled the intermediate translation $\boldsymbol{e}$ from a K-best list generated by model $\boldsymbol{\theta}_{fe}$ using beam search (Cheng et al., 2016; He et al., 2016). However, beam search is not differentiable which prevents back-propagating reconstruction errors to $\boldsymbol{\theta}_{fe}$. As a result, reinforcement learning algorithms, or independent updates to $\boldsymbol{\theta}_{fe}$ and $\boldsymbol{\theta}_{ef}$ were required.

In this paper, we focus on the problem of making input reconstruction differentiable to simplify training. In past work, Tu et al. (2017) addressed this issue by reconstructing source sentences from the decoder's hidden states. However, this reconstruction task can be artificially easy if hidden states over-memorize the input. This approach also requires a separate auxiliary reconstructor, which introduces additional parameters.

We propose instead to combine benefits from differentiable sampling and bi-directional NMT to obtain a compact model that can be trained end-to-end with back-propagation. Specifically,

- Translations are sampled using the Straight-Through Gumbel Softmax (STGS) estimator (Jang et al., 2017; Bengio et al., 2013), which allows back-propagating reconstruction errors.

- Our approach builds on the bi-directional NMT model (Niu et al., 2018; Johnson et al., 2017), which improves low-resource translation by jointly modeling translation in both directions (e.g., Swahili ↔ English). A single bi-directional model is used as a translator and a reconstructor (i.e. $\boldsymbol{\theta}_{ef} = \boldsymbol{\theta}_{fe}$) without introducing more parameters.

Experiments show that our approach outperforms reconstruction from hidden states. It achieves consistent improvements across various low-resource language pairs and directions, showing its effectiveness in making better use of limited parallel data.

2 Background

Using round-trip translations ($\boldsymbol{f} \to \boldsymbol{e} \to \hat{\boldsymbol{f}}$) as a training signal for NMT usually requires auxiliary models to perform back-translation and cannot be trained end-to-end without reinforcement learning. For instance, Cheng et al. (2016) added a reconstruction loss for monolingual examples to the training objective. He et al. (2016) evaluated the quality of $\boldsymbol{e}$ by a language model and $\hat{\boldsymbol{f}}$ by a reconstruction likelihood. Both approaches have symmetric forward and backward translation models which are updated alternatively. This require policy gradient algorithms for training, which are not always stable.

Back-translation (Sennrich et al., 2016a) performs half of the reconstruction process, by generating a synthetic source side for monolingual target language examples: $\boldsymbol{e} \to \hat{\boldsymbol{f}}$. It uses an auxiliary backward model to generate the synthetic data but only updates the parameters of the primary forward model. Iteratively updating forward and backward models (Zhang et al., 2018; Niu et al., 2018) is an expensive solution as back-translations are regenerated at each iteration.

Prior work has sought to simplify the optimization of reconstruction losses by side-stepping beam search. Tu et al. (2017) first proposed to reconstruct NMT input from the decoder's hidden states while Wang et al. (2018a,b) suggested to use both encoder and decoder hidden states to improve translation of dropped pronouns. However, these models might achieve low reconstruction errors by learning to copy the input to hidden states. To avoid copying the input, Artetxe et al. (2018) and Lample et al. (2018) used denoising autoencoders (Vincent et al., 2008) in unsupervised NMT.

Our approach is based instead on the Gumbel Softmax (Jang et al., 2017; Maddison et al., 2017), which facilitates differentiable sampling of sequences of discrete tokens. It has been successfully applied in many sequence generation tasks, including artificial language emergence for multi-agent communication (Havrylov and Titov, 2017), composing tree structures from text (Choi et al., 2018), and tasks under the umbrella of generative adversarial networks (Goodfellow et al., 2014) such as generating the context-free grammar (Kusner and Hernández-Lobato, 2016), machine comprehension (Wang et al., 2017) and machine translation (Gu et al., 2018b).

3 Approach

NMT is framed as a conditional language model, where the probability of predicting target token e_t at step t is conditioned on the previously generated sequence of tokens $\boldsymbol{e}_{<t}$ and the source sequence $\boldsymbol{f}$ given the model parameter $\boldsymbol{\theta}$. Suppose each token is indexed and represented as a one-hot vector, its probability is realized as a softmax function over a linear transformation $a(\boldsymbol{h}_t)$ where $\boldsymbol{h}_t$ is the decoder's hidden state at step t:

$$P(e_t|\boldsymbol{e}_{<t}, \boldsymbol{f}; \boldsymbol{\theta}) = \mathrm{softmax}(a(\boldsymbol{h}_t))^\top e_t. \quad (1)$$

The hidden state is calculated by a neural network g given the embeddings of the previous target tokens $\boldsymbol{e}_{<t}$ in the embedding matrix $\boldsymbol{E}(\boldsymbol{e}_{<t})$ and the context $\boldsymbol{c}_t$ coming from the source:

$$\boldsymbol{h}_t = g(\boldsymbol{E}(\boldsymbol{e}_{<t}), \boldsymbol{c}_t). \quad (2)$$

In our bi-directional model, the source sentence can be either $\boldsymbol{f}$ or $\boldsymbol{e}$ and is respectively translated to $\boldsymbol{e}$ or $\boldsymbol{f}$. The language is marked by a tag (e.g., `<en>`) at the beginning of each source sentence (Johnson et al., 2017; Niu et al., 2018). To facilitate symmetric reconstruction, we also add language tags to target sentences. The training data corpus is then built by swapping the source and target sentences of a parallel corpus and appending the swapped version to the original.

3.1 Bi-Directional Reconstruction

Our bi-directional model performs both forward translation and backward reconstruction. By contrast, uni-directional models require an auxiliary reconstruction module, which introduces additional parameters. This module can be either a decoder-based reconstructor (Tu et al., 2017; Wang et al., 2018a,b) or a reversed dual NMT model (Cheng et al., 2016; He et al., 2016; Wang et al., 2018c; Zhang et al., 2018).

Here the reconstructor, which shares the same parameter with the translator $T(\cdot)$, can also be trained end-to-end by maximizing the log-likelihood of reconstructing $\boldsymbol{f}$:

$$\mathcal{L}_R = \sum_{\boldsymbol{f}} \log P(\boldsymbol{f} \,|\, T(\boldsymbol{f}; \boldsymbol{\theta}); \boldsymbol{\theta}), \quad (3)$$

Combining with the forward translation likelihood

$$\mathcal{L}_T = \sum_{(\boldsymbol{f} \| \boldsymbol{e})} \log P(\boldsymbol{e} \,|\, \boldsymbol{f}; \boldsymbol{\theta}), \quad (4)$$

we use $\mathcal{L} = \mathcal{L}_T + \mathcal{L}_R$ as the final training objective for $\boldsymbol{f} \rightarrow \boldsymbol{e}$. The dual $\boldsymbol{e} \rightarrow \boldsymbol{f}$ model is trained simultaneously by swapping the language direction in bi-directional NMT.

Reconstruction is reliable only with a model that produces reasonable base translations. Following prior work (Tu et al., 2017; He et al., 2016; Cheng et al., 2016), we pre-train a base model with $\mathcal{L}_T$ and fine-tune it with $\mathcal{L}_T + \mathcal{L}_R$.

3.2 Differentiable Sampling

We use differentiable sampling to side-step beam search and back-propagate error signals. We use the Gumbel-Max reparameterization trick (Maddison et al., 2014) to sample a translation token at each time step from the softmax distribution in Equation 1:

$$e_t = \text{one-hot}\left(\arg\max_k \left(a(\boldsymbol{h}_t)_k + G_k\right)\right) \quad (5)$$

where G_k is i.i.d. and drawn from $\text{Gumbel}(0,1)$[1]. We use scaled Gumbel with parameter β, i.e. $\text{Gumbel}(0,\beta)$, to control the randomness. The sampling becomes deterministic (which is equivalent to greedy search) as β approaches 0.

Since $\arg\max$ is not a differentiable operation, we approximate its gradient with the Straight-Through Gumbel Softmax (STGS) (Jang et al., 2017; Bengio et al., 2013): $\nabla_{\boldsymbol{\theta}} e_t \approx \nabla_{\boldsymbol{\theta}} \tilde{e}_t$, where

$$\tilde{e}_t = \text{softmax}\left((a(\boldsymbol{h}_t) + G)/\tau\right) \quad (6)$$

As τ approaches 0, softmax is closer to $\arg\max$ but training might be more unstable. While the STGS estimator is biased when τ is large, it performs well in practice (Gu et al., 2018b; Choi et al., 2018) and is sometimes faster and more effective than reinforcement learning (Havrylov and Titov, 2017).

To generate coherent intermediate translations, the decoder used for sampling only consumes its previously predicted $\hat{\boldsymbol{e}}_{<t}$. This contrasts with the usual *teacher forcing* strategy (Williams and Zipser, 1989), which always feeds in the ground-truth previous tokens $\boldsymbol{e}_{<t}$ when predicting the current token $\hat{e}_t$. With teacher forcing, the sequence concatenation $[\boldsymbol{e}_{<t}; \hat{e}_t]$ is probably coherent at each time step, but the actual predicted sequence $[\hat{\boldsymbol{e}}_{<t}; \hat{e}_t]$ would break the continuity.[2]

# sent.	Training	Dev.	Test
`SW↔EN`	60,570	500	3,000
`TL↔EN`	70,703	704	3,000
`SO↔EN`	68,550	844	3,000
`TR↔EN`	207,021	1,001	3,007

Table 1: Experiments are conducted on four low-resource language pairs, in both translation directions.

4 Experiments

4.1 Tasks and Data

We evaluate our approach on four low-resource language pairs. Parallel data for Swahili↔English (`SW↔EN`), Tagalog↔English (`TL↔EN`) and Somali↔English (`SO↔EN`) contains a mixture of domains such as news and weblogs and is collected from the IARPA MATERIAL program[3], the Global Voices parallel corpus[4], Common Crawl (Smith et al., 2013), and the LORELEI Somali representative language pack (LDC2018T11). The test samples are extracted from the held-out ANALYSIS set of MATERIAL. Parallel Turkish↔English (`TR↔EN`) data is provided by the WMT news translation task (Bojar et al., 2018). We use pre-processed "corpus", "newsdev2016", "newstest2017" as training, development and test sets.[5]

We apply normalization, tokenization, truecasing, joint source-target BPE with 32,000 operations (Sennrich et al., 2016b) and sentence-filtering (length 80 cutoff) to parallel data. Itemized data statistics after preprocessing can be found in Table 1. We report case-insensitive BLEU with the WMT standard '13a' tokenization using SacreBLEU (Post, 2018).

4.2 Model Configuration and Baseline

We build NMT models upon the attentional RNN encoder-decoder architecture (Bahdanau et al., 2015) implemented in the Sockeye toolkit (Hieber et al., 2017). Our translation model uses a bi-directional encoder with a single LSTM layer of size 512, multilayer perceptron attention with a layer size of 512, and word representations of size 512. We apply layer normalization (Ba et al.,

---

[1] i.e. $G_k = -\log(-\log(u_k))$ and $u_k \sim \text{Uniform}(0,1)$.

[2] Sampling with teacher forcing yielded consistently worse BLEU than baselines in preliminary experiments.

Table 2: BLEU scores on eight translation directions. The numbers before and after '±' are the mean and standard deviation over five randomly seeded models. Our proposed methods ($\beta = 0/0.5$) achieve small but consistent improvements. ΔBLEU scores are in bold if mean−std is above zero while in red if the mean is below zero.

2016) and add dropout to embeddings and RNNs (Gal and Ghahramani, 2016) with probability 0.2. We train using the Adam optimizer (Kingma and Ba, 2015) with a batch size of 48 sentences and we checkpoint the model every 1000 updates. The learning rate for baseline models is initialized to 0.001 and reduced by 30% after 4 checkpoints without improvement of perplexity on the development set. Training stops after 10 checkpoints without improvement.

The bi-directional NMT model ties source and target embeddings to yield a bilingual vector space. It also ties the output layer's weights and embeddings to achieve better performance in low-resource scenarios (Press and Wolf, 2017; Nguyen and Chiang, 2018).

We train five randomly seeded bi-directional baseline models by optimizing the forward translation objective $\mathcal{L}_T$ and report the mean and standard deviation of test BLEU. We fine-tune baseline models with objective $\mathcal{L}_T + \mathcal{L}_R$, inheriting all settings except the learning rate which is re-initialized to 0.0001. Each randomly seeded model is fine-tuned independently, so we are able to report the standard deviation of ΔBLEU.

4.3 Contrastive Reconstruction Model

We compare our approach with reconstruction from hidden states (HIDDEN). Following the best practice of Wang et al. (2018a), two reconstructors are used to take hidden states from both the encoder and the decoder. The corresponding two reconstruction losses and the canonical translation loss were originally uniformly weighted (i.e. $1, 1, 1$), but we found that balancing the reconstruction and translation losses yields better results (i.e. $0.5, 0.5, 1$) in preliminary experiments.[6]

We use the reconstructor exclusively to compute the reconstruction training loss. It has also been used to re-rank translation hypotheses in prior work, but Tu et al. (2017) showed in ablation studies that the gains from re-ranking are small compared to those from training.

4.4 Results

Table 2 shows that our reconstruction approach achieves small but consistent BLEU improvements over the baseline on all eight tasks.[7]

We evaluate the impact of the Gumbel Softmax hyperparameters on the development set. We select $\tau = 2$ and $\beta = 0/0.5$ based on training stability and BLEU. Greedy search (i.e. $\beta = 0$) performs similarly as sampling with increased Gumbel noise (i.e. more random translation selection when $\beta = 0.5$): increased randomness in sampling does not have a strong impact on BLEU, even though random sampling may approximate the data distribution better (Ott et al., 2018). We hypothesize that more random translation selection introduces lower quality samples and therefore noisier training signals. This is consistent with the observation that random sampling is less effective for back-translation in low-resource settings (Edunov et al., 2018).

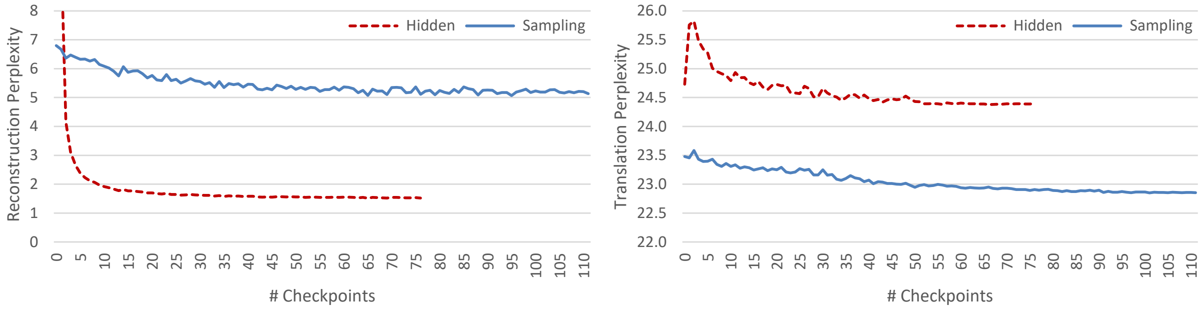
Sampling-based reconstruction is effective even if there is moderate domain mismatch between the training and the test data, such as in the case that the word type out-of-vocabulary (OOV) rate of TR→EN is larger than 20%. Larger improvements can be achieved when the test data is closer to training examples. For example, the OOV rate of SW→EN is much smaller than the OOV rate of TR→EN and the former obtains higher ΔBLEU.

Our approach yields more consistent results than reconstructing from hidden states. The latter fails to improve BLEU in more difficult cases, such as TR↔EN with high OOV rates. We observe extremely low training perplexity for HID-

---

[6] We observed around 0.2 BLEU gains for TR↔EN tasks.

[7] The improvements are significant with $p < 0.01$.



(a) training set (b) development set

Figure 1: Training curves of perplexity on the training and the development sets for TR↔EN. Reconstructing from hidden states (HIDDEN) and reconstructing from sampled translations ($\beta = 0$) are compared. HIDDEN achieves extremely low training perplexity and suffers from unstable training during the early stage.

DEN compared with our proposed approach (Figure 1a). This suggests that HIDDEN yields representations that memorize the input rather than improve output representations.

Another advantage of our approach is that all parameters were jointly pre-trained, which results in more stable training behavior. By contrast, reconstructing from hidden states requires to initialize the reconstructors independently and suffers from unstable early training behavior (Figure 1).

5 Conclusion

We studied reconstructing the input of NMT from its intermediate translations to better exploit training samples in low-resource settings. We used a bi-directional NMT model and the Straight-Through Gumbel Softmax to build a fully differentiable reconstruction model that does not require any additional parameters. We empirically demonstrated that our approach is effective in low-resource scenarios. In future work, we will investigate the use of differentiable reconstruction from sampled sequences in unsupervised and semi-supervised sequence generation tasks. In particular, we will exploit monolingual corpora in addition to parallel corpora for NMT.

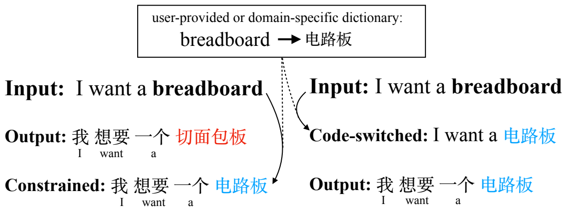
Abstract

Leveraging user-provided translation to constrain NMT has practical significance. Existing methods can be classified into two main categories, namely the use of placeholder tags for lexicon words and the use of hard constraints during decoding. Both methods can hurt translation fidelity for various reasons. We investigate a data augmentation method, making code-switched training data by replacing source phrases with their target translations. Our method does not change the NMT model or decoding algorithm, allowing the model to learn lexicon translations by copying source-side target words. Extensive experiments show that our method achieves consistent improvements over existing approaches, improving translation of constrained words without hurting unconstrained words.

1 Introduction

One important research question in domain-specific machine translation (Luong and Manning, 2015) is how to impose translation constraints (Crego et al., 2016; Hokamp and Liu, 2017; Post and Vilar, 2018). As shown in Figure 1 (a), the word “breadboard” can be translated into “切面包板 (a wooden board that is used to cut bread on)” in the food domain, but “电路板 (a construction base for prototyping of electronics)” in the electronic domain. To enhance translation quality, a lexicon can be leveraged for domain-specific or user-provided words (Arthur et al., 2016; Hasler et al., 2018). We investigate the method of leveraging pre-specified translation for NMT using such a lexicon.



(a) Constrained NMT (b) Constrained NMT: Our Method

Figure 1: Constrained NMT

For leveraging pre-specified translation, one existing approach uses *placeholder tags* to substitute named entities (Crego et al., 2016; Li et al., 2016; Wang et al., 2017b) or rare words (Luong et al., 2014) on both the source and target sides during training, so that a model can translate such words by learning to translate placeholder tags. For example, the i-th named entity in the source sentence is replaced with “tag_i”, as well as its corresponding translation in the target side. Placeholder tags in the output are replaced with pre-specified translation as a post-processing step. One disadvantage of this approach, however, is that the meaning of the original words in the pre-specified translation is not fully retained, which can be harmful to both adequacy and fluency of the output.

Another approach (Hokamp and Liu, 2017; Post and Vilar, 2018) imposes pre-specified translation via *lexical constraints*, making sure such constraints are satisfied by modifying NMT decoding. This method ensures that pre-specified translations appear in the output. A problem of this method is that it does not explicitly explore the correlation between pre-specified translations and their corresponding source words during decoding, and thus can hurt translation fidelity (Hasler et al., 2018). There is not a mechanism that allows the model to *learn* constraint translations during training, which the placeholder method allows.

We investigate a novel method based on *data augmentation*, which combines the advantages of both methods above. The idea is to construct synthetic parallel sentences from the original parallel training data. The synthetic sentence pairs resemble code-switched source sentences and their translations, where certain source words are replaced with their corresponding target translations. The motivation is to make the model learn to "translate" embedded pre-specified translations by copying them from the modified source. During decoding, the source is similarly modified as a preprocessing step. As shown in Figure 1 (b), translation is executed over the code-switched source, without further constraints or post-processing.

In contrast to the placeholder method, our method keeps lexical semantic information (i.e. target words v.s. placeholder tags) in the source, which can lead to more adequate translations. Compared with the lexical constraint method, pre-specified translation is *learned* because such information is available both in training and decoding. As a data augmentation method, it can be used on any NMT architecture. In addition, our method enables the model to translate code-switched source sentences, and preserve its strength in translating un-replaced sentences.

To further strengthen copying, we propose two model-level adjustments: First, we share target-side embeddings with source-side target words, so that target vocabulary words have a unique embedding in the NMT system. Second, we integrate pointer network (Vinyals et al., 2015; Gulcehre et al., 2016; Gu et al., 2016; See et al., 2017) into the decoder. The copy mechanism was firstly proposed to copy source words. In our method, it is further used to copy source-side *target* words.

Results on large scale English-to-Russian (En-Ru) and Chinese-to-English (Ch-En) tasks show that our method outperforms both placeholder and lexical constraint methods over a state-of-the-art Transformer (Vaswani et al., 2017) model on various test sets across different domains. We also show that shared embedding and pointer network can lead to more successful applications of the copying mechanism. We release four high-quality En-Ru e-commerce test sets translated by Russian language experts, totalling 7169 sentences with an average length of 21[1].

2 Related Work

Using placeholders. Luong et al. (2014) use *annotated unk tags* to present the *unk* symbols in training corpora, where the correspondence between source and target *unk* symbols are obtained from word alignment (Brown et al., 1993). Output *unk tags* are replaced through a post-processing stage by looking up a pre-specified dictionary or copying the corresponding source word. Crego et al. (2016) extended *unk tags* symbol to specific symbols that can present name entities. Wang et al. (2017b) and Li et al. (2016) use a similar method. This method is limited when constrain NMT with pre-specified translations consisting of more general words, due to the loss of word meaning when representing them with placeholder tags. In contrast to their work, word meaning is fully kept in modified source in our work.

Lexical constraints. Hokamp and Liu (2017) propose an altered beam search algorithm, namely grid beam search, which takes target-side pre-specified translations as lexical constraints during beam search. A potential problem of this method is that translation fidelity is not specifically considered, since there is no indication of a matching source of each pre-specific translation. In addition, decoding speed is significantly reduced (Post and Vilar, 2018). Hasler et al. (2018) use alignment to gain target-side constraints' corresponding source words, simultaneously use finite-state machines and multi-stack (Anderson et al., 2016) decoding to guide beam search. Post and Vilar (2018) give a fast version of Hokamp and Liu (2017), which limits the decoding complexity linearly by altering the beam search algorithm through dynamic beam allocation.

In contrast to their methods, our method does not make changes to the decoder, and therefore decoding speed remains unchanged. Translation fidelity of pre-specified source words is achieved through a combination of training and decoding procedure, where replaced source-side words still contain their target-side meaning. As a soft method of inserting pre-specified translation, our method does not guarantee that all lexical constraints are satisfied during decoding, but has better overall translation quality compared to their method.

Using probabilistic lexicons. Aiming at making use of one-to-many phrasal translations, the following work is remotely related to our work. Tang et al. (2016) use a phrase memory to provide extra information for their NMT encoder, dynamically switching between word generation and

---

[1] To best of our knowledge, this is the first public e-commerce test set.

phrase generation during decoding. Wang et al. (2017a) use SMT to recommend prediction for NMT, which contains not only translation operations of a SMT phrase table, but also alignment information and coverage information. Arthur et al. (2016) incorporate discrete lexicons by converting lexicon probabilities into predictive probabilities and linearly interpolating them with NMT probability distributions.

Our method is similar in the sense that external translations of source phrases are leveraged. However, their tasks are different. In particular, these methods regard one-to-many translation lexicons as a *suggestion*. In contrast, our task aims to *constrain* NMT translation through **one-to-one** pre-specified translations. Lexical translations can be used to generate code-switched source sentences during training, but we do not modify NMT models by integrating translation lexicons. In addition, our data augmentation method is more flexible, because it is model-free.

Alkhouli et al. (2018) simulate a dictionary-guided translation task to evaluate NMT's alignment extraction. A one-to-one word translation dictionary is used to guide NMT decoding. In their method, a dictionary entry is limited to only one word on both the source and target sides. In addition, a pre-specified translation can come into effect only if the corresponding source-side word is successfully aligned during decoding.

On translating named entities, Currey et al. (2017) augment the training data by copying target-side sentences to the source-side, resulting in augmented training corpora where the source and the target sides contain identical sentences. The augmented data is shown to improve translation performance, especially for proper nouns and other words that are identical in the source and target languages.

3 Data augmentation

Our method is based on *data augmentation*. During training, augmented data are generated by replacing source words or phrases directly with their corresponding target translations. The motivation is to sample as many code-switched translation pairs as possible. During decoding, given pre-specified translations, the source sentence is modified by replacing phrases with their pre-specified translations, so that the trained model can directly copy embedded target translations in the output.

3.1 Training

Given a bilingual training corpus, we sample augmented sentence pairs by leveraging a SMT phrase table, which can be trained over the same bilingual corpus or a different large corpus. We extract source-target phrase pairs[2] from the phrase table, replacing source-side phrases of source sentences using the following sampling steps:

1. Indexing between source-target phrase pairs and training sentences: (a) For each source-target phrase pair, we record all the matching bilingual sentences that contain both the source and target. Word alignment can be used to ensure the phrase pairs that are mutual translation. (b) We also sample bilingual sentences that match two source-target phrase pairs. In particular, given a combination of two phrase pairs, we index bilingual sentences that match both simultaneously.

2. Sampling: (a) For each source-target phrase pair, we keep at most k_1 randomly selected matching sentences. The source-side phrase is replaced with its target-side translation. (b) For each combination of two source-target phrase pairs, we randomly sample at most k_2 matching sentences. Both source-side matching phrases are replaced with their target translations.[3]

The sampled training data is added to the original training data to form a final set of training sentences.

3.2 Decoding

We impose target-side pre-specified translations to the source by replacing source phrases with their translations. Lexicons are defined in the form of one-to-one source-target phrase pairs. Different from training, the number of replaced phrases in a source sentence is not necessarily restricted to one or two, which will be discussed in Section 5.5. In practice, pre-specified translations can be provided by customers or through user feedback, which contains one identified translation for specified source segment.

4 Model

Transformer (Vaswani et al., 2017) uses self-attention network for both encoding and decod-

---

[2] Source-side phrase is at most trigram.

[3] We set $k_1 = 100, k_2 = 30$ empirically.

ing. The encoder is composed of n stacked neural layers. For time step i in layer j, the hidden state $h_{i,j}$ is calculated by employing self-attention over the hidden states in layer $j-1$, which are $\{h_{1,j-1}, h_{2,j-1}, ..., h_{m,j-1}\}$, where m is the number of source-side words.

In particular, $h_{i,j}$ is calculated as follows: First, a self-attention sub-layer is employed to encode the context. Then *attention weights* are computed as scaled dot product between the current query $h_{i,j-1}$ and all keys $\{h_{1,j-1}, h_{2,j-1}, ..., h_{m,j-1}\}$, normalized with a softmax function. After that, the context vector is represented as *weighted sum* of the values projected from hidden states in the previous layer, which are $\{h_{1,j-1}, h_{2,j-1}, ..., h_{m,j-1}\}$. The hidden state in the previous layer and the context vector are then connected by residual connection, followed by a layer normalization function (Ba et al., 2016), to produce a candidate hidden state $h'_{i,j}$. Finally, another sub-layer including a feed-forward network (FFN) layer, followed by another residual connection and layer normalization, are used to obtain the hidden state $h_{i,j}$.

In consideration of translation quality, multi-head attention is used instead of single-head attention as mentioned above, positional encoding is also used to compensate the missing of position information in this model.

The decoder is also composed of n stacked layers. For time step t in layer j, a self-attention sub-layer of hidden state $s_{t,j}$ is calculated by employing self-attention mechanism over hidden states in previous target layer, which are $\{s_{1,j-1}, s_{2,j-1}, ..., s_{t-1,j-1}\}$, resulting in candidate hidden state $s'_{t,j}$. Then, a second target-to-source sub-layer of hidden state $s_{t,j}$ is inserted above the target self-attention sub-layer. In particular, the queries(Q) are projected from $s'_{t,j}$, and the keys(K) and values(V) are projected from the source hidden states in the last layer of encoder, which are $\{h_{1,n}, h_{2,n}, ..., h_{m,n}\}$. The output state is another candidate hidden state $s''_{t,j}$. Finally, a last feed-forward sub-layer of hidden state $s_{t,j}$ is calculated by employing self-attention over $s''_{t,j}$.

A softmax layer based on decoder's last layer $s_{t,n}$ is used to gain a probability distribution $P_{predict}$ over target-side vocabulary.

$$p(y_t|y_1, ..., y_{t-1}, \mathbf{x}) = \text{softmax}(s_{t,n} * \mathbf{W}), \quad (1)$$

where $\mathbf{W}$ is the weight matrix which is learned, $\mathbf{x}$ represent the source sentence, $\{y_1, y_2, ..., y_t\}$ represent target words.

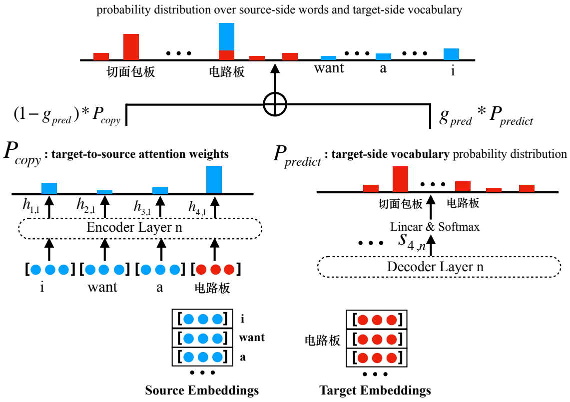


Figure 2: Shared embeddings and pointer network

4.1 Shared Target Embeddings

Shared target embeddings enforces the correspondence between source-side and target-side expressions on the embedding level. As shown in Figure 2, during encoding, source-side target word embeddings are identical to their embeddings in the target-side vocabulary embedding matrix. This makes it easier for the model to copy source-side target words to the output.

4.2 Pointer Network

To strengthen copying through locating source-side target words, we integrate *pointer network* (Gulcehre et al., 2016) into the decoder, as shown in Figure 2. At each decoding time step t, the target-to-source attention weights $\alpha_{t,1}, ..., \alpha_{t,m}$ are utilized as a probability distribution P_{copy}, which models the probability of *copying* a word from the i-th source-side position. The i-th source-side position may represent a source-side word or a source-side target word. P_{copy} is added to $P_{predict}$, the probability distribution over target-side vocabulary, to gain a new distribution over both the source and the target side vocabulary[4]:

$$P = (1 - g_{pred}) * P_{copy} + g_{pred} * P_{predict}, \quad (2)$$

where g_{pred} is used to control the contribution of two probability distributions. For time step t, g_{pred} is calculated from the context vector c_t and the current hidden state of the decoder's last layer $s_{t,n}$:

---

[4] For the words which belong to the source-side vocabulary but are not appeared in the source-side sentence, the probabilities are set to 0.

$$g_{pred} = \sigma(c_t * W_p + s_{t,n} * W_q + b_r), \quad (3)$$

where W_p, W_q, and b_r are parameters trained and σ is the sigmoid function. In addition, the context vector c_t is calculated as $c_t = \sum_{i=1}^{m} \alpha_{t,i} * h_{i,n}$, where $\alpha_{t,i}$ is attention weight mentioned earlier. $\{h_{1,n}, h_{2,n}, ..., h_{m,n}\}$ are the source-side hidden states of the encoder's last layer.

5 Experiments

We compare our method with strong baselines on large-scale En-Ru and Ch-En tasks on various test sets across different domains, using a strongly optimized Transformer (Vaswani et al., 2017). BLEU (Papineni et al., 2002) is used for evaluation.

5.1 Data

Our training corpora are taken from the WMT2018 news translation task.
