KB-aware attention module Not all words in a question are created equal. We use a KB-aware attention mechanism to focus on important components of a question, as shown in Fig. 3. Specifically, we first apply self-attention (SelfAtt) over all question word vectors $\mathbf{H}^Q$ to get a d-dimensional question vector $\mathbf{q}$ as follows

$$\begin{aligned} \mathbf{q} &= \text{BiLSTM}([\mathbf{H}^Q \mathbf{A}^{QQ^T}, \mathbf{H}^Q]) \\ \mathbf{A}^{QQ} &= \text{softmax}((\mathbf{H}^Q)^T \mathbf{H}^Q) \end{aligned} \tag{2}$$

where softmax is applied over the last dimension of an input tensor by default. Using question summary $\mathbf{q}$, we apply another attention (AddAtt) over the memory to obtain answer type $\mathbf{m}_t$, path $\mathbf{m}_p$ and context summary $\mathbf{m}_c$:

$$\begin{aligned} \mathbf{m}_x &= \sum_{i=1}^{|A|} a_i^x \cdot \mathbf{M}_i^{v_x} \\ \mathbf{a}^x &= \text{Att}_{\text{add}}(\mathbf{q}, \mathbf{M}^{k_x}) \end{aligned} \tag{3}$$

where $x \in \{t, p, c\}$, and $\text{Att}_{\text{add}}(\mathbf{x}, \mathbf{y}) = \text{softmax}(\tanh([\mathbf{x}^T, \mathbf{y}]\mathbf{W_1})\mathbf{W_2})$, with $\mathbf{W_1} \in \mathbb{R}^{2d\times d}$ and $\mathbf{W_2} \in \mathbb{R}^{d\times 1}$ being trainable weights.

So far, we have obtained the KB summary $\mathbf{m} = [\mathbf{m}_t;\mathbf{m}_p;\mathbf{m}_c]$ in light of the question. We proceed to compute the question-to-KB attention between question word q_i and KB aspects as formulated by $\mathbf{A}^{Qm} = \mathbf{H}^{Q^T}\mathbf{m}$. By applying max pooling over the last dimension (i.e., the KB aspect dimension) of $\mathbf{A}^{Qm}$, that is, $\mathbf{a}_i^Q = \max_j \mathbf{A}_{ij}^{Qm}$, we select the strongest connection between q_i and the KB. The idea behind it is that each word in a question serves a specific purpose (i.e., indicating answer type, path or context), and max pooling can help find out that purpose. We then apply a softmax over the resulting vector to obtain $\tilde{\mathbf{a}}^Q$ which is a *KB-aware question attention vector* since it indicates the importance of q_i in light of the KB.

Importance module The importance module focuses on important KB aspects as measured by their relevance to the questions. We start by computing a $|Q| \times |A| \times 3$ attention tensor $\mathbf{A}^{QM}$ which indicates the strength of connection between each pair of $\{q_i, A_j^x\}^{x=\{t,p,c\}}$. Then, we take the max of the question word dimension of $\mathbf{A}^{QM}$ and normalize it to get an attention matrix $\tilde{\mathbf{A}}^M$, which indicates the importance of each answer aspect for each candidate answer. After that, we proceed to compute question-aware memory representations $\tilde{\mathbf{M}}^k$. Thus, we have:

$$\begin{aligned}
\tilde{\mathbf{M}}^v &= \{\tilde{\mathbf{M}}_i^v\}_{i=1}^{|A|} \in \mathbb{R}^{|A|\times d} \quad & \tilde{\mathbf{M}}_i^v &= \sum_{j=1}^{3} \mathbf{M}_{ij}^v \\
\tilde{\mathbf{M}}^k &= \{\tilde{\mathbf{M}}_i^k\}_{i=1}^{|A|} \in \mathbb{R}^{|A|\times d} \quad & \tilde{\mathbf{M}}_i^k &= \tilde{\mathbf{A}}_i^M \mathbf{M}_i^k \\
\tilde{\mathbf{A}}^M &= \text{softmax}(\mathbf{A}^{M^T})^T \quad & \mathbf{A}^M &= \max_i \{\mathbf{A}_i^{QM}\}_{i=1}^{|Q|} \\
\mathbf{A}^{QM} &= \left(\mathbf{M}^k \mathbf{H}^Q\right)^T
\end{aligned} \tag{4}$$

Enhancing module We further enhance the question and KB representations by exploiting two-way attention. We compute the KB-enhanced question representation $\tilde{\mathbf{q}}$ which incorporates the relevant KB information by applying max pooling over the last dimension (i.e., the answer aspect dimension) of $\mathbf{A}^{QM}$, that is, $\mathbf{A}_M^Q = \max_k\{\mathbf{A}_{.,.,k}^{QM}\}_{k=1}^3$, and then normalizing it to get a question-to-KB attention matrix $\tilde{\mathbf{A}}_M^Q$ from which we compute the question-aware KB summary and incorporate it into the question representation $\tilde{\mathbf{H}}^Q = \mathbf{H}^Q + \tilde{\mathbf{a}}^Q \odot (\tilde{\mathbf{A}}_M^Q \tilde{\mathbf{M}}^v)^T$. Finally, we obtain a d-dimensional KB-enhanced question representation $\tilde{\mathbf{q}} = \tilde{\mathbf{H}}^Q \tilde{\mathbf{a}}^Q$.

Similarly, we compute a question-enhanced KB representation $\overline{\mathbf{M}}^k$ which incorporates the relevant question information:

$$\begin{aligned}
\overline{\mathbf{M}}^k &= \tilde{\mathbf{M}}^k + \tilde{\mathbf{a}}^M \odot (\tilde{\mathbf{A}}_Q^M (\tilde{\mathbf{H}}^Q)^T) \\
\tilde{\mathbf{a}}^M &= (\tilde{\mathbf{A}}_M^Q)^T \tilde{\mathbf{a}}^Q \in \mathbb{R}^{|A|\times 1} \\
\tilde{\mathbf{A}}_Q^M &= \text{softmax}(\mathbf{A}_M^{Q\,T}) \in \mathbb{R}^{|A|\times|Q|}
\end{aligned} \tag{5}$$

Generalization module We add a one-hop attention process before answering. We use the question representation $\tilde{\mathbf{q}}$ to query over the key memory $\overline{\mathbf{M}}^k$ via an attention mechanism, and fetch the most relevant information from the value memory, which is then used to update the question vector using a GRU (Cho et al., 2014). Finally, we apply a residual layer (He et al., 2016) (i.e., $y = f(x) + x$) and batch normalization (BN) (Ioffe and Szegedy, 2015), which help the model performance in practice. Thus, we have

$$\begin{aligned}
&\hat{\mathbf{q}} = \text{BN}(\tilde{\mathbf{q}} + \mathbf{q}') \quad \mathbf{q}' = \text{GRU}(\tilde{\mathbf{q}}, \tilde{\mathbf{m}}) \\
&\tilde{\mathbf{m}} = \sum_{i=1}^{|A|} a_i \cdot \tilde{\mathbf{M}}_i^v \quad \mathbf{a} = \text{Att}_{\text{add}}^{\text{GRU}}(\tilde{\mathbf{q}}, \overline{\mathbf{M}}^k)
\end{aligned} \tag{6}$$

3.4 Answer module

Given the representation of question Q which is $\hat{\mathbf{q}}$ and the representation of candidate answers $\{A_i\}_{i=1}^{|A|}$ which is $\{\overline{\mathbf{M}}_i^k\}_{i=1}^{|A|}$, we compute the matching score $S(\hat{\mathbf{q}}, \overline{\mathbf{M}}_i^k)$ between every pair (Q, A_i) as $S(\mathbf{q}, \mathbf{a}) = \mathbf{q}^T \cdot \mathbf{a}$. The candidate answers are then ranked by their scores.

3.5 Training and testing

Training Intermediate modules such as the *enhancing module* generate "premature" representations of questions (e.g., $\tilde{\mathbf{q}}$) and candidate answers (e.g., $\overline{\mathbf{M}}^k$). Even though these intermediate representations are not optimal for answer prediction, we can still use them along with the final representations to jointly train the model, which we find helps the training probably by providing more supervision since we are directly forcing intermediate representations to be helpful for prediction. Moreover, we directly match interrogative words to KB answer types. A question Q is represented by a 16-dimensional interrogative word (we use "which", "what", "who", "whose", "whom", "where", "when", "how", "why" and "whether") embedding $\mathbf{q}^w$ and a candidate answer A_i is represented by entity type embedding $\mathbf{H}_i^{t_2}$ with the same size. We then compute the matching score $S(\mathbf{q}^w, \mathbf{H}_i^{t_2})$ between them. Although we only have weak labels (e.g., incorrect answers do not necessarily imply incorrect types) for the type matching task, and there are no shared representations between two tasks, we find in practice this strategy helps the training process as shown in Section 4.4.
Loss Function: In the training phase, we force positive candidates to have higher scores than negative candidates by using a triplet-based loss function:

$$\begin{aligned}
o = g(\mathbf{H}^Q \tilde{\mathbf{a}}^Q, \sum_{j=1}^{3} \mathbf{M}_{.,j}^k) + g(\tilde{\mathbf{q}}, \overline{\mathbf{M}}^k) \\
+ g(\hat{\mathbf{q}}, \overline{\mathbf{M}}^k) + g(\mathbf{q}^w, \mathbf{H}^{t_2})
\end{aligned} \tag{7}$$

where $g(\mathbf{q}, \mathbf{M}) = \sum_{\substack{a^+ \in A^+ \\ a^- \in A^-}} \ell(S(\mathbf{q}, \mathbf{M}_{a^+}), S(\mathbf{q}, \mathbf{M}_{a^-}))$, and $\ell(y, \hat{y}) = \max(0, 1 + \hat{y} - y)$ is a hinge loss function, and A^+ and A^- denote the positive (i.e., correct) and negative (i.e., incorrect) answer sets, respectively. Note that at training time, the candidate answers are extracted from the KB subgraph of the gold-standard topic entity, with the memory size set to N_{max}. We adopt the following sampling strategy which works well in practice: if N_{max} is larger than the number of positive answers $|A^+|$, we keep all the positive answers and randomly select negative answers to fill up the memory; otherwise, we randomly select $\min(N_{max}/2, |A^-|)$ negative answers and fill up the remaining memory with random positive answers.

Testing At testing time, we need to first find the topic entity. We do this by using the top result returned by a separately trained topic entity predictor (we also compare with the result returned by the Freebase Search API). Then, the *answer module* returns the candidate answer with the highest scores as predicted answers. Since there can be multiple answers to a given question, the candidates whose scores are close to the highest score within a certain margin, θ, are regarded as good answers as well. Therefore, we formulate the inference process as follows:

$$\hat{A} = \{\hat{a} \quad | \ \hat{a} \in A \ \& \ \max_{a' \in A}\{S(\hat{\mathbf{q}}, \overline{\mathbf{M}}^k_{a'})\} - S(\hat{\mathbf{q}}, \overline{\mathbf{M}}^k_{\hat{a}}) < \theta\} \tag{8}$$

where $\max_{a' \in A}\{S(\hat{\mathbf{q}}, \overline{\mathbf{M}}^k_{a'})\}$ is the score of the best matched answer and $\hat{A}$ is the predicted answer set. Note that θ is a hyper-parameter which controls the degree of tolerance. Decreasing the value of θ makes the model become stricter when predicting answers.

3.6 Topic entity prediction

Given a question Q, the goal of a topic entity predictor is to find the best topic entity $\hat{c}$ from the candidate set $\{C_i\}_{i=1}^{|C|}$ returned by external topic entity linking tools (we use the Freebase Search API and S-MART (Yang and Chang, 2016) in our experiments). We use a convolutional network (CNN) to encode Q into a d-dimensional vector $\mathbf{e}$. For candidate topic entity C_i, we encode three types of KB aspects, namely, the entity name, entity type and surrounding relations where both entity name and type are represented as a sequence of words while surrounding relations are represented as a bag of sequences of words. Specifically, we use three CNNs to encode them into three d-dimensional vectors, namely, $\mathbf{C}_i^n$, $\mathbf{C}_i^t$ and $\mathbf{C}_i^{r_1}$. Note that for surrounding relations, we first encode each of the relations and then compute their average. Additionally, we compute an average of the relation embeddings via a relation embedding layer which we denote as $\mathbf{C}_i^{r_2}$. We then apply linear projections on the above vectors as follows:

$$\begin{aligned} \mathbf{P}_i^k &= f^k([\mathbf{C}_i^n; \mathbf{C}_i^t; \mathbf{C}_i^{r_1}; \mathbf{C}_i^{r_2}]) \\ \mathbf{P}_i^v &= f^v([\mathbf{C}_i^n; \mathbf{C}_i^t; \mathbf{C}_i^{r_1}; \mathbf{C}_i^{r_2}]) \end{aligned} \tag{9}$$

where $\mathbf{P}_i^k$ and $\mathbf{P}_i^v$ are d-dimensional key and value representations of candidate C_i, respectively. Furthermore, we compute the updated question vector $\hat{\mathbf{e}}$ using the generalization module mentioned earlier. Next, we use a dot product to compute the similarity score between Q and C_i. A triplet-based loss function is used as formulated by $o = g(\mathbf{e}, \mathbf{P}_i^k) + g(\hat{\mathbf{e}}, \mathbf{P}_i^k)$ where $g(.)$ is the aforementioned hinge loss function. When training the predictor, along with the candidates returned from external entity linking tools, we do negative sampling (using string matching) to get more supervision. In the testing phase, the candidate with the highest score is returned as the best topic entity and no negative sampling is applied.

4 Experiments

This section provides an extensive evaluation of our proposed BAMnet model against state-of-the-art KBQA methods. The implementation of BAMnet is available at `https://github.com/hugochan/BAMnet`.

4.1 Data and metrics

We use the Freebase KB and the WebQuestions dataset, described below:

Freebase This is a large-scale KB (Google, 2018) that consists of general facts organized as subject-property-object triples. It has 41M non-numeric entities, 19K properties, and 596M assertions.

WebQuestions This dataset (Berant et al., 2013) (`nlp.stanford.edu/software/sempre`) contains 3,778 training examples and 2,032 test examples. We further split the training instances into a training set and development set via a 80%/20% split. Approximately 85% of questions can be directly answered via a single FreeBase predicate. Also, each question can have multiple answers. In our experiments, we use a development version of the dataset (Baudis and Pichl, 2016), which additionally provides (potentially noisy) entity mentions for each question.

Following (Berant et al., 2013), macro F1 scores (i.e., the average of F1 scores over all questions) are reported on the WebQuestions test set.

4.2 Model settings

When constructing the vocabularies of words, entity types or relation types, we only consider those questions and their corresponding KB subgraphs appearing in the training and validation sets. The vocabulary size of words is $V = 100,797$. There are 1,712 entity types and 4,996 relation types in the KB subgraphs. Notably, in FreeBase, one entity might have multiple entity types. We only use the first one available, which is typically the most concrete one. For those non-entity nodes which are boolean values or numbers, we use "bool" or "num" as their types, respectively.

We also adopt a **query delexicalization** strategy where for each question, the topic entity mention as well as constraint entity mentions (i.e., those belonging to "date", "ordinal" or "number") are replaced with their types. When encoding KB context, if the overlap belongs to the above types, we also do this delexicalization, which will guarantee it matches up with the delexicalized question well in the embedding space.

Given a topic entity, we extract its 2-hop subgraph (i.e., $h = 2$) to collect candidate answers, which is sufficient for *WebQuestions*. At training time, the memory size is limited to $N_{max} = 96$ candidate answers (for the sake of efficiency). If there are more potential candidates, we do random sampling as mentioned earlier. We initialize word embeddings with pre-trained GloVe vectors (Pennington et al., 2014) with word embedding size $d_v = 300$. The relation embedding size d_p, entity type embedding size d_t and hidden size d are set as 128, 16 and 128, respectively. The dropout rates on the word embedding layer, question encoder side and the answer encoder side are 0.3, 0.3 and 0.2, respectively. The batch size is set as 32, and answer module threshold $\theta = 0.7$. As for the topic entity prediction, we use the same hyperparameters. For each question, there are 15 candidates after negative sampling in the training time. When encoding a question, we use a CNN with filter sizes 2 and 3. A linear projection is applied to merge features extracted with different filters. When encoding a candidate aspect, we use a CNN with filter size 3. Linear activation and max-pooling are used together with CNNs. In the training process, we use the Adam optimizer (Kingma and Ba, 2014) to train the model. The initial learning rate is set as 0.001 which is reduced by a factor of 10 if no improvement is observed on the validation set in 3 consecutive epochs. The training procedure stops if no improvement is observed on the validation set in 10 consecutive epochs. The hyper-parameters are tuned on the development set.

4.3 Performance comparison

As shown in Table 1, our method can achieve an F1 score of 0.557 when the gold topic entity is known, which gives an upper bound of our model performance. When the gold topic entity is unknown, we report the results using: 1) the Freebase Search API, which achieves a recall@1 score of 0.857 on the test set for topic entity linking, and 2) the topic entity predictor, which achieves a recall@1 score of 0.898 for entity retrieval.

As for the performance of BAMnet on WebQuestions, it achieves an F1 score of 0.518 using the topic entity predictor, which is significantly better than the F1 score of 0.497 using the Freebase Search API. We can observe that BAMnet significantly outperforms previous state-of-the-art IR-based methods, which conclusively demonstrates the effectiveness of modeling bidirectional interactions between questions and the KB.

It is important to note that unlike the state-of-the-art SP-based methods, BAMnet relies on no external resources and very few hand-crafted features, but still remains competitive with those approaches. Based on careful hand-drafted rules, some SP-based methods (Bao et al., 2016; Yih et al., 2015) can better model questions with constraints and aggregations. For example, (Yih et al., 2015) applies many manually designed rules and features to improve performance on questions with constraints and aggregations, and (Bao et al., 2016) directly models temporal (e.g., "after 2000"), ordinal (e.g., "first") and aggregation constraints (e.g., "how many") by adding detected constraint nodes to query graphs. In contrast, our method is end-to-end, with very few hand-crafted rules.

Additionally, (Yavuz et al., 2016; Bao et al., 2016) train their models on external Q&A datasets to get extra supervision. For a fairer comparison, we only show their results without training on external Q&A datasets. Similarly, for hyhrid systems (Feng et al., 2016; Xu et al., 2016), we only report results without using Wikipedia free text. It is in-

Methods (ref)	Macro F_1

(Hao et al., 2017)	0.429
Our Method: BAMnet	
w/ gold topic entity	0.557
w/ Freebase Search API	0.497
w/ topic entity predictor	**0.518**

Table 1: Results on the WebQuestions test set. Bold: best in-category performance.

teresting to note that both (Yih et al., 2015) and (Bao et al., 2016) also use the ClueWeb dataset for learning more accurate semantics. The F1 score of (Yih et al., 2015) drops from 0.525 to 0.509 if ClueWeb information is removed. To summarize, BAMnet achieves state-of-the-art performance of 0.518 without recourse to any external resources and relies only on very few hand-crafted features. If we assume gold-topic entities are given then BAMnet achieves an F1 of 0.557.

4.4 Ablation study

Methods	Macro F_1
all	**0.557**
w/o two-layered bidirectional attn	0.534
w/o kb-aware attn (+self-attn)	0.544
w/o importance module	0.540
w/o enhancing module	0.550
w/o generalization module	0.542
w/o joint type matching	0.545
w/o topic entity delexicalization	0.529
w/o constraint delexicalization	0.554

Table 2: Ablation results on the WebQuestions test set. Gold topic entity is assumed to be known.

We now discuss the performance impact of the different modules and strategies in BAMnet. Note that gold topic entity is assumed to be known when we do this ablation study, because the error introduced by topic entity prediction might reduce the real performance impact of a module or strategy. As shown in Table 2, significant performance drops were observed after turning off some key attention modules, which confirms that the real power of our method comes from the idea of hierarchical two-way attention. As we can see, when turning off the *two-layered bidirectional attention network*, the model performance drops from 0.557 to 0.534. Among all submodules in the attention network, the *importance module* is the most significant since the F1 score drops to 0.540 without it, thereby confirming the effectiveness of modeling the query-to-KB attention flow. On the flip side, the importance of modeling the KB-to-query attention flow is confirmed by the fact that replacing the *KB-aware attention module* with self-attention significantly degrades the performance. Besides, the secondary attention layer, the *enhancing module*, also contributes to the overall model performance. Finally, we find that the topic entity delexicalization strategy has a big influence on the model performance while the constraint delexicalization strategy only marginally boosts the performance.

4.5 Interpretability analysis

Here, we show that our method does capture the mutual interactions between question words

KB Aspects	Questions	BAMnet w/o BiAttn.	BAMnet	Gold Answers
Answer Type	What degrees did Obama get in college?	Harvard Law School, Columbia University, Occidental College	Bachelor of Arts, Juris Doctor, Political Science	Juris Doctor, Bachelor of Arts
	What music period did Beethoven live in?	Austrian Empire, Germany, Bonn	Classical music, Opera	Opera, Classical music
Answer Path	Where did Queensland get its name from?	Australia	Queen Victoria	Queen Victoria
	Where does Delaware river start?	Delaware Bay	West Branch Delaware River, Mount Jefferson	West Branch Delaware River, Mount Jefferson
Answer Context	What are the major cities in Ukraine?	Kiev, Olyka, ... Vynohradiv, Husiatyn	Kiev	Kiev
	Who is running for vice president with Barack Obama 2012?	David Petraeus	Joe Biden	Joe Biden

Table 3: Predicted answers of BAMnet w/ and w/o bidirectional attention on the WebQuestions test set.

and KB aspects, by visualizing the attention matrix $\mathbf{A}^{QM}$ produced by the *reasoning module*. Fig. 4 shows the attention heatmap generated for a test question "who did location surrender to in __number__" (where "location" and "__number__" are entity types which replace the topic entity mention "France" and the constraint entity mention "ww2", respectively in the original question). As we can see, the attention network successfully detects the interactions between "who" and answer type, "surrender to" and answer path, and focuses more on those words when encoding the question.

To further examine the importance of the two-way flow of interactions, in Table 3, we show the predicted answers of BAMnet with and without the *two-layered bidirectional attention network* on samples questions from the WebQuestions test set. We divide the questions into three categories based on which kind of KB aspect is the most crucial for answering them. As we can see, compared to the simplified version which is not equipped with bidirectional attention, our model is more capable of answering all the three types of questions.

4.6 Error analysis

To better examine the limitations of our approach, we randomly sampled 100 questions on which our method performed poorly (i.e., with per-question F1 score less than 0.6), and categorized the errors. We found that around 33% of errors are due to label issues of gold answers and are not real mistakes. This includes incomplete and erroneous labels, and also alternative correct answers. Constraints are another source of errors (11%), with temporal constraints accounting for most. Some questions have implicit temporal (e.g., tense) constraints which our method does not model. A third source of error is what we term type errors (13%), for which our method generates more answers than needed because of poorly utilizing answer type information. Lexical gap is another source of errors (5%). Finally, other sources of errors (38%) include topic entity prediction error, question ambiguity, incomplete answers and other miscellaneous errors.

5 Conclusions and future work

We introduced a novel and effective bidirectional attentive memory network for the purpose of KBQA. To our best knowledge, we are the first to model the mutual interactions between questions and a KB, which allows us to distill the information that is the most relevant to answering the questions on both sides of the question and KB. Experimental results show that our method significantly outperforms previous IR-based methods while remaining competitive with hand-crafted SP-based methods. Both ablation study and interpretability analysis verify the effectiveness of the idea of modeling mutual interactions. In addition, our error analysis shows that our method actually performs better than what the evaluation metrics indicate.

In the future, we would like to explore effective ways of modeling more complex types of constraints (e.g., ordinal, comparison and aggregation).

Abstract

In this paper we study yes/no questions that are *naturally occurring* — meaning that they are generated in unprompted and unconstrained settings. We build a reading comprehension dataset, BoolQ, of such questions, and show that they are unexpectedly challenging. They often query for complex, non-factoid information, and require difficult entailment-like inference to solve. We also explore the effectiveness of a range of transfer learning baselines. We find that transferring from entailment data is more effective than transferring from paraphrase or extractive QA data, and that it, surprisingly, continues to be very beneficial even when starting from massive pre-trained language models such as BERT. Our best method trains BERT on MultiNLI and then re-trains it on our train set. It achieves 80.4% accuracy compared to 90% accuracy of human annotators (and 62% majority-baseline), leaving a significant gap for future work.

Q: Has the UK been hit by a hurricane?
P: The Great Storm of 1987 was a violent extratropical cyclone which caused casualties in England, France and the Channel Islands . . .
A: Yes. [An example event is given.]

Q: Does France have a Prime Minister and a President?
P: . . . The extent to which those decisions lie with the Prime Minister or President depends upon . . .
A: Yes. [Both are mentioned, so it can be inferred both exist.]

Q: Have the San Jose Sharks won a Stanley Cup?
P: . . . The Sharks have advanced to the Stanley Cup finals once, losing to the Pittsburgh Penguins in 2016 . . .
A: No. [They were in the finals once, and lost.]

Figure 1: Example yes/no questions from the BoolQ dataset. Each example consists of a question (**Q**), an excerpt from a passage (**P**), and an answer (**A**) with an explanation added for clarity.

1 Introduction

Understanding what facts can be inferred to be true or false from text is an essential part of natural language understanding. In many cases, these inferences can go well beyond what is immediately stated in the text. For example, a simple sentence like “Hanna Huyskova won the gold medal for Belarus in freestyle skiing.” implies that (1) Belarus is a country, (2) Hanna Huyskova is an athlete, (3) Belarus won at least one Olympic event, (4) the USA did *not* win the freestyle skiing event, and so on.

To test a model’s ability to make these kinds of inferences, previous work in natural language inference (NLI) proposed the task of labeling candidate statements as being entailed or contradicted by a given passage. However, in practice, generating candidate statements that test for complex inferential abilities is challenging. For instance, evidence suggests (Gururangan et al., 2018; Jia and Liang, 2017; McCoy et al., 2019) that simply asking human annotators to write candidate statements will result in examples that typically only require surface-level reasoning.

In this paper we propose an alternative: we test models on their ability to answer naturally occurring yes/no questions. That is, questions that were authored by people who were not prompted to write particular kinds of questions, including even being required to write yes/no questions, and who did not know the answer to the question they were asking. Figure 1 contains some examples from our dataset. We find such questions often query for

Proceedings of NAACL-HLT 2019, pages 2924–2936
Minneapolis, Minnesota, June 2 - June 7, 2019.

non-factoid information, and that human annotators need to apply a wide range of inferential abilities when answering them. As a result, they can be used to construct highly inferential reading comprehension datasets that have the added benefit of being directly related to the practical end-task of answering user yes/no questions.

Yes/No questions do appear as a subset of some existing datasets (Reddy et al., 2018; Choi et al., 2018; Yang et al., 2018). However, these datasets are primarily intended to test other aspects of question answering (QA), such as conversational QA or multi-step reasoning, and do not contain naturally occurring questions.

We follow the data collection method used by Natural Questions (NQ) (Kwiatkowski et al., 2019) to gather 16,000 naturally occurring yes/no questions into a dataset we call BoolQ (for Boolean Questions). Each question is paired with a paragraph from Wikipedia that an independent annotator has marked as containing the answer. The task is then to take a question and passage as input, and to return "yes" or "no" as output. Figure 1 contains some examples, and Appendix A.1 contains additional randomly selected examples.

Following recent work (Wang et al., 2018), we focus on using transfer learning to establish baselines for our dataset. Yes/No QA is closely related to many other NLP tasks, including other forms of question answering, entailment, and paraphrasing. Therefore, it is not clear what the best data sources to transfer from are, or if it will be sufficient to just transfer from powerful pre-trained language models such as BERT (Devlin et al., 2018) or ELMo (Peters et al., 2018). We experiment with state-of-the-art unsupervised approaches, using existing entailment datasets, three methods of leveraging extractive QA data, and using a few other supervised datasets.

We found that transferring from MultiNLI, and the unsupervised pre-training in BERT, gave us the best results. Notably, we found these approaches are surprisingly complementary and can be combined to achieve a large gain in performance. Overall, our best model reaches 80.43% accuracy, compared to 62.31% for the majority baseline and 90% human accuracy. In light of the fact BERT on its own has achieved human-like performance on several NLP tasks, this demonstrates the high degree of difficulty of our dataset. We present our data and code at `https://goo.gl/boolq`.

2 Related Work

Yes/No questions make up a subset of the reading comprehension datasets CoQA (Reddy et al., 2018), QuAC (Choi et al., 2018), and HotPotQA (Yang et al., 2018), and are present in the ShARC (Saeidi et al., 2018) dataset. These datasets were built to challenge models to understand conversational QA (for CoQA, ShARC and QuAC) or multi-step reasoning (for HotPotQA), which complicates our goal of using yes/no questions to test inferential abilities. Of the four, QuAC is the only one where the question authors were not allowed to view the text being used to answer their questions, making it the best candidate to contain naturally occurring questions. However, QuAC still heavily prompts users, including limiting their questions to be about pre-selected Wikipedia articles, and is highly class imbalanced with 80% "yes" answers.

The MS Marco dataset (Nguyen et al., 2016), which contains questions with free-form text answers, also includes some yes/no questions. We experiment with heuristically identifying them in Section 4, but this process can be noisy and the quality of the resulting annotations is unknown. We also found the resulting dataset is class imbalanced, with 80% "yes" answers.

Yes/No QA has been used in other contexts, such as the templated bAbI stories (Weston et al.) or some Visual QA datasets (Antol et al., 2015; Wu et al., 2017). We focus on answering yes/no questions using natural language text.

Question answering for reading comprehension in general has seen a great deal of recent work (Rajpurkar et al., 2016; Joshi et al., 2017), and there have been many recent attempts to construct QA datasets that require advanced reasoning abilities (Yang et al., 2018; Welbl et al., 2018; Mihaylov et al., 2018; Zellers et al., 2018; Zhang et al., 2018). However, these attempts typically involve engineering data to be more difficult by, for example, explicitly prompting users to write multi-step questions (Yang et al., 2018; Mihaylov et al., 2018), or filtering out easy questions (Zellers et al., 2018). This risks resulting in models that do not have obvious end-use applications since they are optimized to perform in an artificial setting. In this paper, we show that yes/no questions have the benefit of being very challenging even when they are gathered from natural sources.

Natural language inference is also a well studied area of research, particularly on the MultiNLI (Williams et al., 2018) and SNLI (Bowman et al., 2015) datasets. Other sources of entailment data include the PASCAL RTE challenges (Bentivogli et al., 2009, 2011) or SciTail (Khot et al., 2018). We note that, although SciTail, RTE-6 and RTE-7 did not use crowd workers to generate candidate statements, they still use sources (multiple choices questions or document summaries) that were written by humans with knowledge of the premise text. Using naturally occurring yes/no questions ensures even greater independence between the questions and premise text, and ties our dataset to a clear end-task. BoolQ also requires detecting entailment in paragraphs instead of sentence pairs.

Transfer learning for entailment has been studied in GLUE (Wang et al., 2018) and SentEval (Conneau and Kiela, 2018). Unsupervised pre-training in general has recently shown excellent results on many datasets, including entailment data (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018).

Converting short-answer or multiple choice questions into entailment examples, as we do when experimenting with transfer learning, has been proposed in several prior works (Demszky et al., 2018; Poliak et al., 2018; Khot et al., 2018). In this paper we found some evidence suggesting that these approaches are less effective than using crowd-sourced entailment examples when it comes to transferring to natural yes/no questions.

Contemporaneously with our work, Phang et al. (2018) showed that pre-training on supervised tasks could be beneficial even when using pre-trained language models, especially for a textual entailment task. Our work confirms these results for yes/no question answering.

This work builds upon the Natural Questions (NQ) (Kwiatkowski et al., 2019), which contains some natural yes/no questions. However, there are too few (about 1% of the corpus) to make yes/no QA a very important aspect of that task. In this paper, we gather a large number of additional yes/no questions in order to construct a dedicated yes/no QA dataset.

3 The BoolQ Dataset

An example in our dataset consists of a question, a paragraph from a Wikipedia article, the title of the article, and an answer, which is either "yes" or "no". We include the article title since it can potentially help resolve ambiguities (e.g., coreferent phrases) in the passage, although none of the models presented in this paper make use of them.

3.1 Data Collection

We gather data using the pipeline from NQ (Kwiatkowski et al., 2019), but with an additional filtering step to focus on yes/no questions. We summarize the complete pipeline here, but refer to their paper for a more detailed description.

Questions are gathered from anonymized, aggregated queries to the Google search engine. Queries that are likely to be yes/no questions are heuristically identified: we found selecting queries where the first word is in a manually constructed set of indicator words[3] and are of sufficient length, to be effective.

Questions are only kept if a Wikipedia page is returned as one of the first five results, in which case the question and Wikipedia page are given to a human annotator for further processing.

Annotators label question/article pairs in a three-step process. First, they decide if the question is *good*, meaning it is comprehensible, unambiguous, and requesting factual information. This judgment is made before the annotator sees the Wikipedia page. Next, for good questions, annotators find a passage within the document that contains enough information to answer the question. Annotators can mark questions as "not answerable" if the Wikipedia article does not contain the requested information. Finally, annotators mark whether the question's answer is "yes" or "no". Annotating data in this manner is quite expensive since annotators need to search entire Wikipedia documents for relevant evidence and read the text carefully.

Note that, unlike in NQ, we only use questions that were marked as having a yes/no answer, and pair each question with the selected passage instead of the entire document. This helps reduce ambiguity (ex., avoiding cases where the document supplies conflicting answers in different paragraphs), and keeps the input small enough so that existing entailment models can easily be applied to our dataset.

We combine 13k questions gathered from this

[3] The full set is: {"did", "do", "does", "is", "are", "was", "were", "have", "has", "can", "could", "will", "would"}.

Question Topic

Category	Example	Percent	Yes%
Entertainment Media	Is You and I by Lady Gaga a cover?	22.0	65.9
Nature/Science	Are there blue whales in the Atlantic Ocean?	22.0	56.8
Sports	Has the US men's team ever won the World Cup?	11.0	54.5
Law/Government	Is there a seat belt law in New Hampshire?	10.0	70.0
History	Were submarines used in the American Civil War?	5.0	70.0
Fictional Events	Is the Incredible Hulk part of the avengers?	4.0	87.5
Other	Is GDP per capita same as per capita income?	26.0	65.4

Question Type

Category	Example	Percent	Yes%
Definitional	Is thread seal tape the same as Teflon tape?	14.5	55.2
Existence	Is there any dollar bill higher than a 100?	14.5	69.0
Event Occurrence	Did the great fire of London destroy St. Paul's Cathedral?	11.5	73.9
Other General Fact	Is there such thing as a dominant eye?	29.5	62.7
Other Entity Fact	Is the Arch in St. Louis a national park?	30.0	63.3

Table 1: Question categorization of BoolQ. Question topics are shown in the top half and question types are shown in the bottom half.

pipeline with an additional 3k questions with yes/no answers from the NQ training set to reach a total of 16k questions. We split these questions into a 3.2k dev set, 3.2k test set, and 9.4k train set, ensuring questions from NQ are always in the train set. "Yes" answers are slightly more common (62.31% in the train set). The queries are typically short (average length 8.9 tokens) with longer passages (average length 108 tokens).

3.2 Analysis

In the following section we analyze our dataset to better understand the nature of the questions, the annotation quality, and the kinds of reasoning abilities required to answer them.

3.3 Annotation Quality

First, in order to assess annotation quality, three of the authors labelled 110 randomly chosen examples. If there was a disagreement, the authors conferred and selected a single answer by mutual agreement. We call the resulting labels "gold-standard" labels. On the 110 selected examples, the answer annotations reached 90% accuracy compared to the gold-standard labels. Of the cases where the answer annotation differed from the gold-standard, six were ambiguous or debatable cases, and five were errors where the annotator misunderstood the passage. Since the agreement was sufficiently high, we elected to use singly-annotated examples in the training/dev/test sets in order to be able to gather a larger dataset.

3.4 Question Types

Part of the value of this dataset is that it contains questions that people genuinely want to answer. To explore this further, we manually define a set of topics that questions can be about. An author categorized 200 questions into these topics. The results can be found in the upper half of Table 1.

Questions were often about entertainment media (including T.V., movies, and music), along with other popular topics like sports. However, there are still a good portion of questions asking for more general factual knowledge, including ones about historical events or the natural world.

We also broke the questions into categories based on what kind of information they were requesting, shown in the lower half of Table 1. Roughly one-sixth of the questions are about whether anything with a particular property exists (Existence), another sixth are about whether a particular event occurred (Event Occurrence), and another sixth ask whether an object is known by a particular name, or belongs to a particular category (Definitional). The questions that do not fall into these three categories were split between requesting facts about a specific entity, or requesting more general factual information.

We do find a correlation between the nature of the question and the likelihood of a "yes" answer. However, this correlation is too weak to help outperform the majority baseline because, even if the topic or type is known, it is never best to guess the minority class. We also found that question-only models perform very poorly on this task (see Section 5.3), which helps confirm that the questions

Reasoning Types		Yes/No Question Answering Examples
Paraphrasing (38.7%) The passage explicitly asserts or refutes what is stated in the question.	**Q**:	Is Tim Brown in the Hall of Fame?
	P:	Brown has also played for the Tampa Bay Buccaneers. In 2015, he was inducted into the Pro Football Hall of Fame.
	A:	Yes. ["inducted into" directly implies he is in Hall of Fame.]
By Example (11.8%) The passage provides an example or counter-example to what is asserted by the question.	**Q**:	Are there any nuclear power plants in Michigan?
	P:	. . . three nuclear power plants supply Michigan with about 30% of its electricity.
	A:	Yes. [Since there must be at least three.]
Factual Reasoning (8.5%) Answering the question requires using world-knowledge to connect what is stated in the passage to the question.	**Q**:	Was designated survivor filmed in the White House?
	P:	The series is. . . filmed in Toronto, Ontario.
	A:	No. [The White House is not located in Toronto.]
Implicit (8.5%) The passage mentions or describes entities in the question in way that would not make sense if the answer was not yes/no.	**Q**:	Is static pressure the same as atmospheric pressure?
	P:	The aircraft designer's objective is to ensure the pressure in the aircraft's static pressure system is as close as possible to the atmospheric pressure. . .
	A:	No. [It would not make sense to bring them "as close as possible" if those terms referred to the same thing.]
Missing Mention (6.6%) We can conclude the answer is yes or no because, if this was not the case, it would have been mentioned in the passage.	**Q**:	Did Bonnie Blair's daughter make the Olympic team?
	P:	Blair and Cruikshank have two children: a son, Grant, and daughter, Blair.... Blair Cruikshank competed at the 2018 United States Olympic speed skating trials at the 500 meter distance.
	A:	No. [The passage describes Blair Cruikshank's daughter's skating accomplishments, so it would have mentioned it if she had qualified.]
Other Inference (25.9%) The passage states a fact that can be used to infer whether the answer is true or false, and does not fall into any of the other categories.	**Q**:	Is the sea snake the most venomous snake?
	P:	. . . the venom of the inland taipan, drop by drop, is the most toxic among all snakes
	A:	No. [If inland taipan is the most venomous snake, the sea snake must not be.]

Table 2: Kinds of reasoning needed in the BoolQ dataset.

do not contain sufficient information to predict the answer on their own.

3.5 Types of Inference

Finally, we categorize the kinds of inference required to answer the questions in BoolQ[4]. The definitions and results are shown in Table 2.

Less than 40% of the examples can be solved by detecting paraphrases. Instead, many questions require making additional inferences (categories "Factual Reasoning", "By Example", and "Other Inference") to connect what is stated in the passage to the question. There is also a significant class of questions (categories "Implicit" and "Missing Mention") that require a subtler kind of inference based on how the passage is written.

3.6 Discussion

Why do natural yes/no questions require inference so often? We hypothesize that there are several factors. First, we notice factoid questions that ask about simple properties of entities, such as "Was Obama born in 1962?", are rare. We suspect this is because people will almost always prefer to phrase such questions as short-answer questions (e.g., "When was Obama born?"). Thus, there is a natural filtering effect where people tend to use yes/no questions exactly when they want more complex kinds of information.

Second, both the passages and questions rarely include negation. As a result, detecting a "no" answer typically requires understanding that a positive assertion in the text excludes, or makes unlikely, a positive assertion in the question. This requires reasoning that goes beyond paraphrasing (see the "Other-Inference" or "Implicit" examples).

We also think it was important that annotators only had to answer questions, rather than generate them. For example, imagine trying to construct questions that fall into the categories of "Missing Mention" or "Implicit". While possible, it would require a great deal of thought and creativity. On the other hand, detecting when a yes/no question can be answered using these strategies seems much easier and more intuitive. Thus, having annotators answer pre-existing questions opens the door to building datasets that contain more inference and have higher quality labels.

---

[4] Note the dataset has been updated since we carried out this analysis, so it might be slighly out-of-date.

4 Training Yes/No QA Models

Models on this dataset need to predict an output class given two pieces of input text, which is a well studied paradigm (Wang et al., 2018). We find training models on our train set alone to be relatively ineffective. Our best model reaches 69.6% accuracy, only 8% better than the majority baseline. Therefore, we follow the recent trend in NLP of using transfer learning. In particular, we experiment with *pre-training* models on related tasks that have larger datasets, and then *fine-tuning* them on our training data. We list the sources we consider for pre-training below.

Entailment: We consider two entailment datasets, *MultiNLI* (Williams et al., 2018) and *SNLI* (Bowman et al., 2015). We choose these datasets since they are widely-used and large enough to use for pre-training. We also experiment with ablating classes from MultiNLI. During fine-tuning we use the probability the model assigns to the "entailment" class as the probability of predicting a "yes" answer.

Multiple-Choice QA: We use a multiple choice reading comprehension dataset, *RACE* (Lai et al., 2017), which contains stories or short essays paired with questions built to test the reader's comprehension of the text. Following what was done in SciTail (Khot et al., 2018), we convert questions and answer-options to statements by either substituting the answer-option for the blanks in fill-in-the-blank questions, or appending a separator token and the answer-option to the question. During training, we have models independently assign a score to each statement, and then apply the softmax operator between all statements per each question to get statement probabilities. We use the negative log probability of the correct statement as a loss function. To fine-tune on BoolQ, we apply the sigmoid operator to the score of the question given its passage to get the probability of a "yes" answer.

Extractive QA: We consider several methods of leveraging extractive QA datasets, where the model must answer questions by selecting text from a relevant passage. Preliminary experiments found that simply transferring the lower-level weights of extractive QA models was ineffective, so we instead consider three methods of constructing entailment-like data from extractive QA data.

First, we use the *QNLI* task from GLUE (Wang et al., 2018), where the model must determine if a sentence from SQuAD 1.1 (Rajpurkar et al., 2016) contains the answer to an input question or not. Following previous work (Hu et al., 2018), we also try building entailment-like training data from *SQuAD 2.0* (Rajpurkar et al., 2018). We concatenate questions with either the correct answer, or with the incorrect "distractor" answer candidate provided by the dataset, and train the model to classify which is which given the question's supporting text.

Finally, we also experiment with leveraging the long-answer portion of NQ, where models must select a paragraph containing the answer to a question from a document. Following our method for Multiple-Choice QA, we train a model to assign a score to (question, paragraph) pairs, apply the softmax operator on paragraphs from the same document to get a probability distribution over the paragraphs, and train the model on the negative log probability of selecting an answer-containing paragraph. We only train on questions that were marked as having an answer, and select an answer-containing paragraph and up to 15 randomly chosen non-answer-containing paragraphs for each question. On BoolQ, we compute the probability of a "yes" answer by applying the sigmoid operator to the score the model gives to the input question and passage.

Paraphrasing: We use the Quora Question Paraphrasing (*QQP*) dataset, which consists of pairs of questions labelled as being paraphrases or not.[5] Paraphrasing is related to entailment since we expect, at least in some cases, passages will contain a paraphrase of the question.

Heuristic Yes/No: We attempt to heuristically construct a corpus of yes/no questions from the MS Marco corpus (Nguyen et al., 2016). MS Marco has free-form answers paired with snippets of related web documents. We search for answers starting with "yes" or "no", and then pair the corresponding questions with snippets marked as being related to the question. We call this task *Y/N MS Marco*; in total we gather 38k examples,

---

[5] data.quora.com/First-Quora-Dataset-Release-Question-Pairs

80% of which are "yes" answers.

Unsupervised: It is well known that unsupervised pre-training using language-modeling objectives (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018), can improve performance on many tasks. We experiment with these methods by using the pre-trained models from *ELMo*, *BERT*, and OpenAI's Generative Pre-trained Transformer (*OpenAI GPT*) (see Section 5.2).

5 Results

5.1 Shallow Models

First, we experiment with using a linear classifier on our task. In general, we found features such as word overlap or TF-IDF statistics were not sufficient to achieve better than the majority-class baseline accuracy (62.17% on the dev set). We did find there was a correlation between the number of times question words occurred in the passage and the answer being "yes", but the correlation was not strong enough to build an effective classifier. "Yes" is the most common answer even among questions with zero shared words between the question and passage (with a 51% majority), and more common in other cases.

5.2 Neural Models

For our experiments that do not use unsupervised pre-training (except the use of pre-trained word vectors), we use a standard recurrent model with attention. Our experiments using unsupervised pre-training use the models provided by the authors. In more detail:

Our *Recurrent* model follows a standard recurrent plus attention architecture for text-pair classification (Wang et al., 2018). It embeds the premise/hypothesis text using fasttext word vectors (Mikolov et al., 2018) and learned character vectors, applies a shared bidirectional LSTM to both parts, applies co-attention (Parikh et al., 2016) to share information between the two parts, applies another bi-LSTM to both parts, pools the result, and uses the pooled representation to predict the final class. See Appendix A.2 for details.

Our *Recurrent +ELMo* model uses the language model from Peters et al. (2018) to provide contextualized embeddings to the baseline model outlined above, as recommended by the authors.

Our *OpenAI GPT* model fine-tunes the 12 layer 768 dimensional uni-directional transformer from Radford et al. (2018), which has been pre-trained as a language model on the Books corpus (Zhu et al., 2015).

Our $BERT_L$ model fine-tunes the 24 layer 1024 dimensional transformer from Devlin et al. (2018), which has been trained on next-sentence-selection and masked language modelling on the Book Corpus and Wikipedia.

We fine-tune the $\mathrm{BERT_L}$ and the OpenAI GPT models using the optimizers recommended by the authors, but found it important to tune the optimization parameters to achieve the best results. We use a batch size of 24, learning rate of 1e-5, and 5 training epochs for BERT and a learning rate of 6.25e-5, batch size of 6, language model loss of 0.5, and 3 training epochs for OpenAI GPT.

5.3 Question/Passage Only Results

Following the recommendation of Gururangan et al. (2018), we first experiment with models that are only allowed to observe the question or the passage. The pre-trained $\mathrm{BERT_L}$ model reached 64.48% dev set accuracy using just the question and 66.74% using just the passage. Given that the majority baseline is 62.17%, this suggests there is little signal in the question by itself, but that some language patterns in the passage correlate with the answer. Possibly, passages that present more straightforward factual information (like Wikipedia introduction paragraphs) correlate with "yes" answers.

5.4 Transfer Learning Results

The results of our transfer learning methods are shown in Table 3. All results are averaged over five runs. For models pre-trained on supervised datasets, both the pre-training and the fine-tuning stages were repeated. For unsupervised pre-training, we use the pre-trained models provided by the authors, but continue to average over five runs of fine-tuning.

QA Results: We were unable to transfer from RACE or SQuAD 2.0. For RACE, the problem might be domain mismatch. In RACE the passages are stories, and the questions often query for passage-specific information such as the author's intent or the state of a particular entity from the passage, instead of general knowledge.

We would expect SQuAD 2.0 to be a better match for BoolQ since it is also Wikipedia-based, but its possible detecting the adversarially-

Transfer Task	Model	Transfer Data	#Examples	Source Acc.	BoolQ Acc.
N/A	Majority	-	-	-	62.17
N/A	Recurrent	-	-	-	69.60
Extractive QA	Recurrent	QNLI	108k	79.66	71.36
		SQuAD 2.0	130k	69.45	69.83
		NQ Long Answer	93k	71.78	72.78
Paraphrasing	Recurrent	QQP	364k	89.58	71.30
Heuristic Y/N	Recurrent	Y/N MS Marco	39k	87.26	71.40
Entailment	Recurrent	MultiNLI	392k	78.23	75.57
		- w/o Entail	262k	84.26	72.95
		- w/o Contradict	262k	81.16	72.85
		- w/o Neutral	262k	89.72	74.83
		SNLI	351k	88.17	73.16
MC QA	Recurrent	RACE	549k	42.30	68.40
Unsupervised	Recurrent +ELMo	Billion Word	1000M	-	71.41
	OpenAI GPT	Books	800M	-	72.87
	BERT_L	Books/Wikipedia	3,300M	-	76.90

Table 3: Transfer learning results on the BoolQ dev set after fine-tuning on the BoolQ training set. Results are averaged over five runs. In all cases directly using the pre-trained model without fine-tuning did not achieve results better than the majority baseline, so we do not include them here.

constructed distractors used for negative examples does not relate well to yes/no QA.

We got better results using QNLI, and even better results using NQ. This shows the task of selecting text relevant to a question is partially transferable to yes/no QA, although we are only able to gain a few points over the baseline.

Entailment Results: The MultiNLI dataset out-performed all other supervised methods by a large margin. Remarkably, this approach is only a few points behind BERT despite using orders of magnitude less training data and a much more light-weight model, showing high-quality pre-training data can help compensate for these deficiencies.

Our ablation results show that removing the neutral class from MultiNLI hurt transfer slightly, and removing either of the other classes was very harmful, suggesting the neutral examples had limited value. SNLI transferred better than other datasets, but worse than MultiNLI. We suspect this is due to limitations of the photo-caption domain it was constructed from.

Other Supervised Results: We obtained a small amount of transfer using QQP and Y/N MS Marco. Although Y/N MS Marco is a yes/no QA dataset, its small size and class imbalance likely contributed to its limited effectiveness. The web snippets it uses as passages also present a large domain shift from the Wikipedia passages in BoolQ.

Model	Dev Acc.	Test Acc.
Majority Class	62.17	62.31
Recurrent	70.28	67.52
+MultiNLI	76.15	74.24
Pre-trained BERT_L	78.09	76.70
+MultiNLI	82.20	80.43

Table 4: Test set results on BoolQ, "+MultiNLI" indicates models that were additionally pre-trained on MultiNLI before being fine-tuned on the train set.

Unsupervised Results: Following results on other datasets (Wang et al., 2018), we found BERT_L to be the most effective unsupervised method, surpassing all other methods of pre-training.

5.5 Multi-Step Transfer Results

Our best single-step transfer learning results were from using the pre-trained BERT_L model and

MultiNLI. We also experiment with combining these approaches using a two-step pre-training regime. In particular, we fine-tune the pre-trained BERT_L on MultiNLI, and then fine-tune the resulting model again on the BoolQ train set. We found decreasing the number of training epochs to 3 resulted in a slight improvement when using the model pre-trained on MultiNLI.

We show the test set results for this model, and some other pre-training variations, in Table 4. For these results we train five versions of each model using different training seeds, and show the model that had the best dev-set performance.

Given how extensively the BERT_L model has been pre-trained, and how successful it has been across many NLP tasks, the additional gain of 3.5 points due to using MultiNLI is remarkable. This suggests MultiNLI contains signal orthogonal to what is found in BERT's unsupervised objectives.

5.6 Sample Efficiency

In Figure 2, we graph model accuracy as more of the training data is used for fine-tuning, both with and without initially pre-training on MultiNLI. Pre-training on MultiNLI gives at least a 5-6 point gain, and nearly a 10 point gain for BERT_L when only using 1000 examples. For small numbers of examples, the recurrent model with MultiNLI pre-training actually out-performs BERT_L.

5.7 Discussion

A surprising result from our work is that the datasets that more closely resemble the format of BoolQ, meaning they contain questions and multi-sentence passages, such as SQuAD 2.0, RACE, or Y/N MS Marco, were not very useful for transfer. The entailment datasets were stronger despite consisting of sentence pairs. This suggests that adapting from sentence-pair input to question/passage input was not a large obstacle to achieving transfer. Preliminary work found attempting to convert the yes/no questions in BoolQ into declarative statements did not improve transfer from MultiNLI, which supports this hypothesis.

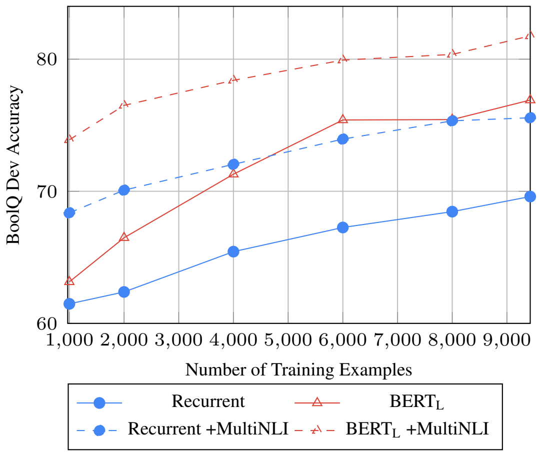

Figure 2: Accuracy for various models on the BoolQ dev set as the number of training examples varies.

The success of MultiNLI might also be surprising given recent concerns about the generalization abilities of models trained on it (Glockner et al., 2018), particularly related to "annotation artifacts" caused by using crowd workers to write the hypothesis statements (Gururangan et al., 2018). We have shown that, despite these weaknesses, it can still be an important starting point for models being used on natural data.

We hypothesize that a key advantage of MultiNLI is that it contains examples of contradictions. The other sources of transfer we consider, including the next-sentence-selection objective in BERT, are closer to providing examples of entailed text vs. neutral/unrelated text. Indeed, we found that our two step transfer procedure only reaches 78.43% dev set accuracy if we remove the contradiction class from MultiNLI, regressing its performance close to the level of BERT_L when just using unsupervised pre-training.

Note that it is possible to pre-train a model on several of the suggested datasets, either in succession or in a multi-task setup. We leave these experiments to future work. Our results also suggest pre-training on MultiNLI would be helpful for other corpora that contain yes/no questions.

6 Conclusion

We have introduced BoolQ, a new reading comprehension dataset of naturally occurring yes/no questions. We have shown these questions are challenging and require a wide range of inference abilities to solve. We have also studied how transfer learning performs on this task, and found crowd-sourced entailment datasets can be leveraged to boost performance even on top of language model pre-training. Future work could include building a document-level version of this task, which would increase its difficulty and its correspondence to an end-user application.

A Appendices

A.1 Randomly Selected Examples

We include a number of randomly selected examples from the BoolQ train set in Figure 3. For each example we show the question in bold, followed by the answer in parentheses, and then the passage below.

A.2 Recurrent Model

Our recurrent model is a standard model from the text pair classification literature, similar to the one used in the GLUE baseline (Wang et al., 2018) and the model from Chen et al. (2017). Our model has the following stages:

Embed: Embed the words using a character CNN following what was done by Seo et al. (2017), and the fasttext crawl word embeddings (Mikolov et al., 2018). Then run a BiLSTM over the results to get context-aware word hypothesis embeddings $\langle u_1, u_2, u_3, ...\rangle$ and premise embeddings $\langle v_1, v_2, v_3, ...\rangle$.

Co-Attention: Compute a co-attention matrix, A, between the hypothesis and premise where $A_{ij} = w_1 \cdot u_i + w_2 \cdot v_j + w_3 \cdot (u_i \circ v_j)$, $\circ$ is elementwise multiplication, and w_1, w_2, and w_3 are weights to be learned.

Attend: For each row in A, apply the softmax operator and use the results to compute a weighed sum of the hypothesis embeddings, resulting in attended vectors $\langle \tilde{u}_1, \tilde{u}_2, ...\rangle$. We use the transpose of A to compute vectors $\langle \tilde{v}_1, \tilde{v}_2, ...\rangle$ from the premise embeddings in a similar manner.

Pool: Run another BiLSTM over $\langle [v_1; \tilde{v}_1; \tilde{v}_1 \circ v_1], [v_2; \tilde{v}_2; \tilde{v}_2 \circ v_2], ...\rangle$ to get embeddings $\langle h_1, h_2, ...\rangle$. Then pool these embeddings by computing attention scores $a_i = w \cdot h_i$, $p = softmax(a)$, and then the sum v^* = $\sum_i p_i h_i$. Likewise we compute p^* from the premise.

Classify: Finally we feed $[v^*; p^*]$ into a fully connected layer, and then through a softmax layer to predict the output class.

We apply dropout at a rate of 0.2 between all layers, and train the model using the Adam optimizer (Kingma and Ba, 2014). The learning rate is decayed by 0.999 every 100 steps. We use 200 dimensional LSTMs and a 100 dimensional fully connected layer.

Is there a catalytic converter on a diesel? (Y)

A catalytic converter is an exhaust emission control device that converts toxic gases and pollutants in exhaust gas from an internal combustion engine into less-toxic pollutants by catalyzing a redox reaction (an oxidation and a reduction reaction). Catalytic converters are usually used with internal combustion engines fueled by either gasoline or diesel–including lean-burn engines as well as kerosene heaters and stoves.

Is there a season 2 of Pride and Prejudice? (N)

Pride and Prejudice is a six-episode 1995 British television drama, adapted by Andrew Davies from Jane Austen's 1813 novel of the same name. Jennifer Ehle and Colin Firth starred as Elizabeth Bennet and Mr. Darcy. Produced by Sue Birtwistle and directed by Simon Langton, the serial was a BBC production with additional funding from the American A&E Network. BBC1 originally broadcast the 55-minute episodes from 24 September to 29 October 1995. The A&E Network aired the series in double episodes on three consecutive nights beginning 14 January 1996. There are six episodes in the series.

Is Saving Private Ryan based on a book? (N)

In 1994, Robert Rodat wrote the script for the film. Rodat's script was submitted to producer Mark Gordon, who liked it and in turn passed it along to Spielberg to direct. The film is loosely based on the World War II life stories of the Niland brothers. A shooting date was set for June 27, 1997.

Is The Talk the same as The View? (N)

In November 2008, the show's post-election day telecast garnered the biggest audience in the show's history at 6.2 million in total viewers, becoming the week's most-watched program in daytime television. It was surpassed on July 29, 2010, during which former President Barack Obama first appeared as a guest on The View, which garnered a total of 6.6 million viewers. In 2013, the show was reported to be averaging 3.1 million daily viewers, which outpaced rival talk show The Talk.

Does the concept of a contact force apply to both a macroscopic scale and an atomic scale? (N)

In the Standard Model of modern physics, the four fundamental forces of nature are known to be non-contact forces. The strong and weak interaction primarily deal with forces within atoms, while gravitational effects are only obvious on an ultra-macroscopic scale. Molecular and quantum physics show that the electromagnetic force is the fundamental interaction responsible for contact forces. The interaction between macroscopic objects can be roughly described as resulting from the electromagnetic interactions between protons and electrons of the atomic constituents of these objects. Everyday objects do not actually touch; rather, contact forces are the result of the interactions of the electrons at or near the surfaces of the objects.

Legal to break out of prison in Germany? (Y)

In Mexico, Belgium, Germany and Austria, the philosophy of the law holds that it is human nature to want to escape. In those countries, escapees who do not break any other laws are not charged for anything and no extra time is added to their sentence. However, in Mexico, officers are allowed to shoot prisoners attempting to escape, and an escape is illegal if violence is used against prison personnel or property, or if prison inmates or officials aid the escape.

Is the movie sand pebbles based on a true story? (N)

The Sand Pebbles is a 1966 American war film directed by Robert Wise in Panavision. It tells the story of an independent, rebellious U.S. Navy machinist's mate, first class aboard the fictional gunboat USS San Pablo in 1920s China.

Is Burberrys of London the same as Burberry? (Y)

Burberry was founded in 1856 when 21-year-old Thomas Burberry, a former draper's apprentice, opened his own store in Basingstoke, Hampshire, England. By 1870, the business had established itself by focusing on the development of outdoors attire. In 1879, Burberry introduced in his brand the gabardine, a hardwearing, water-resistant yet breathable fabric, in which the yarn is waterproofed before weaving. "Burberry" was the original name until it became "Burberrys", due to many customers from around the world began calling it "Burberrys of London". In 1999, the name was reverted to the original, "Burberry". However, the name "Burberrys of London" is still visible on many older Burberry products. In 1891, Burberry opened a shop in the Haymarket, London. Before being termed as trench, it was known as the Tielocken worn by the British officers and featured a belt with no buttons, was double breasted, and protected the body from neck to knees.

Is the Saturn Vue the same as the Chevy Equinox? (N)

Riding on the GM Theta platform, the unibody is mechanically similar to the Saturn Vue and the Suzuki XL7. However, the Equinox and the Torrent are larger than the Vue, riding on a 112.5 in (2,858mm) wheelbase, 5.9 in (150mm) longer than the Vue. Front-wheel drive is standard, with optional all-wheel drive. They are not designed for serious off-roading like the truck-based Chevrolet Tahoe and Chevrolet TrailBlazer.

Is Destin FL on the Gulf of Mexico? (Y)

The city is located on a peninsula separating the Gulf of Mexico from Choctawhatchee Bay. The peninsula was originally an island; hurricanes and sea level changes gradually connected the island to the mainland.

Abstract

Traditional Key-value Memory Neural Networks (KV-MemNNs) are proved to be effective to support shallow reasoning over a collection of documents in domain specific Question Answering or Reading Comprehension tasks. However, extending KV-MemNNs to Knowledge Based Question Answering (KB-QA) is not trivia, which should properly decompose a complex question into a sequence of queries against the memory, and update the query representations to support multi-hop reasoning over the memory. In this paper, we propose a novel mechanism to enable conventional KV-MemNNs models to perform interpretable reasoning for complex questions. To achieve this, we design a new *query updating* strategy to mask previously-addressed memory information from the query representations, and introduce a novel *STOP* strategy to avoid invalid or repeated memory reading without strong annotation signals. This also enables KV-MemNNs to produce structured queries and work in a semantic parsing fashion. Experimental results on benchmark datasets show that our solution, trained with question-answer pairs only, can provide conventional KV-MemNNs models with better reasoning abilities on complex questions, and achieve state-of-art performances.

1 Introduction

Memory Neural Networks (MemNNs) [Weston *et al.*, 2014; Sukhbaatar *et al.*, 2015b] are a family of neural network models that aim to learn how to reason with a long-term memory component and various inference components. The memory component serves as a knowledge base to recall facts from the past. MemNNs have been successfully applied in many natural language processing applications such as question answering and reading comprehension (RC). Recently, Miller *et al.* [2016] proposed a variant of MemNNs, namely Key-Value Memory Neural Networks (KV-MemNNs), which generalizes the original MemNNs by storing facts in a key-value structured memory. Figure 1 illustrates the basic architecture of KV-MemNNs, which consists of five components. The question is first fed to the **Embedding** component and the **Hashing** component. The former converts the incoming question to an internal feature representation. The Hashing component uses the question to pre-select a list of facts to compose the key-value memory. The **Key Addressing** component takes the input question representation and the current memory to compute the relevance probability between the question and each key in the memory. The **Value Reading** component reads the values of all addressed memories by taking their weighted sum using the relevance probabilities. The obtained value representation is then added to the query representation to change the query focus for the next round of memory reading. After multiple hops of reasoning over the memories, the final value representation is treated as the answer representation to perform the final prediction over all candidate answers in the **Rank-**

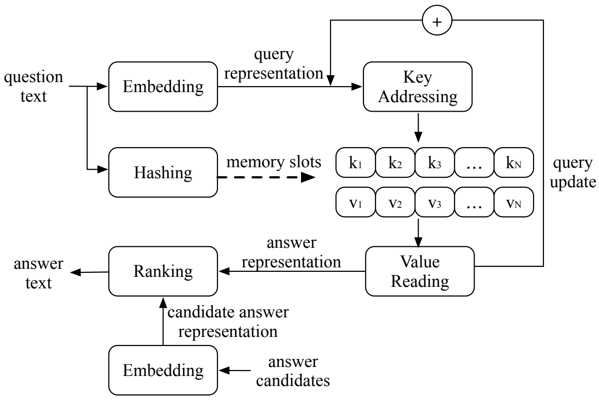

Figure 1: The Key-Value Memory Neural Network Architecture.

Minneapolis, Minnesota, June 2 - June 7, 2019.

ing component.

The KV-MemNNs have been shown to support shallow reasoning in domain-specific knowledge based question answering (KB-QA) tasks such as MovieQA [Tapaswi *et al.*, 2016]. However, when applied to a more challenging scenario, e.g., open domain KB-QA, the KV-MemNNs models do not perform as well as expected, possibly due to two reasons. First of all, the focus of conventional KV-MemNNs is about understanding the facts in the memory rather than properly understanding the questions, where the latter requires incrementally decomposing a complex natural language question into a set of focused queries with the help of the facts in the memory. However, in open domain KB-QA, questions are usually more complicated, e.g., multi-relation questions such as *who does maggie grace play in taken*, where more than one entity and relation are mentioned. Secondly, as shown in Figure 1, KV-MemNNs usually work in an information retrieval (IR) fashion, which first retrieve a set of candidate answers from KB, then rank them by computing the similarity between the value representation and candidates, and finally select the top one or a fixed number of top candidates as the answer. We can imagine that it is not trivial for such IR-styled KV-MemNNs to properly resolve complex constraints from natural language questions, or to handle questions with multiple answers.

We believe that an ideal framework for open domain KB-QA should first understand the natural language questions, explicitly represent the meaning, and make the answer retrieval process more interpretable. To build such an interpretable KV-MemNN KB-QA model, we need to deal with the following challenges: (1) KV-MemNNs often read the memory repeatedly since they do not know when to stop; (2) during multiple memory readings, conventional KV-MemNNs often fail to precisely update the queries for multi-relation questions; (3) strong annotations are usually required to train an interpretable QA model, e.g., the supervision for the memory selection at each hop. To address the challenges, we propose a novel solution to make conventional KV-MemNNs feasible to open domain KB-QA. In particular, we introduce a flexible KV-MemNN solution that can work in both the IR and semantic parsing style with large-scale memory. To this end, we first present a novel query updating method that is able to decompose complex questions and precisely address a relevant key at each hop. Secondly, we introduce a new **STOP** strategy during memory readings, which imports a special key **STOP** into the memory and guides our model to avoid repeated or invalid memory readings. In addition, our proposed model can learn to reason over memory slots with weak supervision, e.g., question-answer pairs only, opposing the strong supervision that most current neural semantic parsers demand, which incurs high labor costs. Experimental results on two benchmark datasets show that our proposed model can not only enhance the reasoning capability of KV-MemNNs, but also be flexible enough to work as a semantic parser, with state-of-the-art performances.

2 Related Work

There are usually two main challenges in the open domain KB-QA task: (1) it often requires the ability to properly analyze and represent the natural language questions against knowledge bases, especially for those involving multiple entities and relations, which we also call as reasoning over the KBs; (2) training such interpretable question understanding models requires considerable strong annotations, which is expensive to obtain in practice. Existing works address these using either the information retrieval (IR) based solutions or the semantic paring (SP) based approaches. The IR-based models [Yao and Van Durme, 2014; Yao, 2015; Bast and Haussmann, 2015; Bordes *et al.*, 2015; Dong *et al.*, 2015; Jain, 2016; Lai *et al.*, 2019] tackle the KB-QA task by developing various ranking models towards the candidate answers, which implicitly meet the reasoning requirements during the candidate-searching step or in designing the ranking functions. In contrast, the SP-based approaches [Berant *et al.*, 2013; Kwiatkowski *et al.*, 2013; Berant and Liang, 2014; Reddy *et al.*, 2014; Yih *et al.*, 2015; Xu *et al.*, 2016] explicitly represent the meaning of questions as logical forms or structured queries that naturally support reasoning over structured KBs.

More recently, memory based reasoning solutions [Weston *et al.*, 2014; Miller *et al.*, 2016] are proposed to tackle the task. [Weston *et al.*, 2014] proposed the Memory Neural Networks (MemNNs), which enable the neural network models read/write on an external memory component, and are further extended into an End-to-End fashion [Sukhbaatar *et al.*, 2015a]. [Miller *et al.*, 2016] further proposed the Key-Value Memory Network, which generalizes the MemNN by storing facts in a key-value structured memory. Both of the two models could perform shallow reasoning over the memory, since they can find answers by consecutively making predictions over multiple memory slots. Compared to the flat memory slots in MemNNs, the Key-Value design can precisely accommodate more complex structured resources, e.g., discriminating subjects and objects in structured KBs, thus makes KV-MemNNs more flexible and better fit to different applications. These neural networks models are often trained in an end-to-end fashion, making the models relatively less interpretable.

Conceptually similar to our STOP strategy, Shen *et al.* [2017] propose the termination gate mechanism based on a random variable generated from the internal state for reading comprehension. In contrast, our model attempts to learn a general STOP key embedding based on the incrementally updated query representations, which can be learned from question-answer pairs only and lead to more explicit reasoning interpretations over structured KBs. This make our model potentially suit more real scenarios.

Our work is also related to [Jain, 2016; Bao *et al.*, 2016], which are designed to support reasoning for multi-relation questions by exploring the relation path and certain KB schema, e.g., CVT nodes, in the Freebase. The former also considers previously-addressed keys during query updating, but ignores the value representations. Thus, it still requires predefined rules and threshold to artificially add intermediate value representations to update the query. The latter also relies on a set of predefined rules to perform reasoning over Freebase. In contrast, our model incorporates both the key and value representations into the query representations, and update in a more uniform way, thus is more general and supports more reasoning scenarios in KB-QA.

3 Our Model

For a given question x, a knowledge base $\mathcal{KB}$ and the question's answer y, we aim to learn a model such that

$$\mathcal{F}(x, \mathcal{KB}) = \hat{y} \rightarrow y$$

where $\hat{y}$ is the predicted answer. In standard KV-MemNNs, the function $\mathcal{F}$ can be composed of five components, i.e., key hashing, key addressing, value reading, query updating and answer prediction. Next, we will introduce how we design a novel mechanism upon those components to equip KV-MemNNs with more powerful reasoning ability. The architecture of our model is shown in Figure 2.

3.1 Key Hashing

The knowledge facts in $\mathcal{KB}$ are usually organized in a triple <subject, *relation*, object>, such as <Maggie Grace, *fb:actor_character*, Kim>. In KV-MemNNs, these facts are stored in a key-value structured memory, where the key k is composed of the left-hand side entity (subject) and the relation, e.g., $\underline{\text{Maggie Grace } \textit{fb:actor\_character}}$, and the value v is the right-hand side entity (object), e.g., $\underline{\text{Kim}}$. Traditional KV-MemNNs first preselect a list of candidate KB facts $(k_1,v_1),...,(k_n,v_n)$ to compose the key-value memory. Particularly, one can first detect entity mentions in the question, and include all KB facts that contains with one of those entities as subject into the memory. In our experiments, we directly use the entity linking results of Xu *et al.* [2016] and filter out their relations that have more than 100 objects. In practice, we find this strategy could effectively avoid the memory exploding for popular entities. In order to help the model avoid repeated or invalid memory reading, we introduce a special key, **STOP**, into the memory for all questions. The corresponding value of the STOP key is a special symbol represented by an all-zero vector. The STOP key is designed to tell our model that we has already accumulated sufficient facts at hand to answer the question, so there is no need to find other knowledge facts from the memory in later hops.

3.2 Key Addressing & Value Reading

Key addressing is basically a matching process, aiming to find the most suitable key for a given query. It can be formulated as a function that computes the relevance probability p_i between the question x and each key k_i:

$$p_i = \text{Softmax}(A\Phi(x) \cdot A\Phi(k_i))$$

where Φ is a feature map of dimension D, A is a $d \times D$ matrix. The values of memories are then read by taking their weighted sum using the relevance probabilities, and the value representation o is returned to locate the answers or update the

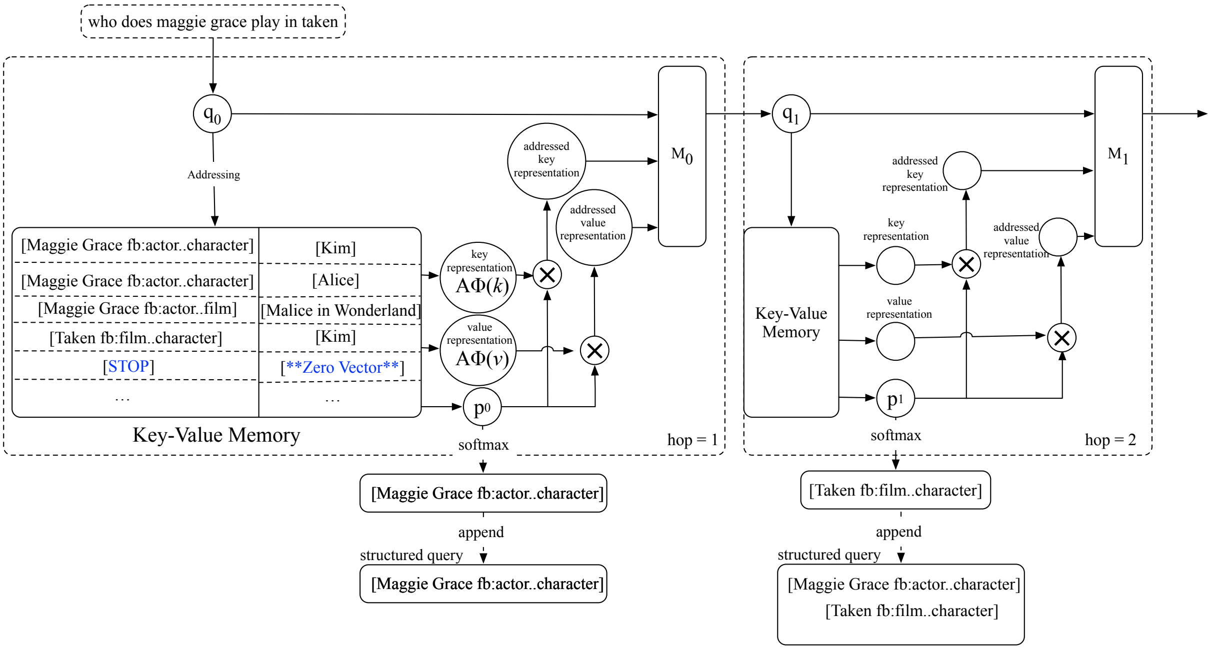

Figure 2: A running example of our key-value memory network model to answer the question *who does maggie grace play in taken*.

query for further memory addressing:

$$o = \sum_i p_i A\Phi(v_i)$$

There are many methods to represent questions and memory slots, including keys and values. Here we simply use the Bag-of-Words model to produce the representations, where we sum the embedding of each word in the question or memory slot together to obtain their vector representations.

3.3 Query Updating

After reading the addressed memory, the initial query representation $q = A\Phi(x)$ should be updated so that the new evidence o collected in the current hop can be properly considered to retrieve more pertinent information in later steps. Traditional KV-MemNNs simply add the initial query q and the returned value o, then perform a linear transformation to obtain the new query representation. This updating strategy is effective in the RC task, since the questions in RC are relatively simple, and their main emphasis is to select proper memory values to change the focus of the query, until reaching the answer. However, the questions in open domain KB-QA tasks are more complicated, usually involved with multiple relations or constraints.

Take the question "*who does maggie grace play in taken*" as an example, the expected answer should follow two constraints: (1) *Maggie_Grace* plays this answer; and (2) this answer is from the movie *Taken*. To answer this question, the model needs to perform two hops of inference consecutively, i.e., matching two keys `Maggie_Grace fb:actor..character` and `Taken fb:film..character` in the memory. Conventional query updating methods, e.g., adding q and o, may not be helpful in guiding the model to predict the other key in later hops, and possibly even hurt the performance, since it may introduce unrelated information into the new query. Intuitively, in KB-QA, masking previously-addressed keys from the query could benefit latter inference, since the model will be able to focus on the next hop, e.g., the movie *Taken*. Therefore, we take into account the query and addressed memories at the t-th hop when updating the query q^{t+1} for the next hop:

$$q^{t+1} = \mathbf{M}_t \cdot (q^t \oplus \underbrace{\sum_i p_i^t A\Phi(k_i)}_{\textit{addressed key}} \oplus \underbrace{\sum_i p_i^t A\Phi(v_i)}_{\textit{addressed value}})$$

where $\oplus$ denotes the concatenation of vectors. The query updating step is parameterized with a different matrix M_t on the t-th hop, which is designed to learn a proper way to combine these three representations.

3.4 Answer Prediction

Conventional KV-MemNNs use the value o at the final hop of inference to retrieve the answers, by simply computing the similarity between o and all candidate answers. This may be of risk for our task. First of all, many questions in the open domain KB-QA have multiple answers, but, KV-MemNNs are supposed to select the candidate with the highest similarity score as the only answer. Secondly, the value representation at the final step may not fully capture the answer information throughout the whole inference process. For example, for multi-constraint questions, the model may address different constraints at different hops, which requires the model to take the value representations in every hop into consideration in order to produce the final answer representation from a global view.

We therefore propose to accumulate the value representations of all hops to make the resulting answer representation lean more on satisfying all constraints. We compute the answer representation m at each hop by adding the value representations of both the current hop and the previous one: $m^{t+1} = o^{t+1} + o^t$, $m^0 = o^0$.

With the final m at hand, we could follow traditional IR-based methods to use the final **A**nswer **R**epresentation to find the best match over all possible candidate values in the memory, namely the **AR** approach. Instead, we can also collect all the best matched keys at every hop to construct a **S**tructured **Q**uery and execute it over the KB to obtain all qualified answers, namely the **SQ** approach. Specifically, the structured query can be constructed as: we select the keys that have the highest relevance probabilities in every hop, resulting a sequence of keys sk_0,.... Starting from sk_0, we append the key sk_i into the final structured query until we see the **STOP** key for the first time at the k-th hop, i.e., $SQ = \{sk_0, ..., sk_{k-1}\}$.

Apparently, the SQ approach can easily output all qualified answers through excuting the queries over the KB, while the AR approach still has difficulties in selecting multiple answers from a ranked list. However, keep in mind that, we do not have gold-standard structured queries for training. As a result, we have to adopt different strategies to find answers in the training and test phases. During **training**, after a fixed number H hops, we follow the AR approach to use the final m^H to compute a prediction over possible candidates, and we train the model by minimizing the cross-entropy between the prediction and gold-standard answers. During **testing**, we follow the SQ approach to collect the final answers by constructing and executing the structured queries over the KB to obtain all answers. As illustrated in Figure 2, for the example question *who does maggie grace play in taken*, our model selects three keys, i.e., [`<maggie grace, fb:actor..character>`, `<taken, film..character>`, and `<STOP>`]. We combine the previous two triples to construct the structured query, which is then executed over the KB to get the answer. We should point out that our model could still use the AR approach to predict the answers just like in the training phase. And as far as we know, our model is the first one that is suitable to tackle the KB-QA task in both the information retrieval and semantic parsing fashions.

3.5 Objective Function and Learning

Given an input question x, the network with parameters θ uses the answer representation m_x^h to perform the prediction over candidate answers at hop h, resulting a prediction vector a_x^h, where the i-th component is respect to the probability of candidate answer i. We denote t_x as the target distribution vector. We compute the standard cross-entropy loss between a_x^h and t_x, and further define the objective function over all training data:

$$L(\theta) = \sum_x \sum_{h=1}^{H} t_x \log a_x^h + \lambda ||\theta||^2$$

where λ is a vector of regularization parameters. Intuitively, this loss function makes our model generate shorter paths to reach answers from the question. On the other hand, it encourages the query updating method to mask the information already addressed in previous hops for the next query representation. This design, together with the query updating method, are the keys to learn the STOP strategy.

4 Experiments

We evaluate our model on two benchmark datasets to investigate whether our enhanced KV-MemNNs model can better perform reasoning over the memory in the open domain KB-QA task, and whether it can make the QA procedure more interpretable.

Semantic Paring Method	Answer F_1
Berant *et al.* [2013]	35.7%
[Berant and Liang, 2014]	39.9%
Yih *et al.* [2015]	52.5%
Bast and Haussmann [2015]	49.4%
Xu *et al.* [2016] (KB Only)	47.1%
Bao *et al.* [2016]	54.4%
CQU + AR (a)	42.0%
KVQU + AR (b)	43.2%
CQU + SQ (c)	39.6%
KVQU + SQ (d)	41.8%
STOP + CQU + AR (e)	43.3%
STOP + CQU + SQ (f)	45.8%
STOP + KVQU + AR (g)	48.6%
STOP + KVQU + SQ (h)	**54.6%**

Table 1: The performance of different models on the test set of WebQuestions.

4.1 Settings

We use the WebQuestions dataset [Berant *et al.*, 2013] as our main dataset, which contains 5,810 question-answer pairs. This dataset is built on Freebase [Bollacker *et al.*, 2008] and all answers are Freebase entities. We use the same training, development and test split as [Berant *et al.*, 2013], containing 3000, 778 and 2032 questions, respectively.

Our model is trained using the Adam optimizer [Kingma and Ba, 2014] with mini-batch size 60. The learning rate is set to 0.001. The complexity of model was penalized by adding L2 regularization to the cross entropy loss function. Gradients are clipped when their norm is bigger than 20. The hop size is set to 3. We initialize word embeddings using pre-trained word representations from Turian *et al.* [2010] and the dimension of word embedding is set to 50.

We use the average question-wise F_1 as our evaluation metric. We compare our model with representative IR based KB-QA models, and several state-of-the-art semantic parsing models. We also include different variants of our model for comparisons to shed light on the advantages of our proposed strategies, especially our three important building blocks - the STOP strategy, how to update a query, and how to obtain the answers.

CQU+AR: uses the **C**onventional **Q**uery **U**pdating method (CQU) which performs a linear transformation over the sum of the query and value representations. This method adopts the AR approach to predict answers where the one with highest probability is selected as the answer.

KVQU+AR: applies the approach introduced in this paper that additionally considers both the **K**ey and **V**alue representations in the **Q**uery **U**pdating (KVQU). This method updates the query representation after reading the memory values at each hop of inference. Note that this model can be seen as a variant of Jain [2016], which is essentially an IR-based approach.

CQU+SQ: uses the CQU method to update the query representations, and applies the SQ approach to obtain the answers.

KVQU+SQ: uses the KVQU method to update the query representations, and adopts the SQ approach to obtain the answers.

STOP+CQU+AR: introduces the STOP key into the memory, but still uses the conventional query updating method and answer representations to find the answers.

STOP+CQU+SQ: introduces the STOP key and uses the conventional query updating method, but uses the SQ approach to obtain the answers.

STOP+KVQU+AR: introduces the STOP key to the memory, uses the KVQU approach to update the query representations, and adopts the AR approach to retrieve the answers.

STOP+KVQU+SQ: is our **main model** that introduces the STOP key, applies the KVQU query updating method, and retrieves answers using the post-constructed structured queries.

4.2 Results and Discussion

Table 1 summarizes the performance of various methods on the test set of WebQuestions. We can see that our main model (**STOP+KVQU+SQ**) performs the best among all its variations, and significantly outperforms the state-of-the-art methods on WebQuestions (with one-tailed t-test significance of $p < 0.05$). We can also see that even the conventional KV-MemNN model (i.e., model (a)) could still outperform traditional semantic parsing models [Berant *et al.*, 2013; Berant and Liang, 2014], showing the effectiveness of memory networks in organizing and utilizing structured data. By replacing the CQU method with our proposed KVQU method, the KV-MemNN model (i.e., model (b)) could further gain an improvement of 1.2%, indicating a proper query representation updating method is critical to KV-MemNNs. After introducing the STOP strategy, the KV-MemNN model is capable to perform proper multi-hop reasoning over the memory, thus outperform most existing methods by a large margin except Bao *et al.* [2016].

Previously, Bao *et al.* [2016] achieves the state-

The question with **blue** color is correctly answered by introducing the STOP strategy while the **red** ones are still not resolved (see discussion in Session 4.8).

of-the-art performance on the WebQuestions by explicitly addressing the multi-constraint questions. Specifically, Bao *et al.* [2016] designs a multi-constraint graph for such questions based on the Freebase schema, and introduces a set of predefined rules to solve complex representations such as max, min, top-X and so on. On the other hand, our model only requires the KB facts to be stored in a Key-Value memory, independent of certain KB schemas. Although those complex expressions in WebQuestions could be easily covered by hand-crafted rules as many did, our model does not work upon such rules, and we think it is crucial to properly enhance KV-MemNNs with such more advanced reasoning abilities, which we leave for future work.

4.3 Impact of the STOP Key

As shown Table 1, we can see that when introducing the STOP strategy, almost all models improve by around 4%, not only in the SQ setting (e.g., from (d) to (f)), but also in the AR setting (e.g., from (a) to (e)). This is not surprising, since the STOP key is introduced to help our model learn to determine when it should stop reading the memory to avoid repeated or invalid addressing. This apparently will lead to more accurate key addressing at each hop, and produce more accurate structured queries. And, better key addressing can also help to generate better value representations at each hop, and finally better answer representation at the last hop. Keep in mind that we obtain such improvement in the case that we do not have gold-standard annotations for the STOP key, but with question-answer pairs only.

To better investigate how the STOP key works, we randomly select 200 questions from the test set and manually analyze the structured queries generated by our model. We find that, for 184 questions (92%) our model predicts the STOP key after one hop of inference and continuously predicts STOP keys in later hops. For the remaining questions, our model predicts two distinct keys before predicting the STOP key. Among these 184 questions, 178 questions (96.7%) can be resolved using exactly a one-triple query. For the remaining 6 questions, it requires two distinct triples to find the answers. This indicates that our model can successfully utilize the STOP strategy to avoid repeated or invalid reading over the memory, at least, for simple questions.

For the multi-relation questions which require at least two hops of inference to find the answers, we evaluate our model on 326 multi-constraint questions selected in Bao *et al.* [2016]. We find that for 283 questions (86.8%), our model performs two hops of inference before predicting the STOP key while for the remaining 13.2%, our model only performs one hop of inference. This demonstrates that even without strong annotations in terms of structured queries, our model still manages to recognize the multi-relation structure and properly stops the invalid reading process. Table 2 illustrates several examples before and after using the STOP strategy.

4.4 Query Updating

In KV-MemNNs, it is important to properly update the query representation after each hop, since the updated query will be used to address more focused information in the next hop, which is especially crucial to support multi-hop reasoning over the memory. We experimented with two query updating approaches, the traditional adding-based method, CQU, and our proposed KVQU, which additionally considers the addressed key representations in previous hops to update the query representation. From Table 1, we can see that no matter which techniques are used to retrieve the final answers, our model can always benefit from replacing the CQU with our KVQU. The main reason may be that KVQU learns to mask already addressed information and retain those untouched, which leads to more accurate key addressing and more expressive answer representations. But, we also observe that by switching from AR to SQ, STOP+KVQU+SQ achieves more improvement than STOP+CQU+SQ. One possible reason is that the KVQU method, together with the STOP strategy, can help address the most relevant keys (i.e., top#1 key) more accurately than CQU does at each hop, which results in more accurate structured queries.

We randomly select 50 multi-constraint questions from the test set of WebQuestions and analyze the addressed keys at each hop. We find that for 48 questions, the model with CQU (model (f)) repeatedly selects the same keys that have the highest relevance probabilities at the first two hops. However, when replacing CQU with KVQU, the model addresses different keys at the first two hops (examples shown in Table 2). One possible reason is that, in contrast to the CQU that only uses the value representation of current hop to update the query, KVQU additionally considers the addressed keys in the current hop, and aims to mask the already addressed information, so that in later hops, the model will focus on the remaining untouched part of the question.

4.5 Candidate Ranking v.s. Structured Query

We investigate two different answer retrieval methods, the IR styled method AR and the semantic parsing styled method SQ, in the experiments. By comparing CQU+AR (a) and CQU+SQ (c) in Table 1, we can see that replacing the answer retrieval method does not boost the performance, but actually hurts. This is not surprising, because with the vanilla CQU, the model does not know how to stop reading the memory, thus may select repeated/invalid keys after the first hop, which will produce incorrect structured queries. Similarly, the KVQU+SQ also suffers from the incorrect structured queries.

Hop Size	STOP + KVQU + SQ	STOP + KVQU + AR
1	38.7%	35.6%
2	45.9%	41.2%
3	**53.2%**	50.4%
4	53.1%	46.7%
5	53.0%	44.2%

Table 3: Performance (answer F_1) of STOP+KVQU+SQ and STOP+KVQU+AR with different hop sizes on the development set of WebQuestions.

After introduce the STOP key into the memory, we find that no matter which query updating methods are used, the models using structured queries (STOP+*+SQ) significantly outperform their corresponding versions using the ranking based method (STOP+*+AR). Despite of the STOP strategy, the improvement may come from two aspects. First, the structured queries in SQ are built from the best key at every hop, thus have captured more global information throughout the reasoning procedure, while the AR method only uses the o in the last hop to retrieve answers. Secondly, the models with SQ can easily output multiple qualified answers from the KB, while the methods with AR can only output the top one from a ranked list in the memory. Moreover, from a practical perspective, the SQ methods provide more interpretability than the ranking based methods.

4.6 Impact of the Hop Size

To investigate the impact of the hop size to the model performance, we evaluate the model STOP+KVQU+SQ and STOP+KVQU+AR with various hop size settings on the development set of WebQuestions. We evaluate both of the two models since we wonder which answer retrieval method is more sensitive to the hop size. As shown in Table 3, the model with AR answer retrieval method achieves the best performance with hop size of 3. Then with the hop size increasing, the performance drops. In contrast, the model with the SQ method also achieves the best performance when the hop size is 3. When the hop size increases, the performance does not drop significantly, but almost remains unchanged. We think the reason may be that the model with the AR method keeps predicting the keys as the hop size increasing, which inevitably introduces noise to the answer representations. On the other hand, the model with the SQ method is less sensitive to the hop size, since once it sees the STOP key, the latter predictions do not affect the resulted structured query.

4.7 Results on QALD-4

To further examine our model under different conditions, besides WebQuestions, we also evaluate our main model on the QALD-4 dataset [Unger *et al.*], which is built upon another KB, DBpedia [Auer *et al.*, 2007]. Like Freebase, DBpedia stores real world facts in the triple format, making it easier for our model to adapt to this new KB. The QALD-4 dataset consists of three QA datasets, namely, Multilingual QA, Biomedical QA and Hybrid QA. Here we evaluate our model on the multilingual QA dataset which contains 250 English question-SPARQL pairs, where 200 questions (80%) are used for training and 50 questions for testing. These questions are more complicated than those of WebQuestions, e.g., all QALD-4 questions require at least two hops of inference over the KB to answer. Table 4 lists the results of our model and other participated systems [Unger *et al.*]. We can see that our model can achieve the best performance on this dataset, without importing extra rules.

Method	Recall	Precision	F-measure
Xser	0.71	0.72	0.72
gAnswer	0.37	0.37	0.37
CASIA	0.40	0.32	0.36
our model	**0.78**	**0.82**	**0.81**

Table 4: Results of the models on the test set of QALD.

4.8 Error Analysis

We analyze the errors of our main model on the development set of WebQuestions. Around 80% errors are caused by incorrect key addressing. The key addressing errors are mainly due to (1) the entities in the addressed keys are incorrect. Entity linking itself is a challenging task and we do not employ any existing entity linking tools to incorporate the linking confidence score, which may further improve our model; (2) the relations in the addressed keys are incorrect, which is mainly caused by insufficient context in the question. For example, in *what is duncan bannatyne*, the information from the question is quite limited for our model to predict the correct key *fb:profession*. Although the STOP strategy proves to be effective on most questions, there are still some questions where the STOP strategy does not work, e.g., *what team did david beckham play for in 2011* shown in Table 2. We failed to perform reasoning over the time constraint *2011* due to limited context left for *2011* after we addressed *play for* in earlier hops. Also due to this same reason, our model can not correctly answer the second question in Table 2, *who is the governor of India 2009*. Keep in mind that, we actually do not have annotated addressed keys at each hop to explicitly teach our model. The remaining cases also include failures in deep analysis according to specific KBs. For example, in *who is the mother of prince michael jackson*, our model only matches the triple *michael jackson fb:parents*, but fail to spot *female* in the next hop.

5 Conclusions

In this paper, we propose to apply the KV-MemNNs as a semantic parsing module to approach the open-domain KB-QA task. We introduce a novel STOP strategy to derive structured queries with flexible number of query triples during multi-hop memory reading, and present a new query updating method, which considers the already-addressed keys in previous hops as well as the value representations. Experimental results show that the STOP strategy not only enables multi-hop reasoning over the memory, but also acts as the key to construct the structured queries, which help our model achieve the state-of-the-art performances on two benchmark datasets.

Abstract

Question Answering (QA) naturally reduces to an entailment problem, namely, verifying whether some text entails the answer to a question. However, for multi-hop QA tasks, which require reasoning with *multiple* sentences, it remains unclear how best to utilize entailment models pre-trained on large scale datasets such as SNLI, which are based on sentence pairs.

We introduce Multee, a general architecture that can effectively use entailment models for multi-hop QA tasks. Multee uses (i) a local module that helps locate important sentences, thereby avoiding distracting information, and (ii) a global module that aggregates information by effectively incorporating importance weights. Importantly, we show that both modules can use entailment functions pre-trained on a large scale NLI datasets. We evaluate performance on MultiRC and OpenBookQA, two multihop QA datasets. When using an entailment function pre-trained on NLI datasets, Multee outperforms QA models trained only on the target QA datasets and the OpenAI transformer models.

1 Introduction

How can we effectively use textual entailment models for question answering? Previous attempts at this have resulted in limited success (Harabagiu and Hickl, 2006; Sacaleanu et al., 2008; Clark et al., 2012). With recent large scale entailment datasets (Bowman et al., 2015; Williams et al., 2018; Khot et al., 2018) pushing entailment models to high accuracies (Chen et al., 2017; Parikh et al., 2016; Wang et al., 2017), we re-visit this challenge and propose a novel method for re-purposing neural entailment models for QA.

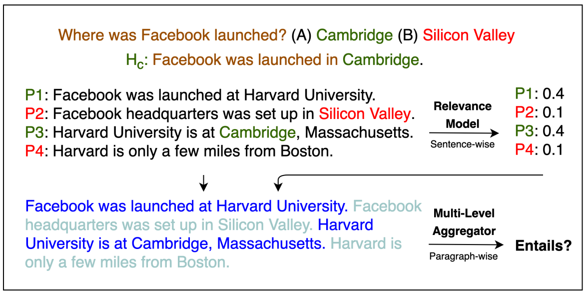

Figure 1: An example illustrating the challenges in using sentence-level entailment model for multi-sentence reasoning needed for QA, and the high-level approach used in Multee.

A key difficulty in using entailment models for QA turns out to be the mismatch between the inputs to the two tasks: large-scale entailment datasets are typically framed at a *sentence level*, whereas question answering requires verifying whether *multiple sentences*, taken together as a premise, entail a hypothesis.

There are two straightforward ways to address this mismatch: (1) aggregate independent entailment decisions over each premise sentence, or (2) make a single entailment decision after concatenating all premise sentences. Neither approach is fully satisfactory. To understand why, consider the set of premises in Figure 1, which entail the hypothesis H_c. Specifically, the combined information in $P1$ and $P3$ entails H_c, which corresponds to the correct answer *Cambridge*. On one hand, aggregating independent decisions will fail because no individual premise entails H_C. On the other hand, simply concatenating premises to form a single paragraph will fail because distracting information in $P2$ and $P4$ can muddle useful information in $P1$ and $P3$. An effective approach, therefore, must recognize relevant sentences (i.e., avoid distracting ones) and compose their sentence-level information.

Our solution to this challenge is based on the observation that a sentence-level entailment function can be re-purposed for both recognizing relevant sentences, and for computing sentence-level representations. Both tasks require comparing in-

Proceedings of NAACL-HLT 2019, pages 2948–2958
Minneapolis, Minnesota, June 2 - June 7, 2019.

formation in a pair of texts, but the objectives of the comparison are different. This means we can take an entailment function that is trained for basic entailment (i.e., comparing information in texts), and adapt it to work for both recognizing relevance and computing representations. Thus, this architecture allows us to incorporate advances in entailment architectures and to leverage pre-trained models obtained using large scale entailment datasets.

To this end, we propose a general architecture that uses a (pre-trained) entailment function f_e for multi-sentence QA. Given a hypothesis statement H_{qa} representing a candidate answer, and the set of premise sentences $\{P_i\}$, our proposed architecture uses the same function f_e for two components: (a) a sentence relevance module that scores each P_i based on its potential relevance to H_{qa}, with the goal of weeding out distractors; and (b) a relevance-weighted aggregator that combines entailment information from multiple P_i.

Thus, we build effective entailment aware representations of larger contexts (i.e., multiple sentences) from those of small contexts (i.e., individual sentences). The main strength of our approach is that, unlike standard attention mechanisms, the aggregator module uses the attention scores from the relevance module at *multiple* levels of abstractions (e.g., multiple layers of a neural network) within f_e, using *join* operations that compose representations at each level. We refer to this **multi-level** aggregation of **te**xtual **e**ntailment representations as Multee (pronounced multi).

Our implementation of Multee uses ESIM (Chen et al., 2017), a recent sentence-level entailment model, pre-trained on SNLI and MultiNLI datasets. We demonstrate its effectiveness on two challenging multi-sentence reasoning datasets: MultiRC (Khashabi et al., 2018) and OpenBookQA (Mihaylov et al., 2018). Multee using ELMo contextual embeddings (Peters et al., 2018) matches state-of-the-art results achieved with large transfomer-based models (Radford et al., 2018) that were trained on a sequence of large scale tasks (Sun et al., 2019). Ablation studies demonstrate that both relevance scoring and multi-level aggregation are valuable, and that pre-training on large entailment corpora is particularly helpful for OpenBookQA.

This work makes three main contributions: **(i)** A novel approach to use pre-trained entailment models for question answering. **(ii)** A model that incorporates local (sentence level) entailment decisions with global (document level) entailment decisions to effectively aggregate information for multi-hop QA task. **(iii)** An empirical evaluation that shows entailment based QA can achieve state-of-the-art performance on two challenging multi-hop QA datasets, OpenBookQA and MultiRC.

2 Question Answering using Entailment

Non-extractive question answering can be seen as a textual entailment problem, where we verify whether a hypothesis constructed out of a question and a candidate answer is entailed by the knowledge—a collection of sentences[1] in the source text. The probability of an answer A, given a question Q, can be modeled as the probability of a set of premises $\{P_i\}$ entailing a hypothesis statement H_{qa} constructed from Q and A:

$$\Pr[A \mid Q, \{P_i\}] \triangleq \Pr[\{P_i\} \vDash H_{qa}] \qquad (1)$$

Here we use $\vDash$ to denote textual entailment. Given QA training data, we can then learn a model that approximates the entailment probability $\Pr[\{P_i\} \vDash H_{qa}]$.

Can one build an effective QA model g_e using an existing entailment model f_e that has been pre-trained on a large-scale entailment dataset? Figure 2 illustrates two straightforward ways of doing so, using f_e as a black-box function:

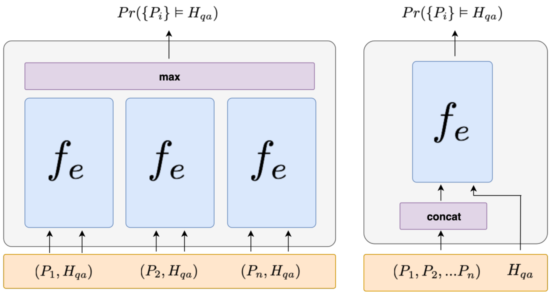

Figure 2: Black Box Applications of Textual Entailment Model for QA: Max and Concat models

(i) Aggregate Local Decisions (Max): Use f_e to check how much each sentence P_i entails H_{qa} on its own, and aggregate these local entailment decisions, for instance, using a max operation.

$$g_e(\{P_i\}, H_{qa}) = \max_i f_e(P_i, H_{qa}) \qquad (2)$$

---

[1] This collection can be a *sequence* in the case of passage comprehension or a *list* of sentences, potentially from varied sources, in the case of QA over multiple documents.

(ii) Concatenate Premises (Concat): Combine the premise sentences in a sequence to form a single large passage P, and use f_e to check whether this passage as a whole entails the hypothesis H_{qa}, making a single entailment decision:

$$g_e(\{P_i\}, H_{qa}) = f_e(P, H_{qa}) \qquad (3)$$

Our experiments reveal, however, that neither approach is an effective means of using pre-trained entailment models for QA (see Table 1). For the example in Figure 1, *Max* model would not be able to consider information from P1 and P3 together. Instead, it will pickup *Silicon Valley* as the answer since P2 is close to H_s, *"Facebook was launched in Silicon Valley"*. Similarly, *Concat* would also be muddled by distracting information in P2, which will weaken its confidence in answer *Cambridge*. Therefore, without careful guidance, simple aggregation can easily add distracting information into the premise representation, causing entailment to fail. This motivates the need for new, effective mechanisms for global reasoning over a collection of premises.

3 Our Approach: Multee

We propose a new entailment based QA model, Multee, with two components: (i) **a sentence relevance model**, which learns to focus on the relevant sentences, and (ii) **a multi-layer aggregator**, which uses an entailment model to obtain multiple layers of question-relevant representations for the premises and then composes them using the sentence-level scores from the relevance model. Finding relevant sentences is a form of local entailment between each premise and the answer hypothesis, whereas aggregating question-relevant representations is a form of global entailment between all premises and the answer hypothesis. This means, we can effectively re-purpose the same pre-trained entailment function f_e for both components. Figure 3 shows an architecture that uses multiple copies of f_e to achieve this.

3.1 Sentence Relevance Model

The goal of this module is to identify sentences in the paragraph that are important for the given hypothesis. As shown in Figure 1, this helps the global module aggregate relevant content while reducing the chances of picking up distracting information. A sentence is considered important if it contains information that is relevant to answering the question. In other words, the importance of a sentence can be modeled as its entailment probability, i.e., how well the sentence by itself supports the answer hypothesis. We can use a pre-trained entailment model to obtain this. The importance α_i of a sentence P_i can be modeled as:

$$\alpha_i = f_e(P_i, H_{qa}) \qquad (4)$$

This can be further improved by modeling the sentence with its surrounding context. This is especially useful for passage-level QA, where the neighboring sentences provide useful context. Given a premise sentence P_i, the entailment function f_e computes a single hypothesis-aware representation x_i containing information in the premise that is relevant to entailing the answer hypothesis H_{qa}. This is essentially the output of last layer of neural function f_e before projecting it to logits. We denote this part of f_e that outputs last *vector* representation as f_{e_v} and full f_e that gives entailment *probability* as f_{e_p}.

We use these hypothesis-aware x_i vectors for each sentence as inputs to a BiLSTM producing a contextual representation c_i for each premise sentence P_i, which is then fed to a feedforward layer that predicts the sentence-level importance as:

$$\alpha_i = \mathrm{softmax}(W^T c_i + b) \qquad (5)$$

The components for generating x_i are part of the original entailment function f_e and can be pre-trained on the entailment dataset. The BiLSTM to compute c_i and the parameters W and b for computing α_i are not part of the original entailment function and thus can only be trained on the target QA task. We perform this additional *contextualization* only when sentences form contiguous text. Additionally, for datasets such as MultiRC, where the relevant sentences have been marked, we introduce a loss term based on the true relevance label and predicted weights, α_i.

3.2 Multi-level Aggregation

The goal of this module is to aggregate representations from important sentences in order to make a global entailment decision. There are two key questions to answer: (1) how to combine the sentence-level information into a paragraph-level representation and (2) how to use the sentence relevance weights $\{\alpha_i\}$.

Most entailment models include many layers that transform the input premise and the hypothesis. A typical neural entailment stack includes en-

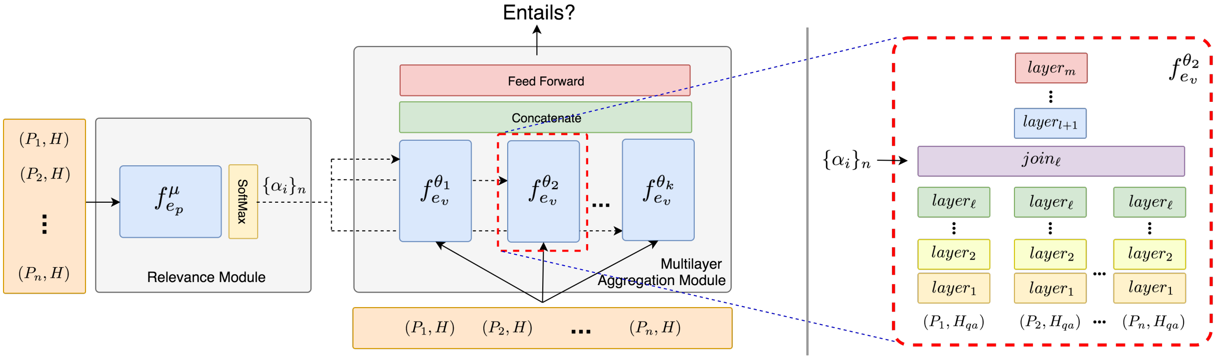

Figure 3: Multee overview: Multee includes two main components, a relevance module, and a multi-layer aggregator module. Both modules use pre-trained entailment functions (f_{e_p} and f_{e_v}). f_{e_p} is the full entailment model that gives entailment probability, and f_{e_v} is part of it excluding last projection to logits and softmax. The multi-level aggregator uses multiple copies of entailment function f_{e_v}, one for each sub-aggregator performing a *join* at a different layer. Right part of figure zooms in on one such sub-aggregator joining at layer ℓ.

coding layers that independently generate contextual representations of the premise and the hypothesis, followed by some cross-attention layer that yields relationships between the premise and hypothesis words, and additional layers that use this cross-attention to generate premise attended representations of the hypothesis and vice versa. The final layers are classification layers which determine entailment based on the representations from the previous layer. Each layer thus generates intermediate representation that captures different type of entailment related information. This presents us with a choice of multiple points for aggregation.

Figure 3 illustrates our approach for aggregating sentence-level representations into a single paragraph level representation. For each premise P_i in the passage, we first process the pair (P_i, H_{qa}) through the entailment stack (f_{e_v}) resulting in a set of intermediate representations $\{\tilde{X_i}^{\ell}\}$ for each layer ℓ. We can choose a particular layer ℓ to be the aggregation layer. We then compute a weighted combination of the sentence-level outputs at this layer $\{\tilde{X_i}^{\ell}\}$ to produce a passage-level representation $\tilde{Y}^{\ell}$. The weights for the sentences are obtained from the *Sentence Relevance* model. We refer to this as a *join* operation as shown in the Figure 3. Layers of the entailment function f_{e_v} that are below the *join* operate at a sentence-level, while layers above the join now operate over paragraph-wise representations. The final layer (i.e. the top most layer) of f_{e_v} thus gives us a vector representation of the entire passage. This type of join can be applied at multiple layers resulting in paragraph vectors that correspond to multiple levels of aggregation. We concatenate these paragraph vectors and pass them through a feed-forward network projecting them down to logits, that can be used to compute the final passage wide entailment probabilities.

3.2.1 Join Operations

Given a set of sentence-wise outputs from the lower layer $\{\tilde{X_i}\}$ and the corresponding sentence-relevance weights $\{\alpha_i\}$, the join operation combines them into a single passage-level representation $\tilde{Y}$, which can be directly consumed by the layer above it in the stack. The specifics of the join operation depends on the shape of the outputs from the lower layer, and the shape of the inputs expected by the layer after the join. Here we show four possible join operations, one for each layer. The ones defined for *Score Layer* and *Embedding Layer* can be reduced to black-box baselines, while we use the other two in Multee.

Score Layer: The score layer outputs the entailment probabilities $\{s_i\}$ for each premise to hypothesis independently, which need to be joined to one entailment score. One way to do this is to simply take a weighted maximum of the individual entailment probabilities. So we have $\tilde{X_i} = s_i \quad \forall i$ and $\tilde{Y} = \max_i \big(\alpha_i s_i\big)$. This reduces to black-box *Max* model (Equation 2) when using $\{\alpha_i\} = \mathbf{1}$.

Embedding Layer: The embedding layer outputs a sequence of embedded vectors of $[\bar{P_i}]$[2] one sequence for each premise P_i and another sequence of embedded vectors $[\bar{H}_{qa}]$ for the answer hypothesis H_{qa}. A join operation in this case scales each embedded vector in a premise by its relevance weight and concatenates them together to

---

[2] We use [.] to denote a sequence and $\bar{.}$ to denote a vector

form $[\bar{P}]$. $\bar{H}_{qa}$ is passed through unchanged.

$$\tilde{X}_i = ([\bar{P}_i], [\bar{H}_{qa}]) \quad \forall i$$
$$[\bar{P}] = [\alpha_1[\bar{P}_1]; \alpha_2[\bar{P}_2]; \ldots; \alpha_n[\bar{P}_n]]$$
$$\tilde{Y} = \left([\bar{P}], [\bar{H}_{qa}]\right)$$

For non-contextual word embeddings, this reduces to *Concat Premises* (Eq. 3) when $\{\alpha_i\} = \mathbf{1}$.

Final Layer (FL): The final layer in the entailment stack usually outputs a single vector $\bar{h}$ which is then used in a linear layer and softmax to produce label probabilities. The join operation here is a weighted sum of the premise-level vectors. So we have $\tilde{X}_i = \bar{h}_i \quad \forall i$ and $\tilde{Y} = \sum_i \alpha_i \bar{h}_i$.

This is similar to a standard attention mechanism, where attended representation is computed by summing the scaled representations. However, such scaled addition is not possible when the outputs from lower layers are not of the same shapes, as in the following case.

Cross Attention Layer (CA): Cross-attention is a standard component of many entailment and reading comprehension models. This layer produces three outputs: (i) For each premise P_i, we get a hypothesis to premise cross attention matrix M^{hp_i} with shape (h $\times$ p_i), where h is the number of hypothesis tokens, and p_i is the number of tokens in premise P_i; (ii) for each premise P_i, we get a sequence of vectors $[\bar{P}_i]$ that corresponds to the token sequence of the premise P_i; and (iii) for the hypothesis, we get a single sequence of vectors $[\bar{H}_{qa}]$ that corresponds to its token sequence. M^{hp_i} attention matrix was generated by cross attention from $[\bar{H}_{qa}]$ to $[\bar{P}_i]$.

The join operation in this layer produces a cross attention matrix that spans the entire passage, i.e., has shape $(h \times p)$, where p is the total number of tokens across all premises. The operation first scales the cross-attention matrices by the sentence-relevance weights $\{\alpha_i\}$ in order to "tone down" the influence of distracting/irrelevant sentences, and then re-normalizes the final matrix:

$$\tilde{X}_i = (M^{hp_i}, [\bar{P}_i], [\bar{H}_{qa}]) \quad \forall i$$
$$M^{hp} = \left[\alpha_i M^{hp_1}; \quad \ldots; \quad \alpha_i M^{hp_n}\right]$$
$$M^{hp}_{ij} = \frac{M^{hp}_{ij}}{\sum_k M^{hp}_{ik}}$$
$$[\bar{P}] = \left[[\bar{P}_1]; \quad [\bar{P}_2]; \ldots; [\bar{P}_n]\right]$$
$$\tilde{Y} = (M^{hp}, \bar{P}, \bar{H}_{qa})$$

where M^{hp}_{ij} is i^{th} row and j^{th} column of M^{hp}.

Multee's multi-layer aggregator module uses join operations at two levels: **Cross Attention Layer (CA)** and **Final Layer (FL)**. The two corresponding aggregators share parameters up till the lower of the two join layers (CA in this case), where they both operate at the sentence level. Above this layer, one aggregator switches to operating at the paragraph level, where it has its own, unshared parameters. In general, if Multee were to aggregate at layers $\ell_{i1}, \ell_{i2}, \ldots, \ell_{ik}$, then the aggregators with joins at layers ℓ and ℓ' respectively could share parameters at layers $1, \ldots, \min\{\ell, \ell'\}$.

3.3 Implementation Details

Multee uses the ESIM stack as the entailment function pre-trained on SNLI and MultiNLI for both the relevance module and for the multi-layer aggregator module. It uses aggregation at two-levels, one at the cross-attention level (CA) and one at the final layer (FL). All uses of the entailment function in Multee are initialized with the same pre-trained entailment model weights. The embedding layer and the BiLSTM layer process paragraph-level contexts but processing at higher layers are done either at premise level or paragraph-level depending on where the join operation is performed.

4 Experiments

Datasets: We evaluate Multee on two datasets, OpenBookQA (Mihaylov et al., 2018) and MultiRC (Khashabi et al., 2018), both of which are specifically designed to test reasoning over multiple sentences. MultiRC is paragraph-based multiple-choice QA dataset derived from varying topics where the questions are answerable based on information from the paragraph. In MultiRC, each question can have more than one correct answer choice, and so it can be viewed as a binary classification task (one prediction per answer choice), with 4,848 / 4,583 examples in Dev/Test sets. OpenBookQA, on the other hand, has multiple-choice science questions with exactly one correct answer choice and no associated paragraph. As a result, this dataset requires the relevant facts to be retrieved from auxiliary resources including the open book of facts released with the paper and other sources such as WordNet (Miller, 1995) and ConceptNet (Speer and Havasi, 2012). It contains 500 questions in the Dev and Test sets.

Table 1: Comparison of Multee with other systems. Starred (*) results are based on contemporaneous system. Results marked (—) are not available. RS is Reading Strategies, KER is Knowledge Enhanced Reader, OFT is OpenAI FineTuned Transformer.

Preprocessing: For each question and answer choice, we create an answer hypothesis statement using a modified version of the script used in SciTail (Khot et al., 2018) construction. We wrote a handful of rules to better convert the question and answer to a hypothesis. We also mark the span of answer in the hypothesis with special begin and end tokens, `@@@answer` and `answer@@@` respectively[3]. For MultiRC, we also apply an off-the-shelf coreference resolution model[4] and replace the mentions when they resolve to pronouns occurring in a different sentence[5]. For OpenBookQA, we use the exact same retrieval as released by the authors of OpenBookQA[6] and use the OpenBook and WordNet as the knowledge source with top 5 sentences retrieved per query.

Training Multee: For OpenBookQA we use cross entropy loss for labels corresponding to 4 answer choices. For MultiRC, we use binary cross entropy loss for each answer-choice separately since in MultiRC each question can have more than one correct answer choice. The entailment components are pre-trained on sentence-level entailment tasks and then fine-tuned as part of end-to-end QA training. The MultiRC dataset includes sentence-level relevance labels. We supervise the Sentence Relevance module with a binary cross entropy loss for predicting these relevance labels when available. We used PyTorch (Paszke et al., 2017) and AllenNLP to implement our models and ran them on Beaker[7]. For pre-training we use the same hyper-parameters of ESIM(Chen et al., 2017) as available in implementation of AllenNLP (Gardner et al., 2017) and fine-tune the model parameters. We do not perform any hyper-parameter tuning for any of our models. We fine-tune all layers in ESIM except for the embedding layer.

Models Compared: We experiment with Glove (Pennington et al., 2014) and ELMo (Peters et al., 2018) embeddings for Multee and compare with following three types of systems:

(A) Baselines using entailment as a black-box We use the pre-trained entailment model as a black-box in two ways: concatenate premises (*Concat*) and aggregate sentence level decisions with a max operation (*Max*). Both models were also pre-trained on SNLI and MultiNLI datasets and fine-tuned on the target QA datasets with same

---

[3] Answer span marking gave substantial gains for all entailment based models including the baselines.

[4] https://github.com/huggingface/neuralcoref

[5] It is hard to learn co-reference, as these target datasets are too small to learn this in an end-to-end fashion.

[6] https://github.com/allenai/OpenBookQA

[7] `https://beaker.org/`

pre-processing.

(B) Previously published results: For MultiRC, there are two published baselines: IR (Information Retrieval) and LR (Logistic Regression). These simple models turn out to be strong baselines on this relatively smaller sized dataset. For OpenBookQA, we report published baselines from (Mihaylov et al., 2018): Question Match with ELMo (QM + ELMo), Question to Answer ESIM with ELMo (ESIM + ELMo) and their best result with the Knowledge Enhanced Reader (KER).

(C) Large Transformer based models: We compare with OpenAI-Transformer (OFT), pre-trained on large-scale language modeling task and fine-tuned on respective datasets. A contemporaneous work,[8] which published these transformer results, also fine-tuned this transformer further on a large scale reading comprehension dataset, RACE (Lai et al., 2017), before fine-tuning on the target QA datasets with their method, *Reading Strategies*.

4.1 Results

Table 1 summarizes the performance of all models. Multee outperforms the black-box entailment baselines (Concat and Max) that were pre-trained on the same data, previously published baselines, OpenAI transformer models. We note that the 95% confidence intervals around baseline accuracy for OpenBookQA and MultiRC are 4.3% and 1.3%, respectively.

On OpenBookQA test set, Multee with GloVe outperforms ensemble version of OpenAI transformer by 3.0 points in accuracy. It also outperforms single model version of Reading Strategies system and is comparable to their ensemble version. On MultiRC dev set, Multee with ELMo outperforms ensemble version of OpenAI transformer by 1.9 points in F1a, 2.7 in F1m and 6.3 in EM. It also outperforms single model version of Reading Strategies system and is comparable to their ensemble version. Recall that the Reading Strategies results are reported with an additional fine-tuning on another larger QA dataset, RACE (Lai et al., 2017) aside from the target QA datasets we use here.

While ELMo contextual embeddings helped in MultiRC, it did not help OpenBookQA. We believe this is in part due to the mismatch between our ELMo training setup where all sentences are treated as a single sequence, which, while true in MultiRC, is not the case in OpenBookQA.

	OpenBookQA	MultiRC
	Accuracy	F1a | F1m
✗α_i	50.6	67.3 | 70.3
✓α_i	**55.8**	67.4 | 71.0
✓α_i + supervise	—	**68.3** | **71.7**

Table 2: Relevance Model Ablation of Multee. ✗α_i: without relevance weights, ✓α_i: with relevance weights respectively, ✓α_i + supervise: with supervised relevance weights. Test results on OpenBookQA and Dev results on MultiRC.

Aggregator	OpenBookQA	MultiRC
	Accuracy	F1a | F1m
Cross Attention (CA)	45.8	67.2 | 71.1
Final Layer (FL)	51.0	68.3 | 71.5
CA +FL	**55.8**	**68.3** | **71.7**

Table 3: Aggregator Level Ablation of Multee. On MultiRC, Multee uses relevance supervision but not on OpenBookQA because of unavailibility. Test results on OpenBookQA and Dev results on MultiRC.

In general, gains from Multee are more prominent in OpenBookQA than in MultiRC. We hypothesize that a key contributor to this difference is distraction being a lesser challenge in MultiRC, where premise sentences come from a single paragraph whose other sentences are often irrelevant and rarely distract towards incorrect answers. OpenBookQA has a noisier set of sentences, since an equal number of sentences is retrieved for the correct and each incorrect answer choice.

4.2 Ablations

Relevance Model Ablation. Table 2 shows the utility of the relevance module. We use the same setting as the full model (aggregation at Cross Attention (CA) and the Final Layer (FL)). As shown in the table, using the relevance module weights (✓α_i) leads to improved accuracy on both datasets (substantially so in OpenBookQA) as compared to ignoring the module, i.e., setting all weights to 1 (✗α_i). In MultiRC, we show that the additional supervision for the relevance module leads to even further improvements in score.

Multi-Level Aggregator Ablation. Multee performs aggregation at two levels: Cross Attention Layer (CA) and Final Layer (FL). We denote this by CA+FL. To show that multi-level aggregation is better than individual aggregations, we train

Table 4: Effect (on test data) of pre-training the entailment model used in Multee.

models with aggregation at only FL and at only CA. Table 3 shows that multi-layer aggregation is better than CA or FL alone on both the datasets.

4.3 Effect of Pre-training

One of the benefits of using entailment based components in a QA model is that we can pre-train them on large scale entailment datasets and fine-tune them as part of the QA model. Table 4 shows that such pre-training is valuable. The model trained from scratch is substantially worse in the case of OpenBookQA, highlighting the benefits of our entailment-based QA model.

Multee benefits come from two sources: (i) Re-purposing of entailment function for multi-sentence question answering, and (ii) transferring from a large-scale entailment task. In the case of OpenBookQA, both are helpful. For MultiRC, only the first is a significant contributor. Table 5 shows that re-purposing was a bigger factor for MultiRC, since Max and Concat models do not work well when trained from scratch.

		OpenBookQa Accuracy	MultiRc F1a | F1m
Max	Snli + MultiNli	**47.6**	**66.8** | **70.3**
	Scratch	32.4	42.8 | 44.0
Concat	Snli + MultiNli	**42.6**	**66.9** | **70.7**
	Scratch	35.8	51.3 | 50.4

Table 5: Pre-training ablations of black-box entailment baselines for OpenBookQA (test) and MultiRC (dev).

5 Analysis

Relevance Loss. The sentence-level relevance model provides a way to dig deeper into the overall QA model's behavior. When sentence-level supervision is available, as in the case of MultiRC, we can analyze the impact of different auxiliary losses for the relevance module. Table 6 shows the QA performance with different relevance losses, and Figure 5 shows a visualization of attention scores for a question in MultiRC. Overall, we find that two types of behaviors emerge from different loss functions. For instance, trying to minimize the sum of attention probability mass on irrelevant sentences i.e. $\sum_i \alpha_i(1 - y_i)$, called *IR Sum Loss*, causes the attention scores to become "peaky" i.e, high for one or two sentences, and close to zero for others. This leads to higher precision but at significantly lower recall for the QA system, as it now uses information from fewer but highly relevant sentences. Binary cross entropy loss (BCE) allows the model to attend to more relevant sentences thereby increasing recall without too much drop in precision.

	F1a precision	F1a recall
IR Sum Loss	**59.5**	68.5
BCE Loss	58.0	**83.2**

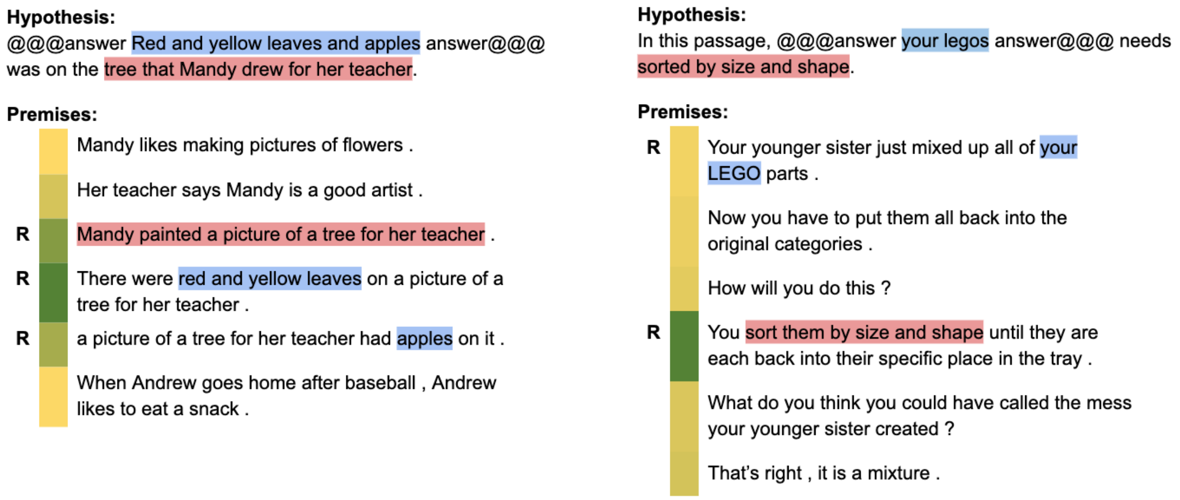
Table 6: F1a precision and recall on MultiRC Dev with 2 kinds of relevance losses. IR Sum is the sum of attention probability mass on irrelevant sentences. BCE is Binary Cross Entropy loss.

Failure Cases. As Figure 5 shows, our model with BCE loss tends to distribute the attention, especially to sentences close to the relevant ones. We hypothesize that the model is learning to use the contextualized BiLSTM representations to incorporate information from neighboring sentences, which is useful for this task and for passage understanding in general. For example, more than 60% of Dev questions in MultiRC have at least one adjacent relevant sentence pair. Figure 4a illustrates this behavior.

On the other hand, if the relevant sentences are far apart, the model finds it difficult to handle such long-range cross sentence dependencies in its contextualized representations. As a result, it ends up focusing attention on the most relevant sentence, missing out on other relevant sentences (Figure 4b). When these unattended but relevant sentences contain the answer, the model fails.

6 Related Work

Entailment systems have been applied to question-answering before but have only had limited success (Harabagiu and Hickl, 2006; Sacaleanu et al., 2008; Clark et al., 2012) in part because of the small size of the early entailment datasets (Dagan et al., 2006, 2013). Recent large scale entailment datasets such as SNLI (Bowman et al.,



Hypothesis:
@@@answer Red and yellow leaves and apples answer@@@ was on the tree that Mandy drew for her teacher.

Premises:
Mandy likes making pictures of flowers .
Her teacher says Mandy is a good artist .
R Mandy painted a picture of a tree for her teacher .
R There were red and yellow leaves on a picture of a tree for her teacher .

2015) and MultiNLI (Williams et al., 2018) have led to many new powerful neural entailment models that are not only more effective, but also produce better representations of sentences (Conneau et al., 2017). Models such as Decomposable Attention (Parikh et al., 2016) and ESIM (Chen et al., 2017), on the other hand, find alignments between the hypothesis and premise words through cross-attention. However, these improvements in entailment models have not yet translated to improvements in end tasks such as question answering.

SciTail (Khot et al., 2018) was created from a science QA task to push for models with a direct impact on QA. Entailment models trained on this dataset show minor improvements on the Aristo Reasoning Challenge (Clark et al., 2018; Musa et al., 2018). However, these QA systems make independent predictions and can not combine information from multiple supporting sentences.

Combining information from multiple sentences is a key problem in language understanding. Recent Reading comprehension datasets (Welbl et al., 2018; Khashabi et al., 2018; Yang et al., 2018; Mihaylov et al., 2018) explicitly evaluate a system's ability to perform such reasoning through questions that need information from multiple sentences in a passage. Most approaches on these tasks perform simple attention-based aggregation (Mihaylov et al., 2018; Song et al., 2018; Cao et al., 2018) and do not exploit the entailment models trained on large scale datasets.

7 Conclusions

Using entailment for question answering has seen limited success. Neural entailment models are designed and trained on tasks defined over sentence pairs, whereas QA often requires reasoning over longer texts spanning multiple sentences. We propose Multee, a novel QA model that addresses this mismatch. It uses an existing entailment model to both focus on relevant sentences and aggregate information from these sentences. Results on two challenging QA datasets, as well as our ablation study, indicate that entailment based QA can achieve state-of-the-art performance and is a promising direction for further research.

Abstract

Language is gendered if the context surrounding a mention is suggestive of a particular binary gender for that mention. Detecting the different ways in which language is gendered is an important task since gendered language can bias NLP models (such as for coreference resolution). This task is challenging since genderedness is often expressed in subtle ways. Existing approaches need considerable annotation efforts for each language, domain, and author, and often require handcrafted lexicons and features. Additionally, these approaches do not provide a quantifiable measure of how gendered the text is, nor are they applicable at the fine-grained mention level.

In this paper, we use existing NLP pipelines to automatically annotate gender of mentions in the text. On corpora labeled using this method, we train a supervised classifier to predict the gender of any mention from its context and evaluate it on unseen text. The model confidence for a mention's gender can be used as a proxy to indicate the level of genderedness of the context. We test this gendered language detector on movie summaries, movie reviews, news articles, and fiction novels, achieving an AUC-ROC of up to 0.71, and observe that the model predictions agree with human judgments collected for this task. We also provide examples of detected gendered sentences from aforementioned domains.

1 Introduction

Language can be extraordinarily gendered (Moulton et al., 1978). *Genderedness* in language is when we use words or phrases that are stereotypical or indicative of a particular gender (we only consider male vs female in this work) (Prior, 2017). It is important to detect this bias in language since not only is this bias propagated to the readers (Menegatti and Rubini, 2017), but also machine learning algorithms trained on gendered corpora tend to become biased (Zhao et al., 2018a; Rudinger et al., 2018), often aggravating the disparity (Zhao et al., 2017).

Bias in language and machine learning systems can lead to unfair treatment, e.g., early work by Moulton et al. (1978) shows that males have an advantage in contexts where they are referred to by a putative neutral term. Recent work on coreference resolution systems (Zhao et al., 2018a) shows that bias in machine learning systems originates from training on existing corpora, resulting in male-stereotyped professions like surgeon and president incorrectly resolved to males instead of females. Such biases in machine learning systems can lead to unintentional biases in downstream tasks producing effects like preferential treatment to male candidates over female candidates when selecting resumes (Dastin, 2018). Detecting these biases is the first step in finding a solution.

Most of the current works for related problems tend to be domain-specific (Fu et al., 2016), rely on techniques such as simple counting of gender occurrences (Ali et al., 2010), or use manually constructed lexicons and features for analysis (Trix and Psenka, 2003), and thus do not generalize well and require expensive manual supervision. Existing approaches also tend to either focus on the whole corpus/article being gendered (Schmader et al., 2007; Trix and Psenka, 2003) or a specific word being gendered (Caliskan et al., 2017; Bolukbasi et al., 2016; Zhao et al., 2018b), thus failing to capture the subtle occurrences of genderedness at mention-level or giving a quantifiable measure of how gendered the text is.

In this paper, we develop a method that eliminates the manual annotation requirement, and can generalize to words, phrases, sentences, articles, as well as whole corpora. We present a framework for automated data labeling by combining existing NLP pipelines to identify sentence boundaries and mentions (using NER tagger) and using a gen-

Proceedings of NAACL-HLT 2019, pages 2959–2969
Minneapolis, Minnesota, June 2 - June 7, 2019.

Female	Their client is 🟥 who has got gorgeous hair.
Male	🟥 intends to marry lovely Gauri.
Female	Raja intends to marry lovely 🟥 .

Figure 1: **Examples of gendered sentences.** Our model predicts gender for mentions located at positions indicated by colored boxes.

der classifier for names to get the gender of the mentions. We build a classifier using this annotation to predict gender of a mention *only from its context* and quantitatively analyze the *genderedness* of various contexts using this model. Figure 1 shows example inputs and outputs for our model. Input to the model is the context sentence around a target mention (indicated by colored boxes), and the model prediction is the gender of this mention. For the first sentence, the model uses context information coming from 'gorgeous hair' to predict the gender of mention to be female, indicating a more gendered sentence. Similarly for the third sentence, model uses contextual information from the adjective 'lovely' and its proximity to the target mention to predict female. For the second sentence, the target mention is subject for the verb in phrase 'intends to marry' and the object to be married is 'lovely Gauri'. Our model uses this information to predict gender of target mention as male.

Since our data labeling pipeline is automated, we can easily annotate millions of documents and train complex classifiers that can accurately model the context. These classifiers can be used to predict the gender of a mention from given context and quantify genderedness. We present instantiations of this framework on four domains: news articles, novels, movie summaries, and movie reviews. Since we are the first to study the task of mention-level gender detection, we evaluate the difficulty of the task and introduce the first benchmark using a user study. We find that the task is challenging, and our model predictions corroborate with human predictions. We present qualitative results of our model showing genderedness at different granularities – word, phrase, sentence, and corpus.

2 Related Work

Gender Bias in Datasets A number of approaches have considered gendered language use. Blatt (2017) shows that *shivered, wept, screamed* are disproportionately used to describe women while *muttered, grinned* are used to describe men. Studies on gender bias in student evaluations for instructors (Eidinger, 2017; MacNell et al., 2015; Boring et al., 2016; Centra and Gaubatz, 2000), and recommendation letters (Trix and Psenka, 2003; Schmader et al., 2007) also show similar disparities in terms of harshness of evaluations, length of letters, descriptive words, and use of standout adjectives. Bias in language has also been studied for textbooks (Otlowski, 2003; Gharbavi and Mousavi, 2012; Macaulay and Brice, 1997), Wikipedia edits (Recasens et al., 2013), political text (Yano et al., 2010), media content (Ali et al., 2010; Len-Ríos et al., 2005; Smith, 1997), sports journalism (Eastman and Billings, 2000; Tyler Eastman, 2001; Kinnick, 1998; Fu et al., 2016) and in movie character portrayals (Ramakrishna et al., 2017; Sap et al., 2017). These approaches are domain-specific and rely on techniques like counting gender occurrences, manually annotating words or mentions, constructing list of keywords and lexicons, carrying out surveys, etc. Our approach works across domains, and does not require manual annotations.

There has been significant amount of work in detecting author's gender (Koppel et al., 2002; Herring and Paolillo, 2006; Sarawgi et al., 2011; Mukherjee and Liu, 2010; Burger et al., 2011) for text, speaker gender for dialogues (Schofield and Mehr, 2016) in films, and to detect and reduce biases in these (Tatman, 2017; Thelwall, 2018; Koolen and van Cranenburgh, 2017). While we do not focus on predicting the gender of the author, our framework can be used as a tool to compare the use of gendered language across various authors, or across various works by the same author.

Gender Bias in NLP Pipelines There has also been recent interest in examining the role of gender bias in existing NLP pipelines. Caliskan et al. (2017) and Bolukbasi et al. (2016) show that word embeddings exhibit gender stereotypes. Garg et al. (2018) build on this idea, using word embeddings to characterize the evolution of gender stereotypes during the 20th and 21st centuries. Subsequent works attempt to mitigate this bias in embeddings (Zhao et al., 2018b). Zhao et al. (2019) extend the idea to contextualized word embeddings (Peters et al., 2018), and quantify and propose ways to mitigate gender bias in them , while Gonen and Goldberg (2019) show that current approaches for debiasing embeddings are superficial.

Researchers have studied gender bias outside word embeddings as well. Zhao et al. (2017) show that datasets for multi-label object classification and visual semantic role labeling are gender-biased and that models trained on these datasets amplify this bias, while Rudinger et al. (2017) find racial, religious and gender stereotypes in the SNLI corpus and Park et al. (2018) analyze gender bias in abusive language datasets. Zhao et al. (2018a) and Rudinger et al. (2018) detect bias in existing coreference resolution systems, and Webster et al. (2018) build a gender-balanced labeled corpus of ambiguous pronoun-name pairs to understand this bias. All of these either focus on whether the corpus as a whole is gendered or if a single word is gendered (in case of word embeddings). Instead, we train a classifier to detect and quantify gendered language at mention-level. Our framework can also be used to quantify genderedness at different levels – mention, sentence, document, or corpus.

3 Gendered Language Detection

In this section, we elaborate on gendered language, and describe our proposed architecture and training method to detect and quantify it.

Gendered Language Gendered language is the use of words and phrases that *discriminate*[1] the gender of a subject. In other words, the gender of mentioned person should be easy to predict from context if the text is gendered. Examples of gendered language can be found in the use of stereotypes like linking women to homemakers and men to programmers (Bolukbasi et al., 2016) or when pronouns, adverbs, adjectives, nouns are used carelessly, e.g., when a masculine pronoun mention 'he' is used to refer to both sexes (Cottier, 2018; Stout and Dasgupta, 2011) or when pronoun mentions are used exclusively to define professions by gender (using 'she' when talking about a nurse). Detecting gendered language is incredibly challenging since the ways in which gender is expressed can vary considerably across authors, domains, and time periods, making any approach that requires annotations to be corpus-specific.

Proposed Architecture We are interested in determining the extent to which language in context of the mention reveals the gender. Humans learn to detect gendered language based on a lifetime of reading and observing society, and learning language specific to each gender. We use this intuition to propose an automated framework for detecting mention-level genderedness for any corpus (an overview is shown in Figure 2).

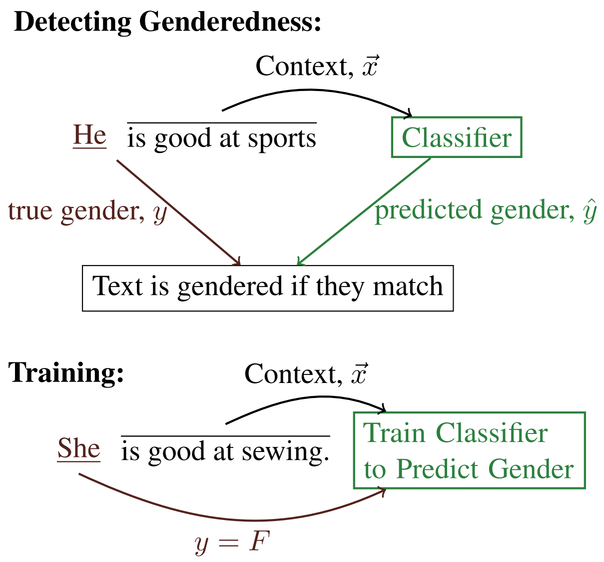

Figure 2: **Model overview.** Using an automatically labeled corpus, we train a classifier to predict the gender for each mention given its context (without the mention). For each target mention and its context sentence, we check whether the predicted gender matches the true prediction; the level of agreement indicates the *genderedness* of the text.

The input to the gender detector is the context (sentence) without the target mention and the output is the detector prediction for gender of that mention. For a mention i, let C_b^i be the context before the mention, C_a^i be the context after the mention and f_θ be the gender detector. Then,

$$p_i = f_\theta(C_a^i, C_b^i) \tag{1}$$

is the detector's probability (confidence) that the mention i is female, i.e. p_i close to 0 indicates high confidence for predicting male while close to 1 indicates high confidence for females.

We use the detector's probability of the *true* gender of the mention (g_i) as an estimate of how gendered the text is: a high probability indicates that gender is heavily reflected in the context. We define this as the gendered score, given by G_m^i here:

$$G_m^i = \begin{cases} p_i & \text{True gender } g_i \text{ is female} \\ 1 - p_i & \text{True gender } g_i \text{ is male} \end{cases} \tag{2}$$

We define gendered score for a document as the average of gender score for all of its mentions. i.e.

$$G_{\text{doc}} = \frac{1}{N} \sum_{i=1}^{N} G_m^i \tag{3}$$

where N is the number of person mentions.

Dataset	Male Mentions	Female Mentions
Reviews	298,580	104,632
Summaries	405,368	186,626
News	19,012,473	3,902,510
Novels	18,433,400	6,982,348

Table 1: **Dataset details.** Number of male and female mentions in the different datasets are shown.

As detector, rather than relying on frequency-based linear models or Naive Bayes model, we can use simple as well as more complex classifiers that can accurately model semantics and syntax of the context. For example, we use bag-of-words models (with logistic regression classifier) and recurrent neural network models as described in Section 4.2.

4 Datasets and Classifiers

In this section, we give details about the datasets, our pipeline for automated data labeling, filtering and processing applied to contexts in order to remove obvious gender information, and the classifiers used to classify gender of a given mention.

4.1 Datasets and data processing

To illustrate the utility of our proposed approach, we analyze text from four different domains:

- New York Times articles from the Annotated Gigaword corpus (Napoles et al., 2012)
- Novels from Gutenberg corpus [2]
- IMDB Movie Reviews (Maas et al., 2011)
- Movie Summaries (Bamman et al., 2013)

These domains cover a variety of writing styles. While the novels represent fictional writing, news articles are non-fictional. Movie summaries dataset describes the plot of the movies, i.e., how gender is represented in the plots, and the movie reviews dataset provides the ways in which people express their views on the plots, i.e., how gender is represented in user perception of the movie.

We train classifiers for each domain to predict the gender of mentions from the context they appear in, and use the resulting classifiers to detect gendered language. Similar idea is explored in Choi et al. (2018) to detect the type of mention from the context. For news, data from the first 6 months for every year is used for training, next three for validation, and last three for testing. For novels and movie summaries, we divide the data randomly into $50:20:30$ split for train, validation and test data. For movie reviews, we use the predefined split for train and test data, further dividing the training data into training and validation data.

1 Miss Mary Briganza will go to Korea with her parents.
2 Miss <*female*> will go to Korea with her parents.
3 <*Title*> <*female*> will go to Korea with <*their*> parents.
4 <*Title*> ____ will go to Korea with <*Their*> parents.

Figure 3: **Annotation pipeline.** We show the annotation and data processing pipeline step-by-step. **1** is the original sentence. **2** is the sentence after detecting positions of all mentions in the sentence, and replacing them with a placeholder for gender of that mention. **3** is the sentence after removing obvious gender information such as replacing gendered-pronouns (*he*, *she*) with a gender-neutral pronoun (*them*), and titles *Mr., Mrs., Miss* with a placeholder title word. **4** is the final input to our classifier where ____ is the position of mention for which classifier needs to predict gender (male or female).

Labeling Gender for Mentions We illustrate our processing pipeline via the example sentence in Figure 3. For mention-level gender prediction, we need a dataset with identified person mentions and their genders. Since we do not have labeled data, we need to identify mentions in contexts, and assign gender labels to them. Along with pronouns 'he' and 'she', we use spacy[3] to tag all corpora with NER tags to identify the set of person mentions. We use the SSN baby names dataset[4] from 1880 to 2016 to assign gender to each name. If a name is associated with more than one sex, we exclude it if it is ambiguous (being less than 4 times more frequent for one sex), but otherwise assign it to the more frequent sex. If a name is absent from our list of names, we replace the mention with a placeholder <*Person*>. Table 1 shows the count of male and female mention-context pairs generated using this pipeline. Processed sentence after this step is sentence 2 in Figure 3.

Filtering and Input Context Processing To remove obvious, uninteresting gender information, we discard sentences that contain any word from a gender-specific lexicon as used by Bolukbasi et al. (2016) such as gender-specific occupation words and gender-specific familial relation words, e.g., 'man', 'woman', 'prince', and 'hostess'. Complete list is given in Appendix A. For contexts that contain gender-indicative pronouns ('him', 'her', 'his',

---

[2] Project Gutenberg, from www.gutenberg.org

[3] https://spacy.io

[4] https://www.ssa.gov/oact/babynames/

'hers', 'himself', 'herself'), we replace them with a gender-neutral pronoun (*'them', 'their'*). All other mentions in the context (including 'he' and 'she') are replaced with a gender neutral word, and titles (*'Mr', 'Mrs', 'Miss'*) are replaced with a gender-neutral title word. Sentence 3 in Figure 3 is the result after this stage.

4.2 Classifier Details

The input to classifier is sentence 4 in Figure 3 and the target is 1 (for female). We extract such mention-context pairs from large text corpora to train classifiers that can predict the gender of individual mentions from their context using minimal manual supervision (as illustrated in Figure 2).

Bag-of-words and ngrams We construct bag-of-word classifiers by selecting the $50,000$ most frequent words from the training subset, and bag-of-ngrams models by selecting the $100,000$ most frequent n-grams (up to 3-grams), for each dataset. We explore a number of classifiers like logistic regression, support vector machines, random forest classifier, and choose logistic regression classifier since it consistently performs better than others.

LSTMs and CNNs We use both uni- and bidirectional LSTM recurrent neural networks for the context. In the 2-way LSTM model, we use two separate LSTMs: one for context before the mention, and the other for context after the mention. The direction of LSTM for latter part is reversed so that the model gives more importance to words closer to the target mention. This is followed by a sigmoid layer after the concatenation of the final hidden states. The input layers are initialized using the Glove vectors (Pennington et al., 2014), and are updated during training. We train the classifier with log-loss and Adam (Kingma and Ba, 2014) optimization algorithm, including dropout (Srivastava et al., 2014) and early stopping for regularization. Hyper-parameters are tuned for different domains separately. We experiment with ELMo embeddings (Peters et al., 2018), convolutional neural network (CNN)-based architectures, vanilla recurrent neural network (RNN), and gated recurrent unit (GRU) (Cho et al., 2014) models as well.

Performance Since our datasets are imbalanced, we use AUC-ROC as a performance metric. Table 2 shows AUC-ROCs for various models for all the datasets. Conventional bag-of-word/ngrams classifiers exhibit AUC-ROCs comparable to more complex LSTM and CNN classifiers. We use 2-way LSTM as the classifier for our final analysis.

	Reviews	**Summaries**	**News**	**Novels**
Bag-of-ngrams	0.64	0.62	**0.70**	**0.71**
Bag-of-word	0.63	0.62	**0.70**	**0.71**
Single LSTM	**0.67**	0.62	0.63	0.63
2-way LSTM	**0.67**	**0.66**	0.68	0.67
2-way LSTM + ELMo	**0.67**	0.65	**0.70**	0.69
2-way RNN	0.65	0.63	0.65	0.63
2-way GRU	**0.67**	**0.66**	0.69	0.66
CNN	0.66	0.64	0.68	0.64

Table 2: **AUC-ROCs for different models (evaluated on test data).**

5 Human Annotation Evaluation

To assess the difficulty of this task and to compare performance of our gendered language detector against a human baseline, we use Amazon Mechanical Turk to get human annotations for 500 random sentences from the test sets of each domain.

Task Description Turkers are shown sentences with missing mention, e.g., *'Sandwich maker ____ said mojo and fresh roasted pork are key to a great Cuban sandwich'*, and are asked to guess the gender of the missing mention. We sample the sentences such that the true labels (male/female) are balanced. For our study, we use two tasks that slightly differ from one another in the decisions turkers need to make. In one task, turkers are given only two options, *male* and *female*, forcing them to make a choice. In the second task, turkers are given five options on the Likert scale: *extremely likely male, likely male, neutral, likely female, extremely likely female* allowing for a finer scale of decision. We include examples in the instructions, and a few extremely easy examples as probes to verify quality (Munro et al., 2010). Each worker is shown 35 sentences from a single domain. On average, we collect 7 human annotations per sentence.

Do humans predict gender well? Sentences that do not have a clear majority are removed from our analysis. As a measure of inter-rater reliability, we compute pairwise and majority agreement, in Table 3. Percentage improvement over chance agreement is higher for 5-scale rating compared to 2-scale rating indicating that users tend to agree more when they are able to tag the borderline (possibly confusing) mentions as gender-neutral (chance agreement is 0.5 for 2-scale, and 0.2 for

Dataset	Pairwise		Majority	
	2-Scale	5-Scale	2-Scale	5-Scale
Reviews	0.62	0.32	0.74	0.52
News	0.65	0.38	0.77	0.55
Novels	0.60	0.33	0.73	0.52
Summaries	0.61	0.33	0.73	0.53
Combined	0.62	0.35	0.74	0.53

Table 3: **Pairwise and majority inter-annotator agreement for instances with clear majority.** 2-Scale indicates when users are asked to indicate male or female, while 5-Scale indicates gender on a scale of 5.

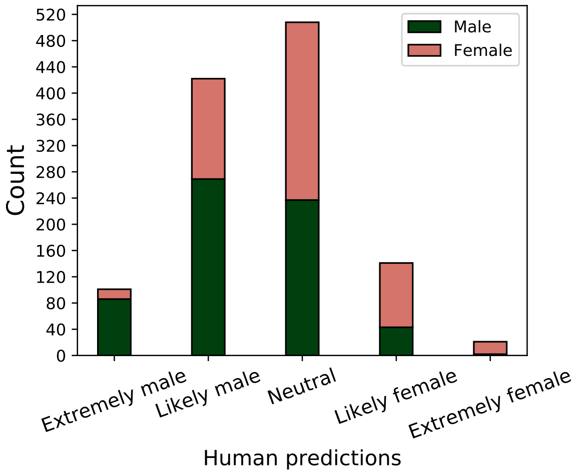

Figure 4: **Comparing Human Predictions to Truth.** x-axis represents the human prediction for mentions, while the green and pink bars represent counts of true male and female mentions respectively.

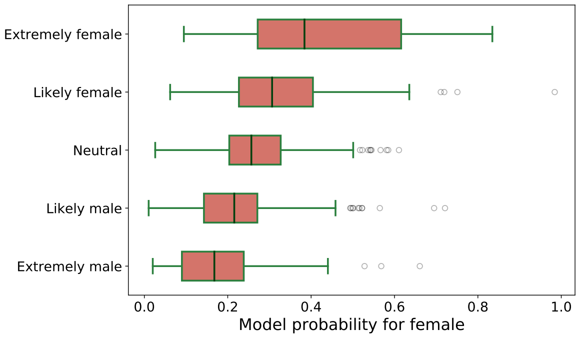

Figure 5: **Human and Model Predictions.** x-axis is the classifier probability where higher probability indicates female prediction. The points outside the range indicate outliers. Right shift of green line (representing median values) as we move from extremely male predictions to extremely female predictions corroborates the agreement between humans and classifiers.

5-scale task). To analyze the kind of mistakes humans make, we show the true distribution of male and female mentions compared against human predictions in Figure 4. 42% of examples are predicted *'Neutral'* by humans showing that the task is pretty difficult for humans as they often find mention gender ambiguous. Further, *'Likely male'* and *'Likely female'* categories have around 30% wrong predictions as well. These high error rates explain low F1 of 0.52 for human annotations. *'Extremely male'* and *'Extremely female'* have the least error rates showing that humans are more precise when they are more confident about the predictions.

Does our model match humans? In order to compare human annotations against model predictions more concretely, we choose to use Kendall's τ_c statistic (Berry et al., 2009), because it allows us to compare two variables when their underlying scales have different numbers of values. Like correlation coeeficients, τ_c ranges from -1 (fully negative association) to +1 (fully positive association). τ_c between humans and our LSTM model predictions vary from 0.23 to 0.36 showing positive correlation. We also look at classifier probability distribution for human decisions shown in box and whisker plot in Figure 5, where x-axis is the classifier probability of the mention being female. The median value of classifier prediction for each category (shown in green line) shifts towards female prediction as we move from 'Extremely male' to 'Extremely female' category, corroborating the agreement between humans and model.

6 Analysing Gendered Language

We first show aggregate word level and phrase level analysis, then show more complex and subtle sources of gendered language on sentence level.

Word-level Analysis Table 4 shows the top nouns and verbs extracted using bag-of-word classifier. We also train separate classifiers only on nouns, on adjectives, and on verbs in order to find out which are most informative for gender. Classifiers trained only on nouns performs best, indicating that nouns have most information. Top male-indicative nouns stem from typically male-dominated sports, while top female-indicative nouns are related to fashion and home industry.

Phrase-level Analysis Table 5 shows some of the top phrases for predicting males and females for different domains extracted using bag-of-ngrams models. We see phrases like *'clasped their hands'*, *'fashion show'*, *'jealous rage'*, *'was asked to'* for females, while *'clockwork orange'*, *'action hero'*,

Female-specific Nouns	**Male-specific Nouns**
Summaries: cherie, elisabet, crawlers, plastics, governess, cheerleader, prostitution, overdosing, bimbo, spinner	**Summaries:** quacker, platoon, tweety, shemp, cellmate, ham, nibbles, falstaff, pup, towel, mousehole, bullies
Novels: godmother, melvina, skirt, girlhood, lucile, womanly, eyebright, womanhood, shawl, dressmaker, demurely	**Novels:** disciples, yussuf, rifle, jr, pepe, cigar, colleague, followers, erasmus, judas, opponents
Reviews: comedienne, floriane, slut, adela, tch, topless, actress, tits, feminist, modeling, redhead, helen, vamp, bettie	**Reviews:** seagal, inventor, panther, opponent, sellers, ratso, comedian, lawman, yossi, creators, brutus, ted
News: gymnasts, dietitian, lpga, hingis, feminist, dowd, sorenstam, wie, receptionist, omnimedia, quilting, homemaker	**News:** spurs, astros, nicks, jets, sprewell, nets, vikings, clippers, lakers, holyfield, sonics, councilman, nba, bucs, pitches
Female-specific Verbs	**Male-specific Verbs**
Summaries: giggles, conceive, type, spurned, distorted, strokes, railing, rehearse, gag, disowned, plaguing, forgo	**Summaries:** commanding, barks, crack, credited, embezzled, executes, opposing, foils, relying, assassinate, engineered
Novels: sobbed, sew, blushed, wailed, pouted, scream, moaned, giggled, weeping, blushing, sob, shrieked, faltered	**Novels:** preached, elected, growled, states, yelled, roared, nominated, voted, grinned, slew, preach, fire, attack
Reviews: swims, bare, willed, raped, married, pouting, pleading, glows, kisses, liberated, seduces, fled, numbed	**Reviews:** direct, assuming, elected, defeat, casted, laid, mumbles, rule, directing, flicks, drinking, produce
News: fax, widowed, choreograph, raped, graduates, decorating, sobbing, majoring, giggling, married, cries, decorate	**News:** coach, pitching, batted, disarm, sacked, benched, fumbled, lightning, averaged, traded, sprained, vetoed

Table 4: Most important nouns and verbs for predicting male/female.

	News	**Reviews**	**Summaries**	**Novels**
Female gendered phrases	was pregnant	femme fetale	fashion show	suffrage association
	administrative assistant	nude scenes	jealous rage	clasped *their* hands
	their baby	strong willed	same way that	glass eye
	staff to vice	pop star	was asked to	corresponding secretary
	social worker	is hot	unborn child	dressing room
Male gendered phrases	defense secretary	action hero	construction worker	lieut col
	their locker	*their* screenplay	of the next	*their* pipe
	super tuesday	clockwork orange	school bully	*their* rifle
	offensive coordinator	court martial	Vietnam war	old fellow
	majority leader	nothing like the	make living	jimmy skunk

Table 5: **Most important phrases for predicting male/female.** *'their'* represents gender-neutral pronoun.

'construction worker' occur for males. Similarly, the term *'secretary'* occurs frequently with females, however phrases like *'defense secretary', 'treasury secretary'* are positive features for male mentions indicating male-domination of certain fields.

Sentence-level Analysis Our approach is the first to find gendered sentences from a huge corpora. We present examples of detected gendered language in Table 6; the first two columns show contexts for which a high level of gendering is estimated (most confident estimates), while the classifier has very low confidence for the examples in third column, indicating gender-neutral use of language. We see several interesting examples, e.g., male-gendered contexts from summaries show that society attributes roles like billionaire computer moguls and FBI-agents to males. The first female gendered example from novels depicts the way in which females are described and portrayed in fiction, which is in stark contrast to male descriptions.

Corpus-level Analysis Our approach allows us to automatically analyze large corpus of text, enabling high-level analysis of what documents are most, or least, gendered. Table 7 shows such an analysis, where the languages for movie reviews and summaries, genres for novels, and news desks for news are organized by their estimated genderedness. We see that children's history books are more gendered than their literature books. Books related to opera and one-act plays are among the least gendered ones, while those related to war, history, and philosophy use gendered language the most. Movie reviews for movies in Vietnamese, Turkish and Polish are among the most gendered, while Greek and Japanese are the least gendered. We see a similar pattern in movie summaries - summaries for movies filmed in Polish and Turkish are more gendered than for movies in Korean or Romanian. *Sports* is the most gendered category for news articles, while *Cultural*, *Leisure*, *Society*, and *Home* are among the least gendered ones. The table also contains some unexpected predictions, such as the low gendering of *Girls* and *Young women* novels.

	Female gendered	Male gendered	Gender neutral
News	– J.J.'s research brings *them* to find *Person*, a farmer who is slowly devouring a 747 to win the heart of lovely 🟥 , editor of the local newspaper. – It's a film about *Person* directed by *Person*, and I play the soprano 🟥 .	– USC is expected to announce that former New England patriots coach 🟥 will be its next football coach. – It has fired up a torrid debate over President-elect 🟥 's $ 1.3 trillion tax cut proposal.	– *Person* had props to bolster *their* story, 🟥 added. – In North Dakota, *Person* and 🟥 - who are married to each other - were running against each other for foster county prosecutor.
Novels	– *Person* looked untidier than ever; 🟥 wore a slatternly wrapper, and *their* hair was thrust unbrushed into its net. –"What is it?" asked *Person*, as 🟥 folded and smoothed *their* best gown.	– If the collector will remember that, though 🟥 is the present owner of *their* prints... – *Person* is not an orator; *person* is not a writer; 🟥 is not a thinker.	– 🟥 got up and went so – so unexpectedly. – The hand of the child admitted *them* to the chamber of death; the door closed, and 🟥 stood motionless.
Reviews	– Lake's secretary, 🟥 , is *Person*'s sweetheart . – Aeon played by the lovely 🟥 in this adaptation, is dexterous as a line-dancer and deadly as a viper-snake.	– Herein, only old-time Broadway producer 🟥 and *their* fey secretary *Person* maintain interest. – 🟥 's rolling in the sheets with *their* beautiful secretary Meredith.boris.	– 🟥 's hysterical and so are *their* backup singers. – 🟥 is the only one worth seeing in this film , but *person* doesn't get to do much.
Summaries	– 🟥 is raped by the estate owner, who then writes off *person*'s debt. – *Person*, an architect, is married to *their* sweetheart 🟥 with two children.	– *Person* befriends a billionaire computer mogul 🟥 and a cafe waitress.. – FBI-agent 🟥 becomes an unwitting pawn of the white hand drug cartel.	– *Person* goes over to check on *them*, insisting *person* reopen the blinds, but 🟥 denies doing it. – In order to stifle *their* theatrical aspirations, 🟥 arranges a screen test.

Table 6: **Examples of gendered and non-gendered mention-context pairs from different domains.** *them/their* represents a gender-pronoun replaced with a gender neutral pronoun. *Person* represents mention. Note that in the first example for news (in female-gendered column), *J.J.* has not been identified as a mention. This is a weakness in the preprocessing.

Reviews Language	Summaries Language	Novels Genre	News News Desk
Vietnamese	Serbian	US Civil War	Sports
Turkish	Arabic	US Politics	Foreign
Polish	Thai	Mathematics	Financial
Cantonese	Czech	Military Science	Week in Review
Arabic	Polish	Evolution	National
Mandarin	Turkish	Dictionaries	Business
Korean	Khmer	Girls	Living
Latin	Korean	Young women	Travel
Portuguese	Sinhala	Sisters	Society
French	Hungarian	Family Life	Home
Greek	Punjabi	Marriage	Style
Japanese	Romanian	Italy	Performing Arts

Table 7: **High-level Analysis of Corpora.** Most and least gendered languages for movie reviews and summaries; genre for novels; news desk for news articles.

7 Discussion and Future Work

Sex vs Gender Since the current English language use is mostly limited to binary gender identities (both due to grammar and usage), we treat gender as a binary concept in this work. Inclusion of genderqueer and non-binary identities will require data annotated by humans with sufficient domain knowledge, which was out of scope for this work. We assume that mentions for which our labeling has associated the wrong 'gender' because of difference in sex/gender identities are sufficiently low in proportion that model is still able to learn relevant signals when trained on large corpora.

Facts vs Stereotypes In this work, we do not delineate between factual information (women get *pregnant*) and the intentional use of stereotypes (women are *sweethearts*). In some domains, such as news, ignoring this difference can be misleading, and exploring approaches that are able to better separate these different biases is important.

Extension to New Domains There remain a number of exciting avenues for future work. Although we analyze a variety of domains that differ from each other, our analysis focused on independently investigating each; it may be much more fruitful to compare and contrast the gendered language across multiple domains. When extending this work to other domains like Twitter, blogs, etc., the performance of the system can be affected by various factors like accuracy of NER system for the domain (e.g., it would be lower for tweets) and names to gender mapping (which can vary for different geographies and cultures).

8 Conclusions

We present a concrete implementation and evaluation of our gendered language detector. The main advantages of our pipeline and method are: (1) *Flexibility*, in application to different domains with minimal manual intervention, (2) *Mention-level* analysis, instead of article-level analysis in previous works, enabling more granular analysis, and (3) *Quantitative measure* of the extent of genderedness of context given a mention, allowing large-scale and detailed analyses and comparisons.

Our pipeline automatically extracts person mentions from a corpus, and by using an accurate gender predictor, trains a classifier to learn the ways in which language is gendered *for that corpus*. This automation provides multiple benefits; not only are there no humans in the loop to inject their biases about what is, and is not, gendered language, but further, collection of a large annotated corpus allows us to train sophisticated neural models that are able to capture semantic and syntactic constructions in the language. Evaluation suggests that our model is fairly accurate on this challenging task, and further, allows us to carry out analysis on multiple domains at varying levels of granularity, demonstrating potential applications of this work. The code to support such endeavours, and to reproduce the results, is available at https://ucinlp.github.io/GenderQuant.

Abstract

We provide an NLP framework to uncover four linguistic dimensions of political polarization in social media: topic choice, framing, affect and illocutionary force. We quantify these aspects with existing lexical methods, and propose clustering of tweet embeddings as a means to identify salient topics for analysis across events; human evaluations show that our approach generates more cohesive topics than traditional LDA-based models. We apply our methods to study 4.4M tweets on 21 mass shootings. We provide evidence that the discussion of these events is highly polarized politically and that this polarization is primarily driven by partisan differences in framing rather than topic choice. We identify framing devices, such as grounding and the contrasting use of the terms "terrorist" and "crazy", that contribute to polarization. Results pertaining to topic choice, affect and illocutionary force suggest that Republicans focus more on the shooter and event-specific facts (news) while Democrats focus more on the victims and call for policy changes. Our work contributes to a deeper understanding of the way group divisions manifest in language and to computational methods for studying them.[1]

1 Introduction

Elites, political parties, and the media in the US are increasingly polarized (Layman et al., 2010; Prior, 2013; Gentzkow et al., forthcoming), and the propagation of partisan frames can influence public opinion (Chong and Druckman, 2007) and party identification (Fiorina and Abrams, 2008).

Americans increasingly get their news from internet-based sources (Mitchell et al., 2016), and political information-sharing is highly ideologically segregated on platforms like Twitter (Conover et al., 2011; Halberstam and Knight, 2016) and Facebook (Bakshy et al., 2015). Prior NLP work has shown, e.g., that polarized messages are more likely to be shared (Zafar et al., 2016) and that certain topics are more polarizing (Balasubramanyan et al., 2012); however, we lack a more broad understanding of the many ways that polarization can be instantiated linguistically.

This work builds a more comprehensive framework for studying linguistic aspects of polarization in social media, by looking at topic choice, framing, affect, and illocutionary force.

1.1 Mass Shootings

We explore these aspects of polarization by studying a sample of more than 4.4M tweets about 21 mass shooting events, analyzing polarization within and across events.

Framing and polarization in the context of mass shootings is well-studied, though much of the literature studies the role of media (Chyi and McCombs, 2004; Schildkraut and Elsass, 2016) and politicians (Johnson et al., 2017). Several works find that frames have changed over time and between such events (Muschert and Carr, 2006; Schildkraut and Muschert, 2014), and that frames influence opinions on gun policies (HaiderMarkel and Joslyn, 2001). Prior NLP work in this area has considered how to extract factual information on gun violence from news (Pavlick et al., 2016) as well as quantify stance and public opinion on Twitter (Benton et al., 2016) and across the web (Ayers et al., 2016); here we advance NLP approaches to the public discourse surrounding gun violence by introducing methods to analyze other linguistic manifestations of polarization.

1.2 The Role of the Shooter's Race

We are particularly interested in the role of the shooter's race in shaping polarized responses to these events. Implicit or explicit racial biases can be central in people's understanding of social

Proceedings of NAACL-HLT 2019, pages 2970–3005
Minneapolis, Minnesota, June 2 - June 7, 2019.

problems (Drakulich, 2015); in the mass shooting context, race is a factor in an event's newsworthiness (Schildkraut et al., 2018) and is often mentioned prominently in media coverage, particularly when the shooter is non-white (Mingus and Zopf, 2010; Park et al., 2012). Duxbury et al. (2018) find that media representations of white shooters disproportionately divert blame by framing them as mentally ill while representations of non-white shooters are more frequently criminalized, highlighting histories of violent behavior.

The important question remains as to how polarized ideologies surrounding race take shape on forums such as Twitter. Therefore, in all of the analyses throughout this paper we consider the race of the shooter as a potential factor. We note that in the 21 shooting events we study, shootings in schools and places of worship are overwhelmingly carried out by white perpetrators, so we cannot fully disentangle the effect of race from other factors.

2 Data: Tweets on Mass Shootings

Data collection. We compiled a list of mass shootings between 2015 and 2018 from the Gun Violence Archive.[2] For each, we identified a list of keywords representative of their location (see Appendix A). Given Twitter search API's limitations on past tweets, we retrieved data from a Stanford lab's archived intake of the Twitter firehose.[3]

For each event, we built a list of relevant tweets for the two weeks following the event. A tweet is relevant if it contained at least one of the event's location-based representative keywords and at least one lemma from the following list: "shoot", "gun", "kill", "attack", "massacre", "victim". We filtered out retweets and tweets from users who have since been deactivated. We kept those 21 events with more than 10,000 tweets remaining. For more details see Appendix A.

Partisan assignment. We estimate the party affiliation of users in the dataset from the political accounts they follow using a method similar to that of Volkova et al. (2014), which takes advantage of homophily in the following behavior of users on twitter (Halberstam and Knight, 2016). We compile a list of Twitter handles of US Congress members in 2017, the 2016 presidential and vice presidential candidates, and other party-affiliated pages.[4] We label a user as a Democrat if they followed more Democratic than Republican politicians in November 2017, and as a Republican if the reverse is true. For each event, 51–72% of users can be assigned partisanship in this way; to validate our method we compare state averages of these inferred partisan labels to state two-party vote shares, finding a high correlation (Figure 1).[5]

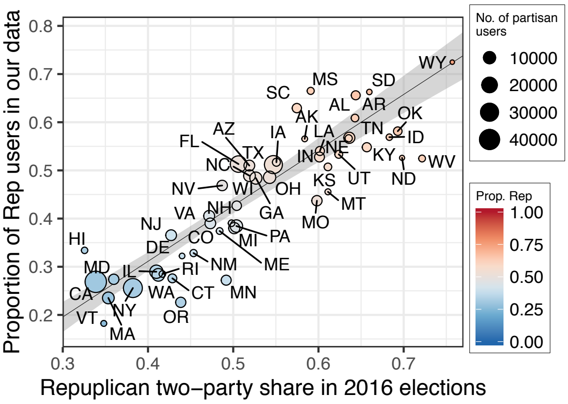

Figure 1: To validate our partisanship assignment, we compare the proportion of users we classify as Republican separately for each US state against the Republican share of the two-party vote. A weighted linear regression with the number of partisan users per state as weights obtains an adjusted R^2 of $.82$, indicating that the distribution of Republican users in our data and that of Republican voters across states is similar.

3 Quantifying Overall Polarization

We begin by quantifying polarization (equivalently, partisanship) between the language of users labeled Democrats and Republicans after mass shooting events. We establish that there is substantial polarization, and that the polarization increases over time within most events.

3.1 Methods

Pre-processing. We first build a vocabulary for each event as follows. Each vocabulary contains unigrams and bigrams that occur in a given event's tweets at least 50 times, counted after stemming via NLTK's SnowballStemmer and stopword removal.[6] We refer to these unigrams and bigrams collectively as *tokens*.

---

[2] `https://www.gunviolencearchive.org`

[3] With the exception of the two most recent shootings in Pittsburgh and Thousand Oaks, for which we collected tweets real time via the Twitter API.

[4] See Appendix B.1 for the complete list.

[5] We performed the sanity check for all partisan users with a valid US state as part of their geo-location (∼350k users).

[6] Stopword list is provided in Appendix A.1

Measure of partisanship. We apply the leave-out estimator of phrase partisanship from Gentzkow et al. (forthcoming). Partisanship is defined as the expected posterior probability that an observer with a neutral prior would assign to a tweeter's true party after observing a single token drawn at random from the tweets produced by the tweeter. If there is no difference in token usage between the two parties, then this probability is .5, i.e. we cannot guess the user's party any better after observing a token.

The leave-out estimator consistently estimates partisanship under the assumption that a user's tokens are drawn from a multinomial logit model. The estimator is robust to corpus size. The leave-out estimate of partisanship π^{LO} between Democrats $i \in D$ and Republicans $i \in R$ is

$$\pi^{LO} = \frac{1}{2}\left(\frac{1}{|D|}\sum_{i\in D}\hat{\mathbf{q}}_i \cdot \hat{\boldsymbol{\rho}}_{-i} + \frac{1}{|R|}\sum_{i\in R}\hat{\mathbf{q}}_i \cdot (1 - \hat{\boldsymbol{\rho}}_{-i})\right)$$

where $\hat{\mathbf{q}}_i = \mathbf{c}_i / m_i$ is the vector of empirical token frequencies for tweeter i, with $\mathbf{c}_i$ being the vector of token counts for tweeter i and m_i the sum of token counts for tweeter i; and $\hat{\boldsymbol{\rho}}_{-i} = (\hat{\mathbf{q}}^{D\setminus i} \oslash (\hat{\mathbf{q}}^{D\setminus i} + \hat{\mathbf{q}}^{R\setminus i}))$ is a vector of empirical posterior probabilities, excluding speaker i and any token that is not used by at least two speakers. Here we let $\oslash$ denote element-wise division and $\hat{\mathbf{q}}^{G} = \sum_{i\in G}\mathbf{c}_i / \sum_{i\in G} m_i$ denote the empirical token frequency of tweeters in group G. The estimator thus captures two intuitive components of partisanship: between-group difference (posterior probability for each feature), and within-group similarity (dot-product between the feature vector of each speaker and that of their group).

User-level measures. As the above leave-out estimator represents the average of user-level polarization values, we take the user-level dot product $(\hat{\mathbf{q}}_i \cdot \hat{\boldsymbol{\rho}}_{-i})$ as an estimate of the polarization of user i's language. We consider the correlation of this value and the number of politicians a user follows in total and from their preferred party.

3.2 Results and Discussion

Overall polarization. As Figure 2 shows, the discussion of each event[7] is highly polarized: values range from .517 to .547. For comparison, this measure, for most events, is similar to or higher than the polarization in the US congress ($\sim$ .53 in recent years) (Gentzkow et al., forthcoming). While we observe a slight increase in polarization over the past three years, this increase is not statistically significant ($p \approx .26$).

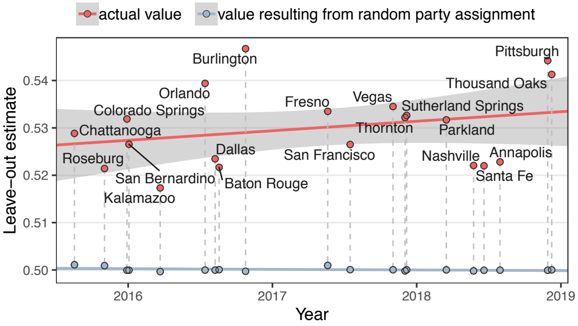

Figure 2: Tweets on mass shootings are highly polarized, as measured by the leave-out estimate of phrase partisanship (Gentzkow et al., forthcoming). The shaded region represents the 95% confidence interval of the linear regression fit to the actual values. To quantify noise, we also calculate the leave-out estimate after randomly assigning users to parties, matching the ratio of parties in the true data. The "values resulting from random assignment" are all close to .5, suggesting that the actual values are not a result of noise.

Post-event polarization. To see how polarization changes at the event level, we computed the leave-out estimate for each of the first 10 days following the events (see Figure 3). An event-day level regression of partisanship on days since the event suggests a slight increase in post-event polarization across events (slope = .002, $p < 0.05$). Fitting separate regressions, we find that the five events with the steepest increase in polarization are Burlington (slope = .03, $p < 0.05$), Orlando (slope = .006, $p < 0.001$), Las Vegas (slope = .003, $p < 0.001$), Chattanooga (slope = .003, $p < 0.05$) and Roseburg (slope = .003, $p < 0.05$) — note that except for Las Vegas, these shootings are all committed by a person of color.

Are the changes in the leave-out score due to *different* users tweeting at different times or due to the *same* users becoming more or less political? We found that while on average only $\sim 10\%$ of users tweeted on multiple days ($SD = 5\%$) across the events, these users contribute $\sim 28\%$ of the tweets ($SD = 15\%$). After removing these users from the leave-out estimation, we found that the temporal patterns remain with the same statistical significance, providing one piece of evidence

---

[7] For all the experiments using the leave-out estimator, we exclude Fort Lauderdale for which we only have tweets for the first day after the event; polarization is most dominant a few days after each event, making it incomparable. For reference, the leave-out estimate for Fort Lauderdale is .51.

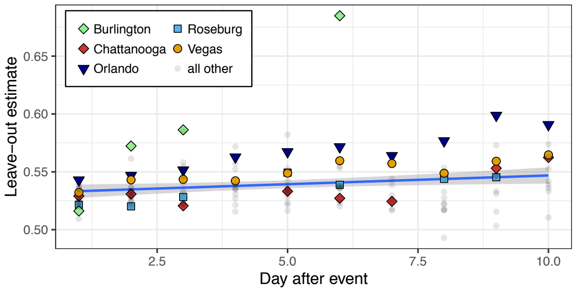

Figure 3: Leave-out estimate post-event.

that changes in polarization are not due to changes within users who tweet on multiple days.

User-level polarization. We estimated a linear regression of the leave-out score on the total number of followed politicians and the number from the user's preferred party, with controls for event indicators. The estimates imply that, fixing the total number of followed politicians, one more followed politician from one's preferred party is associated with an *increase* of .009 SD in the leave-out. Fixing the number of followed politicians from the user's preferred party, one more followed politician is associated with a *decrease* of .02 SD in the leave-out.

4 Topics and Framing

Topic choice can be a tool for agenda-setting by establishing what an author or institution deems worthy of discussion (McCombs, 2002), and works in NLP have used topic modeling as an approach to measure this effect (Tsur et al., 2015; Field et al., 2018). The strategy of highlighting particular aspects within topics as a means of framing (Entman, 2007) has also been quantified in the NLP literature (Boydstun et al., 2013; Card et al., 2015; Naderi and Hirst, 2017).

Previous work largely focuses on the relation between topic and framing in the news media; we study social media, proposing methods to identify general, non-event-specific topics and to quantify between- and within-topic polarization.

4.1 Methods

Topic assignment. Our goal is to induce topics that are salient in our narrow domain and comparable across events. This presents a challenge for traditional topic modeling approaches, since the discourse surrounding these events is inherently tied to concrete aspects of the events that tend to covary with topic usage, like location, setting, and demographics of the shooter and victims.

We build on the ability of vector space models to represent higher-level semantics to develop our own embedding-based topic assignment approach, comparing it with two traditional LDA-based methods: MALLET[8] and the Biterm Topic Model (BTM) (Yan et al., 2013); BTM was developed specifically for tweets. For all of these methods, we first randomly sample 10k tweets from each event forming our subset S of all tweets T; then, we create a vocabulary V of word stems that occur at least ten times in at least three events within S ($\sim$2000 word stems) and remove all stems from T are not part of V. Sampling is crucial for encouraging event-independent topics given the large disparity among event-level tweet counts (the largest event, Orlando, has 225× more tweets than the smallest event, Burlington).

For the embedding-based approach, we:

1. Train GloVe embeddings (Pennington et al., 2014) on V based on 11-50k random samples of tweets from each event.[9]
2. Create sentence embeddings $\mathbf{e}_t, \forall t \in T$ using Arora et al. (2017)'s method, by computing the weighted average $\mathbf{v}_t$ of the embeddings of stems within t and removing $\mathbf{v}_t$'s projection onto the first principal component of the matrix the rows of which are $\mathbf{v}_t, \forall t \in S$. Stem weights are set to be inversely proportional to their frequencies in S.
3. Jointly cluster the embeddings $\mathbf{e}_t, \forall t \in S$ via k-means using cosine distance and assign all tweet embeddings $\mathbf{e}_t, \forall t \in T$ to the centroids to which they are closest.

We also trained MALLET and BTM on S and used the resulting models to infer topics for all tweets in T, assigning each tweet to its highest probability topic. Henceforth, we use d to mean cosine distance for k-means and probabilities for MALLET and BTM.

A manual inspection found that about 25% of the tweets are either difficult to assign to any topic or they represent multiple topics equally. To filter out such tweets, for each tweet we looked at the ratio of d to its closest and second closest topic and removed tweets that have ratios higher than the 75th percentile (calculated at the model-level).[10]

---

[8] `http://mallet.cs.umass.edu/topics.php`

[9] This sample is different from S as it includes more tweets to increase data size, which is important for training the embeddings, where the slightly disproportional representation of events is less problematic.

[10] This procedure filters out 11-26% tweets (M=22%,

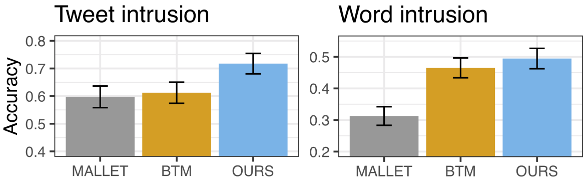

Figure 4: Topic model evaluations, collapsed across $k = 6 - 10$. Error bars denote standard errors.

Topic	10 Nearest Stems
news (19%)	break, custodi, #breakingnew, #updat, confirm, fatal, multipl, updat, unconfirm, sever
investigation (9%)	suspect, arrest, alleg, apprehend, custodi, charg, accus, prosecutor, #break, ap

other (23%)	dude, yeah, eat, huh, gonna, ain, shit, ass, damn, guess

Table 1: Our eight topics (with their average proportions across events) and nearest-neighbor stem embeddings to the cluster centroids. Topic names were manually assigned based on inspecting the tweets.

To compare the models, we ran two MTurk experiments: a word intrusion task (Chang et al., 2009) and our own, analogically defined tweet intrusion task, with the number of topics k ranging between 6-10. Turkers were presented with either a set of 6 words (for word intrusion) or a set of 4 tweets (for tweet intrusion), all except one of which was close (in terms of d) to a randomly chosen topic and one that was far from that topic but close to another topic. Then, Turkers were asked to pick the odd one out among the set of words / tweets. More details in Appendix D.

We find that our model outperforms the LDA-based methods with respect to both tasks, particularly tweet intrusion — see Figure 4. This suggests that our model both provides more cohesive topics at the word level and more cohesive groupings by topic assignment. The choice of k does not yield a significant difference among model-level accuracies. However, since $k = 8$ slightly outperforms other k-s in tweet intrusion, we use it for further analysis. See Table 1 for nearest neighbor stems to each topic and Appendix C.2 for example tweets.

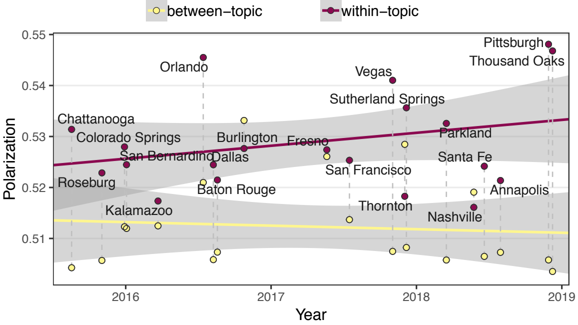

Figure 5: Measurements of between-topic and within-topic polarization of the 21 events in our dataset show that within-topic polarization is increasing over time while between-topic polarization remains stable.

Measuring within-topic and between-topic partisanship. Recall that the leave-out estimator from Section 3.1 provides a measure of partisanship. The information in a tweet, and thus partisanship, can be decomposed into *which* topic is discussed, and *how* it's discussed.

To measure *within-topic* partisanship for a particular event, i.e. how a user discusses a given topic, we re-apply the leave-out estimator. For each topic, we calculate the partisanship using only tweets categorized to that topic. Then, overall within-topic partisanship for the event is the weighted mean of these values, with weights given by the proportion of tweets categorized to each topic within each event.

Between-topic partisanship is defined as the expected posterior that an observer with a neutral prior would assign to a user's true party after learning only the topic — but not the words — of a user's tweet. We estimate this value by replacing each tweet with its assigned topic and applying the leave-out estimator to this data.

4.2 Results

Figure 5 shows that for most events within-topic is higher than between-topic partisanship, suggesting that while topic choice does play a role in phrase partisanship (its values are meaningfully higher than .5), within-topic phrase usage is significantly more polarized. Linear estimates of the relationship between within and between topic partisanship and time show that while within-topic polarization has increased over time, between-topic polarization has remained stable. This finding supports the idea that topic choice and topic-level framing are distinct phenomena.

Partisanship also differs by topic, and within days after a given event. Figure 6 shows polarization within topics for 9 days after Las Ve-

---

SD=4%) across events, for our model, for eight topics.

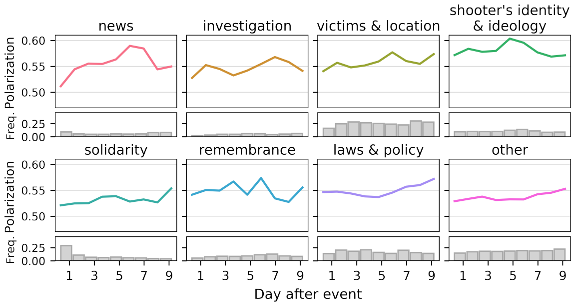

Figure 6: Las Vegas within-topic polarization in the days after the event. The bar charts show the proportion of each topic in the data at a given time.

gas. We find that *solidarity* has the lowest and *shooter's identity & ideology* the highest polarization throughout; polarization in most topics increases over time and *news* has the steepest increase. Similar patterns are present after Orlando (Figure 17 in Appendix I). Measuring polarization of topics for other events over time is noisy, given the sparsity of the data, but overall within-topic polarization is consistent: the most polarized topics on average across events are *shooter's identity & ideology* (.55) and *laws & policy* (.54), where people are apparently polarized about both why an event happened and what to do about it. Fact- and sympathy-based topics display less polarization: *news* (.51), *victims & location* (.52), *solidarity* (.52) and *remembrance* (.52).

As shown in Figure 7, *investigation*, *news*, and *shooter's identity & ideology* are more likely to be discussed by Republicans and *laws & policy* and *solidarity* more likely to be discussed by Democrats across events.[11] Topics preferred by Republicans seem to relate more to the shooter than to the victims, while topics preferred by Democrats seem to relate more closely to the victims. The shooter's race appears to play a role in topic preference: if the shooter is white, Democrats become more likely to focus on *shooter's identity & ideology* and *laws & policy* and Republicans on *news* and *investigation* than if the shooter is a person of color.

5 Specific Framing Devices

In the previous section, we show that topic-level framing and topic choice are different dimensions of polarization. We now look at the specific terms

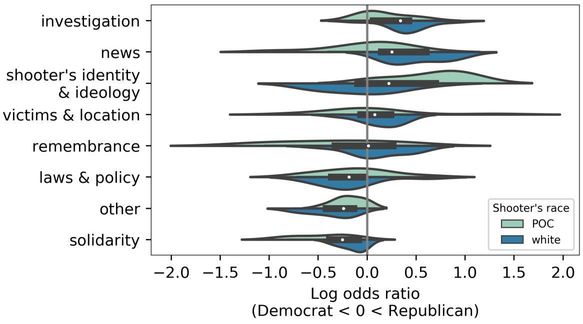

Figure 7: The plot shows the kernel density of the partisan log odds ratios of each topic (one observation per event). The white points show the median and the black rectangles the interquartile range across events.

and types of grounding that are used as partisan framing devices, contributing to polarization.

5.1 Methods

Partisan tokens. We estimate the partisanship of tokens via their event-level log odds ratio of Democrats relative to Republicans (based on the vocabularies we create in Section 3.1). We compare these estimates across events.[12]

Grounding. We study whether there is polarization in which prior tragic events are referenced in the context of a particular mass shooting. We compile a list of keywords representing major events of mass violence in the US in the past two decades and kept those that were mentioned at least 100 times by Democrat or Republican users. For all tweets for each event in our dataset, we counted the mentions of past *context events*. For example, in the following tweet posted after Las Vegas: "Dozens of preventable deaths should not be the cost of living in America. Stand up to the #NRA. #LasVegasShooting #SandyHook #Charleston", Sandy Hook and Charleston are the context events. Finally, we calculated the partisan log odds ratio of each context event.

5.2 Results

We focus on the partisanship of the term "terrorist" and "crazy", which exhibit differential pat-

---

[11] p-values are calculated using a one sample t-test, comparing with zero: *shooter's identity & ideology* ($p < 0.05$), *investigation* ($p < 0.001$), *laws & policy* ($p < 0.1$), *news* ($p < 0.05$), *solidarity* ($p < 0.001$).

[12] To compare the partisanship of tokens at the event- and topic-level, we also z-score the log odds ratios (Monroe et al., 2008) within events and topics; the most partisan tokens are reported in Appendix F. The reason why we do not z-score for the between-event comparison is because data verbosity disproportionately affects the range of the values' magnitudes. Note that the signs of values — which we focus on for the cross-event comparison — are not affected by z-scoring.

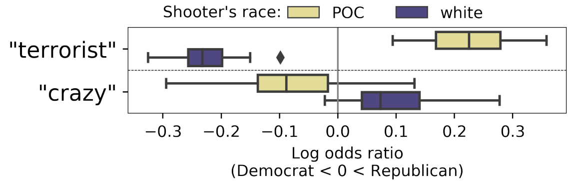

Figure 8: The log odds ratios of "terrorist" and "crazy" across events, grouped by the shooter's race. The boxes show the interquartile range and the diamond an outlier.

terns across events based on the shooter's race.[13] "Terrorist" is *always* more likely to be used by Democrats than Republicans in events where the shooter is white, and the opposite is true when the shooter is a person of color (Figure 8); "crazy" is more likely used by Republicans if the shooter is white than if they are a person of color and the opposite is true (although the pattern is weaker) when a shooter is white.

These findings support related work (Perea, 1997; Delgado and Stefancic, 2017) discussing binary conceptualization of race in the US, and its influence in determining whether a shooter's mental health or aspects of their identity are discussed. However, the fact that the influence of race flips completely for Democrats and Republicans is a striking result that calls for further exploration.

The partisanship of contextual grounding also corroborates our finding that the shooter's race influences how people conceptualize a certain event. Our results in Figure 9 suggest a few key takeaways: the two most frequently employed context events are both highly partisan (Sandy Hook for Democrats and 9/11 for Republicans); shootings at schools and places of worship are more likely to be brought up by Democrats; Democrats are more likely to reference events with white shooters, while Republicans are more likely to reference those with shooters who are people of color.

6 Affect

Affect is intimately tied to ideological reasoning (Redlawsk, 2002; Taber et al., 2009), and so emotional expression represents another semantic layer relevant to polarization (Iyengar et al., 2012; Suhay, 2015). Others have shown that emotion words can help detect political ideology on Twitter (Preoţiuc-Pietro et al., 2017) and that emotive political tweets are more likely to be shared (Stieglitz and Dang-Xuan, 2012). Here, we employ a lexicon-based approach to measure valence (positive and negative) and five basic emotion categories (disgust, fear, trust, anger, and sadness).

6.1 Methods

Since word-affect associations are highly domain dependent, we tailored an existing affect lexicon, the NRC Emotion Lexicon (Mohammad and Turney, 2013), to our domain via label propagation (Hamilton et al., 2016).

Specifically, we stem all the words in the lexicon and select 8-10 representative stems per emotion category that have an association with that emotion in the context of mass shootings. For each emotion category, we compute pairwise cosine distances between the GloVe embedding of each in-vocabulary stem and the representative stems for that emotion, and include the 30 stems with the lowest mean cosine distances. The resulting lexicons can be found in Appendix E.

We use these lexicons to measure the partisanship of each affect category. For each event and each party we aggregate stem frequencies per emotion category. We then calculate the partisan log odds ratio of each category for each event.

6.2 Results

The log odds ratio of each affect category is shown in Figure 10. These findings suggest that positive sentiment, sadness and trust are more likely to be expressed by Democrats across events, while fear and disgust are more likely to be expressed by Republicans, particularly when the shooter is a person of color. Anger, trust and negative sentiment is similarly likely to be expressed by both parties.[14]

Our results about fear and disgust accord with existing literature on emotion and political ideology: conservatives score higher than liberals on subjective measures of fear (e.g. Jost et al., 2017; Federico et al., 2009; Hibbing et al., 2014) and disgust sensitivity is also associated with political conservativism (e.g. Inbar et al., 2009, 2012).

7 Modality and Illocutionary Force

Modality is a lexical category concerned with necessity and possibility (Kratzer, 2002; Fintel,

---

[13] Note that these words in fact have the *largest* difference (negative and positive, respectively) if we calculate the differences between the mean z-scores — grouped by the shooter's race — for all tokens in our joint vocabulary.

[14] p-values are calculated using a one sample t-test, comparing to zero: anger ($p \approx 0.43$), disgust ($p \approx 0.06$), fear ($p < 0.001$), negative ($p \approx .2$), positive ($p < 0.001$), sadness ($p < 0.02$), trust ($p \approx 0.07$).

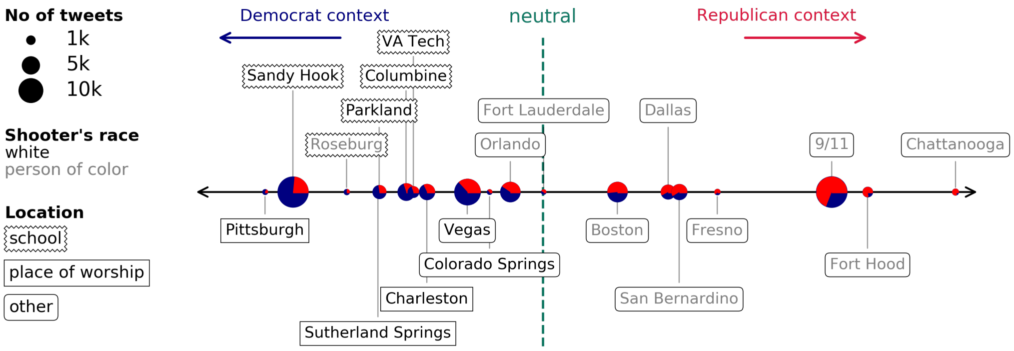

Figure 9: The partisanship of events of mass violence when used as a context for a given mass shooting. The position of the events on the line represents their partisan log odds ratio (Democrat $<$ 0 (neutral) $<$ Republican). The pie charts indicate the proportion of Democrat and Republican users' tweets that involve this "context" event.

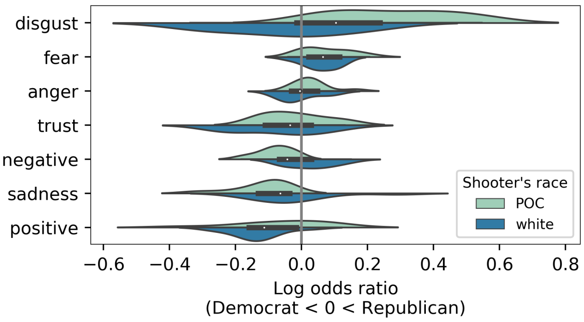

Figure 10: The log odds of each emotion category in our lexicon (one observation represents one event).

2006). In the aftermath of a tragic event, people seek solutions, a process that often involves reflecting on what *should have* happened or *should* happen now or in the future (e.g. to prevent such events). We hypothesize that the use of modals in our data gives insight into the kind of (illocutionary) acts (Austin, 1962) the users are performing via their tweets, such as calling for action, assigning blame, expressing emotions, and stating facts.

7.1 Methods

We work with all forms of the four most frequent necessity modals in our data — *should, must, have to* and *need to*. For each, we quantify its partisanship via its partisan log odds ratio. We also annotate a random sample of 200 tweets containing modals to see whether they are indeed used in contexts that imply calls for change / action (e.g. 'We must have gun control!') and / or to express the user's mental state about the event, such as despair or disbelief (e.g. 'Why do people have to die?').

7.2 Results

Table 2 shows a random sample of tweets containing some form of either *should, must, have to*, or *need to*. More collocations, as well as their partisanship, can be found in Appendix H. These examples, as well as our annotation, support the hypothesis that these modals are primarily used to call for action. Of the 200 modal uses, ∼78% express calls for change/action, ∼40% express the user's mental state.[15] We also compute the representation p^m_x of each modal m in each topic $x \in X$ via $(f^m_x/\sum_{x' \in X} f^m_{x'})/(f_x/\sum_{x' \in X} f_{x'})$, where f_x is the number of tweets from topic x, and f^m_x the number of those also containing m. We find that that modals are over-represented in the *laws & policy* topic (see Figure 11). This evidence suggests that calls for policy change — especially gun control, based on annotated samples — are a dominant subset of calls for action.

This roller coaster debate **MUST** STOP! Sensible gun ownership is one thing but assault weapons massacre innocent lives. The savagery of gore at #Parkland was beyond belief & **must** be the last.
In times of tragedy **shouldn't** we all come together?! Prayers for those harmed in the #PlannedParenthood shooting.
Communities **need to** step up and address white on white crime like the Las Vegas massacre. White men are out of control.
he BLM protest shooting, planned parenthood, now cali... domestic terrorism will crumble this country, SANE PPL **HAVE TO** FIGHT BACK
Shooting cops is horrible, cannot be condoned. But **must be** understood these incidents are outgrowth of decades of police abuses. #BatonRouge
1. Islamic terrorists are at war with us 2. Gun free zones = kill zones 3. Americans **should be** allowed to defend themselves #Chattanooga
Las Vegas shooting Walmart shooting and now 25 people killed in Texas over 90 people killed Mexico **should** build that wall to keep the US out
CNN reporting 20 dead, 42 injured in Orlando night club shooting. Just awful. The US **must** act to control guns or this carnage will continue.

Table 2: Random sample of tweets with modals. Only one of the eight (Ex. 6) tweets expresses ideas traditionally associated with conservative ideology.

The log odds ratio of modals shows that *all* of them are more likely to be used by Democrats across events: *have to* (mean:$-.39$, $p < 0.001$),

---

[15] Other uses are primarily epistemic ones (e.g. 'The suspect must be mentally ill').

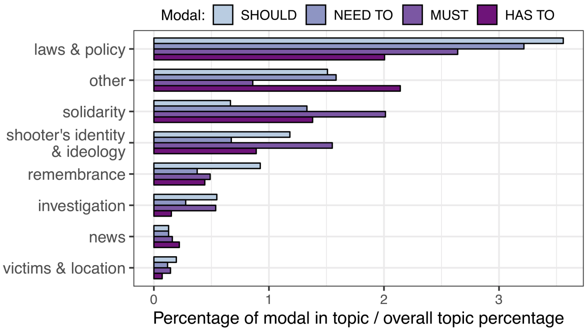

Figure 11: The representation of modals in each topic. Values represent averages across events.

must (mean:$-.3$, $p < 0.001$), *should* (mean:$-.18$, $p < 0.01$), *need to* (mean:$-.18$, $p < 0.01$) — where Democrat and Republican log odds are negative and positive, respectively.[16] A two-tailed t-test shows that only *should* exhibits statistically significant difference based on the shooter's race ($p < 0.03$), as it is even more likely to be used by Democrats when the shooter is white.

To understand whether assigning blame in this domain is a partisan propensity, we also study uses of *should have*.[17] The log odds of *should have* (mean:$-.22$, $p < 0.05$) show that it is similarly likely to be used by Democrats as *should* ($p \approx 0.8$ from two-tailed t-test). Interestingly the log odds ratio of *should have*, unlike that of *should*, does not differ significantly based on the shooter's race ($p \approx 0.8$ from two-tailed t-test). Moreover, we did not find a significant difference in the partisanship of *should have* nor any other modal based on the administration (Obama or Trump) a shooting took place under, suggesting that Democrats are more likely call for change and assign blame even if their preferred party is in power.

8 Conclusion

We show that inspecting polarization on social media from various angles can shed light on salient phenomena pertinent to group divisions. Applying the leave-out estimator of phrase partisanship to data on mass shootings, we find that reactions to these events are highly polarized politically.

To disentangle topic choice and topic-level framing — two phenomena that contribute to polarization — we introduce a tweet-clustering approach. By sampling, requiring words in the vocabulary to appear in multiple events and relying on the abstraction of a vector space model, we generate cohesive topic representations that are robust to disparities among event-level vocabularies and tweet counts. Human evaluation shows that our method outperforms LDA-based approaches.

Our induced topics suggest that Republicans preferentially discuss topics about the shooter's identity and ideology, investigation and news, while Democrats preferentially discuss solidarity and policy-related topics. We also find that the setting and the shooter's race interact with polarization. For example, Democrats are more likely to contextualize any mass shooting among school shootings and call white shooters "terrorists" than are Republicans, who in turn are more likely to liken any shooting to other violent events perpetrated by people of color — whom they are more likely to call "terrorist" than are Democrats. Moreover, Democrats are more likely to frame the shooter as mentally ill when they are a person of color and Republicans when they are white.

We also demonstrate that looking at affect and illocutionary force can help us understand users' polarized responses to these tragic events: Republicans are more likely to express fear and disgust than are Democrats, while Democrats are more likely to express sadness and positive sentiment, to make calls for action and assign blame.

Polarization is a multi-faceted phenomenon: in this paper we present a set of measures to study these different facets through the lens of language. We show that these measures provide convergent evidence, creating a clearer picture of the complex ideological division permeating public life.

---

[16] p-values are from one sample t-test, comparing to 0.

[17] On average across events, forms of *should have* constitute 16% of the uses of *should* (SD=5%).

A Data

Table 3 contains properties of the data. Figure 12 contains the distribution of partisan tweets for each event.

Event-specific keywords. We use the following location-specific keywords (case insensitive) to find tweets on the events:

- Chattanooga: chattanooga, military recruitment center
- Roseburg: umpqua, roseburg
- Colorado Springs: colorado springs, coloradosprings, planned parenthood, plannedparenthood
- San Bernardino: san bernardino, sanbernardino
- Kalamazoo: kalamazoo
- Orlando: orlando, pulse nightclub
- Dallas: dallas
- Baton Rouge: baton rouge, batonrouge
- Burlington: burlington, cascade mall
- Fort Lauderdale: lauderdale
- Fresno: fresno
- San Francisco: ups, san francisco
- Las Vegas: vegas, route91, harvest festival, harvestfestival, mandalay bay
- Thornton: thornton, walmart, denver
- Sutherland Springs: sutherland springs, sutherlandsprings
- Parkland: parkland, marjory stoneman
- Nashville: nashville, waffle house
- Santa Fe: santa fe, santafe
- Annapolis: annapolis, capital gazette
- Pittsburgh: pittsburgh, treeoflife, tree of life
- Thousand Oaks: thousand oaks, thousandoaks

B.2 Partisan Assignment Sanity Check

In our sanity check, we exclude DC, as 1) it is not an official US state and 2) there the population of users (including politicians and media) is expected to differ from the voting population. Figure 13 gives DC values.

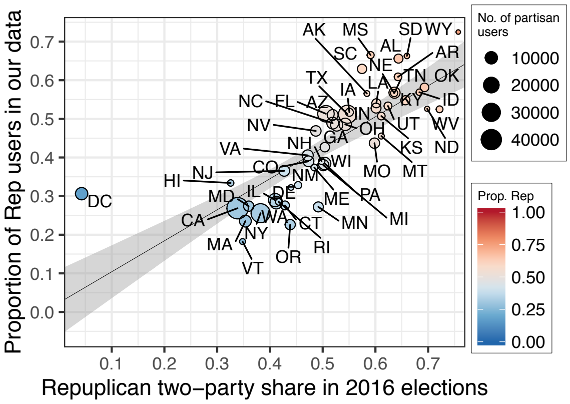

Figure 13: This plot was generated the same way as Figure 1, except that it also includes DC, which shows that it is an outlier in our data due to the fact that there are many Republican politicians and media outlets who are affiliated on Twitter with DC, while DC's voting population tends to be Democratic.

B.3 Russian account presence

We find no substantial presence of Russian accounts in the tweet set that we used for analysis, after all pre-processing. We use the list of Russian accounts identified by Twitter and banned in November 2017.[18] This list is likely to be an underestimate of the true presence of foreign influence, but it nevertheless provides some indication of such activity. Table 4 contains a breakdown by event; we exclude the events that occurred after the accounts were banned. Orlando had one account that tweeted 115 times, and Vegas had 4 that tweeted a total of 70 times.

Event	Number of Russian accounts	Number of tweets
Baton Rouge	8	12
Burlington	3	9
Chattanooga	0	0
Colorado Springs	0	0
Dallas	4	39
Fort Lauderdale	0	0
Fresno	2	2
Kalamazoo	0	0
Orlando	1	115
Roseburg	0	0
San Bernardino	0	0
San Francisco	0	0
Sutherland Springs	0	0
Thornton	0	0
Vegas	4	70

Table 4: Tweets by Russian accounts

---

Table 6: The highest probability stems per topic (for $k = 8$) for BTM.

C Topic Model Outputs

C.1 Topic Words

Table 5 and Table 6 show the highest probability words per topic (for $k = 8$) for MALLET and BTM, respectively.

C.2 Topic Tweets

We present a sample of tweets belonging to one of the 8 topics assigned by our model.

News.

- HAPPENING NOW: Multiple people wounded in shooting at Colorado Walmart
- 3 people are reported dead in #FtLauderdaleshooting
- UPDATE: Baton Rouge 2 Officers confirmed dead 7 officers have been shot in total. Details are slowly coming in.
- San Francisco police responding to reports of a shooting at a UPS facility, according to multiple reports.
- BREAKING: Police confirm several fatalities in #Annapolis newsroom shooting and multiple people seriously injured. The suspect is in custody. @SkyNewsAust

Investigation.

- Alleged synagogue shooter charged in deaths of 11 people
- Michigan prosecutor: Suspect in Kalamazoo rampage that killed 6 admitted to shootings.
- #COSshooting #PlannedParenthood It's over...suspect walked out and they apprehended him-no altercation in arrest. Suspect turned himself in
- Capital Gazette shooter has been identified as Jarrod W. Ramos, 38, who had previously filed a defamation lawsuit against the paper and a columnist in 2012.
- Waffle House gunman's father facing charges for GIVING him gun used to kill four

Shooter's identity & ideology.

- HATE CRIME : Fresno Islamic Killer Referred to White People as "Devils"
- To say that extremist Muslims represent all Muslims is like saying the gunmen in Colorado springs represents all Christians
- So who has #BatonRouge blamed for this shooting Imperialist Obama BLM Movement The Black Man Or the isolated mentally ill white lone wolf
- Again, the Lafayette white killer is a "lone wolf" but the Chattanooga Arab killer is an entire religion. Aggressively insane troll logic.
- Who is surprised that the San Bernardino shooters were radicalized Muslims?

Victims & location.

- 12 Killed in California Shooting; Gunman Targeted Bar in Thousand Oaks
- Synagogue shooting in Pittsburgh: what we know
- Navy Veteran Who Survived Afghanistan Dies in Las Vegas Shooting
- Aaron Feis, who died in the mass shooting at Marjory Stoneman Douglas High, was praised by college recruiters and former players for helping dozens of high school athletes land a chance to play in college.
- Texas church, site of deadly massacre, to be demolished (Via WLTX 19)

Laws & policy.

- This Parkland Tragedy was completely a security meltdown in or security officials. 100% preventable. Gun laws had nothing to do with this massacre. But gun control could have diminish the carnage. Two different things...
- NRA allowed acts like #Chattanooga to become commonplace. Their lobbying permits people on the terror watch list to buy guns. Remember that.
- I will not just #prayforsutherlandsprings, today I vote for @PhilMurphyNJ and stronger gun control laws in NJ #ElectionDay #GunControlNow
- Again the mental health flags were waving about shooter in Santa Fe no one acted. By now, if ones in charge cared and wanted to protect students, Every School would have had a security assessment and have hardened access points. Can never stop these but can make it harder.
- This is a mental health issue, security issue AND a gun issue. Our government has taken action on NONE of these to protect our students. So clearly we are not being heard, and our kids are being executed. What do we do now? #EnoughIsEnough #DoSomething #SantaFe #WeMustBeHeard

Solidarity.

- Our thoughts and prayers go out the victims and their families involved in the #Chattanooga tragedy 2nite.
- Praying for the loved ones of the victims of the shooting yesterday at the synagogue in Pittsburgh.
- Our prayers go out to the victims, families, friends & everyone affected in #SanBernardino #BeSafe #BeAware
- My heart goes out to the friends and family of the victims in that parkland shooting :-(
- Our hearts goes to #UmpquaCommunityCollege in the #oregonshooting #ChristCenteredEnt is praying 4 u #AllLivesMatter

Remembrance.

- @HarfordCC will honor victims @UmpquaCC TODAY by observing a National Moment of Silence 1:45PM in Quad. Students should attend #IamUCC
- Photo: US flag flying at half-staff at White House for victims of Roseburg, Ore., school shooting
- More than 100 Romans gather in solidarity against hate, honor victims of Orlando shooting
- Trump Denies Request To Lower Flags To Honor Capital Gazette Shooting Victims #DouchebagDon #CrookedTrump @FLOTUS @realDonaldTrump
- Live from #ChattanoogaShootings memorial next on #11Alive

Other.

- I'm sure coming from you, this has nothing to do with the Fresno shooting?
- I realize the dude from the Waffle House shooting did a miraculous thing disarming the shooter, but if I see the gaping wound on his forearm one more time I'm gonna lose my mind.
- The only thing that stops a bad guy with a gun, is a good guy with a gun!!! #Kalamazoo
- The little clip I saw of what DT just said about #PittsburghShooting #PittsburghSynagogueShooting was ok (I guess)
- But when is someone gonna reassure me a planned parenthood attack won't happen

D Topic Model Evaluation

In the next two subsections we describe the tasks which we crowdsourced to compare the three topic models: MALLET, BTM and our embedding-based model.

D.1 Word intrusion

Our word intrusion task is the same as is described in Chang et al. (2009). Our topic-word distance metric for MALLET and BTM is probability (we use the exact topic-word matrix that these models output) and for our model it is cosine distance. We created 2850 experimental items (i.e. sets of words) with the following procedure:

1. Sample a model M, a k (between 6 – 10) and a topic x ranging between $1 - k$.
2. For a given choice of M, k and x,
   (a) sample 5 words among the closest 10 words to x.
   (b) sample one word that is among the 5% of the furthest words from x but also among the 5% of the closest words to another topic.
3. Shuffle the words.

Turkers were asked to pick the odd word out among a set of words. Each MTurk HIT consisted of 6 sets of words created via this procedure.

D.2 Tweet intrusion

Since we only assign one topic to each tweet, we would like to evaluate how coherent the tweets are that are assigned to the same topic. Therefore, we define the tweet intrusion task analogously to word intrusion. Our distance metric in this case is the ratio of proximities (probability for MALLET and BTM and cosine for our model) between the closest topic and second closest topic — this value quantifies the proximity to the closest topic as well as how uniquely close that topic is (in contrast to the second topic). We created 1800 experimental items via the following procedure:

1. Sample a model M, a k (between 6 – 10) and a topic x ranging between $1 - k$.
2. For a given choice of M, k and x,
   (a) sample 3 tweets among the closest 1% of tweets to x.
   (b) sample one tweet that is among the 1% of the furthest tweets from x but also among the 1% of the closest tweets to another topic.
3. Shuffle the tweets.

Turkers were asked to pick the odd tweet out from these tweets. Each MTurk HIT consisted of three sets of tweets.

E Emotion Lexicon

The following words were the final stems in our emotional lexicon.

positive love, friend, pray, thought, affect, bless, god, pleas, communiti, hope, stand, thank, help, condol, will, comfort, time, strong, work, support, effect, strength, feel, peac, word, rest, give, great, action, good

negative hate, violenc, hatr, of, evil, tragedi, will, word, attack, sad, feel, anger, murder, shoot, massacr, want, need, pain, kill, griev, crime, ignor, victim, lost, grief, senseless, tragic, fear, loss, sick

sadness senseless, loss, tragedi, lost, devast, sad, love, griev, horrif, terribl, pain, violenc, condol, broken, hurt, feel, victim, mourn, horrifi, will, grief, ach, suffer, sick, kill, aw, sicken, evil, massacr, mad

disgust disgust, sick, shame, ignor, wrong, blame, hell, ridicul, idiot, murder, evil, coward, sicken, feel, disgrac, slaughter, action, bad, insan, attack, pathet, outrag, polit, terrorist, mad, damn, lose, shit, lie, asshol

anger gun, will, murder, kill, violenc, wrong, shoot, bad, death, attack, feel, shot, action, arm, idiot, crazi, crimin, terrorist, mad, hell, crime, blame, fight, ridicul, insan, shit, die, threat, terror, hate

fear danger, threat, fear, arm, gun, still, shooter, attack, feel, fight, hide, murder, shot, shoot, bad, kill, chang, serious, violenc, forc, risk, defend, warn, govern, concern, fail, polic, wrong, case, terrorist

trust school, like, good, real, secur, show, nation, don, protect, call, teacher, help, law, great, save, true, wonder, respons, sad, answer, person, feel, safe, thought, continu, love, guard, church, fact, support

The following words were used as seeds to generate this lexicon, as described in the main text.

positive love, donat, heart, thought, strength, bless, solidar

negative hatr, hate, griev, grief, wrong

sadness mourn, sadden, griev, grief, sad, suffer, affect, broken, senseless, loss, heartbroken

disgust disgust, disgrac, shame, gut, slaughter, sicken, sick, ill, lunat, coward

anger deserv, lynch, gang, threat, mad, sicken, harm, enforc, firearm, ridicul, assault

fear risk, hide, danger, warn, fear

trust secur, coach, safe, hero, nation

F Most Partisan Phrases

F.1 Most Partisan Phrases Overall

We list the 20 most Democrat and Republican unigrams and bigrams that occur at least 100 times in tweets about a particular event. The number in brackets indicates the z-score of the log odds of these words (Monroe et al., 2008) — values with an absolute value greater than 2 are significantly partisan.

Chattanooga. *Most Republican phrases:* obama (7.41), gun free (5.89), zone (5.70), free (5.69), free zone (5.53), flag (5.33), #tcot (5.33), #chattanoogaattack (5.13), #wakeupamerica (4.94), islam (4.69), #obama (4.01), #islam (3.83), attack (3.67), #gunfreezon (3.66), lower (3.66), liber (3.54), arm (3.44), workplac (3.32), white hous (3.23), workplac violenc (3.21)
Most Democrat phrases: blame georg (-8.62), bush invad (-8.62), invad iraq (-8.60), invad (-8.60), base lie (-8.55), georg bush (-8.53), war base (-8.51), lie happen (-8.51), georg (-8.35), iraq war (-8.31), iraq (-8.24), bush (-7.77), lie (-7.45), #charleston (-6.99), mass (-6.82), #lafayett (-6.48), happen (-6.19), #charlestonshoot (-5.96), blame (-5.40), #gunsens (-5.09)

Roseburg. *Most Republican phrases:* obama (8.02), #2a (6.28), #obama (6.01), gun free (5.37), #tcot (5.32), free (5.22), christian (5.09), zone (5.08), chicago (5.06), shooter (4.78), free zone (4.75), #gunfreezon (4.04), agenda (3.95), religion (3.85), train (3.79), liber (3.73), #christian (3.71), secur (3.45), guard (3.40), skarlato (3.39)
Most Democrat phrases: #gunsens (-4.69), heart (-4.59), gun nut (-3.92), fuck (-3.83), mass (-3.82), gun violenc (-3.81), violenc (-3.80), nra (-3.54), thought (-3.47), nut (-3.28), school (-3.22), #gunviol (-3.10), countri (-3.08), chang (-3.04), congress (-3.02), love (-2.99), vigil (-2.86), mass shoot (-2.75), protest (-2.74), america (-2.63)

Colorado Springs. *Most Republican phrases:* babi (13.62), liber (11.39), kill babi (8.77), polic (8.46), kill (8.30), left (7.42), offic (7.01), bank (6.97), babi kill (6.84), lib (6.42), obama (6.34), #activeshoot (6.23), #tcot (6.13), activ (6.12), parenthood kill (6.01), report (5.99), injur (5.90), #break (5.81), activ shooter (5.75), plan (5.72)

G Personal Pronouns

Pronoun usage has been found to express different degrees of self-reflection, awareness, inclusivity, perspective-taking, among several other psychological phenomena, both on Twitter (Qiu et al., 2012) and in various other domains (Hirsh and Peterson, 2009; Yarkoni, 2010; Pennebaker, 2011). We rely on these findings to treat pronouns as proxies to measure polarization in terms of users' personalization of the experience (1st person sg.), inclusion (1st person pl.), deflection (3rd person).

G.1 Methods

To quantify the partisanship of personal pronouns, we take the five personal pronoun categories in LIWC (Pennebaker et al., 2001) (I, You, We, SheHe, They) and then calculate their partisan log-odds ratio.

G.2 Results

The log odds of pronouns suggest that *first and second person pronouns* are significantly more likely to be used by Democrats across the events, while *They* is somewhat more likely to be used by Democrats and *SheHe* is used similarly by the two parties: *I* (mean:$-.26$, $p < .001$), *We* (mean:$-.26$, $p < .001$), *You* (mean:$-.13$, $p < 0.05$), *They* (mean:$-.06$, $p < .1$), *SheHe* (mean:$.05$, $p \approx 0.36$) (see Figure 15).

The use of two pronouns is significantly different based on the shooter's race: *SheHe* and *You* are both more likely to be used by Democrats when the shooter is white and by Republicans if the shooter is a person of color ($p < 0.01$ for *SheHe* and $p < 0.05$ for *You* from two-tailed t test). The pattern pertaining to *SheHe* might be partly explained by differential mentions of the president (see Appendix F with the most partisan words), since it so happens that most of the events where the shooter was a person of color occurred under Obama's presidency while the ones where the shooter was white predominantly occurred under Trump's presidency.

To better understand this result, we are again interested to see if there is a link between pronoun usage and topic preferences — we use the same procedure to measure the representation of pronouns in topics as in the case of modals. Our findings (see Figure 15) show that first *I* predominantly occurs in *solidarity* and *other*, which, coupled with previous findings about these topics being preferred by Democrats and about affect, suggest that Democrats in our dataset are more likely to personalize their tweets and write about their own mental state and feelings towards the event and the victims. Similarly *We* is overrepresented in *laws & policy*, also a topic that is preferred by Democrats, which, building on our results about modals (Section 7.2), provide evidence that Democrats are more likely to call for collective action.

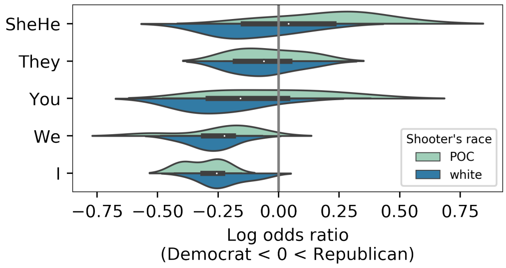

Figure 14: The partisan log odds ratio of pronouns.

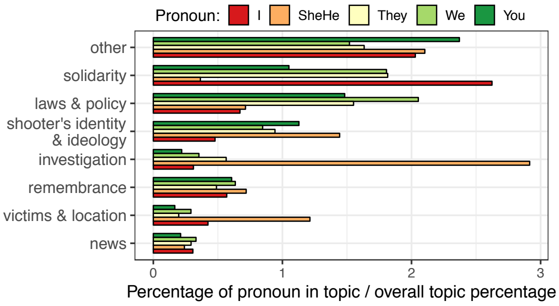

Figure 15: Distribution of pronouns across topics (mean across 21 events).

SheHe, on the other hand, are most frequent in *investigation*, *shooter's identity & ideology* and *victims & location* — topics that are more likely to be discussed by Republicans. This result, supported by our finding about affect, suggests that Republicans in this domain are more likely to author tweets that focus on a third person (e.g. the shooter).

H Modal Collocations

We study the subjects and complements of modals and their partisanship to get a better view of *how* these modals are used. We calculate the z-scored partisan log odds ratio of the collocations (subject + modal + complement constructions) at the event- and modal-level. We keep all collocations that are more likely to be used by Democrats or Republicans by at least .5 SD of the event- and modal-level log odds ratios (in other words, whose z-score has an absolute value that is at least .5). In the list below, we show those collocations that are partisan in the same direction (Democrat or Republican) in at least three events.

Note that before calculating the log odds ratio, we replace contracted forms with their non-contracted form (e.g. "shouldn't" with "should not", "should've" with "should have"). The number following the collocations is the number of events for which a particular term is partisan towards a given party. Often when a collocation seems ungrammatical, it is because it is comes from a question (e.g. "long must we" → "how long must we").

Note that the patterns in the collocations accord with the findings discussed in the paper. Democrats are more likely to use modals to call for collective and proactive action (e.g. "we must do", "we have to do", "something needs to be done", "we need to act") and also to express emotion (e.g. "[why do] people have to die", "[why do] people need to die") than Republicans. Republicans are more likely to use modals epistemically (e.g. "it must have been") and in other, idiomatic, senses that do not imply necessity (e.g. "it has to do [with]", "I have to say", "I must say"). Republicans are less likely to use modals in contexts with first person plural subjects ("we") than Democrats, but are more likely to use "we" in contexts where the modal's prejacent implies "stopping" something rather than "doing" something (e.g. "we must ban", "we must protect", "we should ban", "we need to protect").

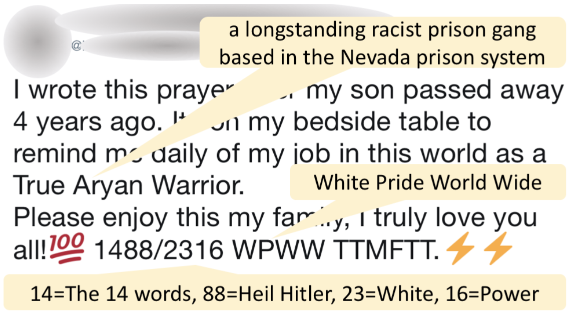
Abstract

Existing computational models to understand hate speech typically frame the problem as a simple classification task, bypassing the understanding of hate symbols (e.g., *14 words*, *kigy*) and their secret connotations. In this paper, we propose a novel task of deciphering hate symbols. To do this, we leverage the Urban Dictionary and collected a new, symbol-rich Twitter corpus of hate speech. We investigate neural network latent context models for deciphering hate symbols. More specifically, we study Sequence-to-Sequence models and show how they are able to crack the ciphers based on context. Furthermore, we propose a novel Variational Decipher and show how it can generalize better to unseen hate symbols in a more challenging testing setting.

1 Introduction

The statistics are sobering. The Federal Bureau of Investigation of United States[1] reported over 6,000 criminal incidents motivated by bias against race, ethnicity, ancestry, religion, sexual orientation, disability, gender, and gender identity during 2016. The most recent 2016 report shows an alarming 4.6% increase, compared with 2015 data[2]. In addition to these reported cases, thousands of Internet users, including celebrities, are forced out of social media due to abuse, hate speech, cyberbullying, and online threats. While such social media data is abundantly available, the broad question we are asking is—What can machine learning and natural language processing do to help and prevent online hate speech?

The vast quantity of hate speech on social media can be analyzed to study online abuse. In recent years, there has been a growing trend of developing computational models of hate speech. However, the majority of the prior studies focus solely on modeling hate speech as a binary or multiclass classification task (Djuric et al., 2015; Waseem and Hovy, 2016; Burnap and Williams, 2016; Wulczyn et al., 2017; Pavlopoulos et al., 2017).



a longstanding racist prison gang based in the Nevada prison system

I wrote this praye my son passed away 4 years ago. I on my bedside table to remind m daily of my job in this world as a True Aryan Warrior.

White Pride World Wide

Please enjoy this my fam y, I truly love you all!💯 1488/2316 WPWW TTMFTT.⚡⚡

14=The 14 words, 88=Heil Hitler, 23=White, 16=Power

Figure 1: An example tweet with hate symbols.

While developing new features for hate speech detection certainly has merits, we believe that understanding hate speech requires us to design computational models that can decipher hate symbols that are commonly used by hate groups. Figure 1 shows an example usage of hate symbols in an otherwise seemingly harmless tweet that promotes hate. For example, *Aryan Warrior* is a longstanding racist prison gang based in the Nevada prison system. *WPWW* is the acronym for *White Pride World Wide*. The hate symbols *1488* and *2316* are more implicit. *14* symbolizes the 14 words: *"WE MUST SECURE THE EXISTENCE OF OUR PEOPLE AND A FUTURE FOR WHITE CHILDREN"*, spoken by members of the Order neo-Nazi movement. *H* is the 8th letter of the alphabet, so *88=HH=Heil Hitler*. Similarly, *W* is the 23rd and *P* is the 16th letter of the alphabet, so *2316=WP=White Power*.

Proceedings of NAACL-HLT 2019, pages 3006–3015
Minneapolis, Minnesota, June 2 - June 7, 2019.

In this work, we propose the first models for deciphering hate symbols. We investigate two families of neural network approaches: the Sequence-to-Sequence models (Sutskever et al., 2014; Cho et al., 2014) and a novel Variational Decipher based on the Conditional Variational Autoencoders (Kingma and Welling, 2014; Sohn et al., 2015; Larsen et al., 2016). We show how these neural network models are able to guess the meaning of hate symbols based on context embeddings and even generalize to unseen hate symbols during testing. Our contributions are three-fold:

- We propose a novel task of learning to decipher hate symbols, which moves beyond the standard formulation of hate speech classification settings.
- We introduce a new, symbol-rich tweet dataset for developing computational models of hate speech analysis, leveraging the Urban Dictionary.
- We investigate a sequence-to-sequence neural network model and show how it is able to encode context and crack the hate symbols. We also introduce a novel Variational Decipher, which generalizes better in a more challenging setting.

In the next section, we outline related work in text normalization, machine translation, conditional variational autoencoders, and hate speech analysis. In Section 3, we introduce our new dataset for deciphering hate speech. Next, in Section 4, we describe the design of two neural network models for the decipherment problem. Quantitative and qualitative experimental results are presented in Section 5. Finally, we conclude in Section 6.

2 Related Work

2.1 Text Normalization in Social Media

The proposed task is related to text normalization focusing on the problems presented by user-generated content in online sources, such as misspelling, rapidly changing out-of-vocabulary slang, short-forms and acronyms, punctuation errors or omissions, etc. These problems usually appear as out-of-vocabulary words. Extensive research has focused on this task (Beaufort et al., 2010; Liu et al., 2011; Gouws et al., 2011; Han and Baldwin, 2011; Han et al., 2012; Liu et al., 2012; Chrupała, 2014). However, our task is different from the general text normalization in social media in that instead of the out-of-vocabulary words, we focus on the symbols conveying hateful meaning. These hate symbols can go beyond lexical variants of the vocabulary and thus are more challenging to understand.

2.2 Machine Translation

An extensive body of work has been dedicated to machine translation. Knight et al. (2006) study a number of natural language decipherment problems using unsupervised learning. Ravi and Knight (2011) further frame the task of machine translation as decipherment and tackle it without parallel training data. Machine translation using deep learning (Neural Machine Translation) has been proposed in recent years. Sutskever et al. (2014) and Cho et al. (2014) use Sequence to Sequence (Seq2Seq) learning with Recurrent Neural Networks (RNN). Bahdanau et al. (2015) further improve translation performance using the attention mechanism. Google's Neural Machine Translation System (GNMT) employs a deep attentional LSTM network with residual connections (Wu et al., 2016). Recently, machine translation techniques have been also applied to explain non-standard English expressions (Ni and Wang, 2017). However, our deciphering task is not the same as machine translation in that hate symbols are short and cannot be modeled as language.

Our task is more closely related to (Hill et al., 2016) and (Noraset et al., 2017). Hill et al. (2016) propose using neural language embedding models to map the dictionary definitions to the word representations, which is the inverse of our task. Noraset et al. (2017) propose the definition modeling task. However, in their task, for each word to be defined, its pre-trained word embedding is required as an input, which is actually the prior knowledge of the words. However, such kind of prior knowledge is not available in our decipherment task. Therefore, our task is more challenging and is not simply a definition modeling task.

2.3 Conditional Variational Autoencoder

Unlike the original Seq2Seq model that directly encodes the input into a latent space, the Variational Autoencoder (VAE) (Kingma and Welling, 2014) approximates the underlying probability distribution of data. VAE has shown promise in multiple generation tasks, such as handwritten digits (Kingma and Welling, 2014; Salimans et al., 2015), faces (Kingma and Welling, 2014; Rezende et al., 2014), and machine translation (Zhang et al., 2016). Conditional Variational Autoencoder (Larsen et al., 2016; Sohn et al., 2015) extends the original VAE framework by incorporating conditions during generation. In addition to image generation, CVAE has been successfully applied to some NLP tasks. For example, Zhao et al. (2017) apply CVAE to dialog generation, while Guu et al. (2018) use CVAE for sentence generation.

2.4 Hate Speech Analysis

Closely related to our work are Pavlopoulos et al. (2017); Gao et al. (2017). Pavlopoulos et al. (2017) build an RNN supplemented by an attention mechanism that outperforms the previous state of the art system in user comment moderation (Wulczyn et al., 2017). Gao et al. (2017) propose a weakly-supervised approach that jointly trains a slur learner and a hate speech classifier. While their work contributes to the automation of harmful content detection and the highlighting of suspicious words, our work builds upon these contributions by providing a learning mechanism that deciphers suspicious hate symbols used by communities of hate to bypass automated content moderation systems.

3 Dataset

In this section, we describe the dataset we collected for hate symbol decipherment.

3.1 Hate Symbols

We first collect hate symbols and the corresponding definitions from the Urban Dictionary. Each term with one of the following hashtags: *#hate, #racism, #racist, #sexism, #sexist, #nazi* is selected as a candidate and added to the set S_0. We collected a total of 1,590 terms. Next, we expand this set by different surface forms using the Urban Dictionary API. For each term s_i in set S_0, we obtain a set of terms R_i that have the same meaning as s_i but with different surface forms. For example, for the term *brown shirt*, there are four terms with different surface forms: *brown shirt, brown shirts, Brownshirts, brownshirt*. Each term in R_i has its own definition in Urban Dictionary, but since these terms have exactly the same meaning, we select a definition d_i with maximum upvote/downvote ratio for all the terms in R_i. For example, for each term in the set R_i={*brown shirt, brown shirts, Brownshirts, brownshirt*}, the corresponding definition is *"Soldiers in Hitler's storm trooper army, SA during the Nazi regime..."* After expanding, we obtain 2,105 distinct hate symbol terms and their corresponding definitions. On average, each symbol consists of 9.9 characters, 1.5 words. Each definition consists of 96.8 characters, 17.0 words.

3.2 Tweet Collection

For each of the hate symbols, we collect all tweets from 2011-01-01 to 2017-12-31 that contain exactly the same surface form of hate symbol in the text. Since we only focus on hate speech, we train an SVM (Cortes and Vapnik, 1995) classifier to filter the collected tweets. The SVM model is trained on the dataset published by Waseem and Hovy (2016). Their original dataset contains three labels: Sexism, Racism, and None. Since the SVM model is used to filter the non-hate speech, we merge the instances labeled as sexism and racism, then train the SVM model to do binary classification. After filtering out all the tweets classified as non-hate, our final dataset consists of 18,667 (tweet, hate symbol, definition) tuples.

4 Our Approach

We formulate hate symbol deciphering as the following equation:

$$Obj = \sum_{(u,s,d^*)\in X} \log p(d^*|(u,s)) \qquad (1)$$

X is the dataset, (u, s, d^*) is the (tweet, symbol, definition) tuple in the dataset. The inputs are the tweet and the hate symbol in this tweet. The output is the definition of the symbol. Our objective is to maximize the probability of the definition given the (tweet, symbol) pair. This objective function is very similar to that of machine translation. So we first try to tackle it based on the Sequence-to-Sequence model, which is commonly used in machine translation.

4.1 Sequence-to-Sequence Model

We implement an RNN Encoder-Decoder model with attention mechanism based on Bahdanau et al. (2015). We use GRU (Cho et al., 2014) for decoding. However, instead of also using GRU for encoding, we found that LSTM (Hochreiter

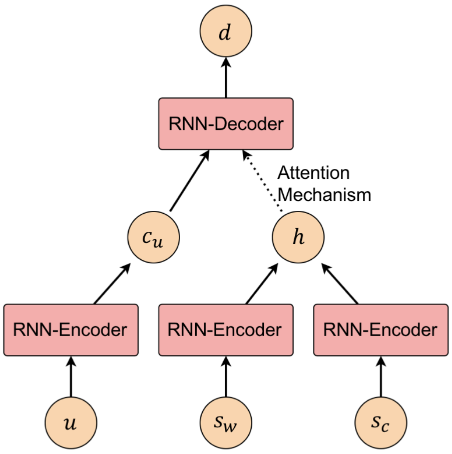

Figure 2: Our Seq2Seq model. u, s_w are the word embeddings of the tweet text and hate symbol. s_c is the character embedding of the symbol. c_u is the encoded tweet and h is the concatenated hidden states. d is the generated text. Detailed explanation is in section 4.1.

and Schmidhuber, 1997) performs better on our task. Therefore, our Seq2Seq model uses LSTM encoders and GRU decoders. An overview of our Seq2Seq model is shown in Figure 2. The computation process is shown as the following equations:

$$c_u, h_u = f_u(u) \tag{2}$$

$$c_{sw}, h_{sw} = f_{sw}(s_w) \tag{3}$$

$$c_{sc}, h_{sc} = f_{sc}(s_c) \tag{4}$$

u is the word embedding of the tweet text, s_w is the word embedding of the hate symbol, s_c is the character embedding of the symbol. f_u, f_{sw}, and f_{sc} are LSTM functions. c_u, c_{sw}, c_{sc} are the outputs of the LSTMs at the last time step and h_u, h_{sw}, h_{sc} are the hidden states of the LSTMs at all time steps. We use two RNN encoders to encode the symbol, one encodes at the word level and the other one encodes at the character level. The character-level encoded hate symbol is used to provide the feature of the surface form of the hate symbol while the word-level encoded hate symbol is used to provide the semantic information of the hate symbol. The hidden states of the two RNN encoders for hate symbols are concatenated:

$$h = h_{sw} \oplus h_{sc} \tag{5}$$

c_u is the vector of encoded tweet text. The tweet text is the context of the hate symbol, which provides additional information during decoding. Therefore, the encoded tweet text it is also fed into the RNN decoder. The detailed attention mechanism and decoding process at time step t are as follows:

$$w_t = \sigma(l_w(d_{t-1} \oplus e_{t-1})) \tag{6}$$

$$a_t = \sum_{i=1}^{T} w_{ti} h_i \tag{7}$$

$$b_t = \sigma(l_c(d_{t-1} \oplus a_t)) \tag{8}$$

$$o_t, e_t = k(c_u \oplus b_t, e_{t-1}) \tag{9}$$

$$p(d_t|u, s) = \sigma(l_o(o_t)) \tag{10}$$

w_t is the attention weights at time step t and w_{ti} is the i_{th} weight of w_t. d_{t-1} is the generated word at last time step and e_{t-1} is the hidden state of the decoder at last time step. h_i is the i_{th} time step segment of h. l_w, l_c, and l_o are linear functions. σ is a nonlinear activation function. k is the GRU function. o_t is the output and e_t is the hidden state of the GRU. $p(d_t|u, s)$ is the probability distribution of the vocabulary at time step t. The attention weights w_t are computed based on the decoder's hidden state and the generated word at time step $t-1$. Then the computed weights are applied to the concatenated hidden states h of encoders. The result a_t is the context vector for the decoder at time step t. The context vector and the last generated word are combined by a linear function l_c followed by a nonlinear activation function. The result b_t is concatenated with the encoded tweet context c_u, and then fed into GRU together with the decoder's last hidden state e_{t-1}. Finally, the probability of each vocabulary word is computed from o_t.

4.2 Variational Decipher

The Variational Decipher is based on the CVAE model, which is another model that can be used to parametrize the conditional probability $p(d^*|(u, s))$ in the objective function (Equation 1). Unlike the Seq2Seq model, which directly parametrizes $p(d^*|(u, s))$, our variational decipher formulates the task as follows:

$$\begin{aligned} Obj &= \sum_{(u,s,d^*)\in X} \log p(d^*|(u, s)) \\ &= \sum_{(u,s,d^*)\in X} \log \int_z p(d^*|z) p(z|(u, s)) dz \end{aligned} \tag{11}$$

where z is the latent variable. $p(d^*|(u, s)$ is written as the marginalization of the product of two terms over the latent space. Since the integration

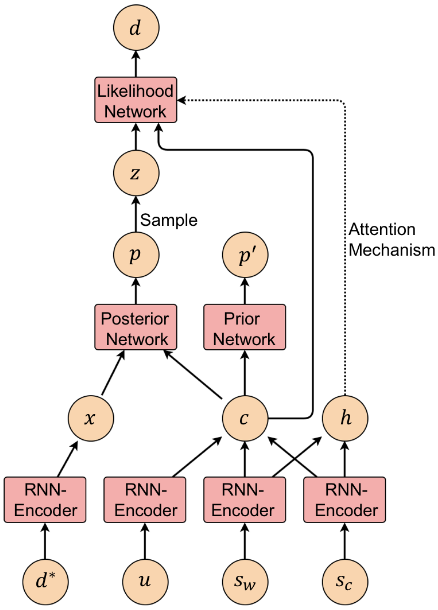

Figure 3: The Variational Decipher. Note that this structure is used during training. During testing, the structure is slightly different. d^* is the word embeddings of the definition. x is the encoded definition. c is the concatenation of the encoded tweet and hate symbol. p and p' are output distributions. z is the latent variable. The definitions of other variables are the same as those in Figure 2. Detailed explanation is in section 4.2.

over z is intractable, we instead try to maximize the evidence lower bound (ELBO). Our variational lower bound objective is in the following form:

$$\begin{aligned} Obj = & E[\log p_\varphi(d^*|z,u,s)] - \\ & D_{KL}[p_\alpha(z|d^*,u,s)||p_\beta(z|u,s)] \end{aligned} \tag{12}$$

where $p_\varphi(d^*|z,u,s)$ is the likelihood, $p_\alpha(z|d^*,u,s)$ is the posterior, $p_\beta(z|u,s)$ is the prior, and D_{KL} is the Kullback-Leibler (KL) divergence. We use three neural networks to model these three probability distributions. An overview of our variational decipher is shown in Figure 3. We first use four recurrent neural networks to encode the (tweet, symbol, definition) pair in the dataset. Similar to what we do in the Seq2Seq model, there are two encoders for the hate symbol. One is at the word level and the other is at the character level. The encoding of symbols and tweets are exactly the same as in our Seq2Seq model (see Equations 2-4). The difference is that we also need to encode definitions for the Variational Decipher.

$$x, h_d = f_d(d^*) \tag{13}$$

Here, f_d is the LSTM function. x is the output of the LSTM at the last time step and h_d is the hidden state of the LSTM at all time steps. The condition vector c is the concatenation of the encoded symbol words, symbol characters, and the tweet text:

$$c = c_u \oplus c_{sw} \oplus c_{sc} \tag{14}$$

We use multi-layer perceptron (MLP) to model the posterior and the prior in the objective function. The posterior network and the prior network have the same structure and both output a probability distribution of latent variable z. The only difference is that the input of the posterior network is the concatenation of the encoded definition x and the condition vector c while the input of the prior network is only the condition vector c. Therefore, the output of the posterior network $p = p_\alpha(z|d^*,u,s)$ and the output of the prior network $p' = p_\beta(z|u,s)$. By assuming the latent variable z has a multivariate Gaussian distribution, the actual outputs of the posterior and prior networks are the mean and variance: (μ, Σ) for the posterior network and (μ', Σ') for the prior network.

$$\mu, \Sigma = g(x \oplus c) \tag{15}$$

$$\mu', \Sigma' = g'(c) \tag{16}$$

g is the MLP function of the posterior network and g' is that of the prior network. During training, the latent variable z is randomly sampled from the Gaussian distribution $\mathcal{N}(\mu, \Sigma)$ and fed into the likelihood network. During testing, the posterior network is replaced by the prior network, so z is sampled from $\mathcal{N}(\mu', \Sigma')$. The likelihood network is modeled by an RNN decoder with attention mechanism, very similar to the decoder of our Seq2Seq model. The only difference lies in the input for the GRU. The decoder in our Variational Decipher model is to model the likelihood $p_\varphi(d^*|z,u,s)$, which is conditioned on the latent variable, tweet context, and the symbol. Therefore, for the Variational Decipher, the condition vector c and the sampled latent variable z are fed into the decoder.

$$o_t, e_t = k(z \oplus c \oplus b_t, e_{t-1}) \tag{17}$$

e_{t-1} is the hidden state of the RNN decoder at the last time step. k is the GRU function. o_t is its output and e_t is its hidden state. Detailed decoding process and explanations are in section 4.1.

According to the objective function in Equation 12, the loss function of the Variational Decipher is as follows:

$$\begin{aligned}\mathcal{L} =& L_{REC} + L_{KL} \\ =& E_{z\sim p_\alpha(z|d^*,u,s)}[-\log p_\varphi(d^*|z,u,s)]+ \\ & D_{KL}[p_\alpha(z|d^*,u,s)||p_\beta(z|u,s)]\end{aligned} \quad (18)$$

It consists of two parts. The first part L_{REC} is called reconstruction loss. Optimizing L_{REC} can push the sentences generated by the posterior network and the likelihood network closer to the given definitions. The second part L_{KL} is the KL divergence loss. Optimizing this loss can push the output Gaussian Distributions of the prior network closer to that of the posterior network. This means we teach the prior network to learn the same knowledge learned by the posterior network, such that during testing time, when the referential definition d^* is no longer available for generating the latent variable z, the prior network can still output a reasonable probability distribution over the latent variable z. The complete training and testing process for the Variational Decipher is shown in Algorithm 1. M is the predefined maximum length of the generated text. BCE refers to the Binary Cross Entropy loss.

5 Experiments

5.1 Experimental Settings

We use the dataset collected as described in section 3 for training and testing. We randomly selected 2,440 tuples for testing and use the remaining 16,227 tuples for training. Note that there are no overlapping hate symbols between the training dataset U and the testing dataset D.

We split the 2,440 tuples of the testing dataset D into two separate parts, D_s and D_d. D_s consists of 1,681 examples and D_d consists of 759 examples. In the first testing dataset D_s, although each hate symbol does not appear in the training dataset, the corresponding definition appears in the training dataset. In the second testing dataset D_d, neither the hate symbols nor the corresponding definitions appear in the training dataset. We do this split because deciphering hate symbols in these two cases has different levels of difficulty.

Algorithm 1 Train & Test Variational Decipher

```
function TRAIN($U$)
    randomly initialize network parameters $\varphi$, $\alpha$, $\beta$;
    for $epoch = 1, E$ do
        for $(tweet, symbol, definition)$ in $U$ do
            get embeddings $u$, $s_w$, $s_c$, $d^*$;
            compute $x$, $c$ and $h$ with RNN encoders;
            compute $\mu$, $\Sigma$ with the posterior network;
            compute $\mu'$, $\Sigma'$ with the prior network;
            compute KL-divergence loss $L_{KL}$;
            sample $z = reparameterize(\mu, \Sigma)$;
            initialize the decoder state $e_0 = c$;
            $L_{REC} = 0$;
            for $t = 1, M$ do
                compute attention weights $w_t$;
                compute $o_t$, $e_t$ and $p(d_t|z, u, s)$;
                $d_t = indmax(p(d_t|z, u, s))$;
                $L_{REC} += BCE(d_t, d^*_t)$;
                if $d_t$==EOS then
                    break;
                end if
            end for
            update $\varphi$, $\alpha$, $\beta$ on $\mathcal{L} = L_{REC} + L_{KL}$;
        end for
    end for
end function

function TEST($V$)
    for $(tweet, symbol, definition)$ in $V$ do
        get embeddings $u$, $s_w$, $s_c$;
        compute $c$ and $h$ with RNN encoders;
        compute $\mu'$, $\Sigma'$ with the prior network;
        sample $z = reparameterize(\mu', \Sigma')$;
        initialize the decoder state $e_0 = c$;
        for $t = 1, M$ do
            compute attention weights $w$;
            compute $o_t$, $e_t$ and $p(d_t|z, u, s)$;
            $d_t = indmax(p(d_t|z, u, s))$;
            if $d_t$==EOS then
                break;
            end if
        end for
    end for
end function
```

This split criterion means that for each hate symbol in D_s, there exists some symbol in the training dataset that has the same meaning but in different surface forms. For example, the hate symbol *wigwog* and *Wig Wog* have the same definition but one is in the training dataset, the other is in the first testing dataset. We assume that such types of hate symbols share similar surface forms or similar tweet contexts. Therefore, the first testing dataset D_s is to evaluate how well the model captures the semantic similarities among the tweet contexts in different examples or the similarities among different surface forms of a hate symbol.

Deciphering the hate symbols in the second testing dataset D_d is more challenging. Both the unseen hate symbols and definitions require the model to have the ability to accurately capture the semantic information in the tweet context and then make a reasonable prediction. The second testing dataset D_d is used to evaluate how well the model generalizes to completely new hate symbols.

Dataset	Method	BLEU	ROUGE-L	METEOR
D_s	Seq2Seq	**37.80**	**41.05**	**36.67**
	VD	34.77	32.96	31.03
D_d	Seq2Seq	25.44	12.96	**5.54**
	VD	**28.38**	**14.01**	5.41
D	Seq2Seq	**33.96**	**32.32**	**26.98**
	VD	32.75	27.00	23.16

Table 1: The BLEU, ROUGE-L and METEOR scores on testing datasets. VD refers to the Variational Decipher. D is the entire testing dataset. D_s is the first part of D and D_d is the second part. The better results are in bold.

For the Seq2Seq model, we use negative log-likelihood loss for training. Both models are optimized using Adam optimizer (Kingma and Ba, 2015). The hyper-parameters of two models are exactly the same. We set the maximum generation length $M = 50$. The hidden size of the encoders is 64. The size of the word embedding is 200 and that of character embedding is 100. The word embeddings and character embeddings are randomly initialized. Each model is trained for 50 epochs. We report the deciphering results of two models on three testing datasets D, D_s and D_d.

5.2 Experimental Results

Quantitative Results: We use equally weighted BLEU score for up to 4-grams (Papineni et al., 2002), ROUGE-L (Lin, 2004) and METEOR (Banerjee and Lavie, 2005) to evaluate the decipherment results. The results are shown in Table 1. Figure 4 shows the BLEU score achieved by the two models on three testing datasets D, D_s and D_d during the training process. Both our Seq2Seq model and Variational Decipher achieve reasonable BLEU scores on the testing datasets. The Seq2Seq model outperforms the Variational Decipher on D_s while Variational Decipher outperforms Seq2Seq on D_d. Note that D_s is more than twice the size of D_d. Therefore, Seq2Seq outperforms Variational Decipher on the entire testing dataset D. The different performance of the two models on D_s and D_d is more obvious in Figure 4. The gap between the performance of the Seq2Seq model on D_s and D_d is much larger than that between the performance of the Variational Decipher on these two datasets.

Human Evaluation: We employed crowd-sourced workers to evaluate the deciphering results of two models. We randomly sampled 100 items of deciphering results from D_s and another 100 items from D_d. Each item composes a choice question and each choice question is assigned to five workers on Amazon Mechanical Turk. In each choice question, the workers are given the hate symbol, the referential definition, the original tweet and two machine-generated plain texts from the Seq2Seq model and Variational Decipher. Workers are asked to select the more reasonable of the two results. In each choice question, the order of the results from the two models is permuted. Ties are permitted for answers. We batch five items in one assignment and insert an artificial item with two identical outputs as a sanity check. The workers who fail to choose "tie" for that item are rejected from our test. The human evaluation results are shown in Table 2, which coincide with the results in Table 1 and Figure 4.

Discussion: When deciphering the hate symbols that have the same definitions as in the training dataset, the model can rely more on the surface forms of hate symbols than the tweet context to make a prediction because usually the hate symbols that share the same definitions also have similar surface forms. However, when it comes to the hate symbols with unseen definitions, simply relying on the surface forms cannot lead to a reasonable deciphering result. Instead, the model should learn the relationships between the con-

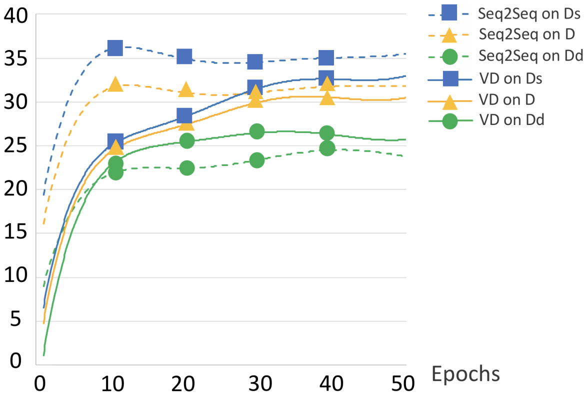

Figure 4: BLEU scores of two models on the testing dataset D, D_s and D_d. The three dotted curves represent the performance of the Seq2Seq model while the three solid curves represent the performance of the Variational Decipher.

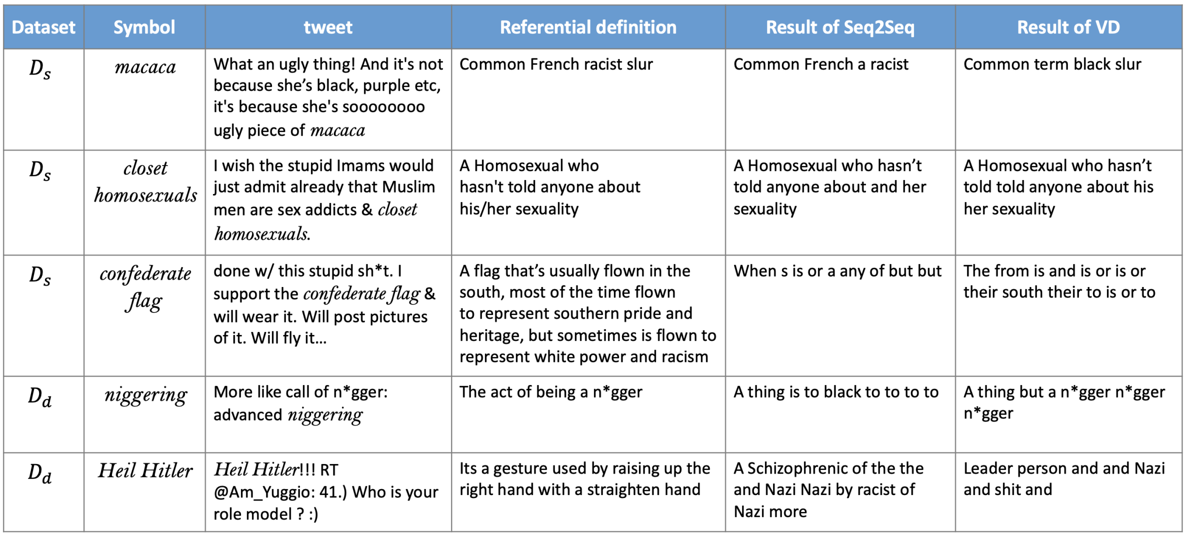
Dataset	Seq2Seq Lose	Seq2Seq Win	Tie
D_s	31.0%	32.0%	37.0%
D_d	30.5%	22.0%	47.5%

Table 2: The results of human evaluation on two separate testing datasets D_s and D_d.



Dataset	Symbol	tweet	Referential definition	Result of Seq2Seq	Result of VD
D_s	*macaca*	What an ugly thing! And it's not because she's black, purple etc, it's because she's soooooooo ugly piece of *macaca*	Common French racist slur	Common French a racist	Common term black slur
D_s	*closet homosexuals*	I wish the stupid Imams would just admit already that Muslim men are sex addicts & *closet homosexuals.*	A Homosexual who hasn't told anyone about his/her sexuality	A Homosexual who hasn't told anyone about and her sexuality	A Homosexual who hasn't told told anyone about his her sexuality
D_s	*confederate flag*	done w/ this stupid sh*t. I support the *confederate flag* & will wear it. Will post pictures of it. Will fly it... Figure 5: Some example errors in the generated results of our Seq2Seq model and Variational Decipher.

text information and the definition of the symbol. Therefore, the different performances of two models on the two testing datasets D_s and D_d indicate that the Seq2Seq model is better at capturing the similarities among different surface forms of a hate symbol, while the Variational Decipher is better at capturing the semantic relationship between the tweet context and the hate symbol. The Sequence-to-Sequence model tries to capture such kinds of relationships by compressing all the context information into a fixed length vector, so its deciphering strategy is actually behavior cloning. On the other hand, the Variational Decipher captures such relationships by explicitly modeling the posterior and likelihood distributions. The modeled distributions provide higher-level semantic information compared to the compressed context, which allows the Variational Decipher to generalize better to the symbols with unseen definitions. This explains why the gap between the performance of the Seq2Seq model on two datasets is larger.

5.3 Error Analysis

Figure 5 shows some example errors of the deciphering results of our Seq2Seq model and Variational Decipher. One problem with the deciphering results is that the generated sentences have poor grammatical structure, as shown in Figure 5. This is mainly because the size of our dataset is small, and the models need a much larger corpus to learn the grammar. We anticipate that the generation performance will be improved with a larger dataset.

For the hate symbols in D_s, the deciphering results are of high quality when the length of referential definitions are relatively short. An example is *macaca*, a French slur shows in Figure 5. The deciphering result of the Seq2Seq model is close to the referential definition. As to the Variational Decipher, although the result is not literally the same as the definition, the meaning is close. *closet homosexuals* in Figure 5 is another example. However, when the length of the referential definition increases, the performance of both models tends to be unsatisfactory, as the third example *confederate flag* shows in Figure 5. Although there exists the symbol *Confederate Flag* with the same definition in the training set, both models fail on this example. One possible reason is that the complexity of generating the referential definition grows substantially with the increasing length, so when the tweet context and the symbol itself cannot provide enough information, the generation model cannot learn the relationship between the symbol and its definition.

Deciphering hate symbols in D_d is much more challenging. Even for humans, deciphering completely new hate symbols is not a simple task. The two examples in Figure 5 show that the models have some ability to capture the semantic similarities. For the symbol *niggering*, the Variational Decipher generates the word *nigger* and Seq2Seq model generates *black*. For *Heil Hitler*, the Variational Decipher generates *leader person* and *Nazi*, while Seq2Seq also generates *Nazi*. Although these generated words are not in the definition, they still make some sense.

6 Conclusion

We propose a new task of learning to decipher hate symbols and create a symbol-rich tweet dataset. We split the testing dataset into two parts to analyze the characteristics of the Seq2Seq model and the Variational Decipher. The different performance of these two models indicates that the models can be applied to different scenarios of hate symbol deciphering. The Seq2Seq model outperforms the Variational Decipher for deciphering the hate symbols with similar definitions to that in the training dataset. This means the Seq2Seq model can better explain the hate symbols when Twitter users intentionally misspell or abbreviate common slur terms. On the other hand, the Variational Decipher tends to be better at deciphering hate symbols with unseen definitions, so it can be applied to explain newly created hate symbols on Twitter. Although both models show promising deciphering results, there still exists much room for improvement.

Abstract

We propose a distance supervised relation extraction approach for long-tailed, imbalanced data which is prevalent in real-world settings. Here, the challenge is to learn accurate "few-shot" models for classes existing at the tail of the class distribution, for which little data is available. Inspired by the rich semantic correlations between classes at the long tail and those at the head, we take advantage of the knowledge from data-rich classes at the head of the distribution to boost the performance of the data-poor classes at the tail. First, we propose to leverage implicit relational knowledge among class labels from knowledge graph embeddings and learn explicit relational knowledge using graph convolution networks. Second, we integrate that relational knowledge into relation extraction model by coarse-to-fine knowledge-aware attention mechanism. We demonstrate our results for a large-scale benchmark dataset which show that our approach significantly outperforms other baselines, especially for long-tail relations.

1 Introduction

Relation extraction (RE) is an important task in information extraction, aiming to extract the relation between two given entities based on their related context. Due to the capability of extracting textual information and benefiting many NLP applications (e.g., information retrieval, dialog generation, and question answering), RE appeals to many researchers. Conventional supervised models have been widely explored in this task (Zelenko et al., 2003; Zeng et al., 2014); however, their performance heavily depends on the scale and quality of training data.

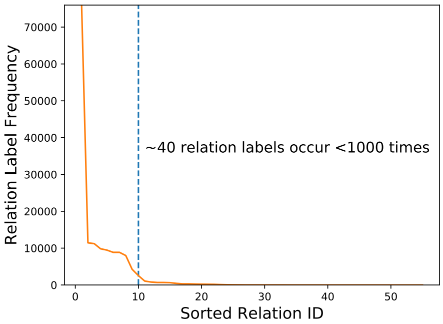

Figure 1: Label frequency distribution of classes without NA in NYT dataset.

To construct large-scale data, (Mintz et al., 2009) proposed a novel distant supervision (DS) mechanism to automatically label training instances by aligning existing knowledge graphs (KGs) with text. DS enables RE models to work on large-scale training corpora and has thus become a primary approach for RE recently (Wu et al., 2017; Feng et al., 2018). Although these DS models achieve promising results on common relations, their performance still degrades dramatically when there are only a few training instances for some relations. Empirically, DS can automatically annotate adequate amounts of training data; however, this data usually only covers a limited part of the relations. Many relations are long-tail and still suffer from data deficiency. Current DS models ignore the problem of long-tail relations, which makes it challenging to extract comprehensive information from plain text.

Long-tail relations are important and cannot be ignored. Nearly 70% of the relations are long-tail in the widely used New York Times (NYT) dataset[1] (Riedel et al., 2010; Lei et al., 2018) as shown in Figure 1. Therefore, it is crucial for mod-

els to be able to extract relations with limited numbers of training instances.

Dealing with long tails is very difficult as few training examples are available. Therefore, it is natural to transfer knowledge from data-rich and semantically similar head classes to data-poor tail classes (Wang et al., 2017). For example, the long-tail relation /people/deceased_person/place_of_burial and head relation /people/deceased_person/place_of_death are in the same branch /people/deceased_person/* as shown in Figure 2. They are semantically similar, and it is beneficial to leverage head relational knowledge and transfer it to the long-tail relation, thus enhancing general performance. In other words, long-tail relations of one entity tuple can have class ties with head relations, which can be leveraged to enhance RE for narrowing potential search spaces and reducing uncertainties between relations when predicting unknown relations (Ye et al., 2017). If one pair of entities contains /people/deceased_person/place_of_death, there is a high probability that it will contain /people/deceased_person/place_of_burial. If we can incorporate the relational knowledge between two relations, extracting head relations will provide evidence for the prediction of long-tail relations.

However, there exist two problems: (1) *Learning relational knowledge:* Semantically similar classes may contain more relational information that will boost transfer, whereas irrelevant classes (e.g., /location/location/contains and /people/family/country) usually contain less relational information that may result in negative transfer. (2) *Leveraging relational knowledge:* Integrating relational knowledge to existing RE models is challenging.

To address the problem of learning relational knowledge, as shown in (Lin et al., 2016; Ye et al., 2017), we use class embeddings to represent relation classes and utilize KG embeddings and graph convolution networks (GCNs) to extract implicit and explicit relational knowledge. Specifically, previous studies (Yang et al., 2015) have shown that the embeddings of semantically similar relations are located near each other in the latent space. For instance, the relation /people/person/place_lived and /people/person/nationality are more relevant, whereas the relation /people/person/profession has less correlation with the former two relations. Thus, it is natural to leverage this knowledge from KGs. However, because there are many one-to-multiple relations in KGs, the relevant information for each class may be scattered. In other words, there may not be enough relational signal between classes. Therefore, we utilize GCNs to learn explicit relational knowledge.

Figure 2: Head and long-tail relations.

To address the problem of leveraging relational knowledge, we first use convolution neural networks (Zeng et al., 2014, 2015) to encode sentences; then introduce coarse-to-fine knowledge-aware attention mechanism for combining relational knowledge with encoded sentences into bag representation vectors. The relational knowledge not only provides more information for relation prediction but also provides a better reference message for the attention module to raise the performance of long-tail classes.

Our experimental results on the NYT dataset show that: (1) our model is effective compared to baselines especially for long-tail relations; (2) leveraging relational knowledge enhances RE and our model is efficient in learning relational knowledge via GCNs.

2 Related Work

Relation Extraction. Supervised RE models (Zelenko et al., 2003; GuoDong et al., 2005; Mooney and Bunescu, 2006) require adequate amounts of annotated data for training which is time-consuming. Hence, (Mintz et al., 2009) proposd DS to automatically label data. DS inevitably accompanies with the wrong labeling problem. To alleviate the noise issue, (Riedel et al., 2010; Hoffmann et al., 2011) proposed multi-instance learning (MIL) mechanisms. Recently, neural models have been widely used for RE; those models can accurately capture textual relations without explicit linguistic analysis (Zeng et al., 2015;

Lin et al., 2016; Zhang et al., 2018a). To further improve the performance, some studies incorporate external information (Zeng et al., 2017; Ji et al., 2017; Han et al., 2018a) and advanced training strategies (Ye et al., 2017; Liu et al., 2017; Huang and Wang, 2017; Feng et al., 2018; Zeng et al., 2018; Wu et al., 2017; Qin et al., 2018). These works mainly adopt DS to make large-scale datasets and reduce the noise caused by DS, regardless of the effect of long-tail relations.

There are only a few studies on long-tail for RE (Gui et al., 2016; Lei et al., 2018; Han et al., 2018b). Of these, (Gui et al., 2016) proposed an explanation-based approach, whereas (Lei et al., 2018) utilized external knowledge (logic rules). These studies treat each relation in isolation, regardless of the rich semantic correlations between the relations. (Han et al., 2018b) proposed a hierarchical attention scheme for RE, especially for long-tail relations. Different from those approaches, we leverage implicit and explicit relational knowledge from KGs and GCNs rather than data-driven learned parameter spaces where similar relations may have distinct parameters, hindering the generalization of long-tail classes.

Knowledge Graph Embedding. Recently, several KG embedding models have been proposed. These methods learn low-dimensional vector representations for entities and relations (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015). TransE (Bordes et al., 2013) is one of the most widely used models, which views relations as translations from a head entity to a tail entity on the same low-dimensional hyperplane. Inspired by the rich knowledge in KGs, recent works (Han et al., 2018a; Wang et al., 2018; Lei et al., 2018) extend DS models under the guidance of KGs. However, these works neglect rich correlations between relations. Relation structure (relational knowledge) has been studied and is quite effective for KG completion (Zhang et al., 2018b). To the best of our knowledge, this is the first effort to consider the relational knowledge of classes (relations) using KGs for RE.

Graph Convolutional Networks. GCNs generalize CNNs beyond two-dimensional and one-dimensional spaces. (Defferrard et al., 2016) developed spectral methods to perform efficient graph convolutions. (Kipf and Welling, 2016) assumed the graph structure is known over input instances and apply GCNs for semi-supervised learning. GCNs were applied to relational data (e.g., link prediction) by (Schlichtkrull et al., 2018). GCNs have also had success in other NLP tasks such as semantic role labeling (Marcheggiani and Titov, 2017), dependency parsing (Strubell and McCallum, 2017), and machine translation (Bastings et al., 2017).

Two GCNs studies share similarities with our work. (1) (Chen et al., 2017) used GCNs on structured label spaces. However, their experiments do not handle long-tail labels and do not incorporate attention but use an average of word vectors to represent each document. (2) (Rios and Kavuluru, 2018) proposed a few-shot and zero-shot text classification method by exploiting structured label spaces with GCNs. However, they used GCNs in the label graph whereas we utilize GCNs in the hierarchy graph of labels.

3 Methodology

In this section, we introduce the overall framework of our approach for RE, starting with the notations.

3.1 Notations

We denote a KG as $\mathcal{G} = \mathcal{E}, \mathcal{R}, \mathcal{F}$, where $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{F}$ indicate the sets of entities, relations and facts respectively. $(h, r, t) \in \mathcal{F}$ indicates that there is a relation $r \in \mathcal{R}$ between $h \in \mathcal{E}$ and $t \in \mathcal{E}$. We follow the MIL setting and split all instances into multiple entity-pair bags $\{\mathcal{S}_{h_1,t_1}, \mathcal{S}_{h_2,t_2}, ...\}$. Each bag $\mathcal{S}_{h_i,t_i}$ contains multiple instances $\{s_1, s_2, ...\}$ mentioning both entities h_i and t_i. Each instance s in these bags is denoted as a word sequence $s = \{w_1, w_2, ...\}$.

3.2 Framework

Our model consists of three parts as shown in Figure 3:

Instance Encoder. Given an instance and its mentioned entity pair, we employ neural networks to encode the instance semantics into a vector. In this study, we implement the instance encoder with convolutional neural networks (CNNs) given both model performance and time efficiency.

Relational Knowledge Learning. Given pretrained KG embeddings (e.g., TransE (Bordes et al., 2013)) as implicit relational knowledge, we employ GCNs to learn explicit relational knowledge. By assimilating generic message-passing inference algorithms with neural-network counterpart, we can learn better embeddings for Knowl-

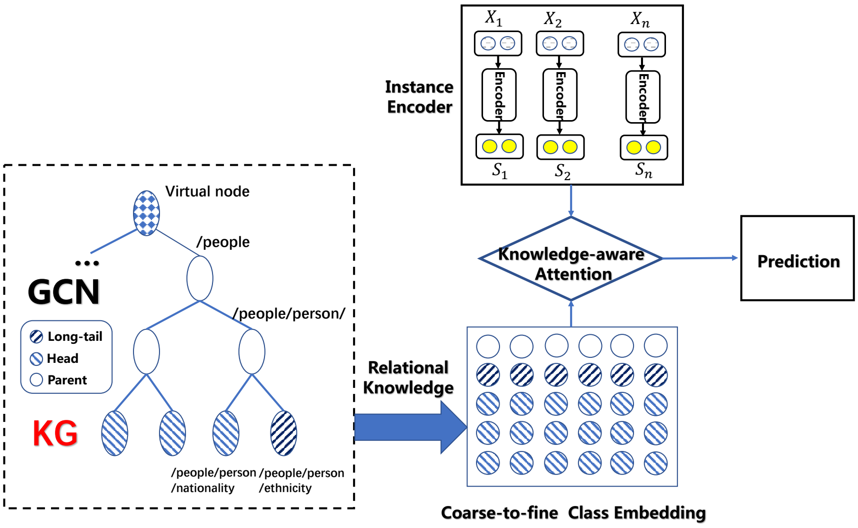

Figure 3: Architecture of our proposed model.

edge Relation. We concatenate the outputs of GCNs and the pretrained KG embeddings to form the final class embeddings.

Knowledge-aware Attention. Under the guidance of final class embeddings, knowledge-aware attention is aimed to select the most informative instance exactly matching relevant relation.

3.3 Instance Encoder

Given an instance $s = \{w_1, ..., w_n\}$ mentioning two entities, we encode the raw instance into a continuous low-dimensional vector x, which consists of an embedding layer and an encoding layer.

Embedding Layer. The embedding layer is used to map discrete words in the instance into continuous input embeddings. Given an instance s, we map each word w_i in the instance to a real-valued pretrained Skip-Gram (Mikolov et al., 2013) embedding $w_i \in \mathbb{R}^{d_w}$. We adopt position embeddings following (Zeng et al., 2014). For each word w_i, we embed its relative distances to the two entities into two d_p-dimensional vectors. We then concatenate the word embeddings and position embeddings to achieve the final input embeddings for each word and gather all the input embeddings in the instance. We thus obtain an embedding sequence ready for the encoding layer.

Encoding Layer. The encoding layer aims to compose the input embeddings of a given instance into its corresponding instance embedding. In this study, we choose two convolutional neural architectures, CNN (Zeng et al., 2014) and PCNN (Zeng et al., 2015) to encode input embeddings into instance embeddings. Other neural architectures such as recurrent neural networks (Zhang and Wang, 2015) can also be used as sentence encoders. Because previous works show that both convolutional and recurrent architectures can achieve comparable state-of-the-art performance, we select convolutional architectures in this study. Note that, our model is independent of the encoder choices, and can, therefore, be easily adapted to fit other encoder architectures.

3.4 Relational Knowledge Learning through KG Embeddings and GCNs.

Given pretrained KG embeddings and predefined class (relation) hierarchies[2], we first leverage the implicit relational knowledge from KGs and initialize the hierarchy label graph; then we apply two layer GCNs to learn explicit fine-grained relational knowledge from the label space.

Hierarchy Label Graph Construction. Given a relation set $\mathcal{R}$ of a KG $\mathcal{G}$ (e.g., Freebase), which consists of base-level relations (e.g., /people/person/ethnicity), we can generate the corresponding higher-level relation set $\mathcal{R}^H$. The relations in a high-level set (e.g., people) are more general and common; they usually contain several sub-relations in the base-level set. The relation hierarchies are tree-structured, and the generation process can be done recursively. We use a virtual father node to construct the highest level associa-

---

[2] For datasets without predefined relation hierarchies, hierarchy clustering (Johnson, 1967) or K-means can construct relation hierarchies (Zhang et al., 2018b); details can be found in supplementary materials.

tions between relations as shown in Figure 3. In practice, we start from $\mathcal{R}^0 = R$ which is the set of all relations we focus on for RE, and the generation process is performed $L-1$ times to get the hierarchical relation sets $\{\mathcal{R}^0, \mathcal{R}^1, ..., \mathcal{R}^L\}$, where $\mathcal{R}^L$ is the virtual father node. Each node has a specific type $t \in \{0, 1, ..., L\}$ to identify its layer hierarchies. For example, as shown in Figure 3, node /people/person/ethnicity has a specific type 0 to indicate it is in the bottom layer of the graph. The vectors of each node in the bottom layer are initialized through pretrained TransE (Bordes et al., 2013) KG embeddings. Other KG embeddings such as TransR (Lin et al., 2015) can also be adopted. Their parent nodes are initialized by averaging all children vectors. For example, the node vector of /people/person/ is initialized by averaging all the nodes under the branch of /people/person/* (all child nodes).

GCN Output Layer. Due to one-to-multiple relations and incompleteness in KGs, the implicit relevant information obtained by KG embeddings for each label is not enough. Therefore, we apply GCNs to learn explicit relational knowledge among labels. We take advantage of the structured knowledge over our label space using a two-layer GCNs. Starting with the pretrained relation embedding $v_i^{implicit} \in \mathbb{R}^d$ from KGs, we combine the label vectors of the children and parents for the i-th label to form,

$$v_i^1 = f(W^1 v_i + \sum_{j \in \mathcal{N}_p} \frac{W_p^1 v_j}{|\mathcal{N}_p|} + \sum_{j \in \mathcal{N}_c} \frac{W_c^1 v_j}{|\mathcal{N}_c|} + b_g^1) \tag{1}$$

where $W^1 \in \mathbb{R}^{q*d}$, $W_p^1 \in \mathbb{R}^{q*d}$, $W_c^1 \in \mathbb{R}^{q*d}$, $b_g^1 \in \mathbb{R}^q$, f is the rectified linear unit (Nair and Hinton, 2010) function, and $\mathcal{N}_c$ ($\mathcal{N}_p$) is the index set of the i-th labels children (parents). We use different parameters to distinguish each edge type where parent edges represent all edges from high level labels and child edges represent all edges from low level labels. The second layer follows the same formulation as the first layer and outputs $v_i^{explicit}$. Finally, we concatenate both pretrained $v_i^{implicit}$ with GCNs node vector $v_i^{explicit}$ to form hierarchy class embeddings,

$$q_r = v_i^{implicit} || v_i^{explicit} \tag{2}$$

where $q_r \in \mathbb{R}^{d+q}$.

3.5 Knowledge-aware Attention

Traditionally, the output layer of PCNN/CNN would learn label specific parameters optimized by a cross-entropy loss. However, the label specific parameters spaces are unique to each relation, matrices associated with the long-tails can only be exposed to very few facts during training, resulting in poor generalization. Instead, our method attempts to match sentence vectors to their corresponding class embeddings rather than learning label specific attention parameters. In essence, this becomes a retrieval problem. Relevant information from class embeddings contains useful relational knowledge for long-tails among labels.

Practically, given the entity pair (h, t) and its bag of instances $S_{h,t} = \{s_1, s_2, ..., s_m\}$, we achieve the instance embeddings $\{s_1, s_2, ..., s_m\}$ using the sentence encoder. We group the class embeddings according to their type (i.e., according to their layers in the hierarchy label graph), e.g., $q_{r^i}, i \in \{0, 1, ..., L\}$. We adopt $q_{r^i}, i \neq L$ (layer L is the virtual father node) as layer-wise attention query vector. Then, we apply coarse-to-fine knowledge-aware attention to them to obtain the textual relation representation $r_{h,t}$. For a relation r, we construct its hierarchical chain of parent relations $(r^0, ..., r^{L-1})$ using the hierarchy label graph, where r^{i-1} is the sub-relation of r^i. We propose the following formulas to compute the attention weight (similarity or relatedness) between each instances feature vector s_k and q_{r^i},

$$\begin{aligned} e_k &= W_s(tanh[s_k; q_{r^i}]) + b_s \\ \alpha_k^i &= \frac{exp(e_k)}{\sum_{j=1}^{m} exp(e_j)} \end{aligned} \tag{3}$$

where $[x_1; x_2]$ denotes the vertical concatenation of x_1 and x_2, W_s is the weight matrix, and b_s is the bias. We compute attention operations on each layer of hierarchy label graph to obtain corresponding textual relation representations,

$$r_{h,t}^i = ATT(q_{r^i}, \{s_1, s_2, ..., s_m\}) \tag{4}$$

Then we need to combine the relation representations on different layers. Direct concatenation of all the representations is a straightforward choice. However, different layers have different contributions for different tuples. For example, the relation /location/br_state/ has only one sub-relation /location/br_state/capital, which indicates that it is more important. In other words, if the sentence has high attention weights on relation /location/br_state/, it has a very high probability to have relation /location/br_state/capital. Hence, we use an attention mechanism to emphasize the layers,

$$\begin{aligned} g_i &= W_g tanh(r_{h,t}) \\ \beta_i &= \frac{exp(g_i)}{\sum_{j=0}^{L-1} exp(g_j)} \end{aligned} \tag{5}$$

where W_g is a weight matrix, $r_{h,t}$ is referred to as a query-based function that scores how well the input textual relation representations and the predict relation r match. The textual relation representations in each layer are computed as,

$$r^i_{h,t} = \beta_i r^i_{h,t} \tag{6}$$

We simply concatenate the textual relation representations on different layers as the final representation,

$$r_{h,r} = Concat(r^0_{h,t}, .., r^{L-1}_{h,t}) \tag{7}$$

The representation $r_{h,t}$ will be finally fed to compute the conditional probability $\mathcal{P}(r|h, t, \mathcal{S}_{h,t})$,

$$\mathcal{P}(r|h, t, \mathcal{S}_{h,t}) = \frac{exp(o_r)}{\sum_{\tilde{r} \in R} exp(o_{\tilde{r}})} \tag{8}$$

where o is the score of all relations defined as,

$$o = M r_{h,t} \tag{9}$$

where M is the representation matrix to calculate the relation scores. Note that, attention weight q_{r^i} is obtained from the outputs of GCNs and pretrained KG embeddings, which can provide more informative parameters than data-driven learned parameters, especially for long-tails.

4 Experiments

4.1 Datasets and Evaluation

We evaluate our models on the NYT dataset developed by (Riedel et al., 2010), which has been widely used in recent studies (Lin et al., 2016; Liu et al., 2017; Wu et al., 2017; Feng et al., 2018). The dataset has 53 relations including the NA relation, which indicates that the relations of instances are not available. The training set has 522611 sentences, 281270 entity pairs, and 18252 relational facts. In the test set, there are 172448 sentences, 96678 entity pairs, and 1950 relational facts. In both training and test set, we truncate sentences with more than 120 words into 120 words.

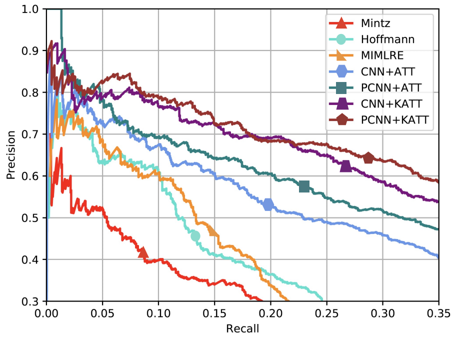

Figure 4: Precision-recall curves for the proposed model and various baseline models.

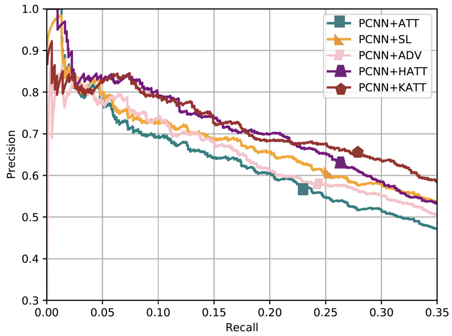

Figure 5: Precision-recall curves for the proposed model and various attention-based neural models.

We evaluate all models in the held-out evaluation. It evaluates models by comparing the relational facts discovered from the test articles with those in Freebase and provides an approximate measure of precision without human evaluation. For evaluation, we draw precision-recall curves for all models. To further verify the effect of our model for long-tails, we follow previous studies (Han et al., 2018b) to report the Precision@N results. The dataset and baseline code can be found on Github [3].

4.2 Parameter Settings[4]

To fairly compare the results of our models with those baselines, we also set most of the experimental parameters by following (Lin et al., 2016). We apply dropout on the output layers of our models to prevent overfitting. We also pretrain the sentence encoder of PCNN before training our model.

4.3 Overall Evaluation Results

To evaluate the performance of our proposed model, we compare the precision-recall curves of our model with various previous RE models. The evaluation results are shown in Figure 4 and Figure 5. We report the results of neural architectures including CNN and PCNN with various attention based methods: **+KATT** denotes our approach, **+HATT** is the hierarchical attention method (Han et al., 2018b), **+ATT** is the plain selective attention method over instances (Lin et al., 2016), **+ATT+ADV** is the denoising attention method by adding a small adversarial perturbation to instance embeddings (Wu et al., 2017), and **+ATT+SL** is the attention-based model using soft-labeling method to mitigate the side effect of the wrong labeling problem at entity-pair level (Liu et al., 2017). We also compare our method with feature-based models, including **Mintz** (Mintz et al., 2009), **MultiR** (Hoffmann et al., 2011) and **MIML** (Surdeanu et al., 2012).

As shown in both figures, our approach achieves the best results among all attention-based models. Even when compared with PCNN+HATT, PCNN+ATT+ADV, and PCNN+ATT+SL, which adopt sophisticated denoising schemes and extra information, our model is still more advantageous. This indicates that our method can take advantage of the rich correlations between relations through KGs and GCNs, which improve the performance. We believe the performance of our model can be further improved by adopting additional mechanisms like adversarial training, and reinforcement learning, which will be part of our future work.

4.4 Evaluation Results for Long-tail Relations

To further demonstrate the improvements in performance for long-tail relations, following the study by (Han et al., 2018b) we extract a subset of the test dataset in which all the relations have fewer than 100/200 training instances. We employ the Hits@K metric for evaluation. For each entity pair, the evaluation requires its corresponding golden relation in the first K candidate relations recommended by the models. Because it is difficult for the existing models to extract long-tail relations, we select K from $\{10,15,20\}$. We report the macro average Hits@K accuracies for these subsets because the micro-average score generally overlooks the influences of long-tails. From the results shown in Table 1, we observe that for both CNN and PCNN models, our model outperforms the plain attention model and the HATT model. Although our KATT method has achieved better results for long-tail relations as compared to both plain ATT method and HATT method, the results of all these methods are still far from satisfactory. This indicates that distantly supervised RE models still suffer from the long-tail relation problem, which may require additional schemes and extra information to solve this problem in the future.

Training Instances	<100			<200		
Hits@K (Macro)	10	15	20	10	15	20

w/o hier	34.2	62.1	65.1	42.5	60.2	68.1
w/o GCNs	30.5	61.9	63.1	39.5	58.4	66.1
Word2vec	30.2	62.0	62.5	39.6	57.5	65.8
w/o KG	30.0	61.0	61.3	39.5	56.5	62.5

Table 2: Results of ablation study with PCNN.

4.5 Ablation Study

To analyze the contributions and effects of different technologies in our approach, we perform ablation tests. **+KATT** is our method; **w/o hier** is the method without coarse-to-fine attention (only utilizes bottom node embeddings of the hierarchy label graph), which implies no knowledge transfer from its higher level classes; **w/o GCN** is the method without GCNs, which implies no explicit relational knowledge; **Word2vec** is the method in which the node is initialized with pretrained Skip-Gram (Mikolov et al., 2013) embeddings; and **w/o KG** is the method in which the node is initialized with random embeddings, which implies no prior relational knowledge from KGs. From the evaluation results in Table 2, we observe that the performance slightly degraded without coarse-to-fine attention, which proves that knowledge transfer from the higher node is useful. We also noticed that the performance slightly degraded without KG or using word embeddings, and the perfor-

Table 3: Example sentences for case study.

4.6 Case Study

We give some examples to show how our method affects the selection of sentences. In Table 3, we display the sentence's attention score in the lowest level[5]. Both the relation /people/deceased_person/place_of_burial (24 instances) and /location/br_state/capital (4 instances) are long-tail relations. On one hand, relation /people/deceased_person/place_of_burial has semantically similar data-rich relation such as /people/deceased_person/place_of_death. We observe that HATT erroneously assigns high attention to the incorrect sentence whereas KATT successfully assigns the right attention weights, which demonstrates the efficacy of knowledge transfer from semantically similar relations (Both HATT and KATT methods can take advantage of knowledge transfer of high-level relations.). On the other hand, the relation /location/br_state/capital does not have semantically similar relations. However, we notice that KATT still successfully assigns the right attention weights, which demonstrates the efficacy of knowledge transfer from high-level relations using coarse-to-fine knowledge-aware attention.

4.7 Visualizations of Class Embeddings

We visualize the class embeddings via t-SNE (Maaten and Hinton, 2008) to further show how GCNs and KG embeddings can help RE for long-tail relations. We observe that (1) Figure 6(a) and 6(d) show that semantically similar class embeddings are closer with GCNs and pretrained KG embeddings, which help select long-tail instances. (2) Figure 6(b) and 6(c) show that KG embeddings and GCNs have different contributions for different relations to learn relational knowledge between classes. For example, /location/location/contain has a sparse hierarchy structure, which leads to inefficient learning for GCNs; therefore, the relative distance changes only slightly, which reveals the necessity of implicit relational knowledge from KGs. (3) Figure 6(d) shows that there are still some semantically similar class embeddings located far away, which may degrade the performance for long-tails. This may be caused by either sparsity in the hierarchy label graph or equal treatment for nodes with the same parent in GCNs, which is not a reasonable hypothesis. We will address this by integrating more information such as relation descriptions or combing logic reasoning as a part of future work.

---

[5] Both HATT and KATT methods can successfully select the correct sentence at the higher-level; details can be found in supplementary materials.

5 Conclusion and Future Work

In this paper, we take advantage of the knowledge from data-rich classes at the head of distribution to boost the performance of the data-poor classes at the tail. As compared to previous methods, our approach provides fine-grained relational knowledge among classes using KG and GCNs, which is quite effective and encoder-agnostic.

In the future, we plan to explore the following directions: (1) We may combine our method with recent denoising methods to further improve performance. (2) We may combine rule mining and reasoning technologies to learn better class embeddings to boost performance. (3) It will be promising to apply our method to zero-shot RE and further adapt to other NLP scenarios.

Acknowledgments

We want to express gratitude to the anonymous reviewers for their hard work and kind comments, which will further improve our work in the future. Abstract

Distant supervision has been widely used in relation extraction tasks without hand-labeled datasets recently. However, the automatically constructed datasets comprise numbers of wrongly labeled negative instances due to the incompleteness of knowledge bases, which is neglected by current distant supervised methods resulting in seriously misleading in both training and testing processes. To address this issue, we propose a novel semi-distant supervision approach for relation extraction by constructing a small accurate dataset and properly leveraging numerous instances without relation labels. In our approach, we construct accurate instances by both knowledge base and entity descriptions determined to avoid wrong negative labeling and further utilize unlabeled instances sufficiently using generative adversarial network (GAN) framework. Experimental results on real-world datasets show that our approach can achieve significant improvements in distant supervised relation extraction over strong baselines.

1 Introduction

Relation extraction aims to identify relations for a pair of entities in a sentence to construct relation triples like [*Steve Jobs, Founder, Apple*]. It has been well studied by supervised approaches with hand-labeled data. However, supervised methods are limited to costly hand-labeled training sets and hard to be extended to large-scale relations. To break the bottleneck of hand-labeled training set, distant supervision (Mintz et al., 2009) automatically construct datasets with knowledge bases. It assumes that if two entities have a known relation in a knowledge base, all sentences that mention these two entities will probably express the same relation and can be called positive instances. At the same time, it treats sentences as negative instances whose entity pairs do not have a known relation in knowledge bases. Due to the strong assumption, instances are likely to be mislabeled. To alleviate the wrong labeling problem, distant supervised methods have been implemented with multi-instance learning and neural networks (Riedel et al., 2010; Hoffmann et al., 2011; Zeng et al., 2015; Lin et al., 2016, 2017). However, previous works focus on positive instances and few methods have addressed the issue of false negative instances.

The false negative instances, which contain true relations, are misclassified sentences in the negative set due to the incomplete nature of knowledge bases. For example, over 70% of people included in Freebase have no known place of birth (Dong et al., 2014). As shown in Figure 1, *S1* presents the relation *place of birth*, while it is labeled as a negative instance. The other three sentences are mislabeled in the same way. The missing relation triples in knowledge bases yield numbers of false negative instances in the automatically labeled dataset. These instances will not only mislead the training method to an unreliable convergence but also make the measurement criteria inaccurate in the testing process. Table 1 compares the precision of automatic and manual evaluation methods for top N predictions by the previous relation extractor (Lin et al., 2016) on the NYT dataset. From the table, we can see that manual evaluation is more precise than automatic evaluation by over 19.8%.

Figure 1: Illustration of the false negative instances in relation extraction by distant supervision. Instances are selected from a widely used dataset NYT (Riedel et al., 2010).

The huge bias mainly comes from false negative instances in the testing set, which severely limits the upper bound of accuracy for relation extraction. Therefore, handling false negative instances is a pivotal issue to improve the performance of distant supervised relation extraction.

Table 1: The Precision at top N predictions (%) of the model Lin et al. (2016) upon automatic and manual evaluations on the NYT Dataset

To alleviate the effect of false negative instances, there are two possible ways. One is improving the accuracy of the automatically labeled dataset, and the other is properly leveraging unlabeled instances which cannot be labeled as positive or negative. The former way is to construct an accurate dataset by filtering credible negative instances but limited by high annotation cost and the resulting dataset size. The latter way is to train relation extraction models with abundant unlabeled instances but restricted by the prerequisite of an accurate dataset used as ground truth. Therefore, we propose a novel semi-distant supervised approach by integrating both ways to decrease the influence of false negative instances for better relation extraction.

In our approach, we additionally use entity descriptions together with a knowledge base to construct an accurate dataset. Supervised by the dataset as ground truth, to effectively exploit numbers of unlabeled instances, we train our relation extractor using a generative adversarial network (GAN) framework. In detail, We propose a three-player min-max game to generate proper relation representations for unlabeled instances in an adversarial way which minimizes the difference between labeled and unlabeled data and maximizes the probability of distinguishing from each other at the same time. The experiments demonstrate that our approach is effective and outperforms the state-of-the-art work. In summary, we make the following major contributions:

- We propose a novel semi-distant supervision method for relation extraction to alleviate the influence of false negative instances.
- To the best of our knowledge, we are the first to generate valid relation representations for sentences by an adversarial algorithm. Numbers of unlabeled instances are used to improve the performance of relation extraction. Moreover, our generative adversarial training strategy is proved effective on an additional sentiment classification with sixteen real-world datasets.
- We construct a new accurate dataset for relation extraction extended from the NYT dataset. Our approach increases the area of the Precision-Recall curve from 0.39 to 0.56 over the baselines.

2 Related Work

To extend relation extraction to large-scale datasets, distant supervision (Mintz et al., 2009) automatically labeled training sets with knowledge bases such as Freebase. Although this method is working well for large-scale relation extraction, it is trapped in the wrong labeling problem for positive instances. To deal with this problem, multi-instance learning was combined with distant supervision (Riedel et al., 2010; Hoffmann et al., 2011). Inspired by the pioneering work, a series of later studies were conducted to further improve distant supervised relation extraction with methods such as multi-instance multi-label learning (Surdeanu et al., 2012), graph model for label generation (Takamatsu et al., 2012), partial supervision (Angeli et al., 2014), matrix completion with low-rank criterion (Fan et al., 2014) and modeling the neighbor consistency with Markov logic (Han and Sun, 2016).

However, the performance of the methods mentioned above strongly depends on the quality of human-designed features. With the development of neural models, relation features with semantic meaning can be accurately, simply and automatically extracted. Zeng et al. (2015) proposed the first neural relation extraction with distant supervision. Mnih et al. (2014), Lin et al. (2016), Zhang et al. (2018), Han et al. (2018) and Du et al. (2018) showed that attention model could improve the accuracy of neural relation extraction. Another similar work (Ji et al., 2017) assigned better attention weights with extra data like entity descriptions. DSGAN (Qin et al., 2018a), a GAN-based method, was also used to recognize true positive instances from noisy datasets. To further alleviate the effect of wrong labeling problem, soft-label training algorithm (Liu et al., 2017b), reinforcement learning methods (Feng et al., 2018; Qin et al., 2018b) and additional side information (Vashishth et al., 2018; Wang et al., 2018) have been used. Most recently, a few methods focused on the pre-training embeddings for word tokens and relations including adversarial training (Wu et al., 2017), transfer learning (Liu et al., 2018) and relation decoder (Su et al., 2018).

All the above methods mainly pay attention to positive instances. Whereas, few studies work on the quality of negative instances, which is exactly the focus of this paper. We effectively construct a reliable dataset with both entity descriptions and a knowledge base, and thus propose a novel semi-distant supervised method to extract relations precisely.

3 Method

In the distant supervised relation extraction paradigm, all sentences labeled by a relation triple constitute a bag, and each sentence is called an instance. The relation triple is described as [*head, relation, tail*], where $head$ and $tail$ are both entities. We extract relation features from labeled training bags and then predict relations for unseen bags in the test set. This section presents our method about constructing an accurate dataset, the sentence encoder for relation representation and the semi-supervised way for relation extraction.

3.1 Dataset Construction

To reduce false negative instances, we construct a new reliable dataset extended from a widely used dataset NYT (Riedel et al., 2010) with entity descriptions. Entity descriptions are crawled from Wikipedia with entity name matching[1]. We assume that if an entity is relevant to another entity, its name is possibly mentioned in the description of the other entity. For example, the entity *Apple Inc.* is mentioned in the description of *Steve Jobs*. To verify the assumption, we count the number of all the accurate positive instances whose entity descriptions mention the other entity name in the NYT corpora. There are 163,108 positive sentences in total, in which 161,392 ones contain entity pairs that related to each other in their descriptions at least once. In other words, over 98.9% instances in positive set fitting our assumption indicates that most entity pairs in positive instances contain each other in their descriptions. Therefore, a former negative instance has a big chance to be credible negative if any of its entities is not mentioned in the description of the other one. Excluding instances that contain entity pairs related to each other in their descriptions, we can obtain more confident negative instances. Finally, we filter credible positive and negative instances from the dataset, and the other instances are unlabeled ones that cannot be labeled as positive or negative.

3.2 Sentence Encoder

3.2.1 Input Embedding

We pre-train input embeddings of word tokens including word and position embeddings. Word embeddings are distributed representations that map each word to a vector $word \in \mathcal{R}^w$, where the parameter w indicates the dimension of the vector. The vectors are trained in advance by $word2vec$ in the setting of Skip-gram (Mikolov et al., 2013). In the task of relation extraction, the relative positions of input tokens are important information.

---

[1] One entity name may refer to multiple entities which have their own pages. In our work, all the matched pages are collected together to obtain its description.

Position embeddings are defined as the combination of the relative distances from the current word to *head* and *tail*. For instance, the relative distances from [*co-founder*] to [*Steve Jobs*] and [*Apple*] are respectively 3 and -6 in the sentence *Steve Jobs was the co-founder and the CEO of the Apple*. We encode distances to vectors $position \in \mathcal{R}^p$, where p is the dimension. The position embeddings are initialized randomly and updated in the training process. Finally, word embeddings and position embeddings are concatenated together to feed the neural model. We denote all the words in an instance as an initial vector sequence $b^* = \{x_1, \cdots, x_i, \cdots, x_q\}$, where $x_i \in \mathcal{R}^{w+p}$ and q is the number of words in the instance b^*.

3.2.2 Convolutional Encoder

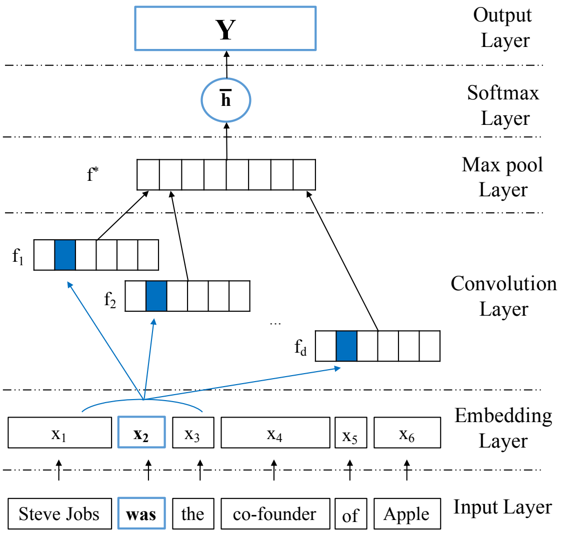

Figure 2: The architecture of our sentence encoder illustrating the procedure for handling one instance and predicting the relation between [Apple] and [Steve Jobs]. All forms of f are hidden states, $\bar{h}$ is relation representation of the sentence and Y represents relation labels.

Convolutional Neural Network (CNN) is a widely used structure for sentence encoder as shown in Figure 2. With the input embeddings, the convolutional layer extracts local features with a sliding window of length k over the input tokens. In the figure, we extract local features from 3 ($k = 3$) adjacent word tokens with dot production between convolutional kernels and input embeddings. The convolutional kernels are weight vectors represented by $W \in \mathcal{R}^{d \times k(w+p)}$ and the number of kernels is d. In summary, the convolutional operation follows the equation,

$$f_{ij} = W_i \cdot [x_{j-1}; x_j; x_{j+1}], \tag{1}$$

where $[x; y]$ denotes the vertical concatenation of x and y. f_{ij} presents j-th value of the i-th filter, where i and j are in range $[1, d]$ and $[1, q]$ respectively. Out-of-range input values such as x_0 and x_{q+1} are taken to be zero. A max-pooling operation selects the most important features of each f_i with $f_i^* = max(f_{ij})$, where $f^* \in \mathcal{R}^d$. Furthermore, PCNN (Zeng et al., 2015) improves the max-pooling operation with a piecewise method whose outputs of convolutional filters are divided into three segments by *head* and *tail* entities. Therefore, the max pooling procedure is performed in three segments separately.

Then, we summarize f^* to $\bar{h}$ by a non-linear function such as the hyperbolic tangent. The final feature vector $\bar{h}$ is fed into output layer after the softmax method $\hat{p} = softmax(W_r \bar{h} + b_r)$, where $W_r \in \mathcal{R}^{z \times d}$ and $b_r \in \mathcal{R}^z$ are variables, $\hat{p} \in \mathcal{R}^z$ is the estimated probability for each class and z is the number of relations. A cost function for one instance is the negative log-likelihood of the relations,

$$J_{truth}(\hat{p}, y, \theta) = -\frac{1}{z} \sum_{j=1}^{z} y_j \log \hat{p}_j, \tag{2}$$

where $y \in \mathcal{R}^z$ is the one-hot represented ground truth and θ presents all the parameters.

3.3 Semi-distant Supervision

The architecture of our semi-distant supervision is shown in Figure 3. To sufficiently utilize the reconstructing dataset including accurately labeled instances and unlabeled ones, we propose a generative adversarial training strategy, which transforms unlabeled instances (x_{ul}) to labeled data (x_l) space by generating valid relation representations (x_{gen}) and making the distribution of labeled instances $p(x_l)$ equal to that of generative data $p(x_{gen})$ in relation space[2]. Inspired by Goodfellow et al. (2014), we further devise a three-player min-max game to generate valid data distribution $p(x_{gen})$ with sentence encoder, generative and discriminative modules. The generative module minimizes the difference of $p(x_l)$ and $p(x_{gen})$, and the discriminative module maximizes the probability of distinguishing from each other at the same

---

[2] $p(x_l)$ and $p(x_{gen})$ represents the data distribution of labeled and generative instances.

end for
```

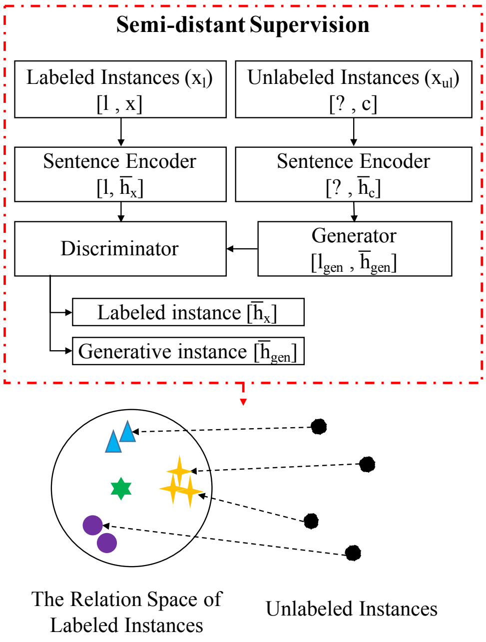

Figure 3: The architecture of GAN driven semi-distant supervision for relation extraction. $\bar{h}_x$ and $\bar{h}_c$ are relation representations of labeled and unlabeled instances respectively. $\bar{h}_{gen}$ is generated relation representation by the generator. l and l_{gen} represent accurate label and generated label respectively. The symbols in relation space represent labeled instances.

time. Sentence encoder is proposed as the third player, which extracts relation features from all the instances and produces a pre-trained relation representation for unlabeled instances. With the sentence encoder, we can control relation features contained in the generated representations.

Therefore, the discriminative module D will try to distinguish labeled data from generative data, while the generative module G makes $p(x_{gen}) \approx p(x_l)$. In addition, the sentence encoder S extracts relation features with all the training instances p_{all}. The training procedure is a three-player min-max game as the following equation,

$$\begin{aligned}\min_{S,G}\max_{D} V(S,D,G) = {} & E_{x\sim p_{all}}[\log S(x)] \\ & + E_{x\sim p_{x_l}}[\log D(x)] \\ & + E_{c\sim p_{x_{gen}}}[\log(1 - D(G(c)))],\end{aligned} \tag{3}$$

In generative adversarial training, the discriminative module is trained by maximizing the gap between labeled data and generative data with the following equation,

$$J_D(x, c, \theta_d) = \log D(x) + \log(1 - D(G(c))), \tag{4}$$

where x and c are instances from accurately labeled set (x_l) and unlabeled set (x_{ul}) respectively.

θ_d presents parameters for the discriminator. $D(x)$ and $D(G(c))$ are defined as follows,

$$D(x) = \sigma(W_d \bar{h}_x), \tag{5}$$

$$D(G(c)) = \sigma(W_d(\bar{h}_c + W_g)), \tag{6}$$

where W_d and W_g are variables for discriminative and generative modules respectively. σ is the sigmoid function. The generative module is trained to make the generated relation representations more similar to real ones by the following loss function, where θ_g presents parameters.

$$J_G(c, \theta_g) = \log(1 - D(G(c))) \tag{7}$$

Finally, we train our sentence encoder S by optimizing the following loss function,

$$\begin{aligned} J_S(x, c, \theta_s) = &-\frac{1}{z}\sum_{j=1}^{z} y_{l_j} \log \hat{p}(y_j|x) \\ &-\frac{1}{z}\sum_{j=1}^{z} y_{g_j} \log \hat{p}(y_j|G(c)), \end{aligned} \tag{8}$$

where y_g means a one-hot vector which labels the most possible relation for unlabeled instances generated by the sentence encoder. θ_s represents parameters of S. The complete training procedure for generative adversarial training is shown as Algorithm 1.

4 Experiments

The experiments are proposed to answer the following three questions, 1) Is the proposed semi-distant supervision method effective for the task of relation extraction? 2) Is the constructed dataset credible enough? 3) Is the generative adversarial training helpful to relation extraction and other semi-supervised tasks?

4.1 Experimental Settings

4.1.1 Dataset

We conduct experiments on a widely used dataset NYT (Riedel et al., 2010) and its new version Accurate-NYT (A-NYT). A-NYT is a credible dataset filtered by our data construction module. We follow the previous work (Lin et al., 2016) to partition training and testing sets for NYT and A-NYT. Besides, we apply sixteen real-world datasets[3] (Liu et al., 2017a) to further verify the effectiveness of our generative adversarial training strategy on the task of sentiment classification. The dataset details are shown in Table 2.

Dataset	Positive	Negative	Unlabeled	Classes

Table 2: Statistics of the datasets

4.1.2 Evaluation Metrics and Baselines

On the dataset NYT and A-NYT, we evaluate our method in the classical held-out evaluation. It evaluates our models by comparing relation facts discovered from the test sentences with those in Freebase. Specifically, we report both the aggregate Precision-Recall (PR) curves and Precision at top N predictions (P@N) in our experiments. For the other datasets, we compute the precision of all the predictions.

We adopt the following baselines for distant supervised relation extraction.

Zeng et al. (2015) extracted relation features with piecewise convolutional neural network (PCNN).

Lin et al. (2016) integrated PCNN with selective attention mechanism (PCNN+ATT).

Wu et al. (2017) added adversarial noise at the level of the word embeddings (PCNN+ATT+AT).

Liu et al. (2017b) relabeled the training instances dynamically by the relation extractor (PCNN+ATT+SL).

Qin et al. (2018a) designed a GAN to recognize true positive samples (PCNN+DSGAN).

Liu et al. (2018) shortened the training instances with the parser tree and pre-trained word embeddings with transfer learning, which is the latest state-of-the-art work.

Self-Training (ST) is a semi-supervised method that can be integrated with PCNN+ATT for unlabeled data, which generates relation types for unlabeled instances with the model itself.

---

[3] The datasets are Amazon product reviews and movie reviews.

4.1.3 Parameters

In our experiments, we use the $word2vec$ in the setting of Skip-gram to train the word embeddings on NYT set. To train our model efficiently, we iterate by randomly selecting a batch from the training set until convergence and apply sentence-level attention mechanism following the previous work (Lin et al., 2016). The parameter n and m are batch sizes for accurate and unlabeled datasets respectively. We update the gradient with adaptive moment estimation (Kingma and Ba, 2015). Furthermore, $L2$ regularization and dropout (Srivastava et al., 2014) are adopted to avoid overfitting. Finally, we use a grid search and cross-validation to determine the optional parameters as shown in Table 3. The hyper-parameters s_i, s_j and s_k are training steps for different modules of generative adversarial training. Since the other parameters have little effect on the results, we follow the settings as the previous work (Lin et al., 2016).

batch size (n, m)	50
s_i, s_j, s_k	2, 1, 2
filter number d	230
kernel size k	3
word dimension w	50
position dimension p	10
learning rate	0.001
dropout probability	0.5
L2 regularization strength	0.0001

Table 3: Parameter settings

4.2 Overall Performance of Semi-Distant Supervision

The overall performance of our method compared with baselines for distant supervised relation extraction is shown in Table 4. We can see that our semi-distant supervised method achieves much better results than the baselines on all metrics. The huge improvement comes from both the accurate dataset and the effective training strategy which leverages unlabeled instances properly.

4.3 Effect of Dataset A-NYT

In this section, we apply two previous methods Zeng et al. (2015) and Lin et al. (2016) on NYT and A-NYT. PR curves for NYT are reported in their papers, while PR curves for A-NYT come from our implementations of the two baselines. NYT and A-NYT share the same positive instances, while A-NYT set has less and credible negative instances. As shown in Figure 4(a), methods on A-NYT always obtain better performance. The huge gap between PR curves is caused by false negative instances in NYT, which are not used for training and testing in A-NYT. To prove that results on A-NYT are according to the actual situation, we do manual evaluations at P@Ns. As shown in Table 5, the huge bias caused by false negative instances on NYT is dramatically alleviated on the dataset A-NYT.

P@N	100	200	300	Mean	PR
Zeng et al. (2015)	72.3	69.7	64.1	68.7	0.33
Lin et al. (2016)	76.2	73.1	67.4	72.2	0.35

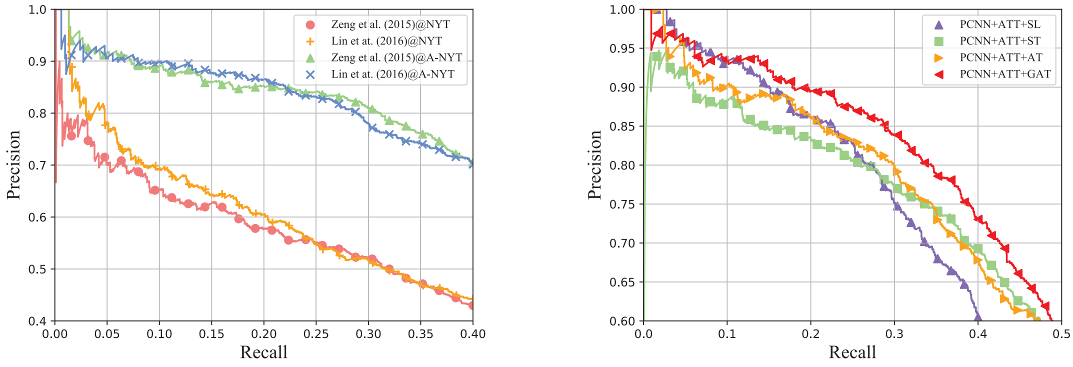
4.4 Effect of Generative Adversarial Training for Relation Extraction

To further demonstrate the effectiveness of our training strategies, we compare Generative Adversarial Training (GAT) with other baselines on the partially labeled dataset A-NYT as shown in Figure 4(b). The figure gives the following insights, 1) PCNN+ATT+ST and PCNN+ATT+AT do not work well, which is caused by the low quality of unlabeled instances. 2) PCNN+ATT+SL works as well as our models at low recall rate because of its excellent ability to extract notable features. Unfortunately, it falls far behind all the baselines at high recall rate, which means it tends to converge to a local optimum. 3) Our model achieves solid PR curves at all range of recall rate.

Meanwhile, we propose a detailed comparison of baselines with P@Ns and PR curve areas as shown in Table 6. From the table, we can see that our training strategy achieves much better result than the other baselines, which indicates that abundant unlabeled instances are helpful to extract relations only if used appropriately. Going



(a) PR curves of baselines on NYT and A-NYT [4]

(b) PR curves of our model and baselines on A-NYT with all the labeled and unlabeled data

Figure 4: PR curves for the comparisons (Better view in color)

deeper in the table, PCNN+ATT+SL works well at top predictions but obtains the worst PR curve. Our semi-distant supervised model with adversarial generations is useful for leveraging unlabeled instances properly.

P@N	100	200	300	Mean	PR
Zeng et al. (2015)‡	91.0	88.5	87.6	89.0	0.513
Lin et al. (2016)‡	93.0	89.5	88.0	88.2	0.513
Qin et al. (2018a)‡	90.0	91.0	88.3	89.8	0.524
Liu et al. (2018)‡	93.0	93.5	91.3	92.6	0.503
PCNN+ATT+SL	**96.0**	93.0	90.6	93.2	0.466

PCNN+ATT+GAT	**96.0**	**93.5**	**93.0**	**94.2**	**0.558**

Table 6: P@Ns(%) and PR curve areas on A-NYT. Methods with ‡ do not use unlabeled data. PCNN+ATT+AT is a semi-supervised extension of original method (Wu et al. (2017)) to make the unlabeled instances consistent with their predictions.

4.5 Effect of Generative Adversarial Training for Sentiment Classification

To verify the expandability of generative adversarial training, we conduct additional experiments on the task of sentiment classification. We implement our model and three baselines based on the Long Short-Term Memory (LSTM) network[5]. The results are shown in Table 7, from which we see that, 1) Self-training obtains poor results compared with the basic LSTM model, which means they fail to utilize unlabeled data correctly. 2) Adversarial training improves the performance on only three of the datasets and performs poorly on others, which means they possibly rely on the quality of unlabeled data. 3) LSTM+GAT achieves better results than the baselines on most of the datasets because of generating high-quality representations for unlabeled sentences.

5 Conclusions

In this paper, we propose a novel semi-distant supervision approach that is capable of jointly exploiting limited accurate and abundant unlabeled ones. We first construct a reliable dataset with a knowledge base and additional entity descriptions.

---

[4] Results on NYT are reported as their papers except Wu et al. (2017) and Qin et al. (2018a). Results of these two methods on NYT and all results on A-NYT are obtained by our implementations.

[5] Our generative adversarial training strategy is model-independent, meaning that it could be applied to other neural models.

With the dataset, the generative adversarial training strategy is proposed to deal with plenty of unlabeled instances, which generates valid relation representations. Our experiments show that the proposed approach achieves significant improvement over previous state-of-the-art baselines.

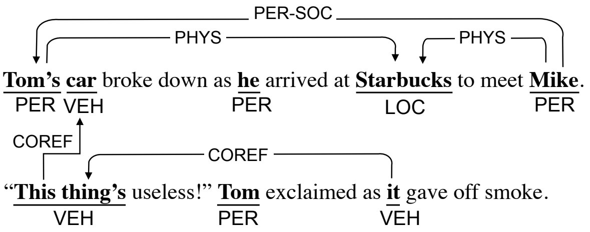
Abstract

We introduce a general framework for several information extraction tasks that share span representations using dynamically constructed span graphs. The graphs are constructed by selecting the most confident entity spans and linking these nodes with confidence-weighted relation types and coreferences. The dynamic span graph allows coreference and relation type confidences to propagate through the graph to iteratively refine the span representations. This is unlike previous multi-task frameworks for information extraction in which the only interaction between tasks is in the shared first-layer LSTM. Our framework significantly outperforms the state-of-the-art on multiple information extraction tasks across multiple datasets reflecting different domains. We further observe that the span enumeration approach is good at detecting nested span entities, with significant F1 score improvement on the ACE dataset.[1]

1 Introduction

Most Information Extraction (IE) tasks require identifying and categorizing phrase spans, some of which might be nested. For example, entity recognition involves assigning an entity label to a phrase span. Relation Extraction (RE) involves assigning a relation type between pairs of spans. Coreference resolution groups spans referring to the same entity into one cluster. Thus, we might expect that knowledge learned from one task might benefit another.

Most previous work in IE (e.g., (Nadeau and Sekine, 2007; Chan and Roth, 2011)) employs a pipeline approach, first detecting entities and then using the detected entity spans for relation extraction and coreference resolution. To avoid cascading errors introduced by pipeline-style systems, recent work has focused on coupling different IE tasks as in joint modeling of entities and relations (Miwa and Bansal, 2016; Zhang et al., 2017), entities and coreferences (Hajishirzi et al., 2013; Durrett and Klein, 2014), joint inference (Singh et al., 2013) or multi-task (entity/relation/coreference) learning (Luan et al., 2018a). These models mostly rely on the first layer LSTM to share span representations between different tasks and are usually designed for specific domains.



Tom's **car** broke down as **he** arrived at **Starbucks** to meet **Mike**.

"**This thing's** useless!" **Tom** exclaimed as **it** gave off smoke.

Figure 1: A text passage illustrating interactions between entities, relations and coreference links. Some relation and coreference links are omitted.

In this paper, we introduce a general framework Dynamic Graph IE (DyGIE) for coupling multiple information extraction tasks through shared span representations which are refined leveraging contextualized information from relations and coreferences. Our framework is effective in several domains, demonstrating a benefit from incorporating broader context learned from relation and coreference annotations.

Figure 1 shows an example illustrating the potential benefits of entity, relation, and coreference contexts. It is impossible to predict the entity labels for *This thing* and *it* from within-sentence context alone. However, the antecedent *car* strongly suggests that these two entities have a VEH type. Similarly, the fact that *Tom* is located at *Starbucks* and *Mike* has a relation to *Tom* provides support for

---

[1] Code and pre-trained models are publicly available at `https://github.com/luanyi/DyGIE`.

Proceedings of NAACL-HLT 2019, pages 3036–3046
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

the fact that *Mike* is located at *Starbucks*.

DYGIE uses multi-task learning to identify entities, relations, and coreferences through shared span representations using dynamically constructed span graphs. The nodes in the graph are dynamically selected from a beam of highly-confident mentions, and the edges are weighted according to the confidence scores of relation types or coreferences. Unlike the multi-task method that only shares span representations from the local context (Luan et al., 2018a), our framework leverages rich contextual span representations by propagating information through coreference and relation links. Unlike previous BIO-based entity recognition systems (Collobert and Weston, 2008; Lample et al., 2016; Ma and Hovy, 2016) that assign a text span to at most one entity, our framework enumerates and represents all possible spans to recognize arbitrarily overlapping entities.

We evaluate DYGIE on several datasets spanning many domains (including news, scientific articles, and wet lab experimental protocols), achieving state-of-the-art performance across all tasks and domains and demonstrating the value of coupling related tasks to learn richer span representations. For example, DYGIE achieves relative improvements of 5.7% and 9.9% over state of the art on the ACE05 entity and relation extraction tasks, and an 11.3% relative improvement on the ACE05 overlapping entity extraction task.

The contributions of this paper are threefold. 1) We introduce the dynamic span graph framework as a method to propagate global contextual information, making the code publicly available. 2) We demonstrate that our framework significantly outperforms the state-of-the-art on joint entity and relation detection tasks across four datasets: ACE 2004, ACE 2005, SciERC and the Wet Lab Protocol Corpus. 3) We further show that our approach excels at detecting entities with overlapping spans, achieving an improvement of up to 8 F1 points on three benchmarks annotated with overlapped spans: ACE 2004, ACE 2005 and GENIA.

2 Related Work

Previous studies have explored joint modeling (Miwa and Bansal, 2016; Zhang et al., 2017; Singh et al., 2013; Yang and Mitchell, 2016)) and multi-task learning (Peng and Dredze, 2015; Peng et al., 2017; Luan et al., 2018a, 2017a) as methods to share representational strength across related information extraction tasks. The most similar to ours is the work in Luan et al. (2018a) that takes a multi-task learning approach to entity, relation, and coreference extraction. In this model, the different tasks share span representations that only incorporate broader context indirectly via the gradients passed back to the LSTM layer. In contrast, DYGIE uses dynamic graph propagation to explicitly incorporate rich contextual information into the span representations.

Entity recognition has commonly been cast as a sequence labeling problem, and has benefited substantially from the use of neural architectures (Collobert et al., 2011; Lample et al., 2016; Ma and Hovy, 2016; Luan et al., 2017b, 2018b). However, most systems based on sequence labeling suffer from an inability to extract entities with overlapping spans. Recently Katiyar and Cardie (2018) and Wang and Lu (2018) have presented methods enabling neural models to extract overlapping entities, applying hypergraph-based representations on top of sequence labeling systems. Our framework offers an alternative approach, forgoing sequence labeling entirely and simply considering all possible spans as candidate entities.

Neural graph-based models have achieved significant improvements over traditional feature-based approaches on several graph modeling tasks. Knowledge graph completion (Yang et al., 2015; Bordes et al., 2013) is one prominent example. For relation extraction tasks, graphs have been used primarily as a means to incorporate pipelined features such as syntactic or discourse relations (Peng et al., 2017; Song et al., 2018; Zhang et al., 2018). Christopoulou et al. (2018) models all possible paths between entities as a graph, and refines pair-wise embeddings by performing a walk on the graph structure. All these previous works assume that the nodes of the graph (i.e. the entity candidates to be considered during relation extraction) are predefined and fixed throughout the learning process. On the other hand, our framework does not require a fixed set of entity boundaries as an input for graph construction. Motivated by state-of-the-art span-based approaches to coreference resolution (Lee et al., 2017, 2018) and semantic role labeling (He et al., 2018), the model uses a beam pruning strategy to dynamically select high-quality spans, and constructs a graph using the selected spans as nodes.

Many state-of-the-art RE models rely upon domain-specific external syntactic tools to construct dependency paths between the entities in a sentence (Li and Ji, 2014; Xu et al., 2015; Miwa and Bansal, 2016; Zhang et al., 2017). These systems suffer from cascading errors from these tools and are hard to generalize to different domains. To make the model more general, we combine the multitask learning framework with ELMo embeddings (Peters et al., 2018) without relying on external syntactic tools and risking the cascading errors that accompany them, and improve the interaction between tasks through dynamic graph propagation. While the performance of DyGIE benefits from ELMo, it advances over some systems (Luan et al., 2018a; Sanh et al., 2019) that also incorporate ELMo. The analyses presented here give insights into the benefits of joint modeling.

3 Model

Problem Definition The input is a document represented as a sequence of words D, from which we derive $S = \{s_1, \ldots, s_T\}$, the set of all possible within-sentence word sequence spans (up to length L) in the document. The output contains three structures: the entity types E for all spans S, the relations R for all span pairs $S \times S$ within the same sentence, and the coreference links C for all spans in S across sentences. We consider two primary tasks. First, *Entity Recognition* is the task of predicting the best entity type labels e_i for each span s_i. Second, *Relation Extraction* involves predicting the best relation type r_{ij} for all span pairs (s_i, s_j). We provide additional supervision by also training our model to perform a third, auxiliary task: *Coreference resolution*. For this task we predict the best antecedent c_i for each span s_i.

Our Model We develop a general information extraction framework (DyGIE) to identify and classify entities, relations, and coreference in a multi-task setup. DyGIE first enumerates all text spans in each sentence, and computes a locally-contextualized vector space representation of each span. The model then employs a *dynamic span graph* to incorporate global information into its span representations, as follows. At each training step, the model identifies the text spans that are most likely to represent entities, and treats these spans as nodes in a graph structure. It constructs confidence-weighted arcs for each node according to its predicted coreference and relation links with the other nodes in the graph. Then, the span representations are refined using broader context from gated updates propagated from neighboring relation types and co-referred entities. These refined span representations are used in a multi-task framework to predict entity types, relation types, and coreference links.

3.1 Model Architecture

In this section, we give an overview of the main components and layers of the DyGIE framework, as illustrated in Figure 2. Details of the graph construction and refinement process will be presented in the next section.

Token Representation Layer We apply a bidirectional LSTM over the input tokens. The input for each token is a concatenation of the character reprensetation, GLoVe (Pennington et al., 2014) word embeddings, and ELMo embeddings (Peters et al., 2018). The output token representations are obtained by stacking the forward and backward LSTM hidden states.

Span Representation Layer For each span s_i, its initial vector representation $\mathbf{g}_i^0$ is obtained by concatenating BiLSTM outputs at the left and right end points of s_i, an attention-based soft "head-word," and an embedded span width feature, following Lee et al. (2017).

Coreference Propagation Layer The propagation process starts from the span representations $\mathbf{g}_i^0$. At each iteration t, we first compute an *update vector* $\mathbf{u}_C^t$ for each span s_i. Then we use $\mathbf{u}_C^t$ to update the current representation $\mathbf{g}_i^t$, producing the next span representation $\mathbf{g}_i^{t+1}$. By repeating this process N times, the final span representations $\mathbf{g}_i^N$ share contextual information across spans that are likely to be antecedents in the coreference graph, similar to the process in (Lee et al., 2018).

Relation Propagation Layer The outputs $\mathbf{g}_i^N$ from the coreference propagation layer are passed as inputs to the relation propagation layer. Similar to the coreference propagation process, at each iteration t, we first compute the update vectors $\mathbf{u}_R^t$ for each span s_i, then use it to compute $\mathbf{g}_i^{t+1}$. Information can be integrated from multiple relation paths by repeating this process M times.

Final Prediction Layer We use the outputs of the relation graph layer $\mathbf{g}_i^{N+M}$ to predict the entity labels E and relation labels R. For entities, we pass $\mathbf{g}_i^{N+M}$ to a feed-forward network (FFNN) to

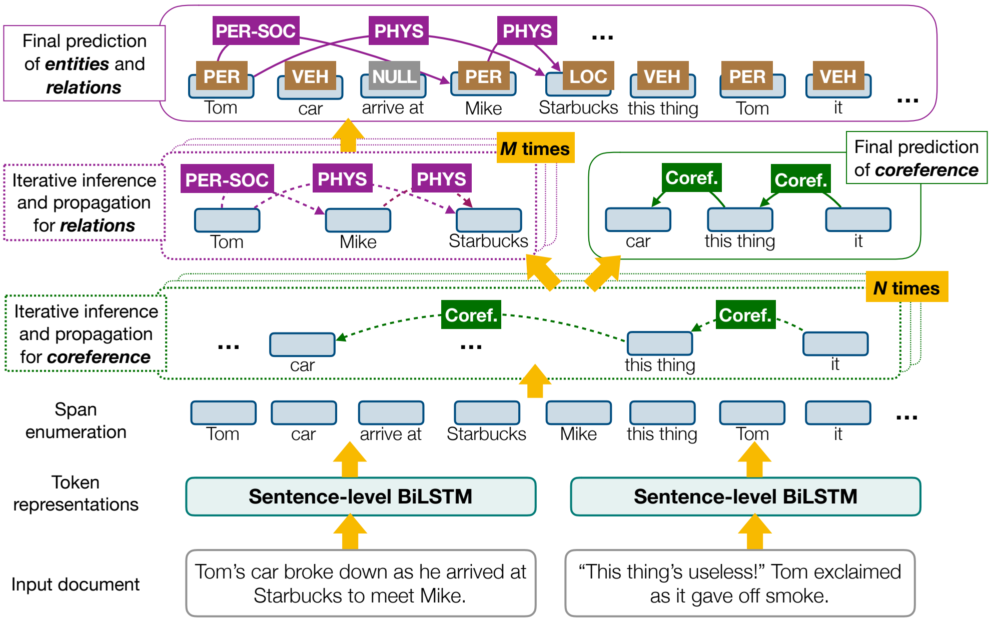


Figure 2: Overview of our DyGIE model. Dotted arcs indicate confidence weighted graph edges. Solid lines indicate the final predictions.

produce per-class scores $\mathbf{P}_E(i)$ for span s_i. For relations, we pass the concatenation of $\mathbf{g}_i^{N+M}$ and $\mathbf{g}_j^{N+M}$ to a FFNN to produce per-class relation scores $\mathbf{P}_R(i,j)$ between spans s_i and s_j. Entity and relation scores are normalized across the label space, similar to Luan et al. (2018a). For coreference, the scores between span pairs (s_i, s_j) are computed from the coreference graph layer outputs $(\mathbf{g}_i^N, \mathbf{g}_j^N)$, and then normalized across all possible antecedents, similar to Lee et al. (2018).

3.2 Dynamic Graph Construction and Span Refinement

The dynamic span graph facilitates propagating broader contexts through soft coreference and relation links to refine span representations. The nodes in the graph are spans s_i with vector representations $\mathbf{g}_i^t \in \mathbb{R}^d$ for the t-th iteration. The edges are weighted by the coreference and relation scores, which are trained according to the neural architecture explained in Section 3.1. In this section, we explain how coreference and relation links can update span representations.

Coreference Propagation Similar to (Luan et al., 2018a), we define a beam B_C consisting of b_c spans that are most likely to be in a coreference chain. We consider $\mathbf{P}_C^t$ to be a matrix of real values that indicate coreference confidence scores between these spans at the t-th iteration. $\mathbf{P}_C^t$ is of size $b_c \times K$, where K is the maximum number of antecedents considered. For the coreference graph, an edge in the graph is single directional, connecting the current span s_i with all its potential antecedents s_j in the coreference beam, where $j < i$. The edge between s_i and s_j is weighted by coreference confidence score at the current iteration $P_C^t(i,j)$. The span update vector $\mathbf{u}_C^t(i) \in \mathbb{R}^d$ is computed by aggregating the neighboring span representations $\mathbf{g}_j^t$, weighted by their coreference scores $P_C^t(i,j)$:

$$\mathbf{u}_C^t(i) = \sum_{j \in B_C(i)} P_C^t(i,j)\mathbf{g}_j^t \qquad (1)$$

where $B_C(i)$ is the set of K spans that are antecedents of s_i,

$$P_C^t(i,j) = \frac{\exp(V_C^t(i,j))}{\sum_{j' \in B_C(i)} \exp(V_C^t(i,j))} \qquad (2)$$

$V_C^t(i,j)$ is a scalar score computed by concatenating the span representations $[\mathbf{g}_i^t, \mathbf{g}_j^t, \mathbf{g}_i^t \odot \mathbf{g}_j^t]$, where $\odot$ is element-wise multiplication. The concatenated vector is then fed as input to a FFNN, similar to (Lee et al., 2018).

Relation Propagation For each sentence, we define a beam B_R consisting of b_r entity spans that are mostly likely to be involved in a relation. Unlike the coreference graph, the weights of relation edges capture different relation types. Therefore, for the t-th iteration, we use a tensor $\mathbf{V}_R^t \in \mathbb{R}^{b_R \times b_R \times L_R}$ to capture scores of each of the L_R relation types. In other words, each edge in the relation graph connects two entity spans s_i and s_j in the relation beam B_R. $\mathbf{V}_R^t(i,j)$ is a L_R-length vector of relation scores, computed with a FFNN with $[\mathbf{g}_i^t, \mathbf{g}_j^t]$ as the input. The relation update vector $\mathbf{u}_R^t(i) \in \mathbb{R}^d$ is computed by aggregating neighboring span representations on the relation graph:

$$\mathbf{u}_R^t(i) = \sum_{j \in B_\mathrm{R}} f(\mathbf{V}_R^t(i,j))\mathbf{A}_R \odot \mathbf{g}_j^t, \quad (3)$$

where $\mathbf{A}_R \in \mathbb{R}^{L_R \times d}$ is a trainable linear projection matrix, f is a non-linear function to select the most important relations. Because only a small number of entities in the relation beam are actually linked to the target span, propagation among all possible span pairs would introduce too much noise to the new representation. Therefore, we choose f to be the ReLU function to remove the effect of unlikely relations by setting the all negative relation scores to 0. Unlike coreference connections, two spans linked via a relation are not expected to have similar representations, so the matrix $\mathbf{A}_R$ helps to transform the embedding $\mathbf{g}_j^t$ according to each relation type.

Updating Span Representations with Gating To compute the span representations for the next iteration $t \in \{1, \ldots, N+M\}$, we define a gating vector $\mathbf{f}_x^t(i) \in \mathbb{R}^d$, where $x \in \{C, R\}$, to determine whether to keep the previous span representation $\mathbf{g}_i^t$ or to integrate new information from the coreference or relation update vectors $\mathbf{u}_x^t(i)$. Formally,

$$\begin{aligned} \mathbf{f}_x^t(i) &= g(\mathbf{W}_x^\mathrm{f}[\mathbf{g}_i^t, \mathbf{u}_x^t(i)]) & (4) \\ \mathbf{g}_i^{t+1} &= \mathbf{f}_x^t(i) \odot \mathbf{g}_i^t + (1 - \mathbf{f}_x^t(i)) \odot \mathbf{u}_x^t(i), \end{aligned}$$

where $\mathbf{W}_x^\mathrm{f} \in \mathbb{R}^{d \times 2d}$ are trainable parameters, and g is an element-wise sigmoid function.

3.3 Training

The loss function is defined as a weighted sum of the log-likelihood of all three tasks:

$$\sum_{(D,R^*,E^*,C^*) \in \mathcal{D}} \Big\{ \lambda_\mathrm{E} \log P(E^* \mid C, R, D) \quad (5)$$
$$+ \lambda_\mathrm{R} \log P(R^* \mid C, D) + \lambda_\mathrm{C} \log P(C^* \mid D) \Big\}$$

where E^*, R^* and C^* are gold structures of the entity types, relations and coreference, respectively. $\mathcal{D}$ is the collection of all training documents D. The task weights λ_E, λ_R, and λ_C are hyperparameters to control the importance of each task.

Table 1: Datasets for joint entity and relation extraction and their statistics. *Ent*: Number of entity categories. *Rel*: Number of relation categories.

We use a 1 layer BiLSTM with 200-dimensional hidden layers. All the feed-forward functions have 2 hidden layers of 150 dimensions each. We use 0.4 variational dropout (Gal and Ghahramani, 2016) for the LSTMs, 0.4 dropout for the FFNNs, and 0.5 dropout for the input embeddings. The hidden layer dimensions and dropout rates are chosen based on the development set performance in multiple domains. The task weights, learning rate, maximum span length, number of propagation iterations and beam size are tuned specifically for each dataset using development data.

4 Experiments

DyGIE is a general IE framework that can be applied to multiple tasks. We evaluate the performance of DyGIE against models from two lines of work: combined entity and relation extraction, and overlapping entity extraction.

4.1 Entity and relation extraction

For the entity and relation extraction task, we test the performance of DyGIE on four different datasets: ACE2004, ACE2005, SciERC and the Wet Lab Protocol Corpus. We include the relation graph propagation layer in our models for all datasets. We include the coreference graph propagation layer on the data sets that have coreference annotations available.

Data All four data sets are annotated with entity and relation labels. Only a small fraction of entities ($< 3\%$ of total) in these data sets have a text span that overlaps the span of another entity. Statistics on all four data sets are displayed in Table 1.

The **ACE2004** and **ACE2005** corpora provide entity and relation labels for a collection of documents from a variety of domains, such as newswire and online forums. We use the same entity and relation types, data splits, and preprocessing as Miwa and Bansal (2016) and Li and Ji (2014). Following the convention established in this line of work, an entity prediction is considered correct

Dataset	System	Entity	Relation
ACE04	Bekoulis et al. (2018)	81.6	47.5
	Miwa and Bansal (2016)	81.8	48.4
	DyGIE	**87.4**	**59.7**
ACE05	Miwa and Bansal (2016)	83.4	55.6
	Zhang et al. (2017)	83.6	57.5
	Sanh et al. (2019)	87.5	62.7
	DyGIE	**88.4**	**63.2**
SciERC	Luan et al. (2018a)	64.2	39.3
	DyGIE	**65.2**	**41.6**
WLPC	Kulkarni et al. (2018)	78.0	*54.9
	DyGIE	**79.5**	**64.1**

Table 2: F1 scores on the joint entity and relation extraction task on each test set, compared against the previous best systems. * indicates relation extraction system that takes gold entity boundary as input.

if its type label and head region match those of a gold entity. We will refer to this version of the ACE2004 and ACE2005 data as ACE04 and ACE05. Since the domain and mention span annotations in the ACE datasets are very similar to those of OntoNotes (Pradhan et al., 2012), and OntoNotes contains significantly more documents with coreference annotations, we use OntoNotes to train the parameters for the auxiliary coreference task. The OntoNotes corpus contains 3493 documents, averaging roughly 450 words in length.

The **SciERC** corpus (Luan et al., 2018a) provides entity, coreference and relation annotations for a collection of documents from 500 AI paper abstracts. The dataset defines scientific term types and relation types specially designed for AI domain knowledge graph construction. An entity prediction is considered correct if its label and span match with a gold entity.

The **Wet Lab Protocol Corpus (WLPC)** provides entity, relation, and event annotations for 622 wet lab protocols (Kulkarni et al., 2018). A wet lab protocol is a series of instructions specifying how to perform a biological experiment. Following the procedure in Kulkarni et al. (2018), we perform entity recognition on the union of entity tags and event trigger tags, and relation extraction on the union of entity-entity relations and entity-trigger event roles. Coreference annotations are not available for this dataset.

Baselines We compare DyGIE with current state of the art methods in different datasets. Miwa and Bansal (2016) provide the current state of the art on ACE04. They construct a Tree LSTM using dependency parse information, and use the representations learned by the tree structure as features for relation classification. Bekoulis et al. (2018) use adversarial training as regularization for a neural model. Zhang et al. (2017) cast joint entity and relation extraction as a table filling problem and build a globally optimized neural model incorporating syntactic representations from a dependency parser. Similar to DyGIE, Sanh et al. (2019) and Luan et al. (2018a) use a multi-task learning framework for extracting entity, relation and coreference labels. Sanh et al. (2019) improved the state of the art on ACE05 using multi-task, hierarchical supervised training with a set of low level tasks at the bottom layers of the model and more complex tasks at the top layers of the model. Luan et al. (2018a) previously achieved the state of the art on SciERC and use a span-based neural model like our DyGIE. Kulkarni et al. (2018) provide a baseline for the WLPC data set. They employ an LSTM-CRF for entity recognition, following Lample et al. (2016). For relation extraction, they assume the presence of gold entities and train a maximum-entropy classifier using features from the labeled entities.

Results Table 2 shows test set F1 on the joint entity and relation extraction task. We observe that DyGIE achieves substantial improvements on both entity recognition and relation extraction across the four data sets and three domains, all in the realistic setting where no "gold" entity labels are supplied at test time. DyGIE achieves 7.1% and 7.0% relative improvements over the state of the art on NER for ACE04 and ACE05, respectively. For the relation extraction task, DyGIE attains 25.8% relative improvement over SOTA on ACE04 and 13.7% relative improvement on ACE05. For ACE05, the best entity extraction performance is obtained by switching the order between `CorefProp` and `RelProp` (`RelProp` first then `CorefProp`).

On SciERC, DyGIE advances the state of the art by 5.9% and 1.9% for relation extraction and NER, respectively. The improvement of DyGIE over the previous SciERC model underscores the ability of coreference and relation propagation to construct rich contextualized representations.

The results from Kulkarni et al. (2018) establish a baseline for IE on the WLPC. In that work, relation extraction is performed using gold entity boundaries as input. Without using any gold entity information, DyGIE improves on the baselines by 16.8% for relation extraction and 2.2% for NER.

	Domain	Docs	Ent	Overlap	Coref
ACE04-O	News	443	7	42%	✓
ACE05-O	News	437	7	32%	✗
GENIA	Biomed	1999	5	24%	✓

Table 3: Datasets for overlapping entity extraction and their statistics. *Ent*: Number of entity categories. *Overlap*: Percentage of sentences that contain overlapping entities.

On the OntoNotes data set used for the auxiliary coreference task with ACE05, our model achieves coreference test set performance of 70.4 F1, which is competitive with the state-of-the-art performance reported in Lee et al. (2017).

4.2 Overlapping Entity Extraction

There are many applications where the correct identification of overlapping entities is crucial for correct document understanding. For instance, in the biomedical domain, a *BRCA1 mutation carrier* could refer to a patient taking part in a clinical trial, while *BRCA1* is the name of a gene.

We evaluate the performance of DyGIE on overlapping entity extraction in three datasets: ACE2004, ACE2005 and GENIA. Since relation annotations are not available for these datasets, we include the coreference propagation layer in our models but not the relation layer.[2]

Data Statistics on our three datasets are listed in Table 3. All three have a substantial number ($>20\%$ of total) of overlapping entities, making them appropriate for this task.

As in the joint case, we evaluate our model on **ACE2004** and **ACE2005**, but here we follow the same data preprocessing and evaluation scheme as Wang and Lu (2018). We refer to these data sets as ACE04-O and ACE05-O. Unlike the joint entity and relation task in Sec. 4.1, where only the entity head span need be predicted, an entity prediction is considered correct in these experiments if both its entity label and its full text span match a gold prediction. This is a more stringent evaluation criterion than the one used in Section 4.1. As before, we use the OntoNotes annotations to train the parameters of the coreference layer.

The **GENIA** corpus (Kim et al., 2003) provides entity tags and coreferences for 1999 abstracts from the biomedical research literature. We only use the IDENT label to extract coreference clusters. We use the same data set split and preprocessing procedure as Wang and Lu (2018) for overlapping entity recognition.

Dataset	System	Entity F1
ACE04-O	Katiyar and Cardie (2018)	72.7
	Wang and Lu (2018)	75.1
	DyGIE	**84.7**
ACE05-O	Katiyar and Cardie (2018)	70.5
	Wang and Lu (2018)	74.5
	DyGIE	**82.9**
GENIA	Katiyar and Cardie (2018)	73.8
	Wang and Lu (2018)	75.1
	DyGIE	**76.2**

Table 4: Performance on the overlapping entity extraction task, compared to previous best systems. We report F1 of extracted entities on the test sets.

	Entity			Relation		
Model	P	R	F1	P	R	F1
DyGIE	87.4	86.7	**87.1**	56.2	60.9	58.4
`−CorefProp`	86.2	85.2	85.7	64.3	56.7	**60.2**
`−RelProp`	87.0	86.7	86.9	60.4	55.8	58.0
`Base`	86.1	85.7	85.9	59.5	55.7	57.6

Table 5: Ablations on the ACE05 development set with different graph propagation setups. `−CorefProp` ablates the coreference propagation layers, while `−RelProp` ablates the relation propagation layers. `Base` is the system without any propagation.

Baselines The current state-of-the-art approach on all three data sets is Wang and Lu (2018), which uses a segmental hypergraph coupled with neural networks for feature learning. Katiyar and Cardie (2018) also propose a hypergraph approach using a recurrent neural network as a feature extractor.

Results Table 4 presents the results of our overlapping entity extraction experiments on the different datsets. DyGIE improves 11.6% on the state of the art for ACE04-O and 11.3% for ACE05-O. DyGIE also advances the state of the art on GENIA, albeit by a more modest 1.5%. Together these results suggest that DyGIE can be utilized fruitfully for information extraction across different domains with overlapped entities, such as bio-medicine.

5 Analysis of Graph Propagation

We use the dev sets of ACE2005 and SciERC to analyze the effect of different model components.

5.1 Coreference and Relation Graph Layers

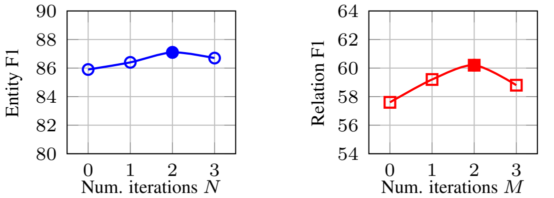
Tables 5 and 6 show the effects of graph propagation on entity and relation prediction accuracy,

---

[2] We use the pre-processed ACE dataset from previous work and relation annotation is not available.

	Entity			Relation		
Model	P	R	F1	P	R	F1
DyGIE	68.6	67.8	**68.2**	46.2	38.5	**42.0**
−`CorefProp`	69.2	66.9	68.0	42.0	40.5	41.2
−`RelProp`	69.1	66.0	67.5	43.6	37.6	40.4
`Base`	70.0	66.3	68.1	45.4	34.9	39.5

Table 6: Ablations on the SciERC development set on different graph progation setups. `CorefProp` has a much smaller effect on entity F1 compared to ACE05.



(a) Entity F1 with different number of `CorefProp` iterations N.

(b) Relation F1 with different number of `RelProp` iterations M.

Figure 3: F1 score of each layer on ACE development set for different number of iterations. $N = 0$ or $M = 0$ indicates no propagation is made for the layer.

where −`CorefProp` and −`RelProp` denote ablating the propagation process by setting $N = 0$ or $M = 0$, respectively. `Base` is the base model without any propagation. For ACE05, we observe that coreference propagation is mainly helpful for entities; it appears to hurt relation extraction. On SciIE, coreference propagation gives a small benefit on both tasks. Relation propagation significantly benefits both entity and relation extraction in both domains. In particular, there are a large portion of sentences with multiple relation instances across different entities in both ACE05 and SciERC, which is the scenario in which we expect relation propagation to help.

Since coreference propagation has more effect on entity extraction and relation propagation has more effect on relation extraction, we mainly focus on ablating the effect of coreference propagation on entity extraction and relation propagation on relation extraction in the following subsections.

5.2 Coreference Propagation and Entities

A major challenge of ACE05 is to disambiguate the entity class for pronominal mentions, which requires reasoning with cross-sentence contexts. For example, in a sentence from ACE05 dataset, "One of **[them]**$_{\text{PER}}$, from a very close friend of **[ours]**$_{\text{ORG}}$." It is impossible to identity whether *them* and *ours* is a person (*PER*) or organization (*ORG*) unless we have read previous sentences. We hypothesize that this is a context where coreference propagation can help. Table 7 shows the effect of the coreference layer for entity categorization of pronouns.[3] DyGIE has 6.6% improvement on pronoun performance, confirming our hypothesis.

Entity Perf. on Pronouns	P	R	F1
DyGIE	79.0	77.1	**78.0**
DyGIE−`CorefProp`	73.8	72.6	73.2

Table 7: Entity extraction performance on pronouns in ACE05. `CorefProp` significantly increases entity extraction F1 on hard-to-disambiguate pronouns by allowing the model to leverage cross-sentence contexts.

Looking further, Table 8 shows the impact on all entity categories, giving the difference between the confusion matrix entries with and without `CorefProp`. The frequent confusions associated with pronouns (*GPE/PER* and *PER/ORG*, where *GPE* is a geopolitical entity) greatly improve, but the benefit of `CorefProp` extends to most categories.

Of course, there are a few instances where `CorefProp` causes errors in entity extraction. For example, in the sentence "[They]$^{\text{ORG}}_{\text{PER}}$ might have been using Northshore...", DyGIE predicted *They* to be of *ORG* type because the most confident antecedent is *those companies* in the previous sentence: "The money was invested in *those companies*." However, *They* is actually referring to *these fund managers* earlier in the document, which belongs to *PER* category.

In the SciERC dataset, the pronouns are uniformly assigned with a *Generic* label, which explains why `CorefProp` does not have much effect on entity extraction performance.

The Figure 3a shows the effect of number of iterations for coreference propagation in the entity extraction task. The figure shows that coreference layer obtains the best performance on the second iteration ($N = 2$).

5.3 Relation Propagation Impact

Figure 4 shows relation scores as a function of number of entities in sentence for DyGIE and DyGIE without relation propagation on ACE05. The figure indicates that relation propagation achieves significant improvement in sentences with more entities, where one might expect that using broader context

---

[3] Pronouns included: `anyone, everyone, it, itself, one, our, ours, their, theirs, them, themselves, they, us, we, who`

ORG	0	0	0	-8	-1	6	0
VEH	0	-2	-1	2	5	-1	1

Table 8: Difference in the confusion matrix counts for ACE05 entity extraction associated with adding `CorefProp`.

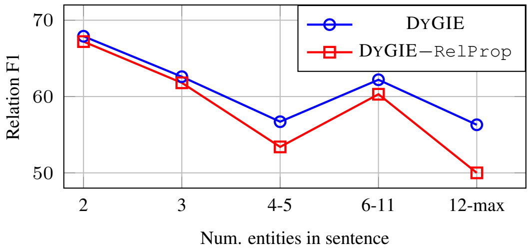

Figure 4: Relation F1 broken down by number of entities in each sentence. The performance of relation extraction degrades on sentences containing more entities. Adding relation propagation alleviates this problem.

could have more impact.

Figure 3b shows the effect of number of iterations for relation propagation in the relation extraction task. Our model achieves the best performance on the second iteration ($M = 2$).

6 Conclusion

We have introduced DyGIE as a general information extraction framework, and have demonstrated that our system achieves state-of-the art results on entity recognition and relation extraction tasks across a diverse range of domains. The key contribution of our model is the dynamic span graph approach, which enhance interaction across tasks that allows the model to learn useful information from broader context. Unlike many IE frameworks, our model does not require any preprocessing using syntactic tools, and has significant improvement across different IE tasks including entity, relation extraction and overlapping entity extraction. The addition of co-reference and relation propagation across sentences adds only a small computation cost to inference; the memory cost is controlled by beam search. These added costs are small relative to those of the baseline span-based model. We welcome the community to test our model on different information extraction tasks. Future directions include extending the framework to encompass more structural IE tasks such as event extraction.

Abstract

Open Information Extraction (OpenIE), the problem of harvesting triples from natural language text whose predicate relations are not aligned to any pre-defined ontology, has been a popular subject of research for the last decade. However, this research has largely ignored the vast quantity of facts available in semi-structured webpages. In this paper, we define the problem of OpenIE from semi-structured websites to extract such facts, and present an approach for solving it. We also introduce a labeled evaluation dataset to motivate research in this area. Given a semi-structured website and a set of seed facts for some relations existing on its pages, we employ a semi-supervised label propagation technique to automatically create training data for the relations present on the site. We then use this training data to learn a classifier for relation extraction. Experimental results of this method on our new benchmark dataset obtained a precision of over 70%. A larger scale extraction experiment on 31 websites in the movie vertical resulted in the extraction of over 2 million triples.

1 Introduction

Knowledge extraction is the problem of extracting *(subject, predicate, object)* triples from unstructured or semi-structured data, where the subject and object are entities and the predicate indicates the relationship between them. In conventional information extraction (which we call "ClosedIE"), a closed set of potential predicates and their semantics are pre-defined in an ontology. Open Information Extraction (OpenIE) is an alternative approach that has no pre-defined ontology and instead represents the predicate with a string extracted from the source data. These extractions can capture a much vaster array of semantic relationships than ClosedIE and have been used to support many downstream use-cases, including question-answering, ontology discovery, embedding generation, fact checking, and summarization (Mausam, 2016). Previous OpenIE work has concentrated on raw text, with the aim to extract "open" triples from natural language sentences (Niklaus et al., 2018), with another line of work focused on extracting from webtables (Cafarella et al., 2008).

Semi-structured websites (e.g. IMDb) contain many pages displaying information in stand-alone fields in relatively consistent locations on each page, with entities and the relationship between them indicated via formatting features such as section headers and lists of key-value pairs. Figure 1 shows an example page and the triples it conveys. Semi-structured websites have recently been shown to be a rich target for IE; the Knowledge Vault large-scale web extraction experiment, which extracted from semi-structured websites, natural language text, webtables, and Semantic Web annotations, found that semi-structured websites contributed 75% of total extracted facts and 94% of high-confidence extractions (Dong et al., 2014); the Ceres system showed that one can automatically extract from semi-structured sites with a precision over 90% using distant supervision (Lockard et al., 2018). These works, however, all build on the tradition of semi-structured ClosedIE techniques (Kushmerick et al., 1997; Soderland, 1999; Gulhane et al., 2011; Furche et al., 2014).

Interestingly, we are not aware of any work that applies OpenIE on semi-structured sources, despite the great potential to identify new relationships and new knowledge triples. We investigated 8 movie websites from the Structured Web Data Extraction (SWDE) corpus (Hao et al., 2011) and found that the IMDb ontology can cover only 7% of semantically unique predicates on these sites.

The major challenges that distinguish natural language text and semi-structured data are the basic unit and the inherent structure of the data. In

Proceedings of NAACL-HLT 2019, pages 3047–3056
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

natural language text, each sentence is a unit; it typically consists of a subject, a verb, and an object, which corresponds naturally to the subject, predicate, and object of a knowledge triple. Similarly, in webtables, each table is a unit; its rows, columns, and cells also naturally correspond to subjects, predicates, and objects in triples.

In the semi-structured setting, the basic unit is the webpage, which may contain hundreds or thousands of entity mentions. There is no fixed layout between the subject entity, object entity, and their relation, which may be far apart on the webpage. For example, Figure 1 contains object strings that are below, to the left, and to the right of their corresponding predicates; even trickier, for object string "Uma Thurman", the correct predicate string "Cast" is much farther away than the incorrect one "Crew". Despite the challenges, semi-structured pages do provide inherent visual structure to help distinguish the subject of a page, and *(predicate, object)* pairs for the subject. In this paper we answer the following question: *Given semi-structured webpages in a website, how can we tell which field contains the subject, and which fields contain the (predicate, object) pairs for the subject through any visual or DOM-structured clue?*

This paper makes three contributions. Our first contribution is to formally define a new problem of OpenIE from semi-structured websites (Section 2). We created a benchmark[1] for this problem by enhancing the SWDE corpus (Hao et al., 2011); our benchmark contains a high accuracy and coverage set of ground truth extractions for 21 websites spanning three domains, comprising 855,748 labels across 27,641 pages (Section 4).

Our second contribution is OpenCeres, a solution for OpenIE on semi-structured websites (Section 3). Our solution is novel in three aspects. First, whereas ClosedIE techniques on semi-structured data focus on extracting objects for given predicates, we also identify predicate strings on the website that represent the relations. Second, while ClosedIE techniques can only learn extraction patterns for predicates where there exists seed knowledge, we identify unseen predicates by applying semi-supervised label propagation. Third, whereas most existing extraction techniques on semi-structured sites leverage only DOM patterns as evidence, we use visual aspects of the webpage for distant supervision and label propagation.

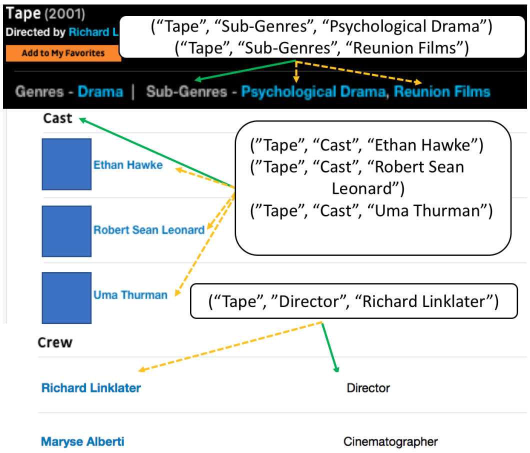

Figure 1: A cropped portion of the detail page from allmovie.com for the film *Tape* with some triples indicated. Solid green and dashed yellow arrows indicate predicate strings and objects respectively.

Our final contribution is a comprehensive evaluation on our new benchmark dataset and online websites (Section 5). Our proposed method obtained an F1 of 0.68, significantly higher than baseline systems, while extracting 7 times as many predicates as were present in the original ontology. In addition, we evaluate on a set of 31 movie websites, yielding 1.17 million extractions at a precision of 0.70. Our results inspire new directions for improvement as discussed in Section 7, and serve as a good baseline for future work.

2 Overview

2.1 Problem Definition

We propose the problem of OpenIE from semi-structured websites. A *semi-structured website* W consists of a set of *detail pages* that each contains information about a particular entity, the *topic entity* of the page. This information is typically populated from an underlying database into an HTML template to create the detail pages. The goal of semi-structured OpenIE is to recover all *(subject, predicate, object)* triples represented in these templatized fields, including the extraction of the string that semantically represents each predicate.

Relation objects are sometimes present without an explicit predicate string defining the relationship; since OpenIE requires extraction of a predicate string, we only consider the case where a meaningful predicate string exists on the page.

Definition 2.1 (Semi-Structured OpenIE) *Let* W *be a semi-structured website, with each page*

---

[1] `https://homes.cs.washington.edu/~lockardc/expanded_swde.html`

w_i *containing facts about a topic entity* t_i. *Semi-Structured OpenIE extracts a set of triples from* W *such that the subject, predicate, and object of each triple is a string value on a page in* W, *with the subject representing* t_i *and the predicate string semantically representing the relation between the subject and object as asserted by the webpage.*

Following the tradition of relation extraction, which considers only binary relationships, we do not consider extraction of compound value types (CVTs) (Freebase, 2018), which express multi-way relationships. In this work, we narrow our focus to Semi-structured OpenIE from a given domain, since we will rely on pre-existing knowledge about that domain to provide us with seed annotations. We leave the extension to the general semi-structured OpenIE problem for future work.

2.2 From ClosedIE to OpenIE

We first summarize the Ceres techniques proposed in (Lockard et al., 2018), which is the state-of-the-art for ClosedIE from semi-structured websites. Ceres learns a model capable of generalizing across variations in a website from training labels automatically generated by the distant supervision technique. The automatic annotation contains two steps. First, *topic annotation* annotates the topic name on the page. Second, *relation annotation* annotates each object field, where the relation is guessed as a relationship in the seed ontology that is valid between the topic and the object.

OpenIE needs to go beyond existing relations in the ontology, identifying relations not existing in seed knowledge. As such, it raises two challenges for the relation annotation step. First, in addition to annotating the objects, we also need to be able to identify the predicate fields in order to extract predicate strings. Second, in addition to annotating the predicates already in the seed knowledge, we also need to identify new predicates on a webpage.

Figure 2 shows the infrastructure of our OpenIE solution, OpenCeres. We propose a relation annotation method that is suitable for OpenIE (shown in the shaded blocks), and inherit other components from Ceres (Lockard et al., 2018). Our key intuition to solve this problem is that different predicates often share some visual features, such as being aligned vertically or horizontally, sharing the same font, size or color, and so on. Thus, if we can identify at least one *(predicate, object)* pair on the page, we can look for other similarly formatted pairs of nodes and assume that they also represent *(predicate, object)* pairs. Accordingly, we propose a three-stage process that combines distant supervision and semi-supervised learning.

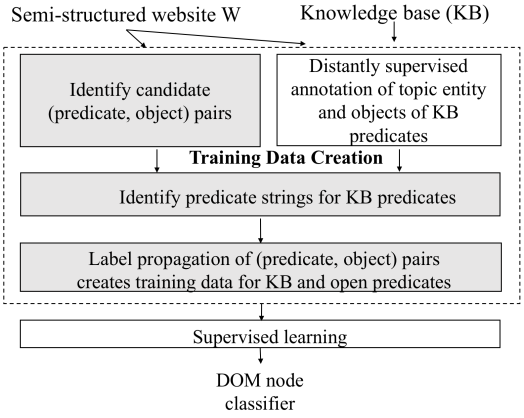

Figure 2: An overview of our proposed semi-structured OpenIE model learning process. Shaded areas indicate contributions of our process.

1. Predicate-object candidate generation: We first generate potential candidate *(predicate, object)* pairs, as described in Section 3.1. The search for these candidate pairs is quasilinear in the number of DOM nodes, thereby avoiding examination of every pair of DOM nodes.
2. Distant supervision: We then use a seed knowledge base (KB) to identify instances of *(predicate, object)* pairs appearing in the seed, where the predicate exists in a pre-defined ontology, as described in Section 3.2. For example, for the page in Figure 1, we would hope to identify *("Director", "Richard Linklater")* assuming that fact was in our KB.
3. Semi-supervised label propagation: We perform a semi-supervised label propagation step to identify pairs of nodes that are formatted similarly to the known *(predicate, object)* pairs as described in Section 3.3; these new *(predicate, object)* pairs give us training labels for new predicates. For example, in Figure 1, we should identify the pair *("Cinematographer", "Maryse Alberti")* since it is formatted similarly to our seed pair, even though the concept of *cinematographer* does not exist in our seed ontology.

3 Approach

We now describe the three key steps we use to generate training labels.

3.1 Candidate pair generation

Recall that for ClosedIE we only need to annotate objects; for OpenIE we need to additionally identify the predicates, which will then allow us to find other predicates not found in the seed KB. Our first step is thus to find all potential *(predicate, object)* pairs on a webpage for further annotation.

Determining which nodes should be checked as potential predicates for a given object is not trivial. On the one hand, there may be hundreds of nodes on the page, so considering all potential pairs of nodes would be computationally expensive. On the other hand, consider that a webpage about a movie may contain a long list of actors under the section header "Cast"; in Euclidean distance, the actor at the bottom of the list may be quite far away from the "Cast" string at the top of the list, so only searching nearby nodes may miss the predicate node.

To identify potential predicate nodes, we use our intuition that predicate strings should be more common across a website than their related object strings. Consider *("Language", "English")* as an example. Even though the object string "English" might be quite common on a site, it should be less frequent than its corresponding predicate string "Language". According to the site-wide frequency rankings, we consider a *(predicate, object)* pair a candidate pair only if the predicate appears more frequently than the object[2].

Following this intuition, we start by computing the frequency of each string found across all pages in the website, and create a ranked list. Second, for each DOM node, we create candidate pairs consisting of the node as object and the k-nearest higher ranking nodes as predicate . Third, to identify potential predicates that may be farther away but still represent a section header for the region of the page containing the object, we recursively travel up the DOM tree, and at each level we find the k-highest ranked candidate predicates paired with any candidate object in that DOM subtree. We create additional candidate pairs pairing those candidate predicates with all candidate objects in that subtree. Thus in total each candidate object is paired with up to dk candidate predicates, where d is the depth of the DOM.

For example, consider the object strings in the Cast section of Figure 1, with a k value of 1. Since "Cast" appears on every page, an initial candidate pair would be created for ("Cast", "Ethan Hawke"). If Hawke is mentioned more frequently across the site than the other actors, he would be paired as the potential predicate for their strings since they are closer to his name than "Cast", such as ("Ethan Hawke", "Robert Sean Leonard"). However, since Hawke and Leonard are in the same `<div>`, the recursive process would add the candidate pair ("Cast", "Robert Sean Leonard") since "Cast" would be the most highly ranked string associated with any object in that section.

3.2 Seed labels

In the second stage, given a webpage, the subject and objects we have identified on the page, and the candidate *(predicate, object)* pairs, we are now ready for distant supervision annotation to generate seed labels that are *(predicate, object)* pairs for the subject appearing in the seed knowledge.

We start with the Ceres object identification to generate a list of nodes containing object strings corresponding to KB predicates, and look up *(predicate, object)* pairs in the candidate list that contain the object node. We use lexical clues to we filter a candidate *(predicate, object)* pair if the predicate name is not semantically similar to the predicate in the ontology. There are multiple ways of doing this. One way is to compare the cosine similarity of word embeddings (such as FastText (Bojanowski et al., 2017)) representing the predicate string and the ontology predicate name and filter using a threshold. Another way is to manually compile a few terms for each predicate in our ontology, and filter a predicate if it does not contain any of the terms as a substring. Empirically we found using a manually compiled list, which takes about a minute per predicate, gives higher precision than using embeddings, though it limits us to the particular language of those terms. After the filtering step, we can fairly safely choose the *(predicate, object)* pair where the predicate is closest to the object in Euclidean distance.

3.3 Semi-supervised Label Propagation

In the third stage, given a set of *(predicate, object)* pairs on a webpage generated in the first stage, we aim at following visual clues to find other *(predicate, object)* pairs on the same page. These new candidate pairs serve as training labels for predicates that may not occur in the seed knowledge.

---

[2] We consider strings consisting of numeric values only as potential objects and not predicates, regardless of their frequency.

We apply semi-supervised learning, which typically resorts to a similarity graph where similar instances are connected by edges in the graph, and propagates existing labels to neighbor nodes. Our intuition is that *(predicate, object)* pairs should share similar formatting; we capture this intuition as we construct the graph.

Graph construction: Each vertex in the similarity graph represents a candidate pair, an edge connecting two vertices indicates that the two candidate pairs are similar, and the edge weight gives the level of similarity. We compute similarity between candidate pairs by visual clues[3], creating an edge between them if they have similar predicate formatting and simliar object formatting. Formatting similarity requires having the same font, font size, font weight, and text alignment, and being either vertically or horizontally aligned.

We then weight the edges by adding up similarities of the horizontal, vertical, and DOM relationship between predicate and object. Similarity of DOM relationship is 1 for exact match and 0 otherwise. Similarity of horizontal relationship is computed by measuring the distance between the predicate and the object in a (pred, obj) pair, and then taking the ratio of minimum distance and maximum distance[4]. We compute similarity of vertical relationship in a similar way, giving:

$$w_{i,j} = \mathbb{1}_{r_d(i)=r_d(j)} + \max\left(0, \frac{\min\left(r_h\left(i\right), r_h\left(j\right)\right)}{\max\left(r_h\left(i\right), r_h\left(j\right)\right)}\right) + \max\left(0, \frac{\min\left(r_v\left(i\right), r_v\left(j\right)\right)}{\max\left(r_v\left(i\right), r_v\left(j\right)\right)}\right)$$

where i and j are candidate pairs, r_d calculates the DOM path, r_h calculates the horizontal distance between candidate predicate and candidate object, and r_v calculates the vertical distance.

A sample graph for the webpage in Figure 1 is shown in Figure 3. The pair ("Director", "Richard Linklater") is connected to the pair ("Cinematographer", "Maryse Alberti") with a weight of 3, since they have identical values for all three relationships, while ("Sub-Genres:", "Psychological Drama") and ("Sub-Genres", "Reunion Films") have an edge weight of 2.1 since the latter's horizontal distance is ten times greater than the former.

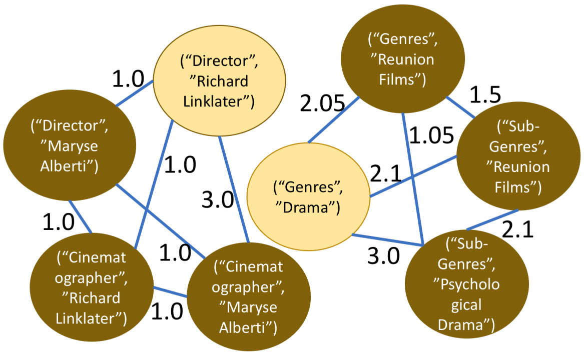

Figure 3: A portion of the graph corresponding to the webpage in Figure 1. Lighter nodes indicate seed pairs labeled by the Ceres process.

To speed up propagation, we keep only the 10 top-weighted edges for each pair. On average, on the dataset in Section 4, pages have 1,142 text fields resulting in 2,813 candidate pairs connected by 14,733 edges, far less than the 1.3 million candidate pairs (and corresponding increase in edges) that would result from a naive pairwise matching.

Label propagation: We use the MultiRankWalk label propagation algorithm (Lin and Cohen, 2010), which has been shown to be successful in very low-data situations. This allows us to propagate even when we only have a single seed label on a page. MultiRankWalk adapts the Personalized PageRank (PPR) algorithm for a classification setting, conducting a PageRank run for each class, with the personalization vector set to equally divide the restart probability among positive labeled examples of the class. The PageRank runs are conducted over the weighted graph constructed in the prior step. Each unlabeled vertex is assigned to the class whose PageRank run gives it the highest score. In our case we have two PPR runs: a positive run for labeled *(predicate, object)* candidates and a negative run for unlabeled candidates.

The results of this process are then used as training data to train a supervised Ceres (Lockard et al., 2018) extraction model.

4 Extended SWDE Benchmark

The Structured Web Data Extraction (SWDE) dataset has served as a benchmark for semi-structured web extraction, with webpages and ground truth extractions from 10 websites in each of 8 domains (Hao et al., 2011). However, the

---

[3] To harvest these features, we render the page using the headless Chrome browser and access element attributes with Selenium (https://www.seleniumhq.org/).

[4] In practice, there are multiple ways to calculate horizontal distance: Left side to left side, left side to right side, right to right, and right to left. The same holds for vertical distance. We calculate each possible ratio and use the one that gives the highest weight. In the case that the ratio is negative (e.g. one pair had predicate to the left of the object while the other pair had it to the right), we set it to 0.

ground truth in SWDE only covers a subset of the predicates found on each site, typically 3-4 predicates per domain.

We extend it as follows: Of the 8 domains, we kept 4 domains whose page topics are named entities. We extended their gold set to include extractions identifying all key-value semi-structured fields on the websites. Since not all SWDE websites can still be rendered in the browser (due to missing resources), we eliminated websites that we were unable to successfully render in the Chrome browser, resulting in 30 websites. We then attempted to create ground truth via a combination of wrapper induction based on manually-labeled training data (with an extractor implementation based on (Gulhane et al., 2011)), hand-crafted extraction rules, and manual cleanup of remaining errors. Eventually, we generated accurate labels for 21 sites in 3 domains.

This new extended benchmark includes both extracted object values as well as the predicate string that accompanies each value on the page. The statistics of the augmented dataset are shown in Table 1. We enhanced SWDE in two ways. First, SWDE on average contains 4,480 triples for 3 predicates from these 21 websites, whereas we have an average of 41K triples for 36 predicates. The number of predicates per website ranges from 5 to 272 (Hollywood features very fine-grained relationships like “Assistant Art Director”). Second, when multiple predicate strings may apply on the webpage, we list all of them in order of specificity. Taking Figure 1 as an example, we include both “Director” and “Crew” for a relation, considering the former to be more specific. To our knowledge, this is the first dataset that represents all key-value pairs found in semi-structured web data.

Domain	Site	# Predicates	# Labels
Movie	AllMovie	65	104,303

Table 1: Statistics of the augmented SWDE dataset.

5 Experimental Evaluation

5.1 Experimental Setup

Datasets: Our primary dataset is the augmented SWDE corpus described in Section 4. In addition, we used the set of 31[5] movie websites (comprising 433,000 webpages) found in CommonCrawl[6] from Lockard et al. (2018). To generate seed KBs for the distant supervision, we relied on the methodology from Lockard et al. (2018), using the IMDb database for the Movie domain, and using the original SWDE ground truth for websites CollegeBoard and ESPN to create a KB for the University and NBAPlayer domains respectively.

Implementations: We compared OpenCeres with two baselines. The three algorithms apply the same method to extract topic subjects but differ in how they extract *(predicate, object)* pairs.

1. *WEIR:* Proposed by Bronzi et al. (2013), the Web Extraction and Integration of Redundant data (WEIR) approach takes as input a set of websites in the same subject domain and makes use of overlap in observed entities across sites to learn extraction rules for predicates. The system is unsupervised, though it does require a dictionary of potential page topic entities for the domain to align pages between sites. WEIR also contains a method for automatically identifying predicate strings for the extraction rules it learned by finding strings that frequently occur nearby extracted objects in the HTML templates of sites in the domain.
2. *Colon Baseline:* Semi-structured pages frequently represent a *(predicate, object)* pair via a set of adjacent DOM nodes, with the predicate string ending in a colon and the object string either to its right or below it. This baseline starts with the *(predicate, object)* candidate pairs generated in Section 3.1,

---

[5] We removed the two sites on which Lockard et al. (2018) reported Ceres made no annotations.

[6] www.commoncrawl.org

identifies those where the predicate field ends with a colon, and extracts them as a predicate along with their closest candidate object either to their right or below.

3. *OpenCeres:* This implements our system exactly as described in Section 3, using the generated training data to train a Ceres extractor.

In addition, to understand the uper bound of OpenCeres, we implemented two versions using ground truth data for training seeds:

4. *OpenCeres-Gold:* This implements our system, but skips the label propagation step and replaces noisy seed labels (Section 3.2) with samples from ground truth triples. We sampled 25% of triples for each predicate, so this method is essentially ClosedIE Ceres with incomplete but clean training labels, giving an upper bound on the system's performance when no errors are introduced during training data generation and label propagation.
5. *OpenCeres-GoldProp:* This implements OpenCeres-Gold, but adds the label propagation step described in Section 3.3. Rather than sampling 25% of ground truth triples from all predicates, we instead sample p% of ground truth predicates for a site (with p varying from 10 to 100) and then sample 25% of the corresponding triples for each page. The process is run five times for each setting of p and the results are averaged.

Evaluation: Evaluation is tricky for semi-structured OpenIE because a page may contain multiple valid predicates for a relation. Recall that the SWDE benchmark data we generated (Section 4) lists all predicate strings that are valid, ranked in their order of specificity. We thus define two scores for an extracted triple.

- A *strict score* that requires an exact match between the extracted predicate and the most-specific predicate string in the ground truth.
- A *lenient score* that counts an extraction as correct if the extracted predicate matches any of the predicate strings in the ground truth.

For the SWDE dataset, where we have complete ground truth, we compute precision, recall, and F1. For the CommonCrawl dataset, where no ground truth exists, we sampled 500 extractions at each confidence threshold (giving a 4% margin of error) and manually scored them; since we cannot calculate true recall, we report precision and yield.

System	**Movie**		**NBA**		**University**	
	P	R	P	R	P	R
WEIR (Bronzi et al., 2013)	0.23	0.17	0.08	0.17	0.13	0.18
Colon Baseline	0.63	0.21	0.51	0.33	0.46	**0.31**
OpenCeres	**0.77**	**0.68**	**0.74**	**0.48**	**0.65**	0.29
OpenCeres-Gold	0.99	0.74	0.98	0.80	0.99	0.60

Table 2: Extraction precision and recall (lenient) on SWDE domains. OpenCeres on average improves over baseline by 36% on precision and by 88% on recall.

5.2 Results on SWDE

Overall results: Table 2 shows the precision and recall obtained via lenient scoring. Our results show that OpenCeres outperformed both baselines, achieving an average precision of 72% across the three domains, with an average recall of 48%. Comparing with OpenCeres-Gold on Movie, our precision is 22% lower, while recall is only 5% lower, showing that our label propagation is fairly effective in preserving recall, but introduces errors reducing precision. WEIR does not perform as well as ColonBaseline, showing that our *(predicate, object)* candidate identification technique works well.

Our recall is a robust 68% in the Movie domain, but is much lower in the other two domains. This is because we failed to make any extraction in 3 of the 5 University sites and 2 of the 8 NBA sites due to the inability to find a predicate string for the seed predicates. In some cases no predicate string existed, but in others the string was not in our lexicon. In fact, if we skip those websites where we extract nothing, our recall increases to 58% for NBA and 44% for University. Other recall misses occur when a page has some semi-structured fields that differ significantly in format from those found in our seed ontology, so they were too dissimilar for the label propagation to extend to them.

Details: We now deep dive to results of OpenCeres, shown in Table 3. First, our scoring under the "strict" rules is only slightly lower than under "lenient" rules, because the case that multiple predicates apply is not common and we are often able to find the most specific ones. Across all triples, the overall lenient F1 is 0.68 and strict F1 is 0.61. Second, at predicate-level, OpenCeres has an average precision of 74% and recall of 39%, showing that our method attains high precision for the new predicates it identifies. Third, through the label propagation technique, we are able to extract an average of 10.5 new predicates for every predicate in our seed ontology.

A sample of 100 erroneous OpenCeres extractions shows that 33% of errors are due to the presence of CVTs on the page. For example, the movie site Rotten Tomatoes contains a “Full Review” predicate that contains review date, writer, publication, and text; we extracted only the date, which arguably is not useful. Considering these extractions as correct will increase the precision to 81%. Among the errors, 22% were due to incoherent predicates such as “See More”, while 20% were due to incorrect extraction of a template string as an object of a correct predicate.

Label propagation: Figure 4 shows how the label propagation process successfully creates new training examples from a small number of seeds. While propagation does introduce some precison errors, when only 10% of predicates are given to OpenCeres-GoldProp as seeds (and only 25% of triples sampled for each predicate), training data recall is already nearly 50%. As the percentage of seed predicates rises, the seeds become more likely to capture the full variety of predicate formatting, and recall rises.

There are a number of reasons why the recall upper bound demonstrated by OpenCeres-Gold (and OpenCeres-GoldProp) is less than perfect. First, a small number of relations in the dataset have predicate or object strings that span multiple text fields (particularly in the University vertical); the implemented system can only extract a single text field, so these will be missed. Second, the Candidate Pair Identification algorithm has imperfect recall. Finally, because only 25% of ground truth triples were used for each page of training data, some true positive examples were sampled as negative examples for training, thereby lowering classification recall.

Parameter setting: Table 4 shows that Candidate Pair Identification has increasing recall in capturing true candidate pairs in the SWDE-Movie vertical with more neighbors considered, with a trade-off in increased runtime due to the creation of more pairs; we used $k = 5$ in our experiments.

5.3 Results on CommonCrawl

We now report results of ClosedIE and OpenIE extractions on the 31 CommonCrawl websites; the ClosedIE implementation is a subset of the OpenIE system, without the shaded components in Figure 2. Of these 31 websites, we successfully extracted from 22 sites using OpenIE, and failed to extract from 9 sites because of our inability to match their predicate strings to our lexicon for seed predicates (4 sites were in foreign languages while our lexicon is in English, on 3 sites the pages had no predicate strings labeling the seed object, and 2 sites used terms outside our lexicon).

	Movie	**NBA Player**	**University**
Triple-level F1	0.72 (0.65)	0.58 (0.58)	0.41 (0.36)
Pred-level Prec	0.55 (0.52)	0.86 (0.86)	0.81 (0.76)
Pred-level Rec	0.35 (0.32)	0.46 (0.46)	0.37 (0.35)
Pred-level F1	0.43 (0.40)	0.60 (0.60)	0.51 (0.48)
New:Existing-pred ratio	4.4 : 1	4.3 : 1	23.0 : 1

Table 3: Detailed results of OpenCeres using lenient scoring, with strict scoring results shown in parentheses.

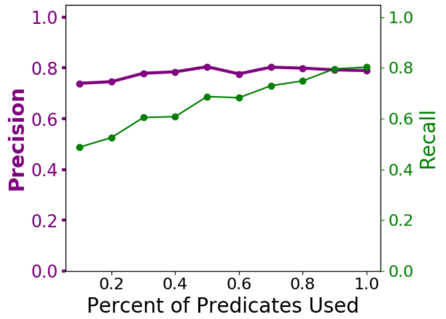

Figure 4: Precision and recall of the training data automatically created for the Movie domain by OpenCeres-GoldProp, after label propagation from seed data created by first sampling varying percents of the ground truth predicates for a site and then sampling a constant 25% of ground truth objects for each predicate.

Figure 5 shows the precision-yield curve of our ClosedIE and OpenIE extractions as we vary the confidence threshold. At a 0.5 confidence threshold, we extracted 2.3M triples at a precision of 0.58, where 1.17M (51%) have new predicates. A higher threshold of 0.8 yielded 1.17M extractions at a precision of 0.70, with 50% of extractions representing new predicates. The high percentage of extractions with new predicates shows the big promise of our method in enriching existing knowledge bases not only with new entities and new facts, but also with new relationships.

6 Related Work

In unstructured text, OpenIE was originally proposed by Banko et al. (2007), an approach extended by ReVerb (Fader et al., 2011) and Ollie (Mausam et al., 2012), which relied on syntactic

k	# candidates	recall
3	1,863	0.92
7	3,044	0.95
11	4,104	0.98

Table 4: Average number of candidate pairs produced by considering k-nearest higher ranking text fields for each candidate object on the SWDE-Movie dataset, along with recall over true pairs.

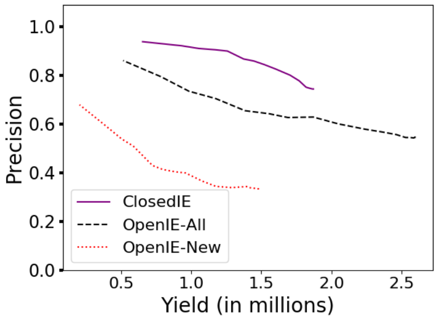

Figure 5: Extraction precision vs. number of extractions on the CommonCrawl dataset at various confidence thresholds; ClosedIE is the implementation of the Ceres system. OpenCeres-All shows all extractions from OpenCeres, while OpenCeres-New shows only the OpenCeres extractions with new predicates.

constraints to identify relation patterns. Our approach is influenced by Wu and Weld (2010), who aligned Wikipedia infobox contents to article text to automatically create training data for an extractor. Recent work on neural extraction models (Cui et al., 2018) has explored entirely supervised models learned from a modified version of the QA-SRL dataset (Stanovsky et al., 2018).

The line of research that has most closely examined the prospect of OpenIE-style extractions using webpage structure is the work on Webtables (Cafarella et al., 2008; Dalvi et al., 2012; Balakrishnan et al., 2015; Cafarella et al., 2018). This work specifically examines the identification of subjects, predicate, and object strings but is limited to fields in rows and columns created using HTML `<table>` tags. Extractions from webtables have recently been harnessed as a source of facts for question-answering systems (Pasupat and Liang, 2015; Krishnamurthy et al., 2017).

In extraction from semi-structured websites, the traditional approach is *wrapper induction*, in which a rule learning algorithm is applied to a set of labeled training examples (Kushmerick et al., 1997). Work in this line of research has achieved high accuracy from only a few labeled examples, but requires manually-annotated examples for each website (Gulhane et al., 2011). To remove this bottleneck, researchers have explored alternative ways to automatically create labeled data and learn models from such potentially noisy labels (Dalvi et al., 2011; Gentile et al., 2015; Furche et al., 2014; Lockard et al., 2018). However, these approaches cannot find triples for predicates that are not in the seed ontology.

The Roadrunner project (Crescenzi et al., 2001) does attempt to identify the objects of all relations represented on a site, but does not extract predicate strings. However, the WEIR project (Bronzi et al., 2013) extended this framework with a heuristic to harvest predicate strings based on words found in DOM nodes that form part of the path of the learned XPath extraction rule. This is the first work that could truly be considered an OpenIE approach to semi-structured extraction. However, as we show in our experiments, the constraints of their heuristic limit the recall of this approach.

7 Conclusions

We presented a new problem of Open Information Extraction from semi-structured websites, and are releasing a new set of over 855,000 ground truth extractions for 21 websites available in the SWDE corpus. We also proposed an algorithm for OpenIE that employs semi-supervised label propagation to discover new predicates based on a set of seed predicates in a known ontology. This method attained a 68% F1 score in OpenIE extractions on our benchmark. In addition, a large-scale evaluation on 31 CommonCrawl movie websites yielded extractions of over two million triples.

In the future, we would like to improve extraction by training a model to extract *(predicate, object)* pairs directly without having to train on particular predicates. Such a model could potentially be based on visual clues common across websites, so a single model could be applied to many sites.

Structured Minimally Supervised Learning for Neural Relation Extraction

Abstract

We present an approach to minimally supervised relation extraction that combines the benefits of learned representations and structured learning, and accurately predicts sentence-level relation mentions given only proposition-level supervision from a KB. By explicitly reasoning about missing data during learning, our approach enables large-scale training of 1D convolutional neural networks while mitigating the issue of label noise inherent in distant supervision. Our approach achieves state-of-the-art results on minimally supervised sentential relation extraction, outperforming a number of baselines, including a competitive approach that uses the attention layer of a purely neural model.[1]

1 Introduction

Recent years have seen significant progress on tasks such as object detection, automatic speech recognition and machine translation. These performance advances are largely driven by the application of neural network methods on large, high-quality datasets. In contrast, traditional datasets for relation extraction are based on expensive and time-consuming human annotation (Doddington et al., 2004) and are therefore relatively small. Distant supervision (Mintz et al., 2009), a technique which uses existing knowledge bases such as Freebase or Wikipedia as a source of weak supervision, enables learning from large quantities of unlabeled text and is a promising approach for scaling up. Recent work has shown promising results from large-scale training of neural networks for relation extraction (Toutanova et al., 2015; Zeng et al., 2015).

There are, however, significant challenges due to the inherent noise in distant supervision. For example, Riedel et al. (2010) showed that, when learning using distant supervision from a knowledge base, the portion of mis-labeled examples can vary from 13% to 31%. To address this issue, another line of work has explored *structured* learning methods that introduce latent variables. An example is MultiR (Hoffmann et al., 2011), which is based on a joint model of relations between entities in a knowledge base and those mentioned in text. This structured learning approach has a number of advantages; for example, by integrating inference into the learning procedure it has the potential to overcome the challenge of missing facts by ignoring the knowledge base when mention-level classifiers have high confidence (Ritter et al., 2013; Xu et al., 2013). Prior work on structured learning from minimal supervision has leveraged sparse feature representations, however, and has therefore not benefited from learned representations, which have recently achieved state-of-the-art results on a broad range of NLP tasks.

In this paper, we present an approach that combines the benefits of structured and neural methods for minimally supervised relation extraction. Our proposed model learns sentence representations that are computed by a 1D convolutional neural network (Collobert et al., 2011) and are used to define potentials over latent relation mention variables. These mention-level variables are related to observed facts in a KB using a set of deterministic factors, followed by pairwise potentials that encourage agreement between extracted propositions and observed facts, but also enable inference to override these soft constraints during learning, allowing for the possibility of missing information. Because marginal inference is intractable in this model, a MAP-based approach to learning is applied (Taskar et al., 2004).

Our approach is related to recent work structured learning with end-to-end learned representa-

tions, including Structured Prediction Energy Networks (SPENs) (Belanger and McCallum, 2016); the key differences are the application to minimally supervised relation extraction and the inclusion of latent variables with deterministic factors, which we demonstrate enables effective learning in the presence of missing data in distant supervision. Our proposed method achieves state-of-the-art results on minimally supervised sentential relation extraction, outperforming a number of baselines including one that leverages the attention layer of a purely neural model (Lin et al., 2016).

2 A Latent Variable Model for Neural Relation Extraction

In this section we present our model, which combines continuous representations with structured learning. We first review the problem setting and introduce notation, next we present our approach to extracting feature representations which is based on the piecewise convolutional neural network (PCNN) model of Zeng et. al. (2015) and includes positional embeddings (Collobert et al., 2011). Finally we describe how this can be combined with structured latent variable models that reason about overlapping relations and missing data during learning.

2.1 Assumptions and Problem Formulation

Given a set of sentences, $\mathbf{s} = s_1, s_2 \ldots, s_n$ that mention a pair of knowledge base entities e_1 and e_2 (dyad), our goal is to predict which relation, r, is mentioned between e_1 and e_2 in the context of each sentence, represented by a set of hidden variables, $\mathbf{z} = z_1, z_2, \ldots z_n$. Relations are selected from a fixed set drawn from a knowledge base, in addition to *NA* (no relation). Minimally supervised learning is more difficult than supervised relation extraction, because we do not have direct access to relation labels on the training sentences. Instead, during learning, we are only provided with information about what relations hold between e_1 and e_2 according to the KB. The problem is further complicated by the fact that most KBs are highly incomplete (this is the reason we want to extend them by extracting information from text in the first place), which effectively leads to false-negatives during learning. Furthermore, there are many overlapping relations between dyads, so it is easy for a model trained using minimal supervision from a KB to confuse these relationships. All of these issues are addressed to some degree by the structured learning approach that we present in Section 2.3. First, however we present our approach to feature representation based on convolutional neural networks.

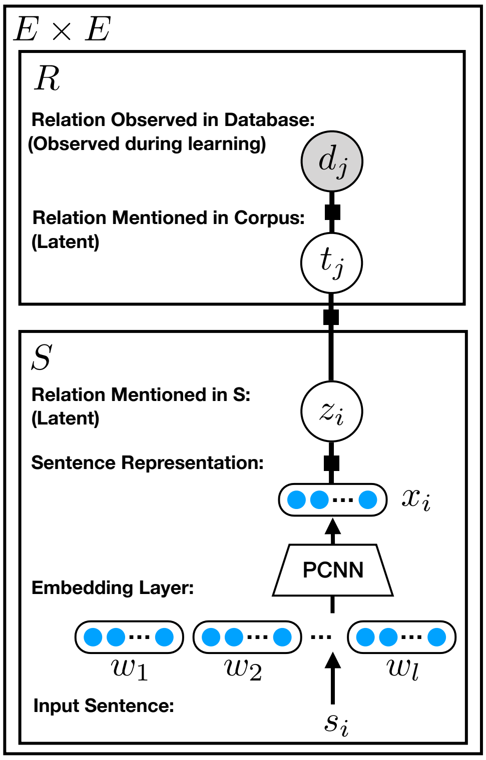

Figure 1: Plate representation of our proposed model. Plates represent replication; $E \times E$ is the number of entity pairs in the dataset, S is the number of sentences mentioning each entity pair and R is the number of relations. Arrows represent functions from input to output. Latent variables are represented as unshaded nodes. Factors over variables are represented as boxes.

2.2 Mention Representation

In the following section we review the Piecewise CNN (PCNN) architecture, first proposed by Zeng et. al. (2015), which is used as the basis for our feature representation.

Input Representation: A sentence, s_i consisting of l words is represented by two types of embeddings: word embeddings, E_i, and position embeddings, P_i relative to the entity pair. Following Lin et. al. (2016), word embeddings were initialized by running Word2Vec on the New York Times corpus and later fine-tuned; position embeddings encode the position of the word relative to KB entities, e_1 and e_2, mentioned in the sentence. The form of input sentence representation is $w_1, w_2, \cdots, w_l$, where $w_i \in \mathbb{R}^d$. The dimension of embedding at each word position is equal to the word embedding dimension plus two times the position embedding size (one position is encoded for each entity).

Convolution: Given an input sentence representation, we perform 1D convolution within a window of length l to extract local features. Assume we have d_f convolutional filters ($F = \{f_1, f_2, \cdots, f_{d_f}\}, f_i \in \mathbb{R}^{l\times d}$). The output of the i-th convolutional filter within the j-th window is:

$$c_{ij} = f_i \cdot w_{j-l+1:j} + b \quad (1 \leq j \leq m + l - 1)$$

Where b is a bias term. We use zero padding when the window slides out of the sentence boundaries.

Piecewise Max Pooling: The output of the convolutional layer c_i is separated into three parts (c_{i1}, c_{i2}, c_{i3}) using the positions of the two entities in the sentence. Max pooling over time is then applied to each of these parts, followed by an elementwise tanh. The final sentence vector is defined as follows:

$$[x]_{ik} = \tanh(\max_j(c_{ikj})) \quad (1 \leq i \leq d_f, 1 \leq k \leq 3)$$

2.3 Structured Minimally Supervised Learning

Our proposed model is based on the PCNN representations described above, in addition to a latent variable model that reasons about missing data and ambiguous relations during learning and is illustrated in Figure 1. The embedding for sentence i, is used to define a factor over the ith input sentence and latent relation mention variable z_i:

$$\phi_{\text{PCNN}}(s_i, z_i) = e^{x_i \cdot \theta_{z_i}}$$

where x_i is the representation for sentence s_i, as encoded by the piecewise CNN.

Another set of factors, ϕ_{OR}, link the sentence-level mention variables, z_i, to aggregate-level variables t_j, representing whether relation j is mentioned between e_1 and e_2 in text. This is modeled using a deterministic OR:

$$\phi_{\text{OR}}(\mathbf{z}, t_j) = \mathbf{1}_{\neg t_j \oplus \exists i: j = z_i}$$

where $\mathbf{1}_x$ is an indicator function that takes the value 1 when x is true. The choice of deterministic OR can be interpreted intuitively as follows: if a proposition is true according to t_j, then it must be extracted from at least one sentence in the training corpus, on the other hand, if it is false, no sentences in the corpus can mention it.

Finally, we incorporate a set of factors that penalize disagreement between observed relations in the KB, d_j, and latent variables t_j, which represent whether relation j was extracted from the text. The penalties for disagreement with the KB are hyperparameters that are adjusted on held-out development data and incorporate entity frequency information from the KB, to model the intuition that more popular entities are less likely to have missing facts:

$$\phi_{\text{A}}(t_j, d_j) = \begin{cases} e^{-\alpha_T}, & \text{if } t_j = 0 \text{ and } d_j = 1 \\ e^{-\alpha_D}, & \text{if } t_j = 1 \text{ and } d_j = 0 \\ 1, & \text{otherwise} \end{cases}$$

Putting everything together, the (unnormalized) joint distribution over $\mathbf{t}$, $\mathbf{d}$ and $\mathbf{z}$ conditioned on sentences $\mathbf{s}$ mentioning a dyad is defined as follows:

$$\begin{aligned} P(\mathbf{d}, \mathbf{t}, \mathbf{z}|\mathbf{s}) \propto & \prod_{i=1}^{|\mathbf{s}|} \phi_{\text{PCNN}}(s_i, z_i) \times \\ & \Big(\prod_{j=1}^{|\mathbf{r}|} \phi_{\text{OR}}(\mathbf{z}, t_j) \phi_{\text{A}}(t_j, d_j)\Big)^{\mu} \\ = & \exp(S_\theta(\mathbf{s}, \mathbf{z}, \mathbf{t}, \mathbf{d})) \end{aligned} \quad (1)$$

Here, μ is a tunable hyperparameter to adjust impact of the disagreement penalty, and $S_\theta(\cdot)$ is the model score for a joint configuration of variables, which corresponds to the log of the unnormalized probability.

A standard conditional random field (CRF) formulation would optimize model parameters, θ so as to maximize marginal probability of the observed KB relations, $\mathbf{d}$ conditioned on observed sentences, $\mathbf{s}$:

$$P(\mathbf{d}|\mathbf{s}) = \sum_{\mathbf{z},\mathbf{t}} P(\mathbf{d}, \mathbf{t}, \mathbf{z}|\mathbf{s})$$

Computing gradients with respect to $P(\mathbf{d}|\mathbf{s})$ (and marginalizing out $\mathbf{z}$ and $\mathbf{t}$) is computationally intractable, so instead we propose an approach that uses maximum-a-posteriori (MAP) parameter learning (Taskar et al., 2004) and is inspired by the latent structured SVM (Yu and Joachims, 2009).

Given a large text corpus in which a set of sentences, $\mathbf{s}$ mention a specific pair of entities (e_1, e_2) and a set of relations $\mathbf{d}$ hold between e_1 and e_2, our goal is to minimize the structured hinge loss: $L_{\text{SH}}(\theta) =$

$$\max\left\{ 0, \begin{array}{c} \max\limits_{\mathbf{z}_e^*,\mathbf{t}_e^*,\mathbf{d}_e^*} \left[S_\theta(\mathbf{s}, \mathbf{z}_e^*, \mathbf{t}_e^*, \mathbf{d}_e^*) + l_{\text{Ham}}(\mathbf{d}_e^*, \mathbf{d})\right] \\ - \max\limits_{\mathbf{z}_g^*,\mathbf{t}_g^*} \left[S_\theta(\mathbf{s}, \mathbf{z}_g^*, \mathbf{t}_g^*, \mathbf{d})\right] \end{array} \right\} \tag{2}$$

Where $l_{\text{Ham}}(\mathbf{d}_e^*, \mathbf{d})$ is the Hamming distance between the bit vector corresponding to the set of observed relations holding between (e_1, e_2) in the KB and those predicted by the model. Minimizing $L_{\text{SH}}(\theta)$ can be understood intuitively as adjusting the parameters so that configurations consistent with observed relations in the KB, $\mathbf{d}$, achieve a higher model score than those with a large hamming distance from the observed configuration. $\mathbf{z}_e^*$ corresponds to the most confusing configuration of the sentence-level relation mention variables (i.e. one that has a large score and also a large Hamming loss) and $\mathbf{z}_g^*$ corresponds to the best configuration that is consistent with the observed relations in the KB.

This objective can be minimized using stochastic subgradient descent. Fixing $\mathbf{z}_g^*$ and $\mathbf{z}_e^*$ to their maximum values in Equation 2, subgradients with respect to the parameters can be computed as follows:

$$\nabla_\theta L_{\text{SH}}(\theta) = \begin{cases} \mathbf{0} & \text{if } L_{\text{SH}}(\theta) \leq 0, \\ \nabla_\theta S_\theta(\mathbf{s},\mathbf{z}_e^*,\mathbf{t}_e^*,\mathbf{d}_e^*) & \\ -\nabla_\theta S_\theta(\mathbf{s},\mathbf{z}_g^*,\mathbf{t}_g^*,\mathbf{d}) & \text{otherwise} \end{cases} \tag{3}$$

$$= \begin{cases} \mathbf{0} & \text{if } L_{\text{SH}}(\theta) \leq 0, \\ \sum_i \nabla_\theta \log \phi_{\text{PCNN}}(s_i, z_{e,i}^*) & \\ -\sum_i \nabla_\theta \log \phi_{\text{PCNN}}(s_i, z_{g,i}^*) & \text{otherwise} \end{cases} \tag{4}$$

Because the second factor of the product in Equation 1 does not depend on θ, it is straightforward to compute subgradients of the scoring function, $\nabla S_\theta(\cdot)$, with fixed values of $\mathbf{z}_g^*$ and $\mathbf{z}_e^*$ using backpropagation (Equation 4).

Inference: The two inference problems, corresponding to maximizing over hidden variables in Equation 2 can be solved using a variety of solutions; we experimented with A* search over left-to-right assignments of the hidden variables. An admissible heuristic is used to upper-bound the maximum score of each partial hypothesis by maximizing over the unassigned PCNN factors, ignoring inconsistencies. This approach is guaranteed to find an optimal solution, but can be slow and memory intensive for problems with many variables. In preliminary experiments on development data, we found that local-search (Eisner and Tromble, 2006) using both relation type and mention search operators (Liang et al., 2010; Ritter et al., 2013) usually finds an optimal solution and also scales up to large training datasets; we use local search with 30 random restarts to compute argmax assignments for the hidden variables, $\mathbf{z}_g^*$ and $\mathbf{z}_e^*$, in all our experiments.

Bag-Size Adaptive Learning Rate: Since the search space of the MAP inference problem increases exponentially as the number of hidden variables goes up, it becomes more difficult to find the exact argmax solution using local search, leading to increased noise in the computed gradients. To mitigate the search-error problem in large bags of sentences, we dynamically modify the learning rate based on the number of sentences in each bag as follows:

$$\lambda_i = \begin{cases} \lambda, & \text{if } |\mathbf{s_i}| < \beta_1 \\ \lambda \times \frac{\beta_1}{|\mathbf{s}_i|}, & \text{if } \beta_1 \leq |\mathbf{s}_i| \leq \beta_2 \\ \lambda \times (\frac{\beta_1}{|\mathbf{s}_i|})^2, & \text{otherwise} \end{cases}$$

where λ_i is the learning rate for ith training entity pair and β_1/β_2 are two tunable bag-size thresholds. In Table 3 and Table 4, we see that this strategy significantly improves performance, especially when training on the larger NYTFB-280K dataset. We also experimented with this method for PCNN+ATT, but found that its performance did not improve.

3 Experiments

In Section 2, we presented an approach that combines the benefits of PCNN representations and structured learning with latent variables for minimally supervised relation extraction. In this section we present the details of our evaluation methodology and experimental results.

Datasets: We evaluate our models on the NYT-Freebase dataset (Riedel et al., 2010) which was created by aligning relational facts from Freebase with the New York Times corpus, and has been used in a broad range of prior work on minimally supervised relation extraction. Several versions of this dataset have been used in prior work; to facilitate the reproduction of prior results, we experiment with two versions of the dataset used by Riedel et. al. (2010) (henceforth NYTFB-68K) and Lin et. al. (2016) (NYTFB-280K). Statistics of these datasets are presented in Table 8. A more detailed discussion about the differences between

Dataset	NYTFB-68K (Riedel et. al. 2010)	NYTFB-280K (Lin et. al. 2016)
Entity pairs	67,946	280,275
Sentences	120,290	523,312

Table 1: Number of entity pairs and sentences in the training portion of Riedel's HELDOUT dataset (NYTFB-68K) and Lin's dataset (NYTFB-280K).

Batch size B	1

Table 2: Untuned hyperparameters in our experiments.

datasets used in prior work is also presented in Appendix B.

Hyperparameters: Following Lin et. al. (2016), we utilize word embeddings pre-trained on the NYT corpus using the word2vec tool, other parameters are initialized using the method described by Glorot and Bengio (2010). The Hoffmann et. al. sentential evaluation dataset is split into a development and test set and grid search on the development set was used to determine optimal values for the learning rate λ among $\{0.001, 0.01\}$, KB disagreement penalty scalar μ among $\{100, 200, \cdots, 2000\}$ and β_1/β_2 bag size threshold for the adaptive learning rate among $\{10, 15, \cdots, 40\}$. Other hyperparameters with fixed values are presented in Table 2.

Neural Baselines: To demonstrate the effectiveness of the our approach, we compare against colless universal schema (Verga et al., 2016) in addition to the PCNN+ATT model of Lin et. al. (2016). After training the Lin et. al. model to predict observed facts in the KB, we use its attention layer to make mention-level predictions as follows:

$$p(r_j|x_i) = \frac{\exp(r_j \cdot x_i)}{\sum_{k=1}^{n_r} \exp(r_k \cdot x_i)}$$

Where r_j indicates the vector representation of the jth relation.

Structured Baselines: In addition to initializing convolutional filters used in the $\phi_{\text{PCNN}}(\cdot)$ factors randomly and performing structured learning of representations as in Equation 4, we also experimented with variants of MultiR and DNMAR, which are based on the structured perceptron (Collins, 2002), using fixed sentence representations: both traditional sparse feature representations, in addition to pre-trained continuous representations generated using our best-performing reimplementation of PCNN+ATT. For the structured perceptron baselines, we also experimented with variants based on MIRA (Crammer and Singer, 2003), which we found to provide consistent improvements. More details are provided in Appendix A.

3.1 Sentential Evaluation

In this work, we are primarily interested in mention-level relation extraction. For our first set of experiments (Tables 3 and 4), we use the manually annotated dataset created by (Hoffmann et al., 2011). Note that sentences in the Hoffman et. al. dataset were selected from the output of systems used in their evaluation, so it is possible there are high confidence predictions made by our systems that are not present. Therefore, we further validate our findings, by performing a manual inspection of the highest confidence predictions in Table 5.

NYTFB-68K **Results:** As illustrated in Table 3, simply applying structured models (MultiR and DNMAR) with pre-trained sentence representations performs competitively. MIRA provides consistent improvements for both sparse and dense representations. PCNN+ATT outperforms most latent-variable models on the sentential evaluation, we found this result to be surprising as the model was designed for extracting proposition-level facts. Col-less universal schema does not perform very well in this evaluation; this is likely due to the fact that it was developed for the KBP slot filling evaluation (Ji et al., 2010), and only uses the part of a sentence between two entities as an input representation, which can remove important context. Our proposed model, which jointly learns sentence representations using a structured latent-variable model that allows for the possiblity of missing data, achieves the best overall performance; its improvements over all baselines were found to be statistically significant according to a paired bootstrap test (Efron and Tibshirani, 1994; Berg-Kirkpatrick et al., 2012).[2]

NYTFB-280K **Results:** When training on the larger dataset provided by Lin et. al. (2016), linguistic features are not available, so only neural representations are included in our evaluation. As illustrated in Table 4, PCNNNMAR also achieves the best performance when training on the larger

	DNMAR_sparse_MIRA	77.5	72.1
	DNMAR_continuous	80.2	70.0
	DNMAR_continuous_MIRA	82.2	74.2
Jointly Learned Representations	PcnnNmar	82.4	83.9
	PcnnNmar (bag size adaptive learning rate)	**85.4**	**86.0**
Baselines	col-less universal schema (Verga et al., 2016)	63.4	61.1
	PCNN+ATT (Lin et al. (2016) code)	81.4	76.4
	PCNN+ATT (our reimplementation with parameter tuning)	83.6	78.4

Table 3: AUC of sentential evaluation precision / recall curves for all models trained on NytFb-68k. Continuous sentence representation works as well as human-engineered sentence representation, and MIRA consistently helps structured perceptron training. PCNN+ATT performs competitively while our PcnnNmar (AdapLR) is statistically significantly better (p-value of bootstrap is less than 0.05)

dataset; its improvements over the baselines are statistically significant. The AUC of most models decreases on the Hoffmann et. al. sentential dataset when training on NytFb-280k. This is not surprising, because the Hoffmann et. al. dataset is built by sampling sentences from positive predictions of models trained on NytFb-68k; changing the training data causes a difference in the ranking of high-confidence predictions for each model, leading to the observed decline in performance against the Hoffmann et. al. dataset. To further validate our findings, we also manually inspect the models' top predictions as described below.

Manual Evaluation: Because the Hoffmann et. al. sentential dataset does not contain the highest confidence predictions, we also manually inspected each model's top 500 predictions for the most frequent 4 relations, and report precision @ N to further validate our results. As shown in Table 5, for NytFb-68k, PCNN+ATT performs comparably on `/location/contains`[3] and `/person/company`, whereas our model has a considerable advantage on the other two relations. For NytFb-280k, our model performs consistently better on all four relations compared with PCNN+ATT. When training on the larger NytFb-280k dataset, we observe trend of increasing mention-level P@N for PcnnNmar, however the performance of PCNN+ATT appears to decrease. We investigate this phenomenon further below.

Performance at Extracting New Facts: To explain PCNN+ATT's drop in mention-level performance after training on the larger NytFb-280k dataset, our hypothesis is that the larger KB-supervised dataset not only contains more true positive training examples but also more false negative examples. This biases models toward predicting facts about popular entities, which are likely to exist in Freebase. To provide evidence in support of this hypothesis, we divide the manually annotated dataset from Hoffmann et. al. into two categories: mentions of facts found in Freebase, and those that are not; this distribution is presented in the Table 6. In Table 7, we present a breakdown of model performance on these two subsets. For PCNN+ATT, although the AUC of in-Freebase mentions on the test set increases after training on the larger NytFb-280k, its Out-Of-Freebase AUC on both dev and test sets drops significantly, which clearly illustrates the problem of increasing false negatives during training. In contrast, our model, which explicitly allows for the possibility of missing data in the KB during learning, has relatively stable performance on the two types of mentions, as the amount of weakly-supervised training data is increased.

3.2 Held-Out Evaluation

In Section 3.1, we evaluated the results of minimally supervised approaches to relation extraction by comparing extracted mentions against human judgments. An alternative approach, which has been used in prior work, is to evaluate a model's performance by comparing predictions against held out facts from a KB. Taken in isolation, this approach to evaluation can be misleading, because it penalizes models that extract many

	Change	**-3.6**	+0.2
TEST			
PCNN+ATT	NYTFB-68K	78.7	75.9
	NYTFB-280K	81.9	56.8
	Change	+3.2	**-19.1**
PCNNNMAR(AdapLR)	NYTFB-68K	85.9	85.4
	NYTFB-280K	83.1	81.5
	Change	-2.8	**-3.9**

Table 7: Top: Comparison of AUCs of In-Freebase and Out-Of-Freebase mentions on sentential DEV set for PCNN+ATT and PCNNNMAR (AdapLR) with two datasets. Bottom: Comparison of AUCs of In-Freebase and Out-Of-Freebase mentions on sentential TEST set for PCNN+ATT and PCNNNMAR (AdapLR) with two datasets. PCNN+ATT has significant drops about Out-Of-Freebase mentions on both sentential DEV and TEST set after training on the larger NYTFB-280K which explains why its overall AUC performances go down while PCNNNMAR (AdapLR) does not have such problem.

new facts that do not already appear in the knowledge base. This is undesirable, because the whole point of an information extraction system is to extract *new* facts that are not already contained in a KB. Furthermore, sentential extraction has the benefit of providing clear provenance for extracted facts, which is crucial in many applications. Having mentioned these limitations of the held-out evaluation metrics, however, we now present results using this approach to facilitate comparison to prior work.

Figure 2 presents precision-recall curves against held out facts from Freebase comparing PCNNNMAR to several baselines and Figure 3 presents results on the larger NYTFB-280K dataset. All models perform better according to the held out evaluation metric when training on the larger dataset, which is consistent with our hypothesis, presented at the end of Section 3.1. Our structured model with learned representations, PCNNNMAR (AdapLR), has lower precision when recall is high. This also fits with our hypothesis, as systems that explicitly model missing data will extract many correct facts that do not appear in the KB, resulting in an under-estimate of precision according to this metric.

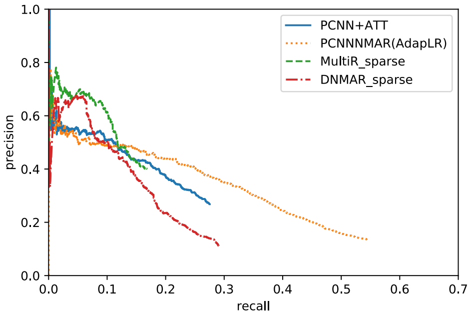

Figure 2: Held-out evaluation precision / recall curves for PCNN+ATT, MultiR, DNMAR and our proposed model PCNNNMAR (AdapLR) on NYTFB-68K.

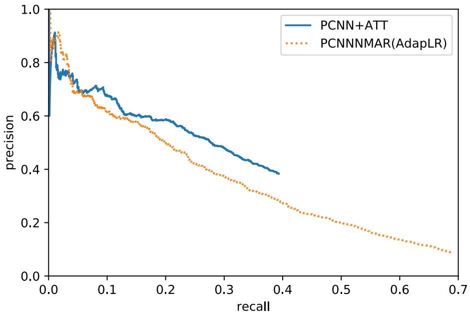

Figure 3: Held-out evaluation precision / recall curves for all NN-based models on NYTFB-280K.

4 Related Work

Knowledge Base Population: There is a long line of prior work on learning to extract relational information from text using minimal supervision. Early work on semantic bootstrapping (Hearst, 1992; Brin, 1998; Agichtein and Gravano, 2000; Carlson et al., 2010; Gupta and Manning, 2014; Qu et al., 2018), applied an iterative procedure to extract lexical patterns and relation instances. These systems tend to suffer from the problem of semantic drift, which motivated work on distant supervision (Craven et al., 1999; Snyder and Barzilay, 2007; Wu and Weld, 2007; Mintz et al., 2009), that explicitly minimizes standard loss functions, against observed facts in a knowledge base. The TAC KBP Knowledge Base Population task was a prominent shared evaluation of relation extraction systems (Ji et al., 2010; Surdeanu, 2013; Surdeanu et al., 2010, 2012). Recent work has explored a variety of new neural network architectures for relation extraction (Wang et al., 2016; Zhang et al., 2017; Yu et al., 2015), experimenting with alternative sentence representations in our framework is an interesting direction for future work. Recent work has also shown improved performance by incorporating supervised training data on the sentence level (Angeli et al., 2014; Beltagy et al., 2018), in contrast our approach does not make use of any sentence-level labels during learning and therefore relies on less human supervision. Finally, prior work has explored a variety of methods to address the issue of noise introduced during distant supervision (Wu et al., 2017; Yaghoobzadeh et al., 2017; Qin et al., 2018).

Another line of work has explored open-domain and unsupervised methods for IE (Yao et al., 2011; Ritter et al., 2012; Stanovsky et al., 2015; Huang et al., 2016; Weber et al., 2017). Universal schemas (Riedel et al., 2013) combine aspects of minimally supervised and unsupervised approaches to knowledge-base completion by applying matrix factorization techniques to multi-relational data (Nickel et al., 2011; Bordes et al., 2013; Chang et al., 2014). Rows of the matrix typically model pairs of entities, and columns represent relations or syntactic patterns (i.e., syntactic dependency paths observed between the entities).

Structured Learning with Neural Representations: Prior work has investigated the combination of structured learning with learned representations for a number of NLP tasks, including parsing (Weiss et al., 2015; Durrett and Klein, 2015; Andor et al., 2016), named entity recognition (Cherry and Guo, 2015; Ma and Hovy, 2016; Lample et al., 2016) and stance detection (Li et al., 2018). We are not aware of any previous work that has explored this direction on the task of minimally supervised relation extraction; we believe structured learning is particularly crucial when learning from minimal supervision to help address the issues of missing data and overlapping relations.

5 Conclusions

In this paper we presented a hybrid approach to minimally supervised relation extraction that combines the benefits of structured learning and learned representations. Extensive experiments show that by performing inference during the learning procedure to address the issue of noise in distant supervision, our proposed model achieves state-of-the-art performance on minimally supervised mention-level relation extraction.

A MIRA

Prior work on minimally supervised structured learning has made use of sparse feature representations in combination with perceptron-style parameter updates. We found these updates result in poor performance on held-out development data, however, when using fixed, pre-trained continuous sentence representations. Perhaps this is not surprising because, intuitively, the margin of the dataset is likely to be smaller when using lower dimensional, continuous representations, leading to a larger mistake bound for convergence of the perceptron. To address this, we applied the the **M**argin **I**nfused **R**elaxation **A**lgorithm (Crammer and Singer, 2003), as described below. In Section 3.1, we show empirically that MIRA is crucial for achieving good performance when using continuous representations, and consistently improves performance when using sparse features as well.

As discussed above, we have $\hat{\mathbf{z}}^{\text{KB}}$ the most likely sentence extractions conditioned on the KB and $\hat{\mathbf{z}}$, the MAP assignment to $\mathbf{z}$, ignoring the KB. MIRA updates parameters of the PCNN factors as follows:

$$\theta_j \quad = \quad \theta_j + \tau \cdot \Big(F_j(x_i, \hat{z}_i^{\text{KB}}) - F_j(x_i, \hat{z}_i)\Big)$$

here τ is an adaptive learning rate that scales the update to the smallest step size that achieves 0 loss on each mention-level classification:

$$\tau \quad = \quad \min\left(C, \frac{1 - \theta \cdot \big(F(x_i, \hat{z}_i^{\text{KB}}) - F(x_i, \hat{z}_i)\big)}{2||x_i||^2}\right)$$

θ is the concatenation of parameters θ_j across relations j, and similarly $F(\cdot)$ is the concatenation of PCNN features across relations. C is a hyper-parameter that truncates large steps and helps to prevent overfitting.

B Differing Versions of the NYT-Freebase Corpus Used in Prior Work

We evaluate our models on the NYT-Freebase dataset (Riedel et al., 2010) which was created by aligning relational facts from Freebase with the New York Times corpus, and has been used in a broad range of prior work on minimally supervised relation extraction. Originally, Riedel et. al. created two separate datasets for their HELDOUT and MANUAL evaluations. In the HELDOUT dataset, Freebase entity pairs are divided into two parts, one for training and one for testing. Training dyads are aligned to the 2005-2006 portion of the NYT corpus while testing dyads are aligned to the year 2007. In the MANUAL evaluation data, **all** Freebase entity pairs are matched against the 2005-2006 articles and used as training instances. Testing data in the Riedel et. al. MANUAL evaluation consists of dyads found within sentences in the 2007 NYT articles, for which at least one entity does not appear in Freebase; their models' predictions on this data were annotated manually. The Riedel et. al. data splits ensure it is not possible to have overlapping train/test entity pairs in either the HELDOUT or MANUAL evaluation.

As neural models with many parameters typically benefit significantly from larger quantities of training data, Lin et. al. (2016) added training data from the Riedel et. al. MANUAL-TRAIN dataset into their training dataset. This modification of the training data leads to overlap in the entity pairs in the Lin et. al. training/test split. We found 11,424 entity pairs appearing in both training and test sets, however no sentences appear in both the training and test sets, as the matched NYT articles came from different time periods.[4] In all our evaluations we remove these overlapping entity pairs from the training set, to ensure the models are not simply memorizing KB facts that appear in the training data. Figure 4 shows that after removing these shared entity pairs from the training data, performance of the Lin et. al. PCNN+ATT model does not change very much when evaluating against held out facts from Freebase.

We name two versions of the NYT-Freebase dataset according to the number of training entity

---

[4] We downloaded the Lin et. al. (2016) dataset from the associated Github repository (`https://github.com/thunlp/NRE`) on June, 2017. The repository was updated in March and May 2018, addressing the overlapping-entity-pairs issue using the same approach described in our paper.

Dataset	NYTFB-68K (Riedel et. al. 2010)	NYTFB-280K (Lin et. al. 2016)
Entity pairs	67,946	280,275
Sentences	120,290	523,312
Distinct sent.	96,340	340,970
Relations	52	53

Table 8: Number of entity pairs and sentences in the training portion of Riedel's HELDOUT dataset (NYTFB-68K) and Lin's dataset (NYTFB-280K).

pairs they include. Table 8 shows that NYTFB-280K training set has around 4 times the number of sentences and entity pairs as NYTFB-68K, and the proportions of multi-sentence entity pairs in NYTFB-280K is higher. In Table 9, we can see that the distribution of relations in the two datasets are comparable, but NYTFB-280K has much more entity pairs for each relation. Also, Figure 5 tells us that NYTFB-280K has a wider bag-size range and more large training bags.

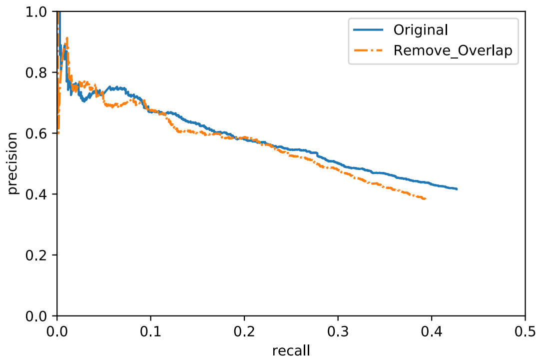

Figure 4: Held-out evaluation precision / recall curves for PCNN+ATT model on original NYTFB-280K and its shared-entity-pairs-removed version.

	AdapLR	83.9	81.3
relation-level	normal	83.9	83.1
	AdapLR	84.6	81.1
mention-level	normal	82.4	83.9
	AdapLR	**85.4**	**86.0**

Table 10: AUC of sentential evaluation precision / recall curves for PCNNNMAR with three loss functions trained on NYTFB-68K. Mention-level hamming loss has some advantages over other two loss functions.

C Variations on Structured Hinge Loss

Since we use the hinge loss as the loss function in our proposed PCNNNMAR model, the way that the hamming loss is calculated decides how we solve the argmax problem in loss-augmented search. In our experiments, we explore three ways to compute the loss: 0/1 loss, relation-level hamming loss and mention-level hamming loss. Table 10 shows that mention-level hamming loss has obvious advantage on AUC performance over other two methods. Although theoretically relation-level hamming loss should be better, it is really hard to find the exact argmax solution in loss-augmented inference with local search while we can easily get it with mention-level hamming loss.

Neural Machine Translation of Text from Non-Native Speakers

Abstract

Neural Machine Translation (NMT) systems are known to degrade when confronted with noisy data, especially when the system is trained only on clean data. In this paper, we show that augmenting training data with sentences containing artificially-introduced grammatical errors can make the system more robust to such errors. In combination with an automatic grammar error correction system, we can recover 1.0 BLEU out of 2.4 BLEU lost due to grammatical errors. We also present a set of Spanish translations of the JFLEG grammar error correction corpus, which allows for testing NMT robustness to real grammatical errors.

1 Introduction

Neural Machine Translation (NMT) is undeniably a success story: public benchmarks (Bojar et al., 2016) are dominated by neural systems, and neural approaches are the *de facto* option for industrial systems (Wu et al., 2016; Hassan Awadalla et al., 2018; Crego et al., 2016; Hieber et al., 2018). Even under low-resource conditions, neural models were recently shown to outperform traditional statistical approaches (Nguyen and Chiang, 2018).

However, there are still several shortcomings of NMT that need to be addressed: a (non-exhaustive) list of six challenges is discussed by Koehn and Knowles (2017), including out-of-domain testing, rare word handling, the wide-beam problem, and the large amount of data needed for learning. An additional challenge is robustness to noise, both during training and at inference time.

In this paper, we study the effect of a specific type of noise in NMT: grammatical errors. We primarily focus on errors that are made by non-native source-language speakers (as opposed to dialectal language, SMS or Twitter language). Not only is this linguistically important, but we believe that it would potentially have great social impact.

Our contributions are three-fold. First, we confirm that NMT is vulnerable to source-side noise when trained on clean data, losing up to 3.6 BLEU on our test set. This is consistent with previous work, yet orthogonal to it, since we use more realistic noise for our experiments. Second, we explore training methods that can deal with noise, and show that including noisy synthetic data in the training data makes NMT more robust to handling similar types of errors in test data. Combining this simple method with an automatic grammar correction system, we find that we can recover 1.5 BLEU. Third, we release Spanish translations of the JFLEG corpus,[1] a standard benchmark for English Grammar Error Correction (GEC) systems. We also release all other data and code used in this paper.

Our additional annotations on both the JFLEG corpus and the English WMT data will enable the evaluation of the robustness of NMT systems on realistic, natural noise: a robust system would ideally produce the same output when presented with either the original or the noisy source sentence. We hope that our datasets will become a benchmark for noise-robust NMT, because we believe that deployed systems should also be able to handle source-side noise.

2 Data

We focus on NMT from English to Spanish. We choose English to be our source-side language because there exist English corpora annotated with grammar corrections, which we can use as a

source of natural noise. Moreover, since English is probably the most commonly spoken non-native language (Lewis et al., 2009), our work could be directly applicable to several translation applications. Our choice of Spanish as a target language enables us to have access to existing parallel data and easily create new parallel corpora (see below, §2.3).

For all experiments, we use the Europarl English-Spanish dataset (Koehn, 2005) as our training set. In the synthetic experiments of Section §2.2, we use the newstest2012 and newstest2013 as dev and test sets, respectively. Furthermore, to test our translation methods on real grammatical errors, we introduce a new collection of Spanish translations of the JFLEG corpus (§2.3).

2.1 Grammar Error Correction Corpora

To our knowledge, there are five publicly available corpora of non-native English that are annotated with corrections, which have been widely used for research in Grammar Error Correction (GEC). The NUS Corpus of Learner English (NUCLE) contains essays written by students at the National University of Singapore, corrected by two annotators using 27 error codes (Dahlmeier et al., 2013). It has become the main benchmark for GEC, as it was used in the CoNLL GEC Shared Tasks (Ng et al., 2013, 2014). Other corpora include the Cambridge Learner Corpus First Certificate in English FCE corpus (Yannakoudakis et al., 2011), which is only partially public, the LANG-8 corpus (Tajiri et al., 2012), which was harvested from online corrections, and the AESW 2016 Shared Task corpus, which contains corrections on texts from scientific journals.

The last corpus is the JHU FLuency-Extended GUG corpus (JFLEG) (Napoles et al., 2017). This corpus covers a wider range of English proficiency levels on the source side, and its correction annotations include extended fluency edits rather than just minimal grammatical ones. That way, the corrected sentence is not just grammatical, but also guaranteed to be fluent.

2.2 Synthetic grammar errors

Ideally, we would train a translation model to translate grammatically noisy language by training it on parallel data with grammatically noisy language. Since, to our knowledge, no such data exist in the quantities that would be needed, an alternative is to add synthetic grammatical noise to clean data. An advantage of this approach is that controlled introduction of errors allows for fine-grained analysis.

Error Type	Confusion Set
ART	{a, an, the, $\emptyset$}
PREP	{on, in, at, from, for, under, over, with, into, during, until, against, among, throughout,of, to, by, about, like, before, after, since, across, behind, but, out, up, down, off, $\emptyset$}
NN	{SG, PL}
SVA	{3SG, not 3SG, 2SG-Past, not 2SG-Past}

Table 1: Confusion sets for each grammar error type. The ART and PREP sets include an empty token ($\emptyset$) allowing for insertions and deletions. SG, PL, 2SG, and 3SG stand for singular, plural, second-person and third-person singular respectively.

This is a two-step process, similar to the methods used in the GEC literature for creating synthetic data based on confusion matrices (Rozovskaya et al., 2014; Rozovskaya and Roth, 2010; Xie et al., 2016; Sperber et al., 2017). First, we mimic the distribution of errors found in real data, and then introduce errors by applying rule-based transformations on automatic parse trees.

The first step involves collecting error statistics on real data. Conveniently, the NUCLE corpus has all corrections annotated with 27 error codes. We focus on five types of errors, with the last four being the most common in the NUCLE corpus:

- DROP: randomly deleting one character from the sentence.[2]
- ART: article/determiner errors
- PREP: preposition errors
- NN: noun number errors
- SVA: subject-verb agreement errors

Using the annotated training set of the NUCLE corpus, we compute error distribution statistics, resulting in confusion matrices for the cases outlined in Table 1. For ART and PREP errors, we obtain probability distributions that an article, determiner, or preposition is deleted, substituted with another member of the confusion set, or inserted in the beginning of a noun phrase. For NN errors,

---

[2] This error is not part of the NUCLE error list.

Dataset	Percentage of Errors Train	 Dev	 Test
sentences	2M	3K	3K
words	55M	74K	73K
DROP	100%	100%	100%
ART	96.4%	98.4%	99.8%
PREP	95.7%	95.9%	98.4%
NN	94.5%	91.0%	98.6%
SVA	93.1%	81.9%	82.0%
CLEAN+DROP	50%	50%	–
CLEAN+ART	48.2%	49.1%	–
CLEAN+PREP	47.8%	47.9%	–
CLEAN+NN	47.3%	45.5%	–
CLEAN+SVA	46.5%	41.0%	–
MIX-ALL	79.9%	77.8%	–

Table 2: Statistics on the original and synthetic En-Es datasets. Each (synthetic) sentence has exactly one introduced error, wherever possible. CLEAN+[ERROR] is the concatenation of the [ERROR] with the original clean dataset, while MIX-ALL includes six versions of each training sentence, one without errors and one for each error.

we obtain the probability of a noun being replaced with its singular or plural form. For SVA errors, the probability that a present tense verb is replaced with its third-person-singular (3SG) or not-3SG form. An additional SVA error that we included is the confusion between the appropriate form for the verb 'to be' in the past tense ('was' and 'were').

The second step involves applying the noise-inducing transformations using our collected statistics as a prior. We obtained parses for each sentence using the Berkeley parser (Petrov et al., 2006). The parse tree allows us to identify candidate error positions in each sentence (for example, the beginning of a noun phrase without a determiner, were one could be inserted). For each error type we introduced exactly *one* error per sentence, wherever possible, which we believe matches more realistic scenarios than previous work. It also allows for controlled analysis of the behaviour of the NMT system (see Section 4).

For each error and each sentence, we first identify candidate positions (based on the error type and the parse tree) and sample one of them based on the specific error distribution statistics. Then, we sample and introduce a specific error using the corresponding probability distribution from the confusion matrix. (In the case of DROP, NN, and SVA errors, we only need to sample the position and only insert/substitute the corresponding error.) If no candidate positions are found (for example, a sentence doesn't have a verb that can be substituted to produce a SVA error) then the sentence remains unchanged.

Following the above procedure, we added errors in our training, dev, and test set (henceforth referred to as [ERROR]). Basic statistics on our produced datasets can be found in Table 2, while example sentences are shown in Table 3. Furthermore, we created training and dev sets that mix clean and noisy data. The CLEAN+[ERROR] training sets are the concatenation of each [ERROR] with the clean data, effectively including a clean and a noisy version of each sentence pair.

We also created a training and dev dataset with mixed error types, in our attempt to study the effect of including all noise types during training. The MIX-ALL dataset includes each training pair six times: once with the original (clean) sentence as the source, and once for every possible error. We experimented with a mixed dataset that included each training sentence once, with the number of noisy sentences being proportional to the real error distributions of the NUCLE dataset, but obtained results similar to the [ERROR] datasets.

2.3 JFLEG-ES: Spanish translations of JFLEG

The JFLEG corpus consists of a dev and test set (no training set), with 747 and 754 English sentences, respectively, collected from non-native English speakers. Each sentence is annotated with four different corrections, resulting in four (fluent and grammatical) reference sentences. About 14% of the sentences do not include any type of error, with the source and references being equivalent.

We created translations of the JFLEG corpus that allow us to evaluate how well NMT fares compared to a human translator, when presented with noisy input. We will refer to the augmented JFLEG corpus as JFLEG-ES.

Two professional translators were tasked with producing translations for the dev and the test set, respectively. The translators were presented only with the original erroneous sentences; they did not have access to the correction annotations. They were asked to produce fluent, grammatical translations in European Spanish (to match the

Error Type	Example

Spanish used in the Europarl corpus). There exist cases where a translator might choose to preserve a source-side error when producing the translation, such as translation of literary works where it's possible that grammar or fluency errors are intentional; however, our translators were explicitly asked not to do that. The exact instructions were as follows:

> Please translate the following sentences. Note that some sentences will have grammatical errors or typos in English. Don't try to translate the sentences word for word (e.g. replicate the error in Spanish). Instead, try to translate it as if it was a grammatical sentence, and produce a fluent grammatical Spanish sentence that captures its meaning.

3 Experiments

In this section, we provide implementation details and the results of our NMT experiments. For convenience, we will refer to each model with the same name as the dataset it was trained on; e.g. the MIX-ALL model will refer to the model trained on the MIX-ALL dataset.

3.1 Implementation Details

All data are tokenized, truecased, and split into subwords using Byte Pair Encoding (BPE) with 32,000 operations (Sennrich et al., 2016). We filter the training set to only contain sentences up to 80 words.

Our LSTM models are implemented using DyNet (Neubig et al., 2017), and our transformer models using PyTorch (Paszke et al., 2017). The transformer model uses 6 layers, 8 attention heads, the dimension for embeddings and positional feed-forward are 512 and 2048 respectively . The sub-layer computation sequence follows the guidelines from Chen et al. (2018). Dropout probability is set to 0.2 (also in the source embeddings, following Sperber et al. (2017)). We use the learning rate schedule in Vaswani et al. (2017) with warm-up steps of 24000 but only decay the learning rate until it reaches 10^{-5} as inspired by Chen et al. (2018). For testing, we select the model with the best performance on the dev set corresponding to the test set. At inference time, we use a beam size of 4 with length normalization (Wu et al., 2016) with a weight of 0.6.

3.2 Results

We report the results obtained with the transformer model, as they were consistently better than the LSTM one. All the result tables for the LSTM models can be found in the Appendix.

The performance of our systems on the synthetic WMT test sets, as measured by detokenized BLEU (Papineni et al., 2002), is summarized in Table 4. When the system is trained only on clean data (first row) and tested on noisy data, it unsurprisingly exhibits degraded performance. We observe significant drops in the range of 1.0–3.6 BLEU.

WMT Training Set	En-Es WMT Test Set						
	CLEAN	DROP	ART	PREP	NN	SVA	AVERAGE ± STDEV
CLEAN	**33.0**	29.6	31.3	**32.0**	29.3	**32.1**	31.2 ± 1.5

MIX-ALL	**32.7**	30.9	**31.4**	**32.0**	**30.6**	**32.0**	**31.6 ± 0.7**

Table 4: BLEU scores on the WMT test set without (CLEAN) and with synthetic grammar errors. The best performing models for each test set are **highlighted**. When training and test match (highlighted) we generally observe higher results. However, including all clean and noisy data in the training set (MIX-ALL) yields the best results across almost all datasets, with the highest average BLEU *and* the lowest variance.

The largest drop (more than 3.5 BLEU) is observed with NN errors in the source sentence. This is not unreasonable: nouns almost always carry content significant for translation. Especially when translating into Spanish, a noun number change can, and apparently does, also affect the rest of the sentence significantly, for example, by influencing the conjugation of a subsequent verb. The second-largest drop (more than 3.0 BLEU points) is observed in the case of DROP errors. This is also to be expected; typos produce out-of-vocabulary (OOV) words, which in the case of BPE are usually segmented to a most likely rarer subword sequence than the original correct word.

We find that a training regime that includes both clean and noisy sentences ([CLEAN+ERROR) results in better systems across the board. Importantly, these models manage to perform en par with the CLEAN model on the CLEAN test set. Since the original training set is part of the [CLEAN+ERROR training sets, this behavior is expected. We conclude, thus, that including the full clean dataset during training is important for performance on clean data – one cannot just train on noisy data.

The [CLEAN+ERROR] systems exhibit a notable pattern: their BLEU scores are generally similar to the CLEAN system on all test sets, except for the test set that matches their training set errors (highlighted in Table 4), where they generally obtain the best performance.

The MIX-ALL model is our best system on all test sets (except DROP) and on average. Unlike the [CLEAN+ERROR] systems, it outperforms the CLEAN model on *all* noisy test sets and not only on a specific one. On average, using the MIX-ALL training set leads to an improvement of 0.4 BLEU over the CLEAN model and 0.1 − 0.7 BLEU over the [CLEAN+ERROR] models. Furthermore, the MIX-ALL model exchibits the smallest performance standard deviation of all models, averaging over all test sets. This is another indication that our system is more robust to multiple source-side variations. We further explore this intuition in Section 4.

On the more realistic JFLEG-ES dev and test sets, we observe same trends but at a smaller scale, as shown in Table 5. Our MIX-ALL model generally achieves comparable results when presented with each of the four reference corrections of the test set (CORX columns). However, when we use the noisy source sentence as input (No CORR column) our MIX-ALL model obtains 1.4 BLEU improvements over the CLEAN model. The *difference* between the performance of the models when presented with clean and noisy input is another indicator for robustness. On the JFLEG-ES test set, the noisy source results in a −3.1 BLEU point drop for the CLEAN model, while the drop for our MIX-ALL model is smaller, at −1.7 BLEU points.

In addition, we experimented with using an automatic error-corrected source as input to our sys-

JFLEG-ES Dev

Training	Manual correction					No	Auto
	COR0	COR1	COR2	COR3	avg.	corr.	corr.
CLEAN	32.1	31.5	32.5	33.3	32.4	31.1	31.2

MIX-ALL	27.7	28.1	28.1	27.5	27.8	**26.8**	**26.7**

Table 5: BLEU scores on the JFLEG-ES dev and test datasets. Our proposed MIX-ALL model is slightly behind the CLEAN model on manually corrected input (COR[0–3]). On noisy input (No corr.) the MIX-ALL outperforms the CLEAN model (26.8 > 26.2). Preprocessing the noisy input with a GEC model (Auto corr.) slightly improves results.

tem (column AUTO CORR of Table 5). We used the publicly available JFLEG outputs of the (almost) state-of-the-art model of Junczys-Dowmunt and Grundkiewicz (2016) as inputs to our NMT system.[3] This experiment envisions a pipeline where the noisy source is first automatically corrected and then translated. As expected, this helps the CLEAN model (by +1.1 BLEU), but our MIX-ALL training helps even further (by another +0.8 BLEU). Interestingly, the automatic GEC system only helps in the test set, while there are no improvements in the dev set. Naturally, since automatic GEC systems are imperfect, the performance of this pipeline still lags behind translating on clean data.

4 Analysis

We attempt an in-depth analysis of the impact of the different source-side error types on the behavior of our NMT system, when trained on clean data and tested on the artificial noisy data that we created.

ART Errors Table 6 shows the difference of the BLEU scores obtained on the sentences, broken down by the type of article error that was introduced. The first observation is that in all cases the difference is negative, meaning that we get higher BLEU scores when testing on clean data. Encouragingly, there is practically no difference when we substitute ‘a’ with ‘an’ or ‘an’ with ‘a’; the model seems to have learned very similar representations for the two indefinite articles, and as a result such an error has no impact on the produced output. However, we observe larger performance drops when substituting indefinite articles with the definite one and vice versa; since the target language makes the same article distinction as the source language, any article source error is propagated to the produced translation.

PREP Errors Due to the large number of prepositions, we cannot present a full analysis of preposition errors, but highlights are shown in Table 7. Deleting a correct preposition or inserting a wrong one leads to performance drops of 1.2 and 0.8 BLEU points for the CLEAN model, but drops of 0.4 and 0.7 for the MIX-ALL model.

NN and SVA Errors We found no significant performance difference between the different NN errors. Incorrectly pluralizing a noun has the same adverse effect as singularizing it, leading to performance reductions of over 4.0 and 3.5 BLEU points respectively. We observe a similar behavior with SVA errors: each error type leads to roughly the same performance degradation.

5 Related Work

The effect of noise in NMT was recently studied by Khayrallah and Koehn (2018), who explored noisy situations during training due to web-crawled data. This type of noise includes misaligned, mistranslated, or untranslated sentences which, when used during training, significantly degrades the performance of NMT. Unlike our

---

[3] This model has been recently surpassed by other systems, e.g. (Junczys-Dowmunt et al., 2018), but their outputs are not available online.

Correct article	Substituted article				
	a	an	the	∅	*all*
a	–	0	−2.0	−2.1	−2.1
an	0	–	−5.7	−7.3	−6.3
the	−4.1	−2.2	–	−1.7	−1.8
∅	−3.1	−3.7	−1.5	–	−1.7
all	−3.8	−3.4	−1.5	−1.8	−1.7

Table 6: Effect of article substitutions in test data (ART) relative to clean test data (CLEAN), broken down by substitution type. Different article substitutions have very different impacts on BLEU; changing an indefinite article to definite is especially damaging.

Substitution	model BLEU difference	
	CLEAN	MIX-ALL
in→with	−6.7	−1.7
on→for	−6.0	−0.1
to→on	−2.9	−0.5
in→ ∅	−1.8	−1.9
∅→for	−1.6	−0.6
∅→*any*	−1.2	−0.4
any→∅	−0.8	−0.7

Table 7: Effect of selected preposition substitutions in test data (PREP) relative to clean test data (CLEAN), for the CLEAN and MIX-ALL models. The MIX-ALL model handles most errors more efficiently.

work, they primarily focus on a setting where the training set is noisy but the test set is clean.

In addition, Heigold et al. (2018) evaluated the robustness of word embeddings against word scrambling noise, and showed that performance in downstream tasks like POS-tagging and MT is especially hurt. Sakaguchi et al. (2017a) studied word scrambling and the *Cmabrigde Uinervtisy (Cambridge University) effect*, where humans are able to understand the meaning of sentences with scrambled words, performing word recognition (word level spelling correction) with a semi-character RNN system.

Focusing only on character-level NMT models, Belinkov and Bisk (2018) showed that they exhibit degraded performance when presented with noisy test examples (both artificial and natural occurring noise). In line with our findings, they also showed that slightly better performance can be achieved by training on data artificially induced with the same kind of noise as the test set.

Sperber et al. (2017) proposed a noise-introduction system reminiscent of WER, based on insertions, deletions, and substitutions. An NMT system tested on correct transcriptions achieves a BLEU score of 55 (4 references), but tested on the ASR transcriptions it only achieves a BLEU score of 35.7. By introducing similar noise in the training data, they were able to make the NMT system slightly more robust. Interestingly, they found that the optimal amount of noise on the training data is smaller than the amount of noise on the test data.

The notion of linguistically plausible corruption is also explored by Li et al. (2017), who created adversarial examples with syntactic and semantic noise (reordering and word substitutions respectively). When training with these noisy datasets, they obtained better performance on several text classification tasks. Furthermore, in accordance with our results, their best system is the one that combines different types of noise.

We present a summary of relevant previous work in Table 8. *Synthetic* errors refer to noise introduced according an artificially created distribution, and *natural* errors refer to actual errorful text produced by humans. As for *semi-natural*, it refers to either noise introduced according to a distribution learned from data (as in our work), or to errors that are learned from data but introduced according to an artificial distribution (as is part of the work of Belinkov and Bisk (2018)).

We consider our work to be complementary to the works of Heigold et al. (2018); Belinkov and Bisk (2018), and Sperber et al. (2017). However, there are several important differences:

1. Belinkov and Bisk (2018) and Sperber et al. (2017) train their NMT systems on fairly small datasets: 235K (Fr-En), 210K (De-En), 122K (Cz-En), and 138K sentences (Es-En) respectively. Even though they use systems like Nematus (Sennrich et al., 2017) or XNMT (Neubig et al., 2018) which generally achieve nearly SOTA results, it is unclear whether their results generalize to larger training data. In contrast, we train our system on almost 2M sentences.
2. All three systems introduce somewhat unrealistic amounts of noise in the data. The natural noise of Belinkov and Bisk (2018) consists of word substitutions based on Wikipedia errors or corrected essays (in the

Work	Errors	Noise Types	NMT level	Languages
(Heigold et al., 2018)	synthetic	character swaps, character flips, word scrambling	char, BPE	De→En
(Sperber et al., 2017)	synthetic	ASR errors	word	Es→En
(Belinkov and Bisk, 2018)	synthetic	character swap, middle scramble, full scramble, keyboard typo	char, BPE	Fr,De,Cz→En
	semi-natural	word substitutions		
this work	semi-natural	grammar errors: article, preposition, noun number, verb agreement	BPE	En→Es
	natural	JFLEG corpus		

Table 8: Previous work on evaluating the effect of noise in NMT systems. Character swaps refer to neighboring character reordering (e.g. noise→nosie), while character flips refer to character substitutions (e.g. noise→noiwe).

Czech case) but they substitute all possible correct words with their erroneous version, ending up with datasets with more than 40% of the tokens being noisy. For that reason, we refer to it as *semi-natural* noise in Table 8. Meanwhile, Sperber et al. (2017) test on the outputs of an ASR system that has a WER of 41.3%. For comparison, in the JFLEG datasets, we calculated that only about 3.5%–5% of the tokens are noisy – the average Levenshtein distance of a corrected reference and its noisy source is 13 characters.

3. The word scrambling noise, albeit interesting, could not be claimed to be applicable to realistic scenarios, especially when applied to all words in a sentence. The solution Belinkov and Bisk (2018) suggested and Sperber et al. (2017) discussed is a character- or spelling-aware model for producing word- or subword-level embeddings. We suspect that such a solution would indeed be appropriate for dealing with typos and other character-level noise, but not for more general grammatical noise. Our method could potentially be combined with GloVe (Pennington et al., 2014) or fastText (Bojanowski et al., 2017) embeddings that can deal with slight spelling variations, but we leave this for future work.

On the other side, Grammar Error Correction has been extensively studied, with significant incremental advances made recently by treating GEC as an MT task: among others, Junczys-Dowmunt and Grundkiewicz (2016) used phrased-based MT, Ji et al. (2017) used hybrid character-word neural sequence-to-sequence systems, Sakaguchi et al. (2017b) used reinforcement learning, and Junczys-Dowmunt et al. (2018) combined several techniques with NMT to achieve the current state-of-the-art. Synthetic errors for training GEC systems have also been studied and applied with mixed success (Rozovskaya and Roth, 2010; Rozovskaya et al., 2014; Xie et al., 2016), while more recently Xie et al. (2018) used backtranslation techniques to add synthetic noise for GEC.

6 Conclusion

In this work, we studied the effect of grammatical errors in NMT. We not only confirmed previous findings, but also expanded on them, showing that *realistic human-like* noise in the form of specific grammatical errors also leads to degraded performance. We added synthetic errors on the English WMT training, dev, and test data (including dev and test sets for all WMT 18 evaluation pairs), and have released them along with the scripts necessary for reproducing them. We also produced Spanish translations of the JFLEG corpus, so that future NMT systems can be properly evaluated on real noisy data.

Abstract

In domain adaptation for neural machine translation, translation performance can benefit from separating features into domain-specific features and common features. In this paper, we propose a method to explicitly model the two kinds of information in the encoder-decoder framework so as to exploit out-of-domain data in in-domain training. In our method, we maintain a private encoder and a private decoder for each domain which are used to model domain-specific information. In the meantime, we introduce a common encoder and a common decoder shared by all the domains which can only have domain-independent information flow through. Besides, we add a discriminator to the shared encoder and employ adversarial training for the whole model to reinforce the performance of information separation and machine translation simultaneously. Experiment results show that our method can outperform competitive baselines greatly on multiple data sets.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017) has made great progress and drawn much attention recently. Most NMT models are based on the encoder-decoder architecture, where all the sentence pairs share the same set of parameters for the encoder and decoder which makes NMT models have a tendency towards overfitting to frequent observations (e.g., words, word co-occurrences, translation patterns), but overlooking special cases that are not frequently observed. However, in practical applications, NMT models usually need to perform translation for some specific domain with only a small quantity of in-domain training data but a large amount of out-of-domain data. Simply combining in-domain training data with out-of-domain data will lead to overfitting to the out-of-domain data. Therefore, some domain adaptation technique should be adopted to improve in-domain translation.

Fortunately, out-of-domain data still embodies common knowledge shared between domains. And incorporating the common knowledge from out-of-domain data can help in-domain translation. Britz et al. (2017) have done this kind of attempts and managed to improve in-domain translation. The common architecture of this method is to share a single encoder and decoder among all the domains and add a discriminator to the encoder to distinguish the domains of the input sentences. The training is based on adversarial learning between the discriminator and the translation , ensuring the encoder can learn common knowledge across domains that can help to generate target translation. Zeng et al. (2018) extend this line of work by introducing a private encoder to learn some domain specific knowledge. They have proven that domain specific knowledge is a complement to domain invariant knowledge and indispensable for domain adaptation. Intuitively, besides the encoder, the knowledge inferred by the decoder can also be divided into domain specific and domain invariant and further improvement will be achieved by employing private decoders.

In this paper, in order to produce in-domain translation with not only common knowledge but in-domain knowledge, we employ a common encoder and decoder among all the domains and also a private encoder and decoder for each domain separately. The differences between our method and the above methods are in two points: first, we employ multiple private encoders rather where all the domains only have one private encoder; sec-

ond, we also introduce multiple private decoders contrast to no private decoder. This architecture is based on the consideration that out-of-domain data is far more than in-domain data and only using one private encoder and/or decoder has the risk of overfitting. Under the framework of our method, the translation of each domain is predicted on the output of both the common decoder and its private decoder. In this way, the in-domain private decoder has direct influence to the generation of in-domain translation and the out-of-domain decoder is used to help train the common encoder and decoder better which can also help in-domain translation. We conducted experiments on English→Chinese and English↔German domain adaptation tasks for machine translation under the framework of RNNSearch (Bahdanau et al., 2014) and Transformer (Vaswani et al., 2017) and get consistently significant improvements over several strong baselines.

2 Related Work

The task of domain adaptation for NMT is to translate a text in-domain for which only a small number of parallel sentences is available. The main idea of the work for domain adaptation is to introduce external information to help in-domain translation which may include in-domain monolingual data, meta information or out-of-domain parallel data.

To exploit in-domain monolingual data, Gülçehre et al. (2015) train a RNNLM on the target side monolingual data first and then use it in decoding. Domhan and Hieber (2017) further extend this work by training the RNNLM part and translation part jointly. Sennrich et al. (2015a) propose to conduct back translation for the monolingual target data so as to generate the corresponding parallel data. Zhang and Zong (2016) employs the self-learning algorithm to generate the synthetic large-scale parallel data for NMT training. To introduce meta information, Chen et al. (2016) use the topic or category information of the input text to assistant the decoder and Kobus et al. (2017) extend the generic NMT models, which are trained on a diverse set of data to, specific domains with the specialized terminology and style.

To make use of out-of-domain parallel data, Luong and Manning (2015) first train an NMT model with a large amount of out-of-domain data, then fine tune the model with in-domain data. Wang et al. (2017a) select sentence pairs from the out-of-domain data set according to their similarity to the in-domain data and then add them to the in-domain training data. Chu et al. (2017) construct the training data set for the NMT model by combining out-of-domain data with the over-sampled in-domain data. Wang et al. (2017b) combine the in-domain and out-of-domain data together as the training data but apply instance weighting to get a weight for each sentence pair in the out-of-domain data which is used in the parameter updating during back propagation. Britz et al. (2017) employ a common encoder to encode the sentences from both the in-domain and out-of-domain data and meanwhile add a discriminator to the encoder to make sure that only domain-invariant information is transferred to the decoder. They focus on the situation that the quantity of the out-of-domain data is almost the same as the in-domain data while our method can handle more generic situations and there is no specific demand for the ratio of the quantity between the in-domain and out-of-domain data. Besides, our method employs a private encoder-decoder for each domain which can hold the domain-specific features. In addition to the common encoder, Zeng et al. (2018) further introduce a domain-specific encoder to each domain together with a domain-specific classifier to ensure the features extracted by the domain-specific encoder is proper. Compared to our method, they focus on the encoder and do not distinguish the information in the decoder.

Adversarial Networks have achieved great success in some areas (Ganin et al., 2016; Goodfellow et al., 2014). Inspired by these work, we also employ a domain discriminator to extract some domain invariant features which has already shown its effectiveness in some related NLP tasks. Chen et al. (2017) use a classifier to exploit the shared information between different Chinese word segment criteria. Gui et al. (2017) tries to learn common features of the out-domain data and in-domain data through adversarial discriminator for the part-of-speech tagging problem. Kim et al. (2017) train a cross-lingual model with language-adversarial training to generate the general information across different languages for the POS tagging problem. All these work try to utilize a discriminator to distinguish invariant features across the divergence.

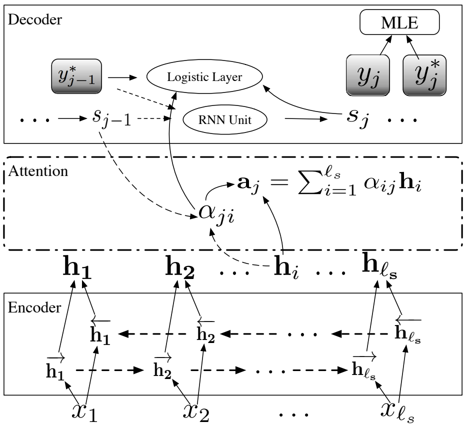

Figure 1: The architecture of the attention-based NMT.

3 RNN-based NMT model

Our method can be applied to both the RNN-based NMT model (Bahdanau et al., 2014) and self-attention-based NMT model (Vaswani et al., 2017). In this paper, we will introduce our method under the RNN-based framework and the application to the self-attention-based framework can be implemented in a similar way. Before introducing our method, we will first briefly describe the RNN-based NMT model with attention shown in Figure 1.

The encoder uses two GRUs to go through source words bidirectionally to get two hidden states $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ for the source word x_i, which are then concatenated to produce the final hidden states for x_i as follows

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i] \tag{1}$$

The attention layer aims to extract the source information which is most related to the generation of each target word. First it evaluates the correlation between the previous decoder hidden state $\mathbf{s}_{j-1}$ and each source hidden state $\mathbf{h}_i$ by

$$e_{ij} = \mathbf{v}_\alpha^T \tanh\left(\mathbf{W}_\alpha \mathbf{s}_{j-1} + \mathbf{U}_\alpha \mathbf{h}_i\right), \tag{2}$$

next calculates α_{ij} which is the correlation degree to each target hidden state $\mathbf{h}_i$, and then gets the attention $\mathbf{c}_j$. The formulation is as follows

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{i'=1}^{l_s}\exp(e_{i'j})}; \quad \mathbf{c}_j = \sum_{i=1}^{l_s} \alpha_{ij}\mathbf{h}_i \tag{3}$$

The decoder also employs a GRU to get the hidden state s_j for the target word y_j as

$$\mathbf{s}_j = g(y_{j-1}, \mathbf{s}_{j-1}, \mathbf{c}_j). \tag{4}$$

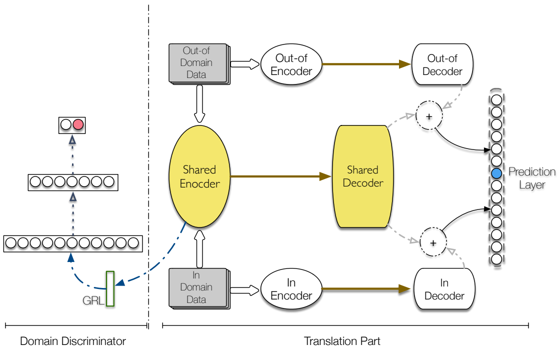

Figure 2: The architecture of the proposed method. GRL means the gradient reversal layer which will multiply a negative constant to the gradients during back-propagation.

Then the probability of the target word y_j is defined as follows

$$p(y_j|\mathbf{s}_j, y_{j-1}, \mathbf{c}_j) \propto \exp(y_j^{\mathsf{T}}\mathbf{W}_o\mathbf{t}_j) \tag{5}$$

where t_j is computed by

$$\mathbf{t}_j = \mathbf{U}_o\mathbf{s}_{j-1} + \mathbf{V}_o\mathbf{E}y_{j-1} + \mathbf{C}_o\mathbf{c}_j \tag{6}$$

4 The Proposed Method

Assume that we have two kinds of training data: out-of-domain and in-domain, and we want to get the translation for the in-domain input. The out-of-domain and in-domain data can be represented as

$$\begin{aligned} \mathbf{out} &= \{(\mathbf{x}^k, \mathbf{y}^{*k})\}_{k=1}^{N_{\mathbf{out}}} \sim \mathcal{D}_{\mathbf{out}}; \\ \mathbf{in} &= \{(\mathbf{x}^k, \mathbf{y}^{*k})\}_{k=1}^{N_{\mathbf{in}}} \sim \mathcal{D}_{\mathbf{in}} \end{aligned} \tag{7}$$

The main idea of our method is to extract domain invariant information from the out-of-domain data to improve in-domain translation. To this end, we employ a common encoder and a common decoder shared by both of the domains, and a private encoder and a private decoder for each domain. The main architecture given in Figure 2.

The working scenario of our method is as follows. When a sentence comes, it is inputted into the shared encoder and the private encoder of the corresponding domain simultaneously. Then the output of the shared encoder is fed into the shared decoder and the output of the private encoder into its corresponding private decoder. Finally, the shared decoder and the private decoder collaborate together to generate the current target word with a gate to decide the contribution ratio.

In addition, our method also introduce a discriminator to distinguish the domain of the input sentence based on the output of the shared encoder. When the discriminator cannot predict the domain of the input sentence, we can think the knowledge encoded in the shared encoder is domain invariant. This is achieved with a gradient reversal layer (GRL) so that the gradients are reversed during back-propagation. In this way, the adversarial training is performed between the translation and the discriminator.

4.1 The Translation Part

The Encoder

Our model has a shared encoder, an in-domain private encoder and an out-of-domain private encoder, where the shared encoder accepts input from the two domains. Given a sentence of domain p (p $\in \{\mathbf{in}, \mathbf{out}\}$), the shared encoder and the private encoder of domain p will roll the sentence as the encoder shown in Section 3 and the outputs of the shared encoder and the private encoder for word x_j are represented as $\mathbf{h}_j^{\mathrm{c}}$ and $\mathbf{h}_j^{\mathrm{p}}$ respectively.

The Attention Layer

As the output of the shared encoder is only fed to the shared decoder and the output of the private encoder of domain p only flows to the private decoder of domain p, we only need to calculate the attention of the shared decoder over the shared encoder and the attention of the private decoder of domain p over the private encoder of domain p. We calculate these two attentions as in Section 3 and denote them as $\mathbf{c}_j^{\mathrm{c}}$ and $\mathbf{c}_j^{\mathrm{p}}$ for the shared decoder and the private decoder, respectively.

The Decoder

We also maintain a shared decoder, an in-domain private decoder and an out-of-domain private decoder For a sentence of domain p (p $\in \{\mathbf{in}, \mathbf{out}\}$), the shared decoder and the private decoder of domain p act in the same way as shown in Equation 4 and Equation 6 and then produce the hidden states $\mathbf{s}_j^{\mathrm{c}}$ and $\mathbf{t}_j^{\mathrm{c}}$ for the shared decoder, and $\mathbf{s}_j^{\mathrm{p}}$ and $\mathbf{t}_j^{\mathrm{p}}$ for the private decoder.

To predict the target word y_j, $\mathbf{t}_j^{\mathrm{c}}$ and $\mathbf{t}_j^{\mathrm{p}}$ are weighted added to get $\mathbf{t}_j$ as

$$\begin{aligned} z_j &= \sigma(\mathbf{W}_z \mathbf{t}_j^{\mathrm{c}} + \mathbf{U}_z \mathbf{t}_j^{\mathrm{p}}); \\ \mathbf{t}_j &= z_j \cdot \mathbf{t}_j^{\mathrm{c}} + (1 - z_j) \cdot \mathbf{t}_j^{\mathrm{p}} \end{aligned} \tag{8}$$

Where $\sigma(\cdot)$ is the sigmoid function and $\mathbf{W}_z$ and $\mathbf{U}_z$ are shared by in-domain and out-of-domain. Finally the probability of the target word y_j is computed with

$$P(y_j | \dots) \propto \exp(y_j^{\mathsf{T}} \mathbf{W}_o \mathbf{t}_j); \tag{9}$$

4.2 The Domain Discriminator

The domain discriminator acts as a classifier to determine the knowledge encoded in the shared encoder is from in-domain or from out-of-domain. When a well trained discriminator can't classify the domain properly, we can think the knowledge in the shared encoder is domain invariant (Ganin et al., 2016). As CNN has shown its effectiveness in some related classification tasks (Zhang et al., 2015; Yu et al., 2017), we construct our discriminator with CNN.

First, the input to the CNN is the representation of the whole source sentence which is got by concatenating the sequence of hidden states generated by the shared encoder as

$$\Pi_{1:I} = \mathbf{h}_1 \oplus \mathbf{h}_2 \oplus \cdots \oplus \mathbf{h}_I \tag{10}$$

where I is the length of the source sentence and $\mathbf{h}_1, ..., \mathbf{h}_I$ is the hidden state of the corresponding source word. $\oplus$ stands for the concatenation operation of the hidden states, and we can get the final source sentence representation $\Pi_{1:I} \in \mathbb{R}^{I \times m}$ where m is the dimension of the hidden state.

We then employ a kernel $w \in \mathbb{R}^{l \times m}$ to apply a convolutional operation to produce a new feature map:

$$\mathbf{f} = \rho(w \otimes \Pi_{1:I} + b_f) \tag{11}$$

where ρ is the ReLU activation function, $\otimes$ stands for the convolutional operation of the kernel and b is the bias term. A number of different kinds of kernels with different windows sizes are used in our work to extract different features at different scales. Next, we apply a max-over-time pooling operation over the feature maps to get a new feature map. To further improve the performance of the discriminator, following the work (Yu et al., 2017), we also add the highway architecture (Srivastava et al., 2015; Zhang et al., 2018) behind the pooled feature maps where we use a gate to control the information flow between the two layers. Finally, the combined feature map is fed into a fully connected network with a sigmoid activation function to make the final predictions:

$$p(d) \propto \exp(\mathbf{W}_d \cdot \mathbf{f} + b_d); \tag{12}$$

where d is the domain label of in-domain or out-of-domain.

5 Training

Our final loss considers the translation loss and the domain prediction loss. For the translation loss, we employ cross entropy to maximize the translation probability of the ground truth, so we have this loss as follows and the training objective is to minimize the loss.

$$\mathcal{L}_{\mathbf{MT}} = -\sum_{k=1}^{N_{\mathbf{in}}+N_{\mathbf{out}}} \sum_{j=1}^{J^k} \log p(y_j^{*k}) \tag{13}$$

where $N_{\mathbf{in}}$ and $N_{\mathbf{out}}$ are the number of training sentences for in-domain and out-of-domain data respectively, J^k is the length of the k-th ground truth sentence, and $p(y_j^{*k})$ is the predicted probability of the j-th word for the k-th ground truth sentence.

Note that we have three different encoders and three different decoders in total, including the shared encoder and decoder, the in-domain private encoder and decoder, and the out-of-domain private encoder and decoder, and all of them have their own parameters.

For the domain prediction loss, we also use cross-entropy to minimize the following loss

$$\mathcal{L}_{\mathfrak{D}} = -\sum_{k=1}^{N_{\mathbf{in}}+N_{\mathbf{out}}} \log p(d^{*k}) \tag{14}$$

where d^{*k} is the ground truth domain label of the k-th input sequence.

Then the final loss is defined as

$$\mathcal{L} = \mathcal{L}_{\mathbf{MT}} + \lambda \mathcal{L}_{\mathfrak{D}} \tag{15}$$

where λ is a hyper-parameter to balance the effects of the two parts of loss. We gradually tried λ from 0.1 to 2.5 and set it to 1.5 in our final experiments.

Borrowing ideas from Ganin et al. (2016), we introduce a special gradient reversal layer (GRL) between the shared encoder and the domain discriminator. During forward propagation, the GRL has no influence to the model, while during back-propagation training, it multiplies a certain negative constant to the gradients back propagated from the discriminator to the shared encoder. In this way, an adversarial learning is applied between the translation part and the discriminator.

At the beginning of the training, we just use the $\mathcal{L}_{\mathbf{MT}}$ to train the translation part on the combined data, including the shared encoder-decoder and the in-domain and out-of-domain private encoder-decoder. Then we use $\mathcal{L}_{\mathfrak{D}}$ to only train the domain discriminator until the precision of the discriminator reach 90% while the parameters of the shared encoder keep unupdated. Finally, we train the whole model with the complete loss $\mathcal{L}$ with all the parameters updated. In the training process, the sentences in each batch is sampled from in-domain and out-of-domain data at the same rate.

During testing, we just use the shared encoder-decoder and the private in-domain encoder-decoder to perform in-domain translation.

6 Experiments

We evaluated our method on the English→Chinese (En-Zh), English→German (En-De) and German→English (De-En) domain adaptation translation task.

6.1 Data Preparation

English→Chinese For this task, out-of-domain data is from the LDC corpus[1] that contains 1.25M sentence pairs. The LDC data is mainly related to the **News** domain. We chose the parallel sentences with the domain label **Laws** from the UM-Corpus (Tian et al., 2014) as our in-domain data. We chose 109K, 1K and 1K sentences from the UM-Corpus randomly as our training, development and test data. We tokenized and lowercased the English sentences with Moses[2] scripts. For the Chinese data, we performed word segmentation using Stanford Segmenter[3].

English→German For this task, the training data is from the Europarl corpus distributed for the shared domain adaptation task of WMT 2007 (Callison-Burch et al., 2007) where the out-of-domain data is mainly related to the **News** domain, containing about 1.25M sentence pairs, and in-domain data is mainly related to the **News Commentary** domain which is more informal compared to the news corpus, containing about 59.1K sentences. We also used the development set of the domain adaptation shared task. Finally, we tested our method on the NC test set of WMT

---

[2] http://www.statmt.org/moses/

[3] https://nlp.stanford.edu/

2006 and WMT 2007. We tokenized and lowercased the corpora.

German→English For this task, out-of-domain corpus is from the WMT 2015 en-de translation task which are mainly **News** texts (Bojar et al., 2015) containing about 4.2M sentence pairs. For the in-domain corpus, we used the parallel training data from the IWSLT 2015 which is mainly from the the **TED talks** containing about 190K sentences. In addition, dev2012 and test2013/2014/2015 of IWSLT 2015 were selected as the development and test data, respectively. We tokenized and truecased the corpora.

Besides, 16K, 16K and 32K merging operations were performed to learn byte-pair encoding(BPE) (Sennrich et al., 2015b) on both sides of the parallel training data and sentences longer than 50, 50 and 80 tokens were removed from the training data, respectively.

6.2 Systems

We implemented the baseline and our model by PyTorch framework[4]. For the En-Zh and En-De translation task, batch size was set to 80 and vocabulary size was set to 25k which covers all the words in the training set. The source and target embedding sizes were both set to 256 and the size of the hidden units in the shared encoder-decoder RNNs was also set to 256. During experiments, we found that the shared encoder-decoder played a major role in the model and the size of the private encoder-decoder didn't influence the results too much. Thus we just set the size of the private encoder-decoder one-quarter of the shared encoder-decoder considering the training and decoding speed.

For the De-En translation task, batch size was set to 40 and vocabulary size was set to 35K in the experiment. The source and target embedding sizes were both set to 620 and the size of the hidden units in the shared encoder and decoder RNNs was set to 1000. As mentioned before, the size of the private encoder-decoder was just one-quarter of the shared encoder-decoder.

All the parameters were initialized by using uniform distribution over $[-0.1, 0.1]$. The adadelta algorithm was employed to train the model. We reshuffled the training set between epochs. Besides, the beam size was set to 10.

Contrast Methods We compared our model with the following models, namely:

- **In** : This model was trained only with the in-domain data.
- **Out + In** : This model was trained with both of the in-domain and out-of-domain data.
- **Sampler** (Chu et al., 2017) : This method over-sampled the in-domain data and concatenated it with the out-of-domain data.
- **Fine Tune** (Luong and Manning, 2015) : This model was trained first on the out-of-domain data and then fine-tuned using the in-domain data.
- **Domain Control (DC)** (Kobus et al., 2017) : This method extend word embedding with an arbitrary number of cells to encode domain information.
- **Discriminative Mixing (DM)** (Britz et al., 2017) : This method adds a discriminator on top of the encoder which is trained to predict the correct class label of the input data. The discriminator is optimized jointly with the translation part.
- **Target Token Mixing (TTM)** (Britz et al., 2017) : This method append a domain token to the target sequence.
- **Adversarial Discriminative Mixing(ADM)** (Britz et al., 2017) : This method is similar with our model which also add a discriminator to extract common features across domains. The biggest difference is that we add private parts to preserve the domain specific features. Besides we also applied a different training strategy as the section 5 describes so that our method can handle more generic situations.

Noting that our model has a private encoder-decoder which brings extra parameters, we just slightly extend the hidden size of the contrast model to make sure that the total parameter number of the contrast model is equal to the number of our model's translation part.

6.3 Main Results

The **En-Zh Experiments** Results are measured using char based 5-gram BLEU score (Papineni et al., 2002) by the *multi-bleu.pl* script. The main results are shown in Table 1. On both of the development set and test set, our model significantly outperforms the baseline models and other contrast models. Furthermore, we got the following conclusions:

First, the baseline model 'In' surpass the 'Out + In' model which shows that the NMT model tends to fit out-of-domain features if we directly include

out-of-domain data into the in-domain data, as the domain specific features embodied in out-of-domain data is in greater quantity than that in in-domain data. However, we also found that the model will over fit so soon if we only use the in-domain data so it is necessary to make use of the out-of-domain data to improve the translation performance.

Second, we found that when the in-domain data is much less than the out-of-domain data, some contrast methods for domain adaptation, such as DC, DM TTM and ADM, didn't perform well. They were worse than the baseline model 'in' and only slightly better than 'out + in'. These methods all try to take domain information into translation in their own ways which actually brings improvement compared with the 'out + in' model. However, as the out-of-domain data is much more than the in-domain data, the model will still tends to fit out-of-domain data and ignore the in-domain information which will degrade the final performance. Therefore, it is necessary to handle the in-domain data separately in some way. The 'Sampler' and 'Fine Tune' perform better because they receive much more information from the in-domain data compared with other methods, but they don't make use of the domain information when translating.

Last, our model achieves the best performance among all the contrast models. The shared encoder extract the domain invariant features of the two domains with the help of the discriminator so that the shared part will be well trained using all the in-domain and out-of-domain data. At the meantime, we also consider the domain specific features and the private encoder-decoder can re-

ceive enough information from the in-domain data to prevent the whole model from overfitting the out-of-domain features.

The **En-De Experiments** and **De-En Experiments** results are shown in the Table 2 and Table 3. Results are measured using word based 4-gram BLEU score (Papineni et al., 2002) by the *multi-bleu.pl* script. In these two experiments, we only compared our method with the baseline model and the competitive contrast methods 'Sampler' (Kobus et al., 2017) and 'Fine Tune' (Luong and Manning, 2015). Similar to the previous experiment results, our method still achieves the best performance compared to all contrast models, which demonstrates again that our model is effective and general to different language pairs and different domains.

6.4 Experiment Analysis

We made some some detailed analysis to empirically show the effectiveness of our model based on En-Zh translation task.

6.4.1 Ablation Study

In order to further understand the impact of the components of the proposed model, we performed some further studies by training multiple versions of our model by removing some components: The first model removed the domain discriminator but preserved the private part. The second one removed the private encoder-decoder but kept the domain discriminator. The last one just removed both of those two parts.

Results are shown in the Table 4. As expected, the best performance is obtained with the simultaneous use of all the tested elements. When we removed the private encoder-decoder, the result shows that the score was reduced by 0.79, which indicates that our private part can preserve some useful domain specific information which is abandoned by the shared encoder. When we removed the discriminator, the result was reduced by 0.76. This result supports our idea that modeling common features from out-of-domain data can benefit in-domain translation. When we removed both of the two components, we got the lowest score. The total result shows that every component of our model plays an important role in our model.

Full Model	(-4.4, 3.0)	(13.2,-9.0)	21.3

Table 5: The average coordinates value and its distance of the the hidden states. '- DCN' is the model without domain discriminator.

6.4.2 Impact of the Discriminator

To verify whether the discriminator have learned the domain invariant knowledge, we did the following experiments using model **without discriminator** and our **full model** with the domain discriminator of the former subsection.

We sampled 3000 sentences randomly from the out-of-domain and 1000 sentences from the in-domain En-Zh parallel sentences as the test data. Then they were fed into the shared encoders of the two models to get the reshaped feature maps as the Equation 11 describes. Next, we used the t-Distributed Stochastic Neighbor Embedding(t-SNE)[5] technique to do a dimensionality reduction to the hidden state. Results are shown in the Figure 3. We also calculate the average value of the coordinates of each domain's hidden state. The results are shown in Table 5

In	32.61	30.33	31.47
Sampler	35.84	33.68	34.76
Fine Tune	36.01	34.03	35.02
our method	37.26**	35.39**	36.33

Table 7: Results of the En-Zh experiments based on the transformer model.

From the figure, we can find that here is an obvious separation in the results of the model without discriminator and the numerical analysis also support this point, which indicates that the shared encoder without the help of discriminator will treat the data from different domains differently. All the domain shared features and domain specific features are just mixed together. On the contrary, the output of the shared encoder of our full model is well distributed. This proves that the discriminator can help the shared encoder to extract domain invariant features which then help to improve the translation performance in in-domain.

6.4.3 Out-of-domain Translation Performance

Despite the fact that the purpose of our work is to improve the in-domain translation performance, the domain invariant features extracted from the training data are also beneficial to the out-of-domain translation performance. To prove this, we use the NIST 03 04 and 05 test sets which are mainly related to the **News** domain as our out-of-domain test set. Noting that the origin set was designed for the Zh-En translation task and each sentence has four English references, we just chose the first reference as the source side sentence for our En-Zh translation task. The results are shown in the Table 6 We can conclude from the results that the "Fine Tune" method suffered a catastrophic forgetting caused by parameter shift during the training process. On the contrary, our method can achieve a mild improvement on the out-of-domain compared to the baseline system.

6.4.4 Combined With Transformer Model

Transformer (Vaswani et al., 2017) is an efficient NMT architecture. To test the generality of our method, we also conducted relevant experiments based on the transformer model. We did the experiment based on the Fairseq code[6]. The implementation on this translation framework is similar with the way on the RNN based models. The encoder and decoder of our final model consist 3 sublayers. The number of the multi-head attention was set to 4 and the embedding dim was set to 256. We also compared with the 'Sampler' and 'Fine Tune' method based on transformer. The results are shown in 7. According to the table, our method still outperforms than other models, which can prove that our method has a good generality across different translation architecture.

7 Conclusions

In this paper, we present a method to make use of out-of-domain data to help in-domain translation. The key idea is to divide the knowledge into domain invariant and domain specific. The realization way is to employ a shared encoder-decoder to process domain invariant knowledge and a private encoder-decoder for each domain to process knowledge of the corresponding domain. In addition, a discriminator is added to the shared encoder and adversarial learning is applied to make sure the shared encoder can learn domain invariant knowledge. We conducted experiments on multiple data sets and get consistent significant improvements. We also verified via experiments that the shared encoder, the domain specific private encoder-decoder and the discriminator all make contribution to the performance improvements.

Abstract

Despite the progress made in sentence-level NMT, current systems still fall short at achieving fluent, good quality translation for a full document. Recent works in context-aware NMT consider only a few previous sentences as context and may not scale to entire documents. To this end, we propose a novel and scalable top-down approach to hierarchical attention for context-aware NMT which uses sparse attention to selectively focus on relevant sentences in the document context and then attends to key words in those sentences. We also propose single-level attention approaches based on sentence or word-level information in the context. The document-level context representation, produced from these attention modules, is integrated into the encoder or decoder of the Transformer model depending on whether we use monolingual or bilingual context. Our experiments and evaluation on English-German datasets in different document MT settings show that our selective attention approach not only significantly outperforms context-agnostic baselines but also surpasses context-aware baselines in most cases.

1 Introduction

Neural machine translation has grown immensely in the past few years, from the simplistic RNN-based encoder-decoder models (Sutskever et al., 2014; Bahdanau et al., 2015) to the state-of-the-art Transformer architecture (Vaswani et al., 2017). Most of these models rely on the attention mechanism as a major component, which involves focusing on different parts of a sequence to compute new representations, and has proven to be quite effective in improving the translation quality (Vaswani et al., 2017). However, all of these models share the same inherent problem: the translation is still performed on a sentence-by-sentence basis, thus ignoring the long-range dependencies which may be useful when it comes to translating discourse phenomena.

More recently, **context-aware NMT** has been gaining significant traction from the MT community with majority of works coming out in the past two years. Most of these focus on using a few previous sentences as context (Jean et al., 2017; Wang et al., 2017; Tu et al., 2018; Voita et al., 2018; Zhang et al., 2018; Miculicich et al., 2018) and neglect the rest of the document. Only one existing work has endeavoured to consider the full document context (Maruf and Haffari, 2018), thus proposing a more generalised approach to document-level NMT. However, the model is restrictive as the document-level attention computed is sentence-based and static (computed only once for the sentence being translated). A more recent work (Miculicich et al., 2018) proposes to use a hierarchical attention network (HAN) (Yang et al., 2016) to model the contextual information in a structured manner using word-level and sentence-level abstractions; yet, it uses a limited number of past source and target sentences as context and is not scalable to entire document.

In this work, we propose a **selective attention** approach to first selectively focus on relevant sentences in the global document-context and then attend to key words in those sentences, while ignoring the rest.[1] Towards this goal, we use **sparse attention**, enabling an efficient and scalable use of the context. The intuition behind this is the way humans translate a sentence containing ambiguous words. They may look for sentences in the whole document which contain similar words and just focus on those for the translation. This attention,

---

[*] Work initiated during an internship at Unbabel.

[1] The term "selective attention" comes from cognitive science and is defined as the act of focusing on a particular object for a period of time while simultaneously ignoring irrelevant information that is also occurring (Dayan et al., 2000).

Proceedings of NAACL-HLT 2019, pages 3092–3102
Minneapolis, Minnesota, June 2 - June 7, 2019.

which we call Hierarchical Attention, is computed dynamically for each query word. Furthermore, we propose a Flat Attention approach which is based on either sentence or word-level information in the context. We integrate the document-level context representation, produced from these attention modules, into the encoder or decoder of the Transformer model depending on whether we consider monolingual (source-side) or bilingual (both source and target-side) context.

Our contributions are as follows: (i) we propose a novel and efficient top-down approach to hierarchical attention for context-aware NMT, (ii) we compare variants of selective attention with both context-agnostic and context-aware baselines, and (iii) we run experiments in both online (only past context) and offline (both past and future context) settings on three English-German datasets. Experiments show that our approach improves upon the Transformer by an overall +1.34, +2.06 and +1.18 BLEU for TED Talks, News-Commentary and Europarl, respectively. It also outperforms two recent context-aware baselines (Zhang et al., 2018; Miculicich et al., 2018) in majority of the cases.

2 Background

2.1 Neural Machine Translation

Generic NMT models are based on an encoder-decoder architecture (Bahdanau et al., 2015; Vaswani et al., 2017). The encoder reads the source sentence denoted by $\boldsymbol{x} = (x_1, x_2, ..., x_M)$ and maps it to a continuous representation $\boldsymbol{z} = (z_1, z_2, ..., z_M)$. Given $\boldsymbol{z}$, an attentional decoder generates the target translation $\boldsymbol{y} = (y_1, y_2, ..., y_N)$ one word at a time in a left-to-right fashion. The popular Transformer architecture (Vaswani et al., 2017) follows the same structure by using stacked self-attention and point-wise, fully connected layers for both the encoder and decoder.

Encoder The encoder stack is composed of L identical layers, each containing two sub-layers. The first, a multi-head self-attention sub-layer, allows each position in the encoder to attend to all positions in the previous layer of the encoder, while the second, a feed-forward network, uses two linear transformations with a ReLU activation.

Decoder The decoder stack is also composed of L identical layers. In addition to the two sub-layers, the decoder inserts a third sub-layer, which performs multi-head attention over the output of the encoder stack. Masking is used in the self-attention sub-layer to prevent positions from attending to subsequent positions thus avoiding leftward flow of information.

2.2 Document-level Machine Translation

In general, the probability of a document translation $\boldsymbol{Y}$ given the source document $\boldsymbol{X}$ is given by:

$$P_{\boldsymbol{\theta}}(\boldsymbol{Y}|\boldsymbol{X}) = \prod_{j=1}^{J} P_{\boldsymbol{\theta}}(\boldsymbol{y}^j|\boldsymbol{x}^j, \boldsymbol{D}_{-j}) \qquad (1)$$

where $\boldsymbol{y}^j$ and $\boldsymbol{x}^j$ denote the j^{th} target and source sentence, respectively, and $\boldsymbol{D}_{-j} = \{\boldsymbol{X}_{-j}, \boldsymbol{Y}_{-j}\}$ is the collection of all other sentences in the source and target document. Since generic NMT models translate one word at a time, Eq. 1 becomes:

$$P_{\boldsymbol{\theta}}(\boldsymbol{Y}|\boldsymbol{X}) = \prod_{j=1}^{J}\prod_{n=1}^{N} P_{\boldsymbol{\theta}}(y_n^j|\boldsymbol{y}_{<n}^j, \boldsymbol{x}^j, \boldsymbol{D}_{-j}) \quad (2)$$

where y_n^j is the n^{th} word of the j^{th} target sentence and $\boldsymbol{y}_{<n}^j$ are the previously generated words.

Training The document-conditioned NMT model $P_{\boldsymbol{\theta}}(\boldsymbol{y}^j|\boldsymbol{x}^j, \boldsymbol{D}_{-j})$ is realised using a neural architecture and usually trained via a two-step procedure (Maruf and Haffari, 2018; Miculicich et al., 2018). The first step involves pre-training a standard sentence-level NMT model, and the second step involves optimising the parameters of the whole model, i.e., both the document-level and the sentence-level parameters.

Decoding To generate the best translation for a full document according to the document MT model, the problem of maximizing Eq. 1 is solved using a two-pass Iterative Decoding strategy (Maruf and Haffari, 2018): first, the translation of each sentence is initialised using the sentence-based NMT model; then, each translation is updated using the context-aware NMT model fixing the other sentences' translations.

3 Proposed Approach

The main goal of this paper is to have a document-level NMT model which is memory-efficient, scalable, and capable of listening to the entire document. To achieve this, we augment a sentence-level NMT model (the Transformer (Vaswani et al., 2017)) with an efficient hierarchical attention mechanism which has the ability to identify the key sentences in the document context and then attend to the key words within those sentences. As mentioned previously, we want to maximise $P_{\boldsymbol{\theta}}(\boldsymbol{y}^j|\boldsymbol{x}^j, \boldsymbol{D}_{-j})$, where we take $\boldsymbol{D}_{-j}$ to be either the monolingual source or bilingual source and target-side context in two settings: *offline*—the context comes from both past and future, and *online*—the context comes from only the past.

In this section, we show how to represent the document-level context using our Context Layer, how to regulate the information at the sentence and document-level using context gating and finally we present our integrated model.

3.1 Document-level Context Layer

The context $\boldsymbol{D}_{-j}$ is modeled via a single Document-level Context Layer comprising of two sub-layers: (i) a Multi-Head Context Attention sub-layer, and (ii) a Feed-Forward sub-layer, where the former consists of either a top-down Hierarchical Attention module or a Flat Attention module (explained shortly), and the latter is similar to the Feed-Forward network in the original Transformer architecture. Each sub-layer is followed by a layer normalisation.[2]

Let us now describe the attention modules which independently form the Multi-Head Context Attention sub-layer.

3.1.1 Hierarchical Attention

Our hierachical attention module H-Attention(Q_s, Q_w, K_s, K_w, V_w) (Figure 1) is a reformulation of the Scaled Dot-Product Attention of Vaswani et al. (2017). Here, we have five inputs consisting of two types of keys and queries, one each for the sentences and the words, while the values are based only on words in the context. The Hierarchical Attention module has four operations:

1. **Sentence-level Key Matching:** This is performed on a set of queries simultaneously, packed together into a matrix Q_s. The sentence-level keys are also packed into a matrix K_s. We will describe in §3.3 how Q_s and K_s are computed. The attention weights are computed as:

$$\alpha_s = \text{sparsemax}(Q_s {K_s}^T / \sqrt{d_k}) \qquad (3)$$

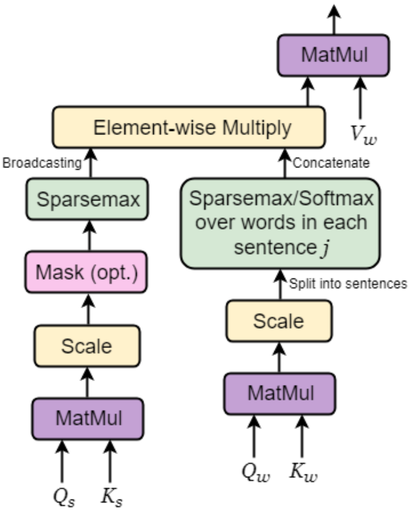

Figure 1: Hierarchical Context Attention module.

where d_k is the dimension of the keys, and α_s has dimensions equal to the total number of sentences in the document. We propose to use **sparsemax** (Martins and Astudillo, 2016), instead of softmax, as this gives us the intended selective attention behavior, that is identifying the key sentences that may potentially be relevant to the current sentence, hence making the model more efficient in compressing its memory. A softmax attention, on the other hand, can still assign low probability to sentences, forming a long-tail and absorbing significant probability mass, and it cannot fully *ignore* those sentences. An additive mask is used (before the *sparsemax* operation) based on whether we train for offline or online setting by masking out only the current sentence or current and future sentences, respectively.

2. **Word-level Key Matching:** Here the query and key matrices, Q_w and K_w, are word-level. We perform a word-level key matching for each sentence j in the document:

$$\alpha_w^j = \text{sparsemax}(Q_w {K_w^j}^T / \sqrt{d_k}) \qquad (4)$$

where α_w^j is the word-level attention vector for j^{th} sentence.[3] We can also use softmax, instead of sparsemax, for a coarser key matching. We explore the two variants in our experiments.

3. **Re-scaling attention weights:** The word-level attention is further re-weighted by the cor-

---

[2] We do not have residual connections after sub-layers in our Document-level Context Layer as we found them to have a deteriorating effect on the translation scores (also reported by Zhang et al. (2018)).

[3] This can be done for only the sentences with non-zero probabilities (obtained from the sentence-level key matching), however, we found it to be computationally expensive, as it required breaking down the batched matrices.

responding sentence-level attention (Nallapati et al., 2016) such that the probability of j^{th} sentence in a document is given by:

$$\alpha^{j}_{hier} = \alpha_s(j)\alpha^{j}_{w} \tag{5}$$

where $\alpha_s(j)$ is the attention weight for the j^{th} sentence obtained via Eq. 3 and α^{j}_{w} is as in Eq. 4. The re-weighting, thus, produces a scaled attention vector $\alpha_{hier} = \text{Concat}(\alpha^{1}_{hier}, ..., \alpha^{J}_{hier})$, each entry of which corresponds to the attention weight for a specific word in the document.

4. **Value Reading:** The set of word-level values is packed together into a matrix V_w and the matrix of outputs is given by $\alpha_{hier}V_w$. This multiplication, combined with sparsemax attention, allows to *prune* the hierarchy.

We further extend the MULTIHEAD attention function proposed by Vaswani et al. (2017) for our Hierarchical Attention module as:

$$\text{H-MULTIHEAD}(Q_s, K_s, Q_w, K_w, V_w) = \text{Concat}(head_1, ..., head_H)W^O$$

where $head_h = \text{H-Attention}(Q_sW_h^{Q_s}, Q_wW_h^{Q_w}, K_sW_h^{K_s}, K_wW_h^{K_w}, V_wW_h^{V_w})$, W's are parameter matrices and all (five) inputs are transformed using separate linear layers.

3.1.2 Flat Attention

Another way to model the context $\boldsymbol{D}_{-j}$ is via single-level attention by re-using the Scaled Dot-Product Attention in Vaswani et al. (2017),

$$\text{Attention}(Q, K, V) = \text{softmax}(QK^T/\sqrt{d_k})V \tag{6}$$

The attention[4] here is of two types: (i) *sentence-level* if K, V are computed for sentences in the document, or (ii) *word-level* if K, V are computed for words in the document. The former module is similar to the Memory Networks architecture of Maruf and Haffari (2018) in that it uses sentence-level information. However, there are two key differences: (i) we use MultiHead attention as in the Transformer architecture, and (ii) our context attention is dynamic such that we have a separate attention for each query word.

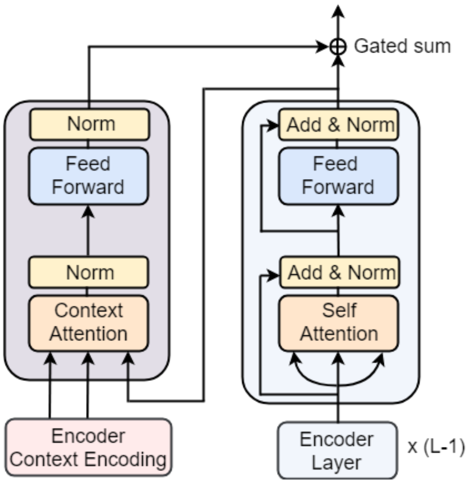

Figure 2: Encoder-side context integration.

3.2 Context Gating

As mentioned previously, the Multi-Head Context Attention sub-layer is part of the Context Layer (Figure 2), the output of which is fed into the Transformer architecture through context gating (Tu et al., 2018). For i^{th} word in source or target:

$$\gamma_i = \sigma(W_r r_i + W_d d_i) \tag{7}$$

$$\tilde{r}_i = \gamma_i \odot r_i + (1 - \gamma_i) \odot d_i \tag{8}$$

where W's are parameter matrices, r_i is the output of encoder or decoder stack for i^{th} word, d_i is the output from the context layer for i^{th} word and $\tilde{r}_i$ is the final hidden representation for the same.

3.3 Integrated Model

The context can be integrated into the encoder or decoder of the NMT model depending on if it is monolingual or bilingual.[5]

Monolingual context integration in Encoder We add the Document-level Context Layer alongside the encoder stack as shown in Figure 2. The Encoder Context Encoding block stores the keys and values produced from the pre-trained sentence-level NMT model. For word-level attention, the keys K_w and values V_w are composed of vector representations (from last encoder layer) of source words in the document, while for the sentence-level attention, the keys K_s and values V_s are composed of vector representations of sentences in the document where the vector representation of each sentence is an average of the word

---

[4] We plan to investigate sparse flat attention in future work.

[5] We do not integrate context into both encoder and decoder as it would have redundant information from the source (the context incorporated in the decoder is bilingual), in addition to increasing the complexity of the model.

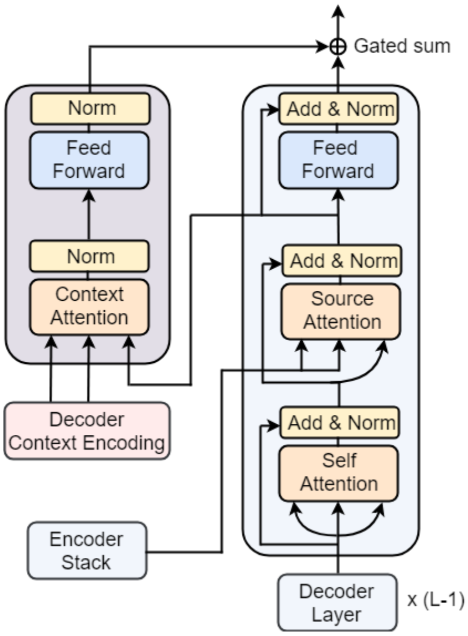

Figure 3: Decoder-side context integration.

representations in that sentence. The queries Q_w, Q_s are linear transformations of the output of the L^{th} encoder layer which are then matched with the corresponding keys and values stored in the Encoder Context Encoding block just described.

Bilingual context integration in Decoder We again add the Document-level Context Layer alongside the decoder stack as in Figure 3. However, instead of choosing the keys and values to be monolingual as in the encoder, we follow Tu et al. (2018) in choosing the key to match to the source-side context, while designing the value to match to the target-side context. Hence, the keys (in the Decoder Context Encoding block) are composed of context vectors from the Source Attention sub-layer, while the values are composed of the hidden representations of the target words, both from the last decoder layer. Again the keys K_w and K_s are either for individual target words or target sentences, and same goes for V_w and V_s. The queries Q_w, Q_s for the Context Layer come from the Source Attention sub-layer in the L^{th} layer of the decoder (Figure 3).

4 Experiments

4.1 Setup

Datasets We conduct experiments for English→German on three different domains: TED talks, News-Commentary and Europarl. These datasets are chosen based on their variance in genre, style and level of formality:

Domain	#Sentences	Document length
TED	0.21M/9K/2.3K	120.89/96.42/98.74
News	0.24M/2K/3K	38.93/26.78/19.35
Europarl	1.67M/3.6K/5.1K	14.14/14.95/14.06

Table 1: Training/development/test corpora statistics: number of sentences (K stands for thousands and M for millions), and average document length (in sentences).

- **TED** This corpus is from the IWSLT 2017 MT track (Cettolo et al., 2012) and contains transcripts of TED talks aligned at sentence level. Each talk is considered to be a document. We combine *tst2016-2017* into the test set and the rest are used for development.
- **News-Commentary** We obtain the sentence-aligned document-delimited News Commentary v11 corpus for training.[6] The WMT'16 *news-test2015* and *news-test2016* are used for development and testing, respectively.
- **Europarl** This dataset is extracted from Europarl v7 (Koehn, 2005). The source and target sentences are aligned using the links provided by Tiedemann (2012). Following Maruf and Haffari (2018), we use the *SPEAKER* tag as the document delimiter. Documents longer than 5 sentences are kept and the resulting corpus is randomly split into training, dev and test sets.

The corpora statistics are provided in Table 1. All datasets are tokenised and truecased using the Moses toolkit (Koehn et al., 2007), and split into subword units using a joint BPE model with 30K merge operations (Sennrich et al., 2016).

Models and Baselines For offline document MT, we have two context-agnostic baselines: (i) a modified version of RNNSearch (Bahdanau et al., 2015), which incorporates dropout on the output layer and improves the attention model by feeding the previously generated word, and (ii) the state-of-the-art Transformer architecture. For the online case, we again have the Transformer as a context-agnostic baseline and two context-aware baselines (Zhang et al., 2018; Miculicich et al., 2018).

All models are implemented in C++ using DyNet (Neubig et al., 2017). For RNNSearch, we modify the sentence-based NMT implementation in *mantis* (Cohn et al., 2016). The encoder is a single layer bidirectional GRU (Cho et al., 2014) and

Table 3: BLEU and Meteor scores for variants of our model and three baselines for online document MT. **bold**: Best performance. $\star$, $\diamondsuit$, $\clubsuit$: Statistically significantly better than our implementations of Zhang et al. (2018), Miculicich et al. (2018), or both. All reported results for our model are significantly better than the Transformer.

the decoder is a 2-layer GRU with embeddings and hidden dimensions set to 512. The dropout rate for the output layer is set to 0.2. For the Transformer, we use *Transformer-DyNet*[7] implementation and extend it for our context-aware NMT model.[8] The hidden dimensions and feed-forward layer size is set to 512 and 2048 respectively. We use 4 layers[9] each in the encoder and decoder with 8 attention heads and employ label smoothing with a value of 0.1. We also employ all four types of dropouts as in the original Transformer with a rate of 0.1 for the sentence-based model and 0.2 for our context-aware model.

For training all models, we use the default Adam optimiser (Kingma and Ba, 2015) with an initial learning rate of 0.0001 and employ early stopping. For our context-aware NMT model, we use a two-stage training strategy as described in §2.2. For inference, we use Iterative Decoding only when using the bilingual context. All experiments are run on a single Nvidia P100 GPU with 16GBs of memory.[10]

Evaluation Metrics For evaluation, we use BLEU (Papineni et al., 2002) and Meteor (Lavie and Agarwal, 2007) scores on tokenised text, and measure statistical significance with respect to the baselines, $p < 0.05$ (Clark et al., 2011).

4.2 Main Results

We divide our experiments into two parts: offline and online document MT.

Offline Document MT From the scores of the two context-agnostic baselines in Table 2, we can see that the Transformer beats the RNNSearch model in all cases by atleast +2.5 BLEU and +2.1 Meteor scores showing that our hyperparameter choice for the Transformer is indeed effective.

For the Encoder Context integration, our Hierarchical Attention models perform the (near) best for News and Europarl datasets with +1.98 and +1 BLEU and +1.99 and +0.82 Meteor improvements with respect to the Transformer. For TED talks, however, we find the Flat Attention based models (sentence and word-level) to be the best with +1.27 BLEU and +1.08 METEOR improvements. For Decoder Context integration, we find the Hierarchical Attention to be the best in majority of the cases both in terms of BLEU and Meteor.

---

[7] `https://github.com/duyvuleo/Transformer-DyNet`

[8] The code is available at `https://github.com/sameenmaruf/selective-attn`

[9] We found this configuration to be much more stable than using 6 layers with almost no difference in performance as reported by Xia et al. (2018).

[10] The experiments can also be run on GPUs with 10-12GBs of memory by reducing the batch size at the expense of increased computational cost.

Online Document MT From Table 3, all our models significantly outperform the context-agnostic baseline and are significantly better than Zhang et al. (2018) in majority cases. For Encoder Context integration, the HAN encoder (Miculicich et al., 2018) is the best for TED and News datasets, however, the results are statistically insignificant with respect to our best model. For Europarl, our Hierarchical Attention model performs significantly better than Miculicich et al. (2018) with a gain of +1.15 BLEU and +1.13 Meteor. For Decoder Context integration, our Hierachical Attention models are the winner in majority cases and our best models beat Miculicich et al. (2018) for all datasets based upon BLEU and Meteor. The main conclusion we draw from these results is that efficiently using the context information at hand is crucial when it comes to improving the performance of context-aware NMT. Furthermore, shorter pieces of text (e.g., the ones in Europarl) benefit more from using global context because their sentences may exhibit higher interdependency than those in a longer piece of text.

Offline vs. Online Document MT Let us compare the overall results for the offline and online document MT settings. For all datasets and model variants, we find the best BLEU and Meteor scores in Tables 2 and 3 (highlighted in bold) to be quite close to each other with those for the online setting slightly better. This is quite self-explanatory, because in essence, all of the datasets comprise of talks, speeches or commentaries, which are in fact produced in an online manner and hence we do not see drastic improvements in terms of BLEU and Meteor when conditioning on the future context. This, in our opinion, does not mean that we should never look into the future, but just that NMT models in general are highly subjective to data, and whether context-aware models benefit from future context is also dependent on that.

4.3 Analysis

Evaluation on Contrastive Pronoun Test Set It has been argued that evaluation metrics which quantify the overall translation quality are somewhat ill-equipped to assess how well models translate inter-sentential phenomena such as pronouns. Hence, we use a test suite of contrastive translations designed to measure accuracy of translating the English pronoun *it* to its German counterparts *es*, *er* and *sie* (Müller et al., 2018). We are interested to see if our global document-context models surpass the local context-aware baselines. Table 4 shows that not only our global-context models are quite effective but our Hierarchical Attention model is most useful when the antecedent is farther than three previous sentences. We also conclude that models for offline MT perform better when antecedent distance is greater than two.

Model	**antecedent distance**				
	0	1	2	3	>3
	Offline document MT				
RNNSearch	0.415	0.310	0.424	0.440	0.647
Transformer	0.586	0.308	0.437	0.48	0.642
+Attention, sentence	0.677	0.314	0.439	0.478	0.697
word	**0.686**	**0.347**	**0.464**	**0.511**	0.679
+H-Attention, sparse-soft	0.676	0.308	0.440	0.480	0.686
sparse-sparse	0.652	0.303	0.435	0.471	**0.701**
	Online document MT				
Zhang et al. (2018)	0.622	0.321	0.450	0.485	0.658
Miculicich et al. (2018)	0.722	0.326	0.451	0.471	0.661
Transformer	0.586	0.308	0.437	0.48	0.642
+Attention, sentence	**0.732**	**0.340**	**0.460**	0.485	0.661
word	0.690	0.317	0.444	0.487	0.683
+H-Attention, sparse-soft	0.692	0.329	0.446	0.464	0.656
sparse-sparse	0.711	0.317	0.437	**0.489**	**0.692**

Table 4: Accuracy on contrastive test set with regard to antecedent distance (in sentences) on TED Talks. Antecedent distance 0 means the pronoun occurs in the same sentence as the antecedent.

Subjective Evaluation We conduct a subjective evaluation to validate the benefit of exploiting document-level context. Three native German speakers were asked to choose the better (with ties allowed) of two translations for each of 18 documents (randomly sampled from Europarl test set). The two translations, one produced by the Transformer and the other by our Hierarchical Attention model, were evaluated in terms of: *adequacy* (Which translation expresses the meaning of the source text more adequately?) and *fluency* (Which text has better German?) (Läubli et al., 2018). Let a, b be number of ratings in favour of Transformer or our model, respectively, and t be number of ties, then number of successes $x = b + 0.5t$ and trials $n = a + b + t$. We test for statistically significant preference of our model over the Transformer by means of two-sided Sign Tests and find that our model is better than the Transformer both in terms of document-level adequacy ($x = 39$, $n = 54$, $p = 0.0015$) and fluency ($x = 38$, $n = 54$, $p = 0.0038$).

Model Complexity Model complexity is reported in Table 5. Our context-aware models introduce only 8% more parameters to the original

Model	#Params	Speed (words/sec.)	
		Training	Decoding
Zhang et al. (2018)	59.5M	3300	84.94
Miculicich et al. (2018)	54.8M	1650	76.90
Transformer	50M	5100	86.33
+Attention, sentence	53.7M	3750	83.84
+H-Attention, sparse-soft	54.2M	2600	74.11

Table 5: Model complexity for Encoder Context integration models (News-Commentary).

Transformer model. In comparison to the Transformer, our Hierarchical Attention model is slow in training, dropping the speed by almost 50%[11], but it is still almost 40% faster than Miculicich et al. (2018). At decoding time, our Hierarchical Attention model is almost equivalent to Miculicich et al. (2018) and only 13% slower than Zhang et al. (2018). Hence, attending to the whole document (instead of few previous sentences) does not add to the time complexity of the model on average.

Qualitative Analysis To analyse the effect of using sparse attention at both the sentence and word-level, we looked at the attention weights computed by *sparsemax*. Table 6 shows an example where our model helped generate a correct translation of the noun "thoughts" (highlighted in bold). The context sentences shown in the bottom box had the highest attention weights as assigned by sparsemax. It seems that this particular attention head focuses more on phrases like "words of sympathy", "support', "symbol of hope" which are related to the query "thoughts". Another example in Table 7 shows how our model correctly translates the pronoun "their". Upon looking at the words in the context sentences, it seems that this particular attention head focuses on the words related to the antecedent "Croatia's Serbian population" with most of the weight concentrated around neighbouring words in sentence s^{j-1}. It is evident from both examples that word-level sparsity is more prevalent in longer sentences in the context. The same holds for sparsity at sentence-level.

5 Related Work

The body of work in document-level MT can be broadly classified into two categories: conventional MT and neural MT.

Src: my **thoughts** are also with the victims .
Ref: meine **Gedanken** sind auch bei den Opfern .
Transformer: ich **denke** auch an die Opfer .
Zhang et al. (2018): ich **denke** auch an die Opfer .
Miculicich et al. (2018): ich **denke** auch an die Opfer .
Our Model: meine **Gedanken** sind auch bei den Opfern .

Head 2: Attention to related words *sympathy, support, hope*
s^{j-2}: (FR) Madam President , many things have already been said , but I would like to echo all the words of sympathy and support that have already been addressed to the peoples of Tunisia and Egypt .
s^{j+4}: it must implement a strong strategy towards these countries .
s^{j-1}: they are a symbol of hope for all those who defend freedom .

Table 6: Example of noun disambiguation. Source context sentences are ordered in decreasing probability mass. The intensity of color corresponds to the attention given to a specific word before rescaling.

Src: Croatia is **their** homeland , too .
Ref: Kroatien ist auch **ihre** Heimat .
Transformer: Kroatien ist auch **seine** Heimat .
Our Model: Kroatien ist auch **ihr** Heimatland .

Head 8: Attention to words related to the antecedent.
s^{j-1}: to name but a few , these include cooperation with the Hague Tribunal , efforts made so far in prosecuting corruption , restructuring the economy and finances and greater commitment and sincerity in eliminating the obstacles to the return of Croatia 's Serbian population .
s^{j-4}: by signing a border arbitration agreement with its neighbour Slovenia , the new Croatian Government has not only eliminated an obstacle to the negotiating process , but has also paved the way for the resolution of other issues .

Table 7: Example of pronoun disambiguation. Context sentences are ordered in decreasing probability mass.

Conventional Document-level MT These can further be classified into two main categories. The first, which use cache-based memories (Tiedemann, 2010; Gong et al., 2011) and the second, which focus on specific discourse phenomema like anaphora (Hardmeier and Federico, 2010), lexical cohesion (Xiong et al., 2013; Gong et al., 2015; Mascarell, 2017) and coreference (Miculicich Werlen and Popescu-Belis, 2017) to name a few. Most of these approaches are, however, restrictive as they mostly involve using handcrafted features similar to the conventional MT approaches.

Document-level Neural MT The works here can again be divided into two categories: *online*—use previous context only, and *offline*—use both past and future contexts. Most works fall into the former category, with those that use only a single

---

[11] DyNet implementation of *sparsemax* is CPU-based and only operates on column vectors. We believe a GPU-based matrix implementation would bring the speed much closer to our Word Attention model (training: 3100, decoding: 81.38).

previous sentence in the source (Jean et al., 2017; Tiedemann and Scherrer, 2017; Voita et al., 2018); one previous sentence both in source and target (Bawden et al., 2018); more than one previous source sentence (Wang et al., 2017; Zhang et al., 2018); or a few previous source and target sentences (Miculicich et al., 2018). Apart from fixing the context length, there are few works which use cache-based memories to store contextual information (Tu et al., 2018; Kuang et al., 2018) and use that to improve the MT system performance. A recent work (Maruf et al., 2018) reports promising results when using the complete history for translating online conversations.

For the offline setting, however, there is only one work that effectively uses the full document-context on both source and target-side using memory networks (Maruf and Haffari, 2018). The debate in document-level NMT today is mostly about how much of the previous context to use and there has been no comparison between the online and offline setting except using only one previous and following sentence (Voita et al., 2018).

Sparse Attention Sparse attention and its constrained variants have been used to address the coverage problem in NMT (Malaviya et al., 2018) by limiting the amount of attention that each source word can receive. Apart from NMT, sparse attention has been shown to yield promising results for NLP tasks of textual entailment (Martins and Astudillo, 2016) and summarization (Niculae and Blondel, 2017).

6 Conclusion

We have proposed a novel approach to hierarchical attention for context-aware NMT, based on sparse attention, which is both scalable and efficient. Experiments and evaluation on three English→German datasets in offline and online document MT settings show that our approach surpasses context-agnostic and two recent context-aware baselines. The qualitative analysis shows that the sparsity at sentence-level allows our model to identify key sentences in the document context and the sparsity at word-level allows it to focus on key words in those sentences allowing for an efficient compression of memory. In future work, we plan to dig deeper on the benefits of sparse attention in terms of better interpretability of context-aware NMT models.

Acknowledgments

The authors are grateful to the anonymous reviewers for their helpful comments and corrections. SM would like to thank her colleagues at Monash University: Veronika Kuchta, Harald Bögeholz and Hagen Lauer, for their help in the subjective evaluation. Abstract

Adversarial examples — perturbations to the input of a model that elicit large changes in the output — have been shown to be an effective way of assessing the robustness of sequence-to-sequence (seq2seq) models. However, these perturbations only indicate weaknesses in the model if they do not change the input so significantly that it legitimately results in changes in the expected output. This fact has largely been ignored in the evaluations of the growing body of related literature. Using the example of untargeted attacks on machine translation (MT), we propose a new evaluation framework for adversarial attacks on seq2seq models that takes the semantic equivalence of the pre- and post-perturbation input into account. Using this framework, we demonstrate that existing methods may not preserve meaning in general, breaking the aforementioned assumption that source side perturbations should not result in changes in the expected output. We further use this framework to demonstrate that adding additional constraints on attacks allows for adversarial perturbations that are more meaning-preserving, but nonetheless largely change the output sequence. Finally, we show that performing untargeted adversarial training with meaning-preserving attacks is beneficial to the model in terms of adversarial robustness, without hurting test performance. [1]

1 Introduction

Attacking a machine learning model with adversarial perturbations is the process of making changes to its input to maximize an adversarial goal, such as mis-classification (Szegedy et al., 2013) or mis-translation (Zhao et al., 2018). These attacks provide insight into the vulnerabilities of machine learning models and their brittleness to samples outside the training distribution. Lack of robustness to these attacks poses security concerns to safety-critical applications, *e.g.* self-driving cars (Bojarski et al., 2016).

Adversarial attacks were first defined and investigated for computer vision systems (Szegedy et al. (2013); Goodfellow et al. (2014); Moosavi-Dezfooli et al. (2016) inter alia), where the input space is continuous, making minuscule perturbations largely imperceptible to the human eye. In discrete spaces such as natural language sentences, the situation is more problematic; even a flip of a single word or character is generally perceptible by a human reader. Thus, most of the mathematical framework in previous work is not directly applicable to discrete text data. Moreover, there is no canonical distance metric for textual data like the ℓ_p norm in real-valued vector spaces such as images, and evaluating the level of semantic similarity between two sentences is a field of research of its own (Cer et al., 2017). This elicits a natural question: *what does the term "adversarial perturbation" mean in the context of natural language processing (NLP)*?

We propose a simple but natural criterion for adversarial examples in NLP, particularly untargeted[2] attacks on seq2seq models: *adversarial examples should be meaning-preserving on the source side, but meaning-destroying on the target side*. The focus on explicitly evaluating meaning preservation is in contrast to previous work on adversarial examples for seq2seq models (Belinkov and Bisk, 2018; Zhao et al., 2018; Cheng et al., 2018; Ebrahimi et al., 2018a). Nonetheless, this feature is extremely important; given two sentences with equivalent meaning, we would expect a good model to produce two outputs with

---

[1] A toolkit implementing our evaluation framework is released at `https://github.com/pmichel31415/teapot-nlp`.

[2] Here we use the term untargeted in the same sense as (Ebrahimi et al., 2018a): an attack whose goal is simply to decrease performance with respect to a reference translation.

Proceedings of NAACL-HLT 2019, pages 3103–3114
Minneapolis, Minnesota, June 2 - June 7, 2019.

equivalent meaning. In other words, any meaning-preserving perturbation that results in the model output changing drastically highlights a fault of the model.

A first technical contribution of this paper is to lay out a method for formalizing this concept of meaning-preserving perturbations (§2). This makes it possible to evaluate the effectiveness of adversarial attacks or defenses either using gold-standard human evaluation, or approximations that can be calculated without human intervention. We further propose a simple method of imbuing gradient-based word substitution attacks (§3.1) with simple constraints aimed at increasing the chance that the meaning is preserved (§3.2).

Our experiments are designed to answer several questions about meaning preservation in seq2seq models. First, we evaluate our proposed "source-meaning-preserving, target-meaning-destroying" criterion for adversarial examples using both manual and automatic evaluation (§4.2) and find that a less widely used evaluation metric (chrF) provides significantly better correlation with human judgments than the more widely used BLEU and METEOR metrics. We proceed to perform an evaluation of adversarial example generation techniques, finding that chrF does help to distinguish between perturbations that are more meaning-preserving across a variety of languages and models (§4.3). Finally, we apply existing methods for adversarial training to the adversarial examples with these constraints and show that making adversarial inputs more semantically similar to the source is beneficial for robustness to adversarial attacks and does not decrease test performance on the original data distribution (§5).

2 A Framework for Evaluating Adversarial Attacks

In this section, we present a simple procedure for evaluating adversarial attacks on seq2seq models. We will use the following notation: x and y refer to the source and target sentence respectively. We denote x's translation by model M as y_M. Finally, $\hat{x}$ and $\hat{y}_M$ represent an adversarially perturbed version of x and its translation by M, respectively. The nature of M and the procedure for obtaining $\hat{x}$ from x are irrelevant to the discussion below.

2.1 The Adversarial Trade-off

The goal of adversarial perturbations is to produce failure cases for the model M. Hence, the evaluation must include some measure of the *target similarity* between y and y_M, which we will denote $\mathrm{s}_{\mathrm{tgt}}(y, \hat{y}_M)$. However, if no distinction is being made between perturbations that preserve the meaning and those that don't, a sentence like "he's very *friendly*" is considered a valid adversarial perturbation of "he's very *adversarial*", even though its meaning is the opposite. Hence, it is crucial, when evaluating adversarial attacks on MT models, that the discrepancy between the original and adversarial input sentence be quantified in a way that is sensitive to meaning. Let us denote such a *source similarity* score $\mathrm{s}_{\mathrm{src}}(x, \hat{x})$.

Based on these functions, we define the *target relative score decrease* as:

$$\mathrm{d}_{\mathrm{tgt}}(y, y_M, \hat{y}_M) = \begin{cases} 0 \text{ if } \mathrm{s}_{\mathrm{tgt}}(y, \hat{y}_M) \geq \mathrm{s}_{\mathrm{tgt}}(y, y_M) \\ \frac{\mathrm{s}_{\mathrm{tgt}}(y, y_M) - \mathrm{s}_{\mathrm{tgt}}(y, \hat{y}_M)}{\mathrm{s}_{\mathrm{tgt}}(y, y_M)} \text{ otherwise} \end{cases} \tag{1}$$

The choice to report the *relative* decrease in $\mathrm{s}_{\mathrm{tgt}}$ makes scores comparable across different models or languages[3]. For instance, for languages that are comparatively easy to translate (*e.g.* French-English), $\mathrm{s}_{\mathrm{tgt}}$ will be higher in general, and so will the gap between $\mathrm{s}_{\mathrm{tgt}}(y, y_M)$ and $\mathrm{s}_{\mathrm{tgt}}(y, \hat{y}_M)$. However this does not necessarily mean that attacks on this language pair are more effective than attacks on a "difficult" language pair (*e.g.* Czech-English) where $\mathrm{s}_{\mathrm{tgt}}$ is usually smaller.

We recommend that both $\mathrm{s}_{\mathrm{src}}$ and $\mathrm{d}_{\mathrm{tgt}}$ be reported when presenting adversarial attack results. However, in some cases where a single number is needed, we suggest reporting the attack's *success* $\mathcal{S} := \mathrm{s}_{\mathrm{src}} + \mathrm{d}_{\mathrm{tgt}}$. The interpretation is simple: $\mathcal{S} > 1 \Leftrightarrow \mathrm{d}_{\mathrm{tgt}} > 1 - \mathrm{s}_{\mathrm{src}}$, which means that the attack has destroyed the target meaning ($\mathrm{d}_{\mathrm{tgt}}$) more than it has destroyed the source meaning ($1 - \mathrm{s}_{\mathrm{src}}$).

Importantly, this framework can be extended beyond strictly meaning-preserving attacks. For example, for targeted keyword introduction attacks (Cheng et al., 2018; Ebrahimi et al., 2018a), the same evaluation framework can be used if $\mathrm{s}_{\mathrm{tgt}}$ (resp. $\mathrm{s}_{\mathrm{src}}$) is modified to account for the presence (resp. absence) of the keyword (or its translation in the source). Similarly this can be extended to other

---

[3] Note that we do not allow negative $\mathrm{d}_{\mathrm{tgt}}$ to keep all scores between 0 and 1.

tasks by adapting s_{tgt} (*e.g.* for classification one would use the zero-one loss, and adapt the success threshold).

2.2 Similarity Metrics

Throughout §2.1, we have not given an exact description of the semantic similarity scores s_{src} and s_{tgt}. Indeed, automatically evaluating the semantic similarity between two sentences is an open area of research and it makes sense to decouple the definition of adversarial examples from the specific method used to measure this similarity. In this section, we will discuss manual and automatic metrics that may be used to calculate it.

2.2.1 Human Judgment

Judgment by speakers of the language of interest is the *de facto* gold standard metric for semantic similarity. Specific criteria such as adequacy/fluency (Ma and Cieri, 2006), acceptability (Goto et al., 2013), and 6-level semantic similarity (Cer et al., 2017) have been used in evaluations of MT and sentence embedding methods. In the context of adversarial attacks, we propose the following 6-level evaluation scheme, which is motivated by previous measures, but designed to be (1) symmetric, like Cer et al. (2017), (2) and largely considers meaning preservation but at the very low and high levels considers fluency of the output[4], like Goto et al. (2013):

How would you rate the similarity between the meaning of these two sentences?

0. The meaning is completely different or one of the sentences is meaningless
1. The topic is the same but the meaning is different
2. Some key information is different
3. The key information is the same but the details differ
4. Meaning is essentially equal but some expressions are unnatural
5. Meaning is essentially equal and the two sentences are well-formed English[a]

[a] Or the language of interest.

2.2.2 Automatic Metrics

Unfortunately, human evaluation is expensive, slow and sometimes difficult to obtain, for example in the case of low-resource languages. This makes automatic metrics that do not require human intervention appealing for experimental research. This section describes 3 evaluation metrics commonly used as alternatives to human evaluation, in particular to evaluate translation models.[5]

BLEU: (Papineni et al., 2002) is an automatic metric based on n-gram precision coupled with a penalty for shorter sentences. It relies on exact word-level matches and therefore cannot detect synonyms or morphological variations.

METEOR: (Denkowski and Lavie, 2014) first estimates alignment between the two sentences and then computes unigram F-score (biased towards recall) weighted by a penalty for longer sentences. Importantly, METEOR uses stemming, synonymy and paraphrasing information to perform alignments. On the downside, it requires language specific resources.

chrF: (Popović, 2015) is based on the character n-gram F-score. In particular we will use the chrF2 score (based on the F2-score — recall is given more importance), following the recommendations from Popović (2016). By operating on a sub-word level, it can reflect the semantic similarity between different morphological inflections of one word (for instance), without requiring language-specific knowledge which makes it a good one-size-fits-all alternative.

Because multiple possible alternatives exist, it is important to know which is the best stand-in for human evaluation. To elucidate this, we will compare these metrics to human judgment in terms of Pearson correlation coefficient on outputs resulting from a variety of attacks in §4.2.

3 Gradient-Based Adversarial Attacks

In this section, we overview the adversarial attacks we will be considering in the rest of this paper.

3.1 Attack Paradigm

We perform gradient-based attacks that replace one word in the sentence so as to maximize an adversarial loss function $\mathcal{L}_{\mathrm{adv}}$, similar to the substitution attacks proposed in (Ebrahimi et al., 2018b).

---

[4] This is important to rule out nonsensical sentences and distinguish between clean and "noisy" paraphrases (*e.g.* typos, non-native speech…). We did not give annotators additional instruction specific to typos.

[5] Note that other metrics of similarity are certainly applicable within the overall framework of §2.2.1, but we limit our examination in this paper to the three noted here.

Original	**Pourquoi** faire cela ?
English gloss	**Why** do this?
Unconstrained	**construisant** (English: building) faire cela ?
kNN	**interrogez** (English: interrogate) faire cela ?
CharSwap	**Puorquoi** (typo) faire cela ?

English gloss	If only I could build my muscle **this** fast.
Unconstrained	Si seulement je pouvais me muscler **etc** rapidement.
kNN	Si seulement je pouvais me muscler **plsu** (typo for "more") rapidement.
CharSwap	Si seulement je pouvais me muscler **asusi** (typo) rapidement.

Table 1: Examples of different adversarial inputs. The substituted word is highlighted.

3.1.1 General Approach

Precisely, for a word-based translation model M[6], and given an input sentence $w_1, \ldots, w_n$, we find the position i^* and word w^* satisfying the following optimization problem:

$$\underset{1\leq i\leq n, \hat{w}\in\mathcal{V}}{\arg\max}\ \mathcal{L}_{\text{adv}}(w_0, \ldots, w_{i-1}, \hat{w}, w_{i+1}, \ldots, w_n) \tag{2}$$

where $\mathcal{L}_{\text{adv}}$ is a differentiable function which represents our adversarial objective. Using the first order approximation of $\mathcal{L}_{\text{adv}}$ around the original word vectors $\mathbf{w}_1, \ldots, \mathbf{w}_n$[7], this can be derived to be equivalent to optimizing

$$\underset{1\leq i\leq n, \hat{w}\in\mathcal{V}}{\arg\max}\ [\hat{\mathbf{w}} - \mathbf{w}_i]^\intercal \nabla_{\mathbf{w}_i} \mathcal{L}_{\text{adv}} \tag{3}$$

The above optimization problem can be solved by brute-force in $\mathcal{O}(n|\mathcal{V}|)$ space complexity, whereas the time complexity is bottlenecked by a $|\mathcal{V}| \times d$ times $n \times d$ matrix multiplication, which is not more computationally expensive than computing logits during the forward pass of the model. Overall, this naive approach is sufficiently fast to be conducive to adversarial training. We also found that the attacks benefited from normalizing the gradient by taking its sign.

Extending this approach to finding the optimal perturbations for more than 1 substitution would require exhaustively searching over all possible combinations. However, previous work (Ebrahimi et al., 2018a) suggests that greedy search is a good enough approximation.

3.1.2 The Adversarial Loss $\mathcal{L}_{\text{adv}}$

We want to find an adversarial input $\hat{x}$ such that, assuming that the model has produced the correct output $y_1, \ldots, y_{t-1}$ up to step $t-1$ during decoding, the probability that the model makes an error at the next step t is maximized.

In the log-semiring, this translates into the following loss function:

$$\mathcal{L}_{\text{adv}}(\hat{x}, y) = \sum_{t=1}^{|y|} \log(1 - p(y_t \mid \hat{x}, y_1, \ldots, y_{t-1})) \tag{4}$$

3.2 Enforcing Semantically Similar Adversarial Inputs

In contrast to previous methods, which don't consider meaning preservation, we propose simple modifications of the approach presented in §3.1 to create adversarial perturbations at the word level that are more likely to preserve meaning. The basic idea is to restrict the possible word substitutions to similar words. We compare two sets of constraints:

kNN: This constraint enforces that the word be replaced only with one of its 10 nearest neighbors in the source embedding space. This has two effects: first, the replacement will be likely semantically related to the original word (if words close in the embedding space are indeed semantically related, as hinted by Table 1). Second, it ensures that the replacement's word vector is close enough to the original word vector that the first order assumption is more likely to be satisfied.

CharSwap: This constraint requires that the substituted words must be obtained by swapping

---

[6] Note that this formulation is also valid for character-based models (see Ebrahimi et al. (2018a)) and subword-based models. For subword-based models, additional difficulty would be introduced due to changes to the input resulting in different subword segmentations. This poses an interesting challenge that is beyond the scope of the current work.

[7] More generally we will use the bold $\mathbf{w}$ when talking about the embedding vector of word w

characters. Word internal character swaps have been shown to not affect human readers greatly (McCusker et al., 1981), hence making them likely to be meaning-preserving. Moreover we add the additional constraint that the substitution must not be in the vocabulary, which will likely be particularly meaning-destroying on the target side for the word-based models we test here. In such cases where word-internal character swaps are not possible or can't produce out-of-vocabulary (OOV) words, we resort to the naive strategy of repeating the last character of the word. The exact procedure used to produce this kind of perturbations is described in Appendix A.1. Note that for a word-based model, every OOV will look the same (a special `<unk>` token), however the choice of OOV will still have an influence on the output of the model because we use unk-replacement.

In contrast, we refer the base attack without constraints as **Unconstrained** hereforth. Table 1 gives qualitative examples of the kind of perturbations generated under the different constraints.

For subword-based models, we apply the same procedures at the subword-level on the original segmentation. We then de-segment and re-segment the resulting sentence (because changes at the subword or character levels are likely to change the segmentation of the resulting sentence).

4 Experiments

Our experiments serve two purposes. First, we examine our proposed framework of evaluating adversarial attacks (§2), and also elucidate which automatic metrics correlate better with human judgment for the purpose of evaluating adversarial attacks (§4.2). Second, we use this evaluation framework to compare various adversarial attacks and demonstrate that adversarial attacks that are explicitly constrained to preserve meaning receive better assessment scores (§4.3).

4.1 Experimental setting

Data: Following previous work on adversarial examples for seq2seq models (Belinkov and Bisk, 2018; Ebrahimi et al., 2018a), we perform all experiments on the IWSLT2016 dataset (Cettolo et al., 2016) in the {French,German,Czech}→English directions (`fr-en`, `de-en` and `cs-en`). We compile all previous IWSLT test sets before 2015 as validation data, and keep the 2015 and 2016 test sets as test data. The data is tokenized with the Moses tokenizer (Koehn et al., 2007). The exact data statistics can be found in Appendix A.2.

MT Models: We perform experiments with two common neural machine translation (NMT) models. The first is an LSTM based encoder-decoder architecture with attention (Luong et al., 2015). It uses 2-layer encoders and decoders, and dot-product attention. We set the word embedding dimension to 300 and all others to 500. The second model is a self-attentional Transformer (Vaswani et al., 2017), with 6 1024-dimensional encoder and decoder layers and 512 dimensional word embeddings. Both the models are trained with Adam (Kingma and Ba, 2014), dropout (Srivastava et al., 2014) of probability 0.3 and label smoothing (Szegedy et al., 2016) with value 0.1. We experiment with both word based models (vocabulary size fixed at 40k) and subword based models (BPE (Sennrich et al., 2016) with 30k operations). For word-based models, we perform `<unk>` replacement, replacing `<unk>` tokens in the translated sentences with the source words with the highest attention value during inference. The full experimental setup and source code are available at `https://github.com/pmichel31415/translate/tree/paul/pytorch_translate/research/adversarial/experiments`.

Automatic Metric Implementations: To evaluate both sentence and corpus level BLEU score, we first de-tokenize the output and use `sacreBLEU`[8] (Post, 2018) with its internal `intl` tokenization, to keep BLEU scores agnostic to tokenization. We compute METEOR using the official implementation[9]. ChrF is reported with the `sacreBLEU` implementation on detokenized text with default parameters. A toolkit implementing the evaluation framework described in §2.1 for these metrics is released at `https://github.com/pmichel31415/teapot-nlp`.

4.2 Correlation of Automatic Metrics with Human Judgment

We first examine which of the automatic metrics listed in §2.2 correlates most with human judgment for our adversarial attacks. For this experiment, we restrict the scope to the case of the

Table 2: Target RDchrF and source chrF scores for all the attacks on all our models (word- and subword-based LSTM and Transformer).

LSTM model on `fr-en`. For the French side, we randomly select 900 sentence pairs $(x, \hat{x})$ from the validation set, 300 for each of the Unconstrained, kNN and CharSwap constraints. To vary the level of perturbation, the 300 pairs contain an equal amount of perturbed input obtained by substituting 1, 2 and 3 words. On the English side, we select 900 pairs of reference translations and translations of adversarial input $(y, \hat{y}_M)$ with the same distribution of attacks as the source side, as well as 300 (y, y_M) pairs (to include translations from original inputs). This amounts to 1,200 sentence pairs in the target side.

These sentences are sent to English and French speaking annotators to be rated according to the guidelines described in §2.2.1. Each sample (a pair of sentences) is rated by two independent evaluators. If the two ratings differ, the sample is sent to a third rater (an auditor and subject matter expert) who makes the final decision.

Finally, we compare the human results to each automatic metric with Pearson's correlation coefficient. The correlations are reported in Table 3. As evidenced by the results, chrF exhibits higher correlation with human judgment, followed by METEOR and BLEU. This is true both on the source side (x vs $\hat{x}$) and in the target side (y vs $\hat{y}_M$). We evaluate the statistical significance of this result using a paired bootstrap test for $p < 0.01$. Notably we find that chrF is significantly better than METEOR in French but not in English. This is not too unexpected because METEOR has access to more language-dependent resources in English (specifically synonym information) and thereby can make more informed matches of these synonymous words and phrases. Moreover the French source side contains more "character-level" errors (from CharSwap attacks) which are not picked-up well by word-based metrics like BLEU and METEOR. For a breakdown of the correlation coefficients according to number of perturbation and type of constraints, we refer to Appendix A.3.

Language	BLEU	METEOR	chrF
French	0.415	0.440	**0.586***
English	0.357	0.478*	**0.497**

Table 3: Correlation of automatic metrics to human judgment of adversarial source and target sentences. "*" indicates that the correlation is significantly better than the next-best one.

Thus, in the following, we report attack results both in terms of chrF in the source (s_{src}) and relative decrease in chrF (RDchrF) in the target (d_{tgt}).

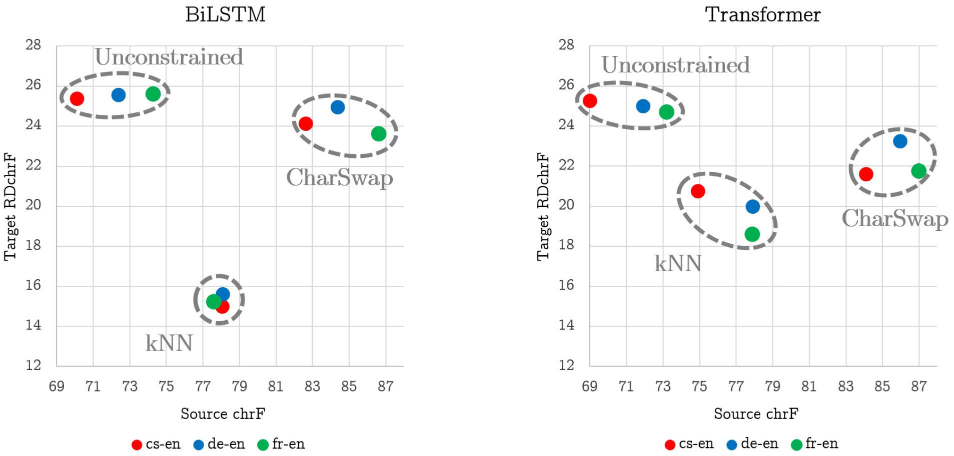

Figure 1: Graphical representation of the results in Table 2 for word-based models. High source chrF and target RDchrF (upper-right corner) indicates a good attack.

4.3 Attack Results

We can now compare attacks under the three constraints Unconstrained, kNN and CharSwap and draw conclusions on their capacity to preserve meaning in the source and destroy it in the target. Attacks are conducted on the validation set using the approach described in §3.1 with 3 substitutions (this means that each adversarial input is at edit distance at most 3 from the original input). Results (on a scale of 0 to 100 for readability) are reported in Table 2 for both word- and subword-based LSTM and Transformer models. To give a better idea of how the different variables (language pair, model, attack) affect performance, we give a graphical representation of these same results in Figure 1 for the word-based models. The rest of this section discusses the implication of these results.

Source chrF Highlights the Effect of Adding Constraints: Comparing the kNN and CharSwap rows to Unconstrained in the "source" sections of Table 2 clearly shows that constrained attacks have a positive effect on meaning preservation. Beyond validating our assumptions from §3.2, this shows that source chrF is useful to carry out the comparison in the first place[10]. To give a point of reference, results from the manual evaluation carried out in §4.2 show that 90% of the French sentence pairs to which humans gave a score of 4 or 5 in semantic similarity have a chrF > 78.

Table 4: Example of CharSwap attacks on the `fr-en` LSTM. The first example is a successful attack (high source chrF and target RDchrF) whereas the second is not.

Different Architectures are not Equal in the Face of Adversity: Inspection of the target-side results yields several interesting observations. First, the high RDchrF of CharSwap for word-based model is yet another indication of their known shortcomings when presented with words out of their training vocabulary, even with `<unk>`-replacement. Second, and perhaps more interestingly, Transformer models appear to be less robust to small embedding perturbations (kNN attacks) compared to LSTMs. Although the exploration of the exact reasons for this phenomenon is beyond the scope of this work, this is a good example that RDchrF can shed light on the different behavior of different architectures when confronted with adversarial input. Overall, we find that the Char-

---

[10] It can be argued that using chrF gives an advantage to CharSwap over kNN for source preservation (as opposed to METEOR for example). We find that this is the case for Czech and German (source METEOR is higher for kNN) but not French. Moreover we find (see A.3) that chrF correlates better with human judgement even for kNN.

Swap constraint is the only one that consistently produces attacks with > 1 average success (as defined in Section 2.1) according to Table 2. Table 4 contains two qualitative examples of this attack on the LSTM model in `fr-en`.

5 Adversarial Training with Meaning-Preserving Attacks

5.1 Adversarial Training

Adversarial training (Goodfellow et al., 2014) augments the training data with adversarial examples. Formally, in place of the negative log likelihood (NLL) objective on a sample x, y, $\mathcal{L}(x, y) = NLL(x, y)$, the loss function is replaced with an interpolation of the NLL of the original sample x, y and an adversarial sample $\hat{x}, y$:

$$\mathcal{L}'(x, y) = (1 - \alpha) NLL(x, y) + \alpha NLL(\hat{x}, y) \tag{5}$$

Ebrahimi et al. (2018a) suggest that while adversarial training improves robustness to adversarial attacks, it can be detrimental to test performance on non-adversarial input. We investigate whether this is still the case when adversarial attacks are largely meaning-preserving.

In our experiments, we generate $\hat{x}$ by applying 3 perturbations on the fly at each training step. To maintain training speed we do not solve Equation (2) iteratively but in one shot by replacing the argmax by top-3. Although this is less exact than iterating, this makes adversarial training time less than $2\times$ slower than normal training. We perform adversarial training with perturbations without constraints (Unconstrained-adv) and with the CharSwap constraint (CharSwap-adv). All experiments are conducted with the word-based LSTM model.

5.2 Results

Test performance on non-adversarial input is reported in Table 5. In keeping with the rest of the paper, we primarily report chrF results, but also show the standard BLEU as well.

We observe that when $\alpha = 1.0$, *i.e.* the model only sees the perturbed input during training[11], the Unconstrained-adv model suffers a drop in test performance, whereas CharSwap-adv's performance is on par with the original. This is likely attributable to the spurious training samples $(\hat{x}, y)$ where y is not an acceptable translation of $\hat{x}$ introduced by the lack of constraint. This effect disappears when $\alpha = 0.5$ because the model sees the original samples as well.

Base	24.11	24.94	23.60
		$\alpha = 1.0$	
Unconstrained-adv	25.99	26.24	25.67
CharSwap-adv	16.46	17.19	15.72
		$\alpha = 0.5$	
Unconstrained-adv	26.52	27.26	24.92
CharSwap-adv	20.41	20.24	16.08

Table 6: Robustness to CharSwap attacks on the validation set with/without adversarial training (RDchrF). Lower is better.

Not unexpectedly, Table 6 indicates that CharSwap-adv is more robust to CharSwap constrained attacks for both values of α, with 1.0 giving the best results. On the other hand, Unconstrained-adv is similarly or more vulnerable to these attacks than the baseline. Hence, we can safely conclude that adversarial training with CharSwap attacks improves robustness while not impacting test performance as much as unconstrained attacks.

6 Related work

Following seminal work on adversarial attacks by Szegedy et al. (2013), Goodfellow et al. (2014) introduced gradient-based attacks and adversarial training. Since then, a variety of attack (Moosavi-

---

[11] This setting is reminiscent of word dropout (Iyyer et al., 2015).

Dezfooli et al., 2016) and defense (Cissé et al., 2017; Kolter and Wong, 2017) mechanisms have been proposed. Adversarial examples for NLP specifically have seen attacks on sentiment (Papernot et al., 2016; Samanta and Mehta, 2017; Ebrahimi et al., 2018b), malware (Grosse et al., 2016), gender (Reddy and Knight, 2016) or toxicity (Hosseini et al., 2017) classification to cite a few.

In MT, methods have been proposed to attack word-based (Zhao et al., 2018; Cheng et al., 2018) and character-based (Belinkov and Bisk, 2018; Ebrahimi et al., 2018a) models. However these works side-step the question of meaning preservation in the source: they mostly focus on target side evaluation. Finally there is work centered around meaning-preserving adversarial attacks for NLP via paraphrase generation (Iyyer et al., 2018) or rule-based approaches (Jia and Liang, 2017; Ribeiro et al., 2018; Naik et al., 2018; Alzantot et al., 2018). However the proposed attacks are highly engineered and focused on English.

7 Conclusion

This paper highlights the importance of performing *meaning-preserving* adversarial perturbations for NLP models (with a focus on seq2seq). We proposed a general evaluation framework for adversarial perturbations and compared various automatic metrics as proxies for human judgment to instantiate this framework. We then confirmed that, in the context of MT, "naive" attacks do not preserve meaning in general, and proposed alternatives to remedy this issue. Finally, we have shown the utility of adversarial training in this paradigm. We hope that this helps future work in this area of research to evaluate meaning conservation more consistently.

A Supplemental Material

A.1 Generating OOV Replacements with Internal Character Swaps

We use the following snippet to produce an OOV word from an existing word:

```python
def make_oov(
  word,
  vocab,
  max_scrambling,
):
  """Modify a word to make it OOV
  (while keeping the meaning)"""
  # If the word has >3 letters
  # try scrambling them
  L = len(word)
  if L > 3:
    # For a fixed number of steps
    for _ in range(max_scrambling):
      # Swap two adjacent letters
      # in the middle of the word
      pos = random.randint(1, L - 3)
      word = word[:pos]
      word += word[pos+1] + word[pos]
      word += word[pos+2:]
      # If we got an OOV already just
      # return it
      if word not in vocab:
        return word
  # If nothing worked, or the word is
  # too short for scrambling, just
  # repeat the last letter ad nauseam
  char = word[-1]
  while word in vocab:
    word = word + char
  return word
```

A.2 IWSLT2016 Dataset

See table 7 for statistics on the size of the IWSLT2016 corpus used in our experiments.

	#train	#valid	#test
`fr-en`	220.4k	6,824	2,213
`de-en`	196.9k	11,825	2,213
`cs-en`	114.4k	5,716	2,213

Table 7: IWSLT2016 data statistics.

A.3 Breakdown of Correlation with Human Judgement

We provide a breakdown of the correlation coefficients of automatic metrics with human judgment for source-side meaning-preservation, both in terms of number of perturbed words (Table 8) and constraint (Table 9). While those coefficients are computed on a much smaller sample size, and their differences are not all statistically significant with $p < 0.01$, they exhibit the same trend as the results from Table 3 (BLEU < METEOR < chrF).

# edits	BLEU	METEOR	chrF
1	0.351	0.352	**0.486***
2	0.403	0.424	**0.588***
3	0.334	0.393	**0.560***

Table 8: Correlation of automatic metrics to human judgment of semantic similarity between original and adversarial source sentences, broken down by number of perturbed words. "*" indicates that the correlation is significantly better than the next-best one.

Constraint	BLEU	METEOR	chrF
Unconstrained	0.274	0.572	**0.599**
CharSwap	0.274	0.319	**0.383**
kNN	0.534	0.584	**0.606**

Table 9: Correlation of automatic metrics to human judgment of semantic similarity between original and adversarial source sentences, broken down by type of constraint on the perturbation. "*" indicates that the correlation is significantly better than the next-best one.

In particular Table 8 shows that the good correlation of chrF with human judgment is not only due to the ability to distinguish between different number of edits.

Accelerated Reinforcement Learning for Sentence Generation by Vocabulary Prediction

Abstract

A major obstacle in reinforcement learning-based sentence generation is the large action space whose size is equal to the vocabulary size of the target-side language. To improve the efficiency of reinforcement learning, we present a novel approach for reducing the action space based on dynamic vocabulary prediction. Our method first predicts a fixed-size small vocabulary for each input to generate its target sentence. The input-specific vocabularies are then used at supervised and reinforcement learning steps, and also at test time. In our experiments on six machine translation and two image captioning datasets, our method achieves faster reinforcement learning ($\sim$2.7x faster) with less GPU memory ($\sim$2.3x less) than the full-vocabulary counterpart. We also show that our method more effectively receives rewards with fewer iterations of supervised pre-training.

1 Introduction

Sentence generation with neural networks plays a key role in many language processing tasks, including machine translation (Sutskever et al., 2014), image captioning (Lin et al., 2014), and abstractive summarization (Rush et al., 2015). The most common approach for learning the sentence generation models is maximizing the likelihood of the model on the gold-standard target sentences. Recently, approaches based on reinforcement learning have attracted increasing attention to reduce the gap between training and test situations and to directly incorporate task-specific and more flexible evaluation metrics such as BLEU scores (Papineni et al., 2002) into optimization (Ranzato et al., 2016).

While reinforcement learning-based sentence generation is appealing, it is often too computationally demanding to be used with large training data. In reinforcement learning for sentence generation, selecting an action corresponds to selecting a word in the vocabulary V. The number of possible actions at each time step is thus equal to the vocabulary size, which often exceeds tens of thousands. Among such a large set of possible actions, at most N actions are selected if the length of the generated sentence is N, where we can assume $N \ll |V|$. In other words, most of the possible actions are not selected, and the large action space slows down reinforcement learning and consumes a large amount of GPU memory.

In this paper, we propose to accelerate reinforcement learning by reducing the large action space. The reduction of action space is achieved by predicting a small vocabulary for each source input. Our method first constructs the small input-specific vocabulary by selecting K (≤ 1000) relevant words, and then the small vocabulary is used at both training and test time.

Our experiments on six machine translation and two image captioning datasets show that our method enables faster reinforcement learning with less GPU memory than the standard full softmax method, without degrading the accuracy of the sentence generation tasks. Our method also works faster at test time, especially on CPUs. The implementation of our method is available at `https://github.com/hassyGo/NLG-RL`.

2 REINFORCE with Small Vocabularies

We first describe a neural machine translation model and an image captioning model as examples of sentence generation models. Machine translation is a text-to-text task, and image captioning is an image-to-text task. We then review how reinforcement learning is used, and present a simple and efficient method to accelerate the training.

2.1 Sentence Generation Models

Recurrent Neural Networks (RNNs) are widely used to generate sentences by outputting words one by one (Sutskever et al., 2014). To generate a sentence $Y = (y_1, y_2, \ldots, y_N)$, where N is its length, given a source input X, a hidden state $h_t \in \mathbb{R}^d$ is computed for each time step t (≥ 1) by using its previous information:

$$h_t = \mathrm{RNN}\left(h_{t-1}, e(y_{t-1}), s_{t-1}\right), \tag{1}$$

where $\mathrm{RNN}(\cdot)$ is an RNN function, $e(y_{t-1}) \in \mathbb{R}^d$ is a word embedding of y_{t-1}, and $s_{t-1} \in \mathbb{R}^d$ is a hidden state optionally used to explicitly incorporate the information about the source input X into the transition. We employ Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) for the RNN function. The task here is to predict the t-th word y_t by computing a target word distribution $p(y|y_{<t}, X) \in \mathbb{R}^{|V|}$, where $|V|$ represents the vocabulary size of the target language. $p(y|y_{<t}, X)$ is used to generate a sentence by either greedy/beam search or random sampling.

To learn the model parameters, the following cross entropy loss is usually employed:

$$L_c(Y_g, X) = -\sum_{t=1}^{N_g} \log p\left(y = y_t | y_{<t}, X\right), \tag{2}$$

where we assume that the target sentence Y_g is the gold sequence. Once we train the model, we can use it to generate unseen sentences.

Machine translation In the context of machine translation, the source input X corresponds to a source sentence $(x_1, x_2, \ldots, x_M)$ of length M. Each word x_i is also associated with a word embedding $\tilde{e}(x_i) \in \mathbb{R}^d$. We assume that a hidden state $\tilde{h}_i \in \mathbb{R}^{2d}$ is computed for each x_i by using a bi-directional RNN with LSTM units (Graves and Schmidhuber, 2005). That is, $\tilde{h}_i$ is the concatenation of x_i's d-dimensional hidden states $[\overrightarrow{h}_i; \overleftarrow{h}_i]$ computed by a pair of forward and backward RNNs. We set the initial hidden state of the sentence generator as $h_0 = \overrightarrow{h}_M + \overleftarrow{h}_1$. Following an attention mechanism proposed in Luong et al. (2015), s_t for predicting y_t is computed as follows:

$$s_t = \tanh\left(W_s\left[h_t; \sum_{i=1}^{M} a_i \tilde{h}_i\right] + b_s\right), \tag{3}$$

where $a_i = f(h_t, i, \tilde{h})$ is the global-attention function in Luong et al. (2015), $W_s \in \mathbb{R}^{d \times 3d}$ is a weight matrix, and $b_s \in \mathbb{R}^d$ is a bias vector. s_t is then used to compute the target word distribution:

$$p(y|y_{<t}, X) = \mathrm{softmax}(W_p s_t + b_p), \tag{4}$$

where $W_p \in \mathbb{R}^{|V| \times d}$ is a weight matrix, and $b_p \in \mathbb{R}^{|V|}$ is a bias vector.

Image captioning In the case of image captioning, the source input X corresponds to an image to be described. We assume that in our preprocessing step, each input image is fed into a convolutional neural network to extract its fixed-length feature vector $f \in \mathbb{R}^{d_f}$. More specifically, we use the pre-computed feature vectors provided by Kiros et al. (2014), and the feature vectors are never updated in any model training processes. The input feature vector is transformed into the initial hidden state $h_0 = \tanh\left(W_f f + b_f\right)$, where $W_f \in \mathbb{R}^{d \times d_f}$ is a weight matrix, and $b_f \in \mathbb{R}^d$ is a bias vector. In contrast to machine translation, we do not use s_{t-1} in Equation (1); more concretely, we do not use any attention mechanisms for image captioning. Therefore, we directly use the hidden state h_t to compute the target word distribution:

$$p(y|y_{<t}, X) = \mathrm{softmax}(W_p h_t + b_p), \tag{5}$$

where the weight and bias parameters are analogous to the ones in Equation (4).

For both of the tasks, we use the weight-tying technique (Inan et al., 2017; Press and Wolf, 2017) by using W_p as the word embedding matrix. That is, $e(y_t)$ is the y_t-th row vector in W_p, and the technique has shown to be effective in machine translation (Hashimoto and Tsuruoka, 2017) and text summarization (Paulus et al., 2018).

2.2 Applying Reinforcement Learning

One well-known limitation of using the cross entropy loss in Equation (2) is that the sentence generation models work differently at the training and test time. More concretely, the models only observe gold sequences at the training time, whereas the models have to handle unseen sequences to generate sentences at the test time.

To bridge the gap, reinforcement learning has started gaining much attention (Ranzato et al., 2016; Wu et al., 2016; Rennie et al., 2017; Zhang and Lapata, 2017; Paulus et al., 2018; Yang et al., 2018). In this work, we focus on the most popular method called REINFORCE (Williams, 1992).[1] In REINFORCE, the sentence generation model sets an initial state given a source input, and then iterates an action selection and its corresponding state transition. The action selection corresponds to randomly sampling a target word from Equation (4) and (5), and the state transition corresponds to the RNN transition in Equation (1).

Once a sentence is generated, an approximated loss function is defined as follows:

$$L_r(Y, X) = -\sum_{t=1}^{N} R_t \log p(y = y_t | y_{<t}, X), \quad (6)$$

where R_t is the reward at time step t, and the loss is approximated by the single example Y. R_t is used to evaluate how good the t-th action selection is. Unlike maximum likelihood training, the reward function can be defined by using task-specific evaluation scores like BLEU for machine translation. In this paper, we employ GLEU proposed by Wu et al. (2016), a variant of sentence-level BLEU. Following the implementation in Ranzato et al. (2016), we define $R_t = \mathrm{GLEU}(Y, Y_g) - b_t$, where b_t is a baseline value estimating the future reward from the next time step to reduce the variance of the gradients. To estimate b_t, we jointly train a linear regression model by minimizing $\|b_t - \mathrm{GLEU}(Y, Y_g)\|^2$, and b_t is computed as $b_t = \sigma(W_r \cdot s_t + b_r)$, where $W_r \in \mathbb{R}^d$ is a weight vector, b_r is a bias, $\sigma(\cdot)$ is the logistic sigmoid function, and in the case of image captioning, h_t is used instead of s_t.

Overall model training The reinforcement learning step is usually applied after pre-training the models with the cross entropy loss in Equation (2). At the REINFORCE phase, we define the following joint loss function:

$$L = \lambda L_c + (1 - \lambda) L_r, \quad (7)$$

where λ is a hyperparameter, and $\lambda = 0.0$ usually leads to unstable training (Wu et al., 2016).

2.3 Large Action-Space Reduction

The vocabulary size $|V|$ is usually more than ten thousands for datasets covering many sentences with a variety of topics. However, for example, at most 100 unique words are selected when generating a sentence of length 100. That is, the output length N is much smaller than the vocabulary size $|V|$, and this fact motivated us to reduce the large action space. Moreover, we have in practice found that REINFORCE runs several times slower than the supervised learning with the cross entropy loss.

To accelerate the training, we propose to construct a small action space for each source input. In other words, our method selects a small vocabulary V' of size K for each source input in advance to the model training. In this section, we assume that V' is given and represented with a sparse binary matrix $M_X \in \mathbb{R}^{K \times |V|}$, where there are only K non-zero elements at position (i, w_i) for $1 \leq i \leq K$. w_i is a unique word index in V. M_X is used to construct a small subset of the parameters in the softmax layer:

$$W'_p = M_X W_p, \quad b'_p = M_X b_p, \quad (8)$$

and $W'_p \in \mathbb{R}^{K \times d}$ and $b'_p \in \mathbb{R}^K$ are used instead of W_p and b_p in Equation (4) and (5). Therefore, in mini-batched processes with a mini-batch size B, our method constructs B different sets of (W'_p, b'_p).

Relationship to previous work Sampling-based approximation methods have previously been studied to reduce the computational cost at the large softmax layer in probabilistic language modeling (Ji et al., 2016; Zoph et al., 2016), and such methods are also used to enable one to train neural machine translation models on CPUs (Eriguchi et al., 2016). The construction of (W'_p, b'_p) in our method is similar to these softmax approximation methods in that they also sample small vocabularies either at the word level (Ji et al., 2016), sentence level (Hashimoto and Tsuruoka, 2017), or mini-batch level (Zoph et al., 2016). However, one significant difference is that the approximation methods work only at training time using the cross entropy loss, and full softmax computations are still required at test time. The difference is crucial because a sentence generation model needs to simulate its test-time behavior in reinforcement learning.

3 Target Vocabulary Prediction

The remaining question is how to construct the input-specific vocabulary V' for each source input X. This section describes our method to construct V' by using a vocabulary prediction model which is separated from the sentence generation models.

---

[1] We tried self critic (Rennie et al., 2017), but did not observe significant improvement over REINFORCE.

3.1 Input Representations

In the vocabulary prediction task, the input is the source X (source sentences or images) to be described, and the output is V'. We should be careful *not* to make the prediction model computationally expensive; otherwise the computational efficiency by our method would be canceled out.

To feed the information about X into our vocabulary prediction model, we define an input vector $v(X) \in \mathbb{R}^{d_v}$. For image captioning, we use the feature vector f described in Section 2.1: $v(X) = W_v f + b_v$, where $W_v \in \mathbb{R}^{d_v \times d_f}$ is a weight matrix, and $b_v \in \mathbb{R}^{d_v}$ is a bias vector. For machine translation, we employ a bag-of-embeddings representation: $v(X) = \frac{1}{M}\sum_{i=1}^{M} \tilde{e}_v(x_i)$, where the d_v-dimensional word embedding $\tilde{e}_v(x_i) \in \mathbb{R}^{d_v}$ is different from $\tilde{e}(x_i)$ used in the machine translation model. By using the different set of the model parameters, we avoid the situation that our vocabulary prediction model is affected during training the sentence generation models.

Relationship to previous work Vocabulary prediction has gained attention for training sequence-to-sequence models with the cross entropy loss (Weng et al., 2017; Wu et al., 2017), but not for reinforcement learning. Compared to our method, previous methods jointly train a vocabulary predictor by directly using source encoders as input to the predictor. One may expect joint learning to improve both of the vocabulary predictor and the sentence generator, but in practice such positive effects are not clearly observed. Weng et al. (2017) reported that the joint learning improves the accuracy of their machine translation models, but our preliminary experiments did not indicate such accuracy gain. Such a joint training approach requires the model to continuously update the vocabulary predictor during REINFORCE, because the encoder is shared. That is, the action space for each input changes during reinforcement learning, and we observed unstable training. Therefore, this work separately models the vocabulary predictor and focuses on the effects of using the small vocabularies for REINFORCE.

Another note is that Jean et al. (2015) and L'Hostis et al. (2016) also proposed to construct small vocabularies in advance to the cross entropy-based training. They suggest that the use of word alignment works well, but using the word alignment is not general enough, considering that there exist different types of source input. By contrast, our method can be straightforwardly applied to the two sentence generation tasks with the different input modalities (i.e. image and text).

3.2 Multi-Label Classification

Once the input representation $v(X)$ is computed, we further transform it by a single residual block (He et al., 2016): $r(X) = \mathrm{Res}\,(v(X)) \in \mathbb{R}^{d_v}$.[2] Then $r(X)$ is fed into a prediction layer:

$$o = \sigma\left(W_o r(X) + b_o\right), \tag{9}$$

where $W_o \in \mathbb{R}^{|V| \times d_v}$ is a weight matrix, and $b_o \in \mathbb{R}^{|V|}$ is a bias vector. The i-th element o_i corresponds to the probability that the i-th word in the target vocabulary V appears in the target sentence Y given its source X.

We use the training data for the sentence generations tasks to train the vocabulary predictor. For each X in the training data, we have its gold target sentence Y_g. We train the vocabulary predictor as a multi-label classification model by the following loss function:

$$-\sum_{i=1}^{|V|}\left(t_i \log o_i + (1 - t_i)\log(1 - o_i)\right), \tag{10}$$

where t_i is equal to 1.0 if the i-th word in V is included in Y_g, and otherwise t_i is 0.0. In practice, we apply the label smoothing technique (Szegedy et al., 2016) to the loss function.

We evaluate the accuracy of the vocabulary predictor by using a separate development split D:

$$\frac{\#\text{ of correctly predicted words in } D}{\#\text{ of words in } D}, \tag{11}$$

where we select the top-K predictions in Equation (9) for each source input X in D, and the evaluation metric is a recall score. We use the top-K words to construct the input-specific vocabularies V' for the sentence generation models, and we restrict that the recall is 100% for the training data.

4 Experimental Settings

We describe our experimental settings, and the details can be found in the supplemental material.

---

[2] We can use arbitrary types of hidden layers or even linear models like SVMs, but we found this one performed the best. We describe the details of this in the supplemental material.

Dataset	Size	$\lvert V\rvert$	$\max(N)$
En-De	100,000	24,482	50
En-Ja (100K)	100,000	23,536	50
En-Ja (2M)	1,998,821	70,668	100
En-Ja (2M, SW)	1,998,816	37,905	200
En-Vi	132,406	14,321	100
Ch-Ja	100,000	23,383	50
MS COCO	413,915	14,543	57
Flickr8K	30,000	4,521	38

Table 1: Statistics of the training datasets.

4.1 Datasets

We used machine translation datasets of four different language pairs: English-to-German (En-De), English-to-Japanese (En-Ja), English-to-Vietnamese (En-Vi), and Chinese-to-Japanese (Ch-Ja). For image captioning, we used two datasets: MS COCO (Lin et al., 2014) and Flickr8K. Table 1 summarizes the statistics of the training datasets, where the number of training examples ("Size"), the target vocabulary size ($|V|$), and the maximum length of the target sentences ($\max(N)$) are shown. For the machine translation datasets, we manually set $\max(N)$ and omitted training examples which violate the constraints.

En-De: We used 100,000 training sentence pairs from `news commentary` and `newstest2015` as our development set, following Eriguchi et al. (2017).

En-Ja: We used parallel sentences in ASPEC (Nakazawa et al., 2016) and constructed three types of datasets: En-Ja (100K), En-Ja (2M), and En-Ja (2M, SW). The 100K and 2M datasets were constructed with the first 100,000 and 2,000,000 sentence pairs, respectively. To test our method using subword units, we further preprocessed the 2M dataset by using the SentencePiece toolkit (Kudo and Richardson, 2018) to construct the En-Ja (2M, SW) dataset.

En-Vi: We used the pre-processed datasets provided by Luong and Manning (2015). Our development dataset is the `tst2012` dataset.

Ch-Ja: We constructed the Ch-Ja dataset by using the first 100,000 sentences from `ASPEC`.

MS COCO and Flickr8K: We used the pre-processed datasets provided by Kiros et al. (2014). We can also download the 4096-dimensional feature vectors f (i.e., $d_f = 4096$).

4.2 Settings of Vocabulary Prediction

We set $d_v = 512$ for all the experiments. We used `AdaGrad` (Duchi et al., 2011) to train the vocabulary predictor with a learning rate of 0.08 and a mini-batch size of 128. The model for each setting was tuned based on recall scores (with $K = 1000$) for the development split.

4.3 Settings of Sentence Generation

We set $d = 256$ with single-layer LSTMs for all the experiments, except for the En-Ja (2M) and (2M, SW) datasets. For the larger En-Ja datasets, we set $d = 512$ with two-layer LSTMs. We used stochastic gradient decent with momentum, with a learning rate of 1.0, a momentum rate of 0.75, and a mini-batch size of 128. The model for each setting was tuned based on BLEU scores for the development split. All of the models achieved the best BLEU scores for all the datasets within 15 to 20 training epochs. Each of the selected models with the best BLEU scores was used for the following REINFORCE step. For REINFORCE, we set $\lambda = 0.005$, and the learning rate was set to 0.01. The REINFORCE steps required around 5 epochs to significantly improve the BLEU scores.

4.4 Computational Resources and Mini-Batch Processing

We used a single GPU of `NVIDIA GeForce GTX 1080`[3] to run experiments for the En-De, En-Ja (100K), En-Vi, Ch-Ja, MS COCO, and Flickr8K datasets. For the En-Ja (2M) and En-Ja (2M, SW) datasets, we used a single GPU of `NVIDIA Tesla V100`[4] to speedup our experiments.

Mini-batch splitting It should be noted that our small softmax method can be run even on the single `GTX 1080` GPU for the larger translation datasets, whereas the full softmax method runs out of the GPU memory. A typical strategy to address such out-of-memory issues is to use multiple GPUs, but we have found that we need at most eight GPUs to conduct our experiments on the full softmax method with REINFORCE.[5] Moreover, using the multiple GPUs does not always speedup the training time. We instead employ another strategy to split the mini-batch at each training iteration. First, we sort the mini-batch examples according to the lengths of the source (or target) text, and then split the mini-batch into S sets of the training examples. For example, in our case the

---

[3] The GPU memory capacity is 11,178MiB.

[4] The GPU memory capacity is 16,152MiB (AWS p3).

[5] This also depends on the mini-batch size.

		Cross entropy		REINFORCE w/ cross entropy

	Flickr8K	16.45±0.28	16.52±0.11	19.04±0.43	19.17±0.24

Table 2: BLEU scores for the development splits of the six datasets. "Small softmax" corresponds to our method.

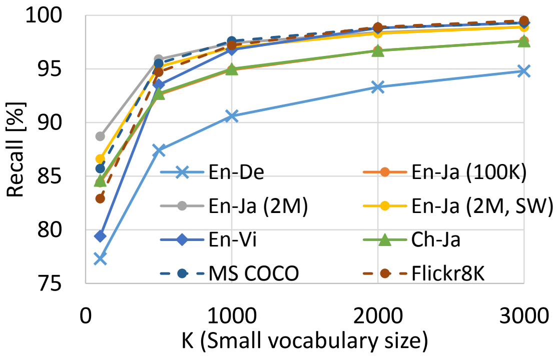

Figure 1: Recall scores of our vocabulary predictor.

mini-batch size is 128, and if S is set to 4, each of the smaller sets includes 32 training examples. We perform back-propagation for each set one by one, and at each step we delete the corresponding computational graphs to reduce the GPU memory consumption. Finally, the accumulated partial derivatives are used to update the model parameters. More details can be found in our Pytorch 0.4 implementation.

5 Results of Sentence Generation Tasks

5.1 Accuracy of Vocabulary Prediction

Figure 1 shows recall scores with respect to different values of the small vocabulary size K for each dataset. We can see that the recall scores reach 95% with $K = 1000$ for most of the datasets. One exception is the En-De dataset, and this is not surprising because a German vocabulary would become sparse by many compound nouns.

These results show that our vocabulary predictor works well for source inputs of different modalities (text and image) and their corresponding different target languages. Our method also works at the subword level as well as at the standard word level. For training the sentence generation models, we set $K = 500$ for the Flickr8K dataset and $K = 1000$ for the other datasets. Our empirical recommendation is $K = 1000$ if $|V|$ is larger than 10,000 and otherwise $K = 500$.

5.2 Accuracy of Sentence Generation

The goal of this paper is achieving efficient reinforcement learning for sentence generation to encourage future research, but before evaluating the efficiency of our method, we show that using the small vocabularies does not degrade the accuracy of the sentence generation models. Table 2 shows BLEU scores for the development splits of the four machine translation and two image captioning datasets. The BLEU scores are averaged over five different runs with different random seeds, and the standard deviations are also reported.

We can see in Table 2 that our method (Small softmax) keeps the BLEU scores as high as those of "Full softmax". For some datasets, the BLEU scores of our method are even better than those of the full softmax method. The trend is consistent in both of the cross entropy training phase and the REINFORCE phase. These results indicate that our method works well for different machine translation and image captioning datasets. We also confirmed that our experimental results are competitive with previously reported results when using the same training datasets; for example, our En-Vi test set result on `tst2013` is 27.87±0.21 (cf. 26.9 in Luong and Manning (2015)).

Better generation of rare words These BLEU scores suggest that our method for reinforcement learning has the potential to outperform the full softmax baseline. However, it is still unclear what is the potential advantage in terms of generation quality. We therefore analyzed the differences between output sentences of the small and full softmax methods, following Ott et al. (2018). Figure 2 shows the results of the En-De translation dataset,

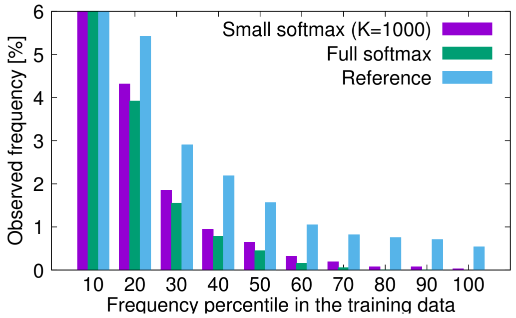

Figure 2: An analysis on the En-De translation results. The small and full softmax results are based on the REINFORCE setting, and "Reference" corresponds to the En-De reference translations of the development split.

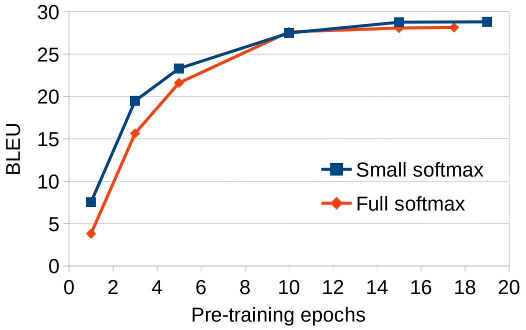

Figure 3: Effects of pre-training for REINFORCE.

	2M	2M, SW
Cross entropy	38.76	39.15

REINFORCE w/ cross entropy (K=1000)	40.16
w/ beam search	40.50
- Cross entropy (1.3M) w/ beam search (Hashimoto and Tsuruoka, 2017)	39.42
- Cross entropy (2M) w/ beam search (Oda et al., 2017b)	40.29
- Cross entropy (2M+1M back-trans.) w/ beam search (Morishita et al., 2017)	41.42

Table 4: BLEU scores for the En-Ja test split, where we use the En-Ja (2M, SW) dataset. The 95% confidence interval by bootstrap resampling (Noreen, 1989) is [39.61, 41.47] for our beam search result.

and we observed the same trend for all the other datasets. Each entry is computed as follows:

$$\frac{\#\text{ of output words in each percentile}}{\#\text{ of output words}}, \quad (12)$$

where the "10" percentile includes the top 10% of the most *frequent* words, and the "100" percentile includes the top 10% of the most *infrequent* words. We can see that our small softmax method better outputs rare words, and these results suggest that using input-specific vocabularies is useful in controlling action spaces for reinforcement learning.

Effectiveness with fewer pre-training steps We followed the standard practice that the models are pre-trained by maximum likelihood before starting reinforcement learning. However, such pre-training may have a negative effect in reinforcement learning. Consider the situation where the pre-training leads to zero cross-entropy loss. In this case, nothing will be learned during reinforcement learning because no exploratory action can be performed. Although pre-training in practice does not lead to zero cross-entropy loss, it can still overfit the data and result in very sharp output distributions, thereby hindering exploration in reinforcement learning. It is therefore important to consider a reinforcement learning setting with less or no pre-training (Liu et al., 2018). In Figure 3 for the En-Ja (100K) dataset, we show that the small softmax method works more effectively with fewer pre-training epochs. For this experiment, we set $\lambda = 0$ in Equation (7) to purely focus on REINFORCE. Using GLEU (or BLEU) scores gives sparse rewards, and thus the resulting BLEU scores are very low with fewer pre-training steps, but the small softmax method has the potential to work well if we can design more effective reward functions.

Results on larger datasets To see whether our method works in larger scales, Table 3 shows BLEU scores for the development split when using the En-Ja (2M) and En-Ja (2M, SW) datasets.[6] These results show that our method consistently works even on these larger datasets at the word and subword levels. In this table we also report how our method works with beam search, and the greedy-based BLEU scores are very close to those of beam search after the REINFORCE phase. When performing a beam search, we can optionally use different sizes of the small vocab-

---

[6] For the 2M dataset, the full softmax baseline achieves BLEU scores of 38.67 and 39.84 for the "Cross entropy" and "REINFORCE w/ cross entropy" settings, respectively.

			Training time [minutes/epoch]				GPU memory [MiB]			
			CE		REINFORCE w/ CE		CE		REINFORCE w/ CE	
	$\|V\|$	$\max(N)$	Small	Full	Small	Full	Small	Full	Small	Full
En-Ja (100K)	23,536	50	4.6	4.8	10.1	21.2	1,781	6,061	2,193	7,443
En-Ja (2M)	70,668	100	95.7	141.4	231.3	635.9	5,033	10,527	6,485	14,803

ulary, but we observe that our method is robust to the changes, whereas Wu et al. (2017) reported that their dynamic vocabulary selection method is sensitive to such changes.

For reference, we report the test set results in Table 4. We cite BLEU scores from previously published papers which reported results of single models (i.e., without ensemble). Our method with greedy translation achieves a competitive score. It should be noted that Morishita et al. (2017) achieve a better score presumably because they used additional in-domain one million parallel sentences obtained by the back-translation technique (Sennrich et al., 2016).

6 Efficiency of the Proposed Method

This section discusses our main contribution: how efficient our method is in accelerating reinforcement learning for sentence generation.

6.1 Speedup at Training Time

We have examined the training-time efficiency of our method. Table 5 shows the training time [minutes/epoch] for five different datasets. We selected the five datasets to show results with different vocabulary sizes and different maximum sentence lengths, and we observed the same trend on the other datasets. The vocabulary size $|V|$ and the maximum sentence length $\max(N)$ are shown for each training dataset. In the training with the standard cross entropy loss, the speedup by our method is not impressive as long as the vocabulary size $|V|$ can be easily handled by the GPUs. We set $S = 2$ for the cross entropy training of the "Full softmax" method in the En-Ja (2M) setting, to reduce the GPU memory consumption as described in Section 4.4.

In the training with the REINFORCE algorithm, the speedup by our method is enhanced. In particular, in the En-Ja (2M) experiments, our method gains a factor of 2.7 speedup compared with the full softmax baseline ($S = 3$). For most of the experimental settings, the speedup significantly accelerates our research and development cycles when working on reinforcement learning for sentence generation tasks. One exception is the Flickr8K dataset whose original vocabulary size $|V|$ is already very small, and the lengths of the target sentences are short. In the supplementary material, we also show the test-time efficiency.

6.2 GPU Memory Consumption

Our method is also efficient in terms of GPU memory consumption at training time. Table 5 also shows the maximum GPU memory consumption during the training. These results show that our method easily fits in the memory of the single `GTX 1080` GPU, whereas "Full softmax" is very sensitive to the vocabulary size $|V|$ and the sentence lengths. In particular, we observe about 56% reduction in memory usage when using the En-Ja (2M) dataset. By saving the memory usage, one could try using larger models, larger mini-batches, larger vocabularies, and longer target sentences without relying on multiple GPUs.

Scalability of our method To further show the memory efficiency our our method, we measured the GPU memory consumption with a larger mini-batch size, 2048. We applied the mini-batch splitting strategy to both the small and full softmax methods to handle such a large mini-batch size. In the En-Ja (2M) experiments with REINFORCE, our small softmax method works with the large batch-size by setting $S = 6$, whereas the full softmax baseline needs $S = 40$. Aggressively splitting the mini-batch (i.e. using larger values of S) slows down the training time, and in that sense our method is much more efficient when we consider the larger mini-batch sizes. If we increase the mini-batch size to 4096, our small softmax method works with $S = 12$.

7 Related Work

Reducing the computational cost at the large softmax layer in language modeling/generation is actively studied (Jean et al., 2015; Ji et al., 2016; Eriguchi et al., 2016; L'Hostis et al., 2016; Zoph et al., 2016; Wu et al., 2017). Most of the existing methods try to reduce the vocabulary size by either negative sampling or vocabulary prediction. One exception is that Oda et al. (2017a) propose to predict a binary code of its corresponding target word. Although such a sophisticated method is promising, we focused on the vocabulary reduction method to apply policy-based reinforcement learning in a straightforward way.

As reported in this paper, one simple way to define a reward function for reinforcement learning is to use task-specific automatic evaluation metrics (Ranzato et al., 2016; Wu et al., 2016; Rennie et al., 2017; Zhang and Lapata, 2017; Paulus et al., 2018), but this is limited in that we can only use training data with gold target sentences. An alternative approach is to use a *discriminator* in generative adversarial networks (Goodfellow et al., 2014), and Yang et al. (2018) showed that REINFORCE with such a discriminator improves translation accuracy. However, Yang et al. (2018) only used the training data, and thus the potential of the generative adversarial networks is not fully realized. One promising direction is to improve the use of the generative adversarial networks for the sentence generation tasks by using our method, because our method can also accelerate the combination of REINFORCE and the discriminator.

8 Conclusion

This paper has presented how to accelerate reinforcement learning for sentence generation tasks by reducing large action spaces. Our method is as accurate as, is faster than, and uses less GPU memory than the standard full softmax counterpart, on sentence generation tasks of different modalities. In future work, it is interesting to use our method in generative adversarial networks to further improve the sentence generation models.

Abstract

The uncertainty measurement of classifiers' predictions is especially important in applications such as medical diagnoses that need to ensure limited human resources can focus on the most uncertain predictions returned by machine learning models. However, few existing uncertainty models attempt to improve overall prediction accuracy where human resources are involved in the text classification task. In this paper, we propose a novel neural-network-based model that applies a new dropout-entropy method for uncertainty measurement. We also design a metric learning method on feature representations, which can boost the performance of dropout-based uncertainty methods with smaller prediction variance in accurate prediction trials. Extensive experiments on real-world data sets demonstrate that our method can achieve a considerable improvement in overall prediction accuracy compared to existing approaches. In particular, our model improved the accuracy from 0.78 to 0.92 when 30% of the most uncertain predictions were handed over to human experts in "20NewsGroup" data.

1 Introduction

Machine learning algorithms are gradually taking over from the human operators in tasks such as machine translation (Bahdanau et al., 2014), optical character recognition (Mithe et al., 2013), and face recognition (Parkhi et al., 2015). However, some real-world applications require higher accuracy than the results achieved by state-of-the-art algorithms, which makes it difficult to directly apply these algorithms in certain scenarios. For example, a medical diagnosis system (van der Westhuizen and Lasenby, 2017) is expected to have a very high accuracy to support correct decision-making for medical practitioners. Although domain experts can achieve a high performance in these challenging tasks, it is not always feasible to rely on limited and expensive human input for large-scale data sets. Therefore, if we have a model with 70% prediction accuracy, it is intuitive to ask what percentage of the data should be handed to domain experts to achieve an overall accuracy rate above 90%? To maximize the value of limited human resources while achieving desirable results, modeling uncertainty accurately is extremely important to ensure that domain experts can focus on the most uncertain results returned by machine learning models.

Most existing uncertainty models are based on Bayesian models, which are not only time-consuming but also unable to handle large-scale data sets. Deep Neural networks (DNNs) have attracted increasing attention in recent years and have been reported to achieve state-of-the-art performance in various machine learning tasks (Yang et al., 2016; Iyyer et al., 2014). However, unlike probabilistic models, DNNs are still at the early development stage in regards to providing the model uncertainty in their predictions. For those seeking to address the prediction uncertainty in DNNs, it is common to suffer from the following issues on the text classification task. Firstly, few researchers have sought to improve overall prediction performance when only limited human resources are available. Different from existing methods which focus on the value of uncertainty, this problem needs to get domain experts involved in emphasis on the order of the uncertain predictions. For example, the importance of distance between feature representations is neglected by the majority of existing models, but actually this is crucial for improving the order of uncertain predictions, especially during the pre-training of embedding vectors. Moreover, the methods proposed for continuous feature space cannot be applied to discrete text data. For example, adversarial train-

Proceedings of NAACL-HLT 2019, pages 3126–3136
Minneapolis, Minnesota, June 2 - June 7, 2019.

ing is used in some uncertainty models (Goodfellow et al., 2014; Lakshminarayanan et al., 2017; Mandelbaum and Weinshall, 2017). However, due to its dependence on gradient-based methods to generate adversarial examples, the method is not applicable to discrete text data.

In order to simultaneously address all these problems in existing methods, the work presented in this paper adopts a DNN-based approach that incorporates a novel dropout-entropy uncertainty measurement method along with metric learning in the feature representation to handle the uncertainty problem in the document classification task. The study's main contributions can be summarized as follows:

- A novel DNN-based text classification model is proposed to achieve higher model accuracy with limited human input. In this new approach, a reliable uncertainty model learns to identify the accurate predictions with smaller estimated uncertainty.

- Metric learning in feature representation is designed to boost the performance of the dropout-based uncertainty methods in the text classification task. Specifically, the shortened intra-class distance and enlarged inter-class distance can reduce the prediction variance and increase the confidence for the accurate predictions.

- A new dropout-entropy method based on the Bayesian approximation property of Dropout in DNNs is presented. Specifically, we measure the model uncertainty in terms of the information entropy of multiple dropout-based evaluations combined with the de-noising mask operations.

- Extensive experiments on real-world data sets demonstrate that the effectiveness of our proposed approach consistently outperforms existing methods. In particular, the macro-F1 score can be increased from 0.78 to 0.92 by assigning 25% of the labeling work to human experts in a 20-class text classification task.

The rest of this paper is organized as follows. Section 2 reviews related work, and Section 3 provides a detailed description of our proposed model. The experiments on multiple real-world data sets are presented in Section 4. The paper concludes with a summary of the research in Section 5.

2 Related Work

The work related to this paper falls into two sub topics, described as follows.

2.1 Model Uncertainty

Existing uncertainty models are usually based on Bayesian models, which is Traditional Bayesian models such as Gaussian Process (GP), can measure uncertainty of model. However, as a nonparametric model, the time complexity of GP is increased by the size of data, which makes it intractable in many real world applications.

Conformal Prediction (CP) was proposed as a new approach to obtain confidence values (Vovk et al., 1999). Unlike the traditional underlying algorithm, conformal predictors provide each of the predictions with a measure of confidence. Also, a measure of “credibility serves as an indicator of how suitable the training data are used for the classification task (Shafer and Vovk, 2008). Different from Bayesian-based methods, CP approaches obtain probabilistically valid results, which are merely based on the independent and identically distributed assumption. The drawback of CP methods is their computational inefficiency, which renders the application CP not applicable for any model that requires long training time such as Deep Neural Networks.

With the recently heated research on DNNs, the associated uncertainty models have received a great deal of attention. Bayesian Neural Networks are a class of neural networks which are capable of modeling uncertainty (Denker and LeCun, 1990) (Hernández-Lobato and Adams, 2015). These models not only generate predictions but also provide the corresponding variance (uncertainty) of predictions. However, as the number of model parameters increases, these models become computationally more expensive (Wang and Yeung, 2016). Lee et al. proposed a computationally efficient uncertainty method that treats Deep Neural Networks as Gaussian Processes (Lee et al., 2017). Due to its kernel-based design, however, it is not straightforward to apply this to the deep network structures for text classification. Gal and Ghahramani used dropout in DNNs as an approximate Bayesian inference in deep Gaussian processes (Gal and Ghahramani, 2016) to mitigate the problem of representing uncertainty in deep learning without sacrificing the computational complexity. Dropout-based methods have also been extended to various tasks such as computer vision (Kendall and Gal, 2017), autonomous vehicle safety (McAllister et al., 2017) and medical decision making (van der Westhuizen and Lasenby, 2017).

However, few of these methods are specifically designed for text classification and lack of considerations on improving the overall accuracy in the scenario that domain experts can be involved in the process.

2.2 Metric Learning

Metric learning (Xing et al., 2003; Weinberger et al., 2006) algorithms design distance metrics that capture the relationships among data representations. This approach has been widely used in various machine learning applications, including image segmentation (Gong et al., 2013), face recognition (Guillaumin et al., 2009), document retrieval (Xu et al., 2012), and collaborative filtering (Hsieh et al., 2017). Weinberger et al. proposed a large margin nearest neighbor (LMNN) method (Weinberger et al., 2006) in learning a metric to minimize the number of class impostors based on pull and push losses. However, as yet there have been no report of work focusing specifically on mitigating prediction uncertainties. Mandelbaum and Weinshall (Mandelbaum and Weinshall, 2017) measured model uncertainty by the distance when comparing to the feature representations in training data, but this makes the uncertainty measurement inefficient because it requires an iteration over the entire training data set. To the best of our knowledge, we are the first to apply metric learning to mitigate model uncertainty in the text classification task. We also demonstrate that metric learning can be applied to dropout-based approaches to improve their prediction uncertainty.

3 Model

In this section, we propose a DNN-based approach to predict document categories with high confidence for the accurate predictions and high uncertainty for the inaccurate predictions. The overall architecture of the proposed model is presented in Section 3.1. The technical details for the metric loss and model uncertainty predictions are described in Sections 3.2 and 3.3, respectively.

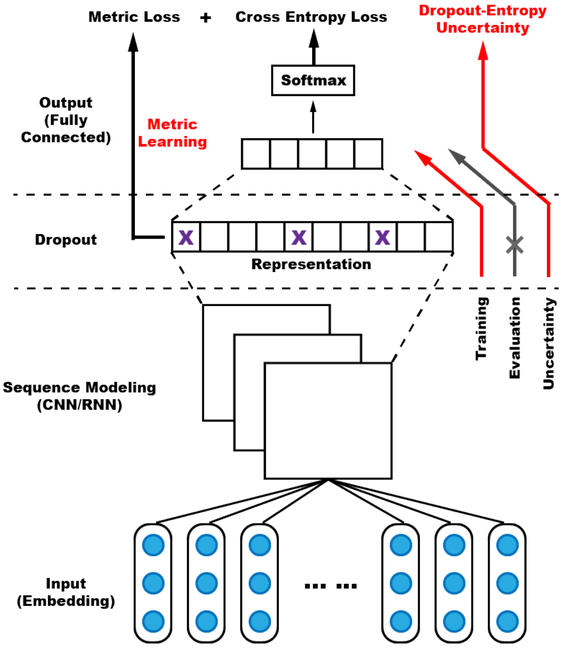

Figure 1: Overall Architecture of Proposed Model

3.1 Model Overview

In order to measure the uncertainty of the predictions for document classification task, we propose a neural-network-based model augmented with dropout-entropy uncertainty measurement and incorporating metric learning in its feature representation. The overall structure of the proposed model is shown in Figure 1. Our proposed model has four layers: 1) **Input Layer**. The input layer is represented by the word embeddings of each words in the document. By default, all word vectors are initialized by Glove (Pennington et al., 2014) pre-trained word vectors in Wikipedia with an embedding dimension of 200. 2) **Sequence Modeling Layer**. The sequence modeling layer extracts the feature representations from word vectors. This is usually implemented by Convolutional Neural Networks (CNN) or Recurrent Neural Networks (RNN). In this paper, we focus on a CNN implementation with max pooling that utilizes 3 kernels with filter sizes of 3, 4 and 5, respectively. After that, a max pooling operation is applied on the output of sequence model. 3) **Dropout layer**. The convolutional layers usually contain a relatively small number of parameters compared to the fully connected layers. It is therefore reasonable to assume that CNN layers suffer less from overfitting, so Dropout is not usually used after CNN layers as it achieves only a trivial performance

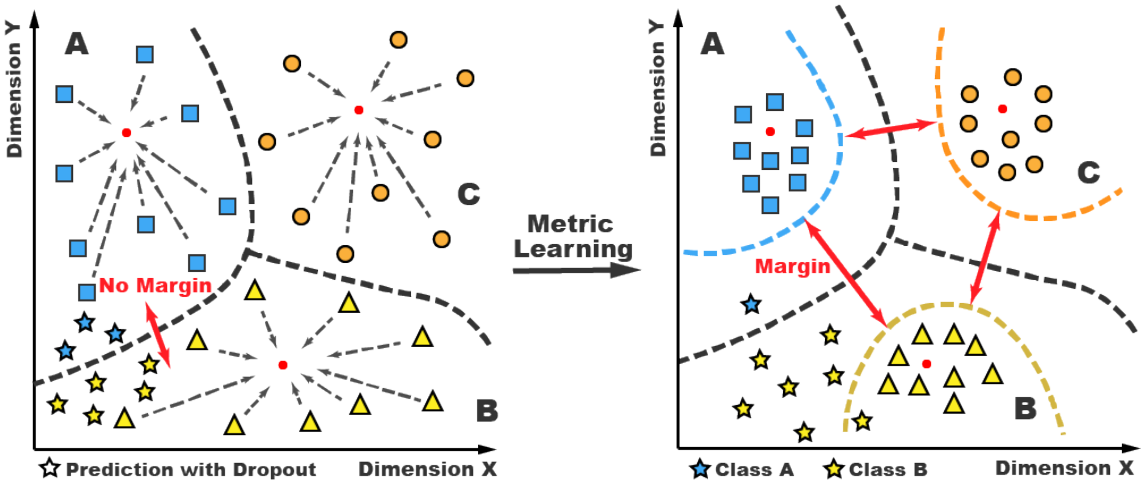

Figure 2: Feature representations with no metric learning (left) and metric learning (right).

improvement (Srivastava et al., 2014). However, since there is only one fully-connected layer in our model, we opted to add one Dropout layer after the CNN layer, not only to prevent overfitting, but also to measure prediction uncertainty (Gal and Ghahramani, 2016). The Dropout operation will be randomly applied to the activations during the training and uncertainty measurement phrases, but will not be applied to the evaluation phrase. 4) **Output layers**. The output is connected by a fully connected layer and the softmax. The loss function of our model is the combination of the cross entropy loss of the prediction and the metric loss of the feature representation. We regard the output of the Dropout layer as the representation of the document and deposit it into a metric loss function. The purpose here is to penalize large distance feature representations in the same class and small distance feature representations among different classes. The details of the metric loss function will be described in Section 3.2.

3.2 Metric Learning on Text Features

For uncertainty learning in text feature space, our purpose is to ensure the Euclidean distance between intra-class instances is much smaller than the inter-class instances. To achieve this, we use metric learning to train the desirable embeddings. Specifically, let $\boldsymbol{r}_i$ and $\boldsymbol{r}_j$ be the feature representations of instances i and j, respectively, then the Euclidean distance between them is defined as $\mathcal{D}(\boldsymbol{r}_i, \boldsymbol{r}_j) = \frac{1}{d}\|\boldsymbol{r}_i - \boldsymbol{r}_j\|_2^2$, where d is the dimension of the feature representation.

Suppose the data instances in the training data contain n classes and these are categorized into n subsets $\{S_k\}_{k=1}^{n}$, where S_k denotes the set of data instances belong to class k. Then the intra-class loss penalizes the large Euclidean distance between the feature representations in the same class, which can be formalized as Equation (1).

$$\mathcal{L}_{\text{intra}}(k) = \frac{2}{|S_k|^2 - |S_k|} \sum_{i,j \in S_k, i<j} \mathcal{D}(\boldsymbol{r}_i, \boldsymbol{r}_j) \tag{1}$$

where $|S_k|$ represents the number of elements in set S_k. The loss is the sum of all the feature distances between each possible pair in the same class set. Then, the loss is normalized by the number of unique pairs belonging to each class set.

The inter-class loss ensures large feature distances between different classes, which is formally defined as Equation (2).

$$\mathcal{L}_{\text{inter}}(p, q) = \frac{1}{|S_p| \cdot |S_q|} \sum_{i \in S_p, j \in S_q} \Big[m - \mathcal{D}(\boldsymbol{r}_i, \boldsymbol{r}_j) \Big]_+ \tag{2}$$

where m is a metric margin constant to distinguish between the intra- and inter-classes and $[z]_+ = \max(0, z)$ denotes the standard hinge loss. If the feature distance between instances from different classes is larger than m, the loss is zero. Otherwise, we use the value of m minus the distance as its penalty loss, with a larger m representing a larger inter-class distance. This parameter usually varies when we use different word embedding methods. In our experiment, we found that a small m is normally needed when the word embedding is initialized by a pre-trained word vector method such as Glove (Pennington et al., 2014); a larger m is required if word vectors are initialized randomly. The overall metric loss function is defined in Equation (3). This combines the intra-class loss and inter-class loss for all the classes.

$$\mathcal{L}_{\text{metric}} = \sum_{k=1}^{n} \left\{ \mathcal{L}_{\text{intra}}(k) + \lambda \sum_{i \neq k} \mathcal{L}_{\text{inter}}(k,i) \right\} \tag{3}$$

where λ is a pre-defined parameter to weight the importance of the intra- and inter-class losses. We set λ to 0.1 by default.

Figure 2 illustrates an example of a three-class feature representation in two dimensions. The left-hand figure shows the feature distribution trained with no metric learning. Obviously, the feature distance of the intra-class is large, sometimes even exceeding those of the inter-class distance near the decision boundary. However, the features trained by metric learning, shown in the right-hand figure, exhibit clear gaps between the inter-class predictions. This means the predictions with dropout are less likely to result in an inaccurate prediction and even reduce the variance of dropout prediction trials. The example shown in Figure 2 has eight dropout predictions, three of which are classified to an inaccurate class when no metric learning is applied compared to only one inaccurate prediction with metric learning.

3.3 Uncertainty Measurement

Bayesian models such as the Gaussian process (Rasmussen, 2004) provide a powerful tool to identify low-confidence regions of input space. Recently, Dropout (Srivastava et al., 2014), which is used in deep neural networks, has been shown to serve as a Bayesian approximation to represent the model uncertainty in deep learning (Gal and Ghahramani, 2016). Based on this work, we propose a novel information-entropy-based dropout method to measure the model uncertainty in combination with metric learning for text classification. Given an input data instance $\boldsymbol{x}^*$, we assume the corresponding output of our model is y^*. The output computed by our model incorporates a dropout mechanism in its evaluation mode, which means the activations of intermediate layers with Dropout are not reduced by a factor. When we repeat the process k times, we obtain the output vector $\boldsymbol{y}^* = \{y_1^*, \ldots, y_k^*\}$. Note that the outputs are not the same since the output here is generated by applying dropout after the feature representation layer in Figure 1.

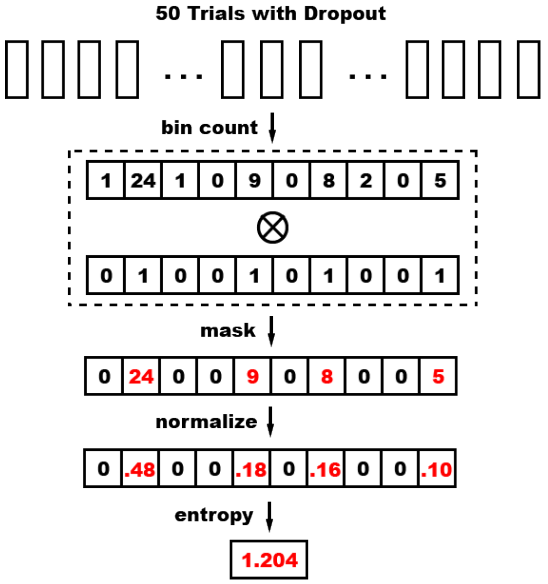

Figure 3: Example of the dropout-entropy method.

Given the output $\boldsymbol{y}^*$ of k trials with Dropout, our proposed uncertainty method has the following four steps, as shown in Figure 3: (1) **Bin count**. We use bin count to calculate the frequency of each class. For example, if the class 2 appears 24 times in the dropout output vector $\boldsymbol{y}^*$, the bin count for class 2 is 24. (2) **Mask**. We use the mask step to avoid random noises in the frequency vector. In this step, we set the largest m elements to have their original values and the remaining ones to zero. The value of m is usually chosen to be $2/3$ of the total class number when the total classes are over 10; otherwise, we just skip the step. (3) **Normalization**. We use the normalization step to calculate the probabilities of each class. (4) **Information entropy**. The information entropy is calculated by $u = -\sum_{i=1}^{c} p_k(i) \log p_k(i)$, where $p_k(i)$ represents the frequency probability of the i-th class in a total k trials and c is the number of classes. We use the entropy value as the uncertainty score here, in which the smaller the entropy value is, the more confident the model is in the output. Take the case in Figure 3 as an example. When the frequency of class 2 is 24, the entropy is 1.204. If the output of the 50 trials all belong to class 2, the entropy becomes 0.401, which means that the model is less uncertain about the predictive results.

4 Experiment

In this section, the performance of the proposed model uncertainty approach is evaluated on multiple real-world document classification data sets.

Table 1: Uncertainty Scores for the 20 NewsGroup Dataset (20 Categories)

After an introduction of the experiment settings in Section 4.1, we compare the performance achieved by the proposed method against those of existing state-of-the-art methods, along with an analysis of the parameter settings and metric learning in Section 4.2. Due to space limitation, the detailed experiment results on different sequence models can be accessed in the full version here[1]. The source code can be downloaded here[2].

4.1 Experimental Setup

In our experiments, all word vectors are initialized by pre-trained Glove (Pennington et al., 2014) word vectors, by default. The word embedding vectors are pre-trained in Wikipedia 2014 with a word vector dimension of 200. We trained all the DNN-based models with a batch size of 32 samples with a momentum of 0.9 and an initial learning rate of 0.001 using the Adam (Kingma and Ba, 2014) optimization algorithm.

4.1.1 Datasets and Labels

We conducted experiments on three publicly available datasets: 1) **20 Newsgroups**[3] (Lang, 1995): The data set is a collection of 20,000 documents, partitioned evenly across 20 different news groups; 2) **IMDb Reviews** (Maas et al., 2011): The data set contains 50,000 popular movie reviews with binary positive or negative labels from the IMDb website; and 3) **Amazon Reviews** (McAuley and Leskovec, 2013): The dataset is a collection of reviews from Amazon spanning the time period from May 1996 to July 2013. We used review data from the Sports and outdoors category, with 272,630 data samples and rating labels from 1 to 5.

For all three data sets, we randomly selected 70% of the data samples as the training set, 10% as the validation set and 20% as the test set.

4.1.2 Evaluation Metrics

In order to answer the question ”*What percentage of data should be transferred to domain experts to achieve an overall accuracy rate above 90%?*”, we measure the classification performance in terms of various uncertainty ratios. Specifically, assuming the entire testing set S has size n and an uncertainty ratio r, we can remove the most uncertain samples S_r from S based on the uncertainty ratio r, where the size of the uncertainty set S_r is $r \cdot n$. We assume the uncertain samples S_r handed to domain experts achieve 100% accuracy. If the uncertainty ratio r equals to 0, the model performs

without uncertainty measurement concerns.

For the binary classification task, we use the accuracy and F1-score to measure the classification performance based on the testing set $S \setminus S_r$ for different uncertainty ratios r. Similarly, for multi-class tasks, we use the micro-F1 and macro-F1 scores utilizing the same settings as for the binary classification.

4.1.3 Comparison Methods

The following methods are included in the performance comparison: 1) Penultimate Layer Variance (PL-Variance). Activations before the softmax layer in a deep neural network always reveal the uncertainty of the prediction (Zaragoza and d'Alche Buc, 1998). As a baseline method, we use the variance of the output of a fully connected layer in Figure 1 as the uncertainty weight. 2) Deep Neural Networks as Gaussian Processes (NNGP) (Lee et al., 2017). This approach applies a Gaussian process to perform a Bayesian inference for deep neural networks, with a computationally efficient pipeline being used to compute the covariance function of the Gaussian process. The default parameter settings in the source code[4] were applied in our experiments. 3) Distance-based Confidence (Distance)(Mandelbaum and Weinshall, 2017). This method assigns confidence scores based on the data embedding compared to the training data. We set its nearest neighbor parameter $k = 10$. 4) Dropout (Gal and Ghahramani, 2016). Here, dropout training in DNNs is treated as an approximation of Bayesian inference in deep Gaussian processes. We set the sample number T as 100 in our experiments. 5) Dropout + Metric. In

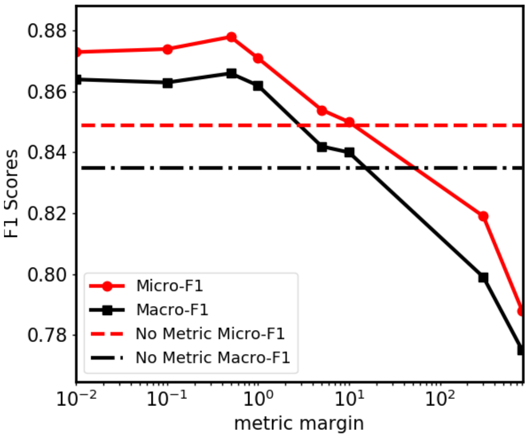

Figure 4: Prediction performance for different metric margin settings.

order to validate the effectiveness of our metric learning, we applied our proposed metric learning method to the Dropout method. The metric margin m and coefficient λ were set as 0.5 and 0.1, respectively. 6) Our proposed method. We evaluate our proposed method in two different settings, Dropout-Entropy alone (DE) and Dropout-Entropy with metric learning (DE + Metric). Here, we set the sample number $T = 100$, coefficient $\lambda = 0.1$ and the metric margin may vary from different data sets.

4.2 Experimental Results

This subsection presents the results of the uncertainty performance comparison and the analysis of the metric learning and parameter settings.

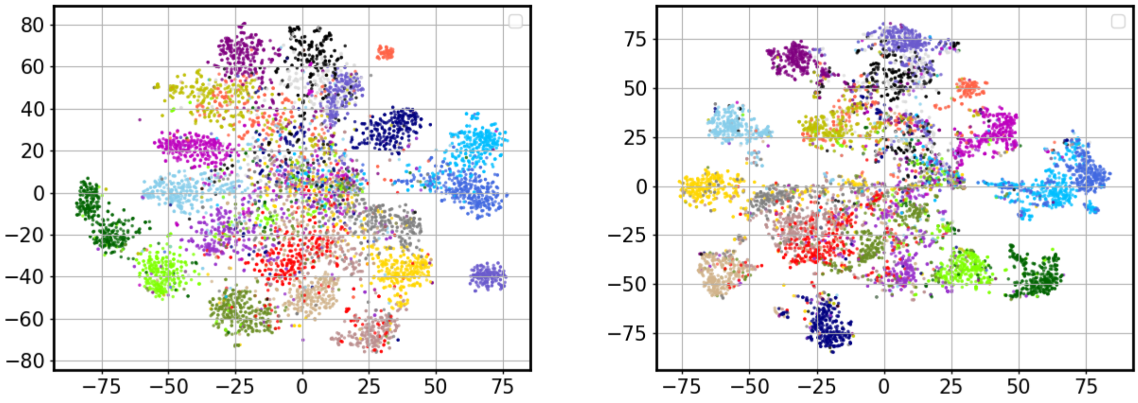
4.2.1 Uncertainty Results

Table 1 shows the Micro-F1 and Macro-F1 scores for ratios of uncertain predictions eliminated ranging from 10 to 40% for the 20NewsGroup data set. To demonstrate its effect, metric learning was also applied to the baseline method Dropout, and our proposed method DE. The improvement ratio compared to the results with no uncertainty elimination, shown in the 0% column, are presented after the F1 scores. Based on these result, we can conclude that: 1) Our proposed method, DE+Metric, significantly improves both the Micro- and Macro-F1 scores when a portion of uncertain predictions are eliminated. For example, the Micro-F1 improves from 0.78 to 0.92 when 30% of the uncertain predictions are eliminated. 2) Comparing the results obtained by DE and DE+Metric, metric learning significantly improves the results obtained for different uncertainty ratio settings. Similar results can be observed when comparing the Dropout and Dropout+Metric. For example, the Micro-F1 scores for Dropout+Metric are around 5% better than the Dropout method alone, boosting them from 0.851 to 0.892, with a 30% uncertainty ratio. 3) The DE method outperforms all the other methods when metric learning is not applied. Specifically, DE is around 4% better than the Dropout method in terms of the Micro-F1 score.

The results for IMDb and Amazon data sets are presented in Table 2 and Table 3. When comparing our proposed model's performance across three data sets, we found that the greater improvements are achieved on multi- instead of binary-class classification data sets. One possible explanation is that a comparatively large portion of multi-class features are close to the decision boundary in the feature space. Through the metric learning strategy of minimizing intra-class distance while maxmizing the inter-class instances, the feature distance between the inter-class predictions is enlarged and the quality of embeddings is greatly enhanced.

4.2.2 Analysis of Metric Learning

The impact of metric learning on feature representation is analyzed in this section. Figure 5 shows the 300-dimension feature representations



(a) No Metric Learning

(b) Metric Margin m = 10

Figure 5: Feature visualization of 20 NewsGroup testing data set in two dimensions by t-SNE algorithm.

for the 20 NewsGroup testing data set, with Figure 5(a) presenting the features trained without metric learning and Figure 5(b) those trained by metric learning with a margin parameter m=10. We used the t-SNE algorithm (Maaten and Hinton, 2008) to visualize the high dimensional features in the form of two dimensional images. From the results, we can clearly see that the distances between the inter-classes are significantly enlarged compared to the features trained without metric learning shown in Figure 5(a). This enlarged inter-class spacing means that dropout-based uncertainty methods have smaller prediction variances in case their dropout prediction trials are accurate.

4.2.3 Parameter Analysis

The impact of the metric margin and word embeddings are discussed in this section.

Metric Margin. Figure 4 shows the impact of metric margin parameters, ranging from 0 to 800 on the 20 NewsGroup data set with a 20% uncertainty ratio. From the results, we can conclude that: (1) The prediction performance is not sensitive to the point at which the metric margin parameter is set as long as its value is not extremely large. (2) Compared to the model trained with no metric learning, our methods consistently achieve better performance when the metric margin is set no larger than 10. When the metric margin is too large, however, the prediction cross-entropy loss is hard to minimize and thus dampens the overall prediction performance. (3) The results of Macro-F1 are similar to Micro-F1 with relatively small scores.

Impact of Word Embedding. We also analyzed the impact of our proposed methods on different word embedding initialization methods, including random and pre-trained Glove word vectors in 200 dimensions. Table 4 shows the results of Micro-F1 for the different uncertainty ratios. We can observe that: 1) The performance of Glove-based methods are around 15% better than that of the randomly initialized methods for different uncertainty ratios. 2) Metric learning based on a Glove initialization generally outperforms a random initialization. For instance, the F1 score of Glove rises by 0.29 when the uncertainty ratio is 20%, while for a random method it only increases by 0.04.

5 Conclusion

In this paper, a DNN-based model is proposed to address the uncertainty mitigation problem in the presence of human involvement in a text classification task. To achieve this, we proposed a dropout-entropy uncertainty measurement method with the metric learning for the feature representation. Extensive experiments on real-world data sets confirmed that our proposed approach dramatically outperforms competing methods, exhibiting a significant improvement in accuracy when a relatively small portion of the uncertainty predictions are handed over to domain experts.

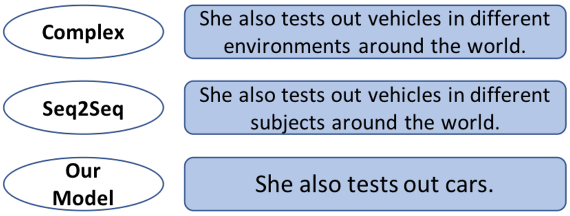
Abstract

Sentence simplification is the task of rewriting texts so they are easier to understand. Recent research has applied sequence-to-sequence (Seq2Seq) models to this task, focusing largely on training-time improvements via reinforcement learning and memory augmentation. One of the main problems with applying generic Seq2Seq models for simplification is that these models tend to copy directly from the original sentence, resulting in outputs that are relatively long and complex. We aim to alleviate this issue through the use of two main techniques. First, we incorporate content word complexities, as predicted with a leveled word complexity model, into our loss function during training. Second, we generate a large set of diverse candidate simplifications at test time, and rerank these to promote fluency, adequacy, and simplicity. Here, we measure simplicity through a novel sentence complexity model. These extensions allow our models to perform competitively with state-of-the-art systems while generating simpler sentences. We report standard automatic and human evaluation metrics.[1]

1 Introduction

Automatic text simplification aims to reduce the complexity of texts and preserve their meaning, making their content more accessible to a broader audience (Saggion, 2017). This process can benefit people with reading disabilities, foreign language learners and young children, and can assist non-experts exploring a new field. Text simplification has gained wide interest in recent years due to its relevance for NLP tasks. Simplifying text during preprocessing can improve the performance of syntactic parsers (Chandrasekar et al., 1996) and semantic role labelers (Vickrey and Koller, 2008; Woodsend and Lapata, 2014), and can improve the grammaticality (fluency) and meaning preservation (adequacy) of translation output (Štajner and Popovic, 2016).



She also tests out vehicles in different environments around the world.

She also tests out vehicles in different subjects around the world.

She also tests out cars.

Figure 1: Example comparison of a simplification generated by a standard Seq2Seq model vs. our model.

Most text simplification work has approached the task as a monolingual machine translation problem (Woodsend and Lapata, 2011; Narayan and Gardent, 2014). Once viewed as such, a natural approach is to use sequence-to-sequence (Seq2Seq) models, which have shown state-of-the-art performance on a variety of NLP tasks, including machine translation (Vaswani et al., 2017) and dialogue systems (Vinyals and Le, 2015).

One of the main limitations in applying standard Seq2Seq models to simplification is that these models tend to copy directly from the original complex sentence too often, as this is the most common operation in simplification. Several recent efforts have attempted to alleviate this problem using reinforcement learning (Zhang and Lapata, 2017) and memory augmentation (Zhao et al., 2018), but these systems often still produce outputs that are longer than the reference sentences. To avoid this problem, we propose to extend the generic Seq2Seq framework at both training and inference time by encouraging the model to choose simpler content words, and by effectively choosing an output based on a large set of can-

didate simplifications. The main contributions of this paper can be summarized as follows:

- We propose a custom loss function to replace standard cross entropy probabilities during training, which takes into account the complexity of content words.
- We include a similarity penalty at inference time to generate more diverse simplifications, and we further cluster similar sentences together to remove highly similar candidates.
- We develop methods to rerank candidate simplifications to promote fluency, adequacy, and simplicity, helping the model choose the best option from a diverse set of sentences.

An analysis of each individual components reveals that of the three contributions, reranking simplifications at post-decoding stage brings about the largest benefit for the simplification system. We compare our model to several state-of-the-art systems in both an automatic and human evaluation settings, and show that the generated simple sentences are shorter and simpler, while remaining competitive with respect to fluency and adequacy. We also include a detailed error analysis to explain where the model currently falls short and provide suggestions for addressing these issues.

2 Related Work

Text simplification has often been addressed as a monolingual translation process, which generates a simplified version of a complex text. Zhu et al. (2010) employ a tree-based translation model and consider sentence splitting, deletion, reordering, and substitution. Coster and Kauchak (2011) use a Phrase-Based Machine Translation (PBMT) system with support for deleting phrases, while Wubben et al. (2012) extend a PBMT system with a reranking heuristic (PBMT-R). Woodsend and Lapata (2011) propose a model based on a quasi-synchronous grammar, a formalism able to capture structural mismatches and complex rewrite operations. Narayan and Gardent (2014) combine a sentence splitting and deletion model with PBMT-R. This model has been shown to perform competitively with neural models on automatic metrics, though it is outperformed using human judgments (Zhang and Lapata, 2017).

In recent work, Seq2Seq models are widely used for sequence transduction tasks such as machine translation (Sutskever et al., 2014; Luong et al., 2015), conversation agents (Vinyals and Le, 2015), summarization (Nallapati et al., 2016), etc. Initial Seq2Seq models consisted of a Recurrent Neural Network (RNN) that encodes the source sentence $\mathbf{x}$ to a hidden vector of a fixed dimension, followed by another RNN that uses this hidden representation to generate the target sentence $\mathbf{y}$. The two RNNs are then trained jointly to maximize the conditional probability of the target sentence given the source sentence, i.e. $P(\mathbf{y}|\mathbf{x})$. Other works have since extended this framework to include attention mechanisms (Luong et al., 2015) and transformer networks (Vaswani et al., 2017).[2] Nisioi et al. (2017) was the first major application of Seq2Seq models to text simplification, applying a standard encoder-decoder approach with attention and beam search. Vu et al. (2018) extended this framework to incorporate memory augmentation, which simultaneously performs lexical and syntactic simplification, allowing them to outperform standard Seq2Seq models.

There are two main Seq2Seq models we will compare to in this work, along with the statistical model from Narayan and Gardent (2014). Zhang and Lapata (2017) proposed DRESS (Deep REinforcement Sentence Simplification), a Seq2Seq model that uses a reinforcement learning framework at training time to reward the model for producing sentences that score high on fluency, adequacy, and simplicity. This work showed state-of-the-art results on human evaluation. However, the sentences generated by this model are in general longer than the reference simplifications. Zhao et al. (2018) proposed DMASS (Deep Memory Augmented Sentence Simplification), a multi-layer, multi-head attention transformer architecture which also integrates simplification rules. This work has been shown to get state-of-the-art results in an automatic evaluation, training on the WikiLarge dataset introduced by Zhang and Lapata (2017). Zhao et al. (2018), however, does not perform a human evaluation, and restricting evaluation to automatic metrics is generally insufficient for comparing simplification models. Our model, in comparison, is able to generate shorter and simpler sentences according to Flesch-Kincaid grade level (Kincaid et al., 1975) and human judgments, and provide a comprehensive analysis using human evaluation and a qualitative error analysis.

---

[2] For a detailed description of Seq2Seq models, please see (Sutskever et al., 2014).

3 Seq2Seq Approach

3.1 Complexity-Weighted Loss Function

Standard Seq2Seq models use cross entropy as the loss function at training time. This only takes into account how similar our generated tokens are to those in the reference simple sentence, and not the complexity of said tokens. Therefore, we first develop a model to predict word complexities, and incorporate these into a custom loss function.

3.1.1 Word Complexity Prediction

Extending the complex word identification model of Kriz et al. (2018), we train a linear regression model using length, number of syllables, and word frequency; we also include Word2Vec embeddings (Mikolov et al., 2013). To collect data for this task, we consider the Newsela corpus, a collection of 1,840 news articles written by professional editors at 5 reading levels (Xu et al., 2015).[3] We extract word counts in each of the five levels; in this dataset, we denote 4 as the original complex document, 3 as the least simplified re-write, and 0 as the most simplified re-write. We propose using Algorithm 1 to obtain the complexity label for each word w, where l_w represents the level given to the word, and c_{w_i} represents the number of times that word occurs in level i.

Algorithm 1 Word Complexity Data Collection

```
procedure DATA COLLECTION
    $l_w \leftarrow 4$
    for $i \in \{3, 0\}$ do
        if $c_{w_i} \geq 0.7 * c_{w_{i+1}}$ then
            if $c_{w_i} \geq 0.4 * c_{w_4}$ then
                $l_w \leftarrow i$
    return $l_w$
```

Here, we initially label the word with the most complex level, 4. If at least 70% of the instances of this word is preserved in level 3, we reassign the label as level 3; if the label was changed, we then do this again for progressively simpler levels.

As examples, Algorithm 1 labels "pray", "sign", and "ends" with complexity level 0, and "proliferation", "consensus", and "emboldened" with complexity level 4. We split the data extracted from Algorithm 1 into Train, Validation and Test sets (90%, 5% and 5%, respectively, and use them for training and evaluating the complexity prediction model. [4]

Model	Correlation	MSE
Frequency Baseline	-0.031	1.90
Length Baseline	0.344	1.51
LinReg	**0.659**	**0.92**

Table 1: Pearson Correlation and Overall Mean Squared Error (MSE) of the word-level complexity prediction model (LinReg). Comparison to length-based and frequency-based baselines.

We report the Mean Squared Error (MSE) and Pearson correlation on our test set in Table 1.[5] We compare our model to two baselines, which predict complexity using log Google n-grams frequency (Brants and Franz, 2006) and word length, respectively. For these baselines, we calculate the minimum and maximum values for words in the training set, and then normalize the values for words in the test set.

3.1.2 Loss Function

We propose a metric that modifies cross entropy loss to upweight simple words while downweighting more complex words. More formally, the probabilities of our simplified loss function can be generated by the process described in Algorithm 2. Since our word complexities are originally from 0 to 4, with 4 being the most complex, we need to reverse this ordering and add one, so that more complex words and non-content words are not given zero probability. In this algorithm, we denote the original probability vector as **CE**, our vocabulary as **V**, the predicted word complexity of a word v as $score_v$, the resulting weight for a word as w_v, and our resulting weights as **SCE**, which we then normalize and convert back to logits.

Here, α is a parameter we can tune during experimentation. Note that we only upweight simple content words, not stopwords or entities.

3.2 Diverse Candidate Simplifications

To increase the diversity of our candidate simplifications, we apply a beam search scoring modification proposed in Li et al. (2016). In standard

---

[3] Newsela is an education company that provides reading materials for students in elementary through high school. The Newsela corpus can be requested at https://newsela.com/data/

[4] Note that we also tried continuous rather than discrete labels for words by averaging frequencies, but found that this increased the noise in the data. For example, "the" and "dog" were incorrectly labeled as level 2 instead of 0, since these words are seen frequently across all levels.

[5] We report MSE results by level in the appendix.

Algorithm 2 Simplified Loss Function

```
procedure SIMPLIFIED LOSS
    CE ← softmax($logits_{CE}$)
    for $v \in \mathbf{V}$ do
        $score_v \leftarrow WordComplexity(v)$
        if $v$ is a content word then
            $w_v \leftarrow (4 - s_v) + 1$
        else
            $w_v \leftarrow 1$
    $w_v \leftarrow \left(\frac{w_v}{\sum_{v \in V} w_v}\right)^{\alpha}$ for $v \in \mathbf{V}$
    SCE ← CE · w
  return SCE
```

beam search with a beam width of b, given the b hypotheses at time $t-1$, the next set of hypotheses is generated by first selecting the top b candidate expansions from each hypothesis. These $b \times b$ hypotheses are then ranked by the joint probabilities of their sequence of output tokens, and the top b according to this ranking are chosen.

We observe that candidate expansions from a single parent hypothesis tend to dominate the search space over time, even with a large beam. To increase diversity, we apply a penalty term based on the rank of a generated token among the b candidate tokens from its parent hypothesis.

If Y^j_{t-1} is the j^{th} top hypothesis at time $t-1$, $j \in [1..b]$, and $y^{j,j'}_t$ is a candidate token generated from Y^j_{t-1}, where $j' \in [1..b]$ represents the rank of this particular token among its siblings, then our modified scoring function is as follows (here, δ is a parameter we can tune during experimentation):

$$S(Y^j_{t-1}, y^{j,j'}_t) = \log p(y^j_1, \ldots, y^j_{t-1}, y^{j,j'}_t | x) - j' * \delta \quad (1)$$

Extending the work of Li et al. (2016), to further increase the distance between candidate simplifications, we can cluster similar sentences after decoding. To do this, we convert each candidate into a document embedding using Paragraph Vector (Le and Mikolov, 2014), cluster the vector representations using k-means, and select the sentence nearest to the centroids. This allows us to group similar sentences together, and only consider candidates that are relatively more different.

Model	Correlation	MSE
Length Baseline	0.503	3.72
CNN (ours)	**0.650**	**1.13**

Table 2: Pearson Correlation and Overall Mean Squared Error (MSE) for the sentence-level complexity prediction model (CNN), compared to a length-based baseline.

3.3 Reranking Diverse Candidates

Generating diverse sentences is helpful only if we are able to effectively rerank them in a way that promotes simpler sentences while preserving fluency and adequacy. To do this, we propose three ranking metrics for each sentence i:

- **Fluency** (f_i): We calculate the perplexity based on a 5-gram language model trained on English Gigaword v.5 (Parker et al., 2011) using KenLM (Heafield, 2011).
- **Adequacy** (a_i): We generate Paragraph Vector representations (Le and Mikolov, 2014) for the input sentence and each candidate and calculate the cosine similarity.
- **Simplicity** (s_i): We develop a sentence complexity prediction model to predict the overall complexity of each sentence we generate.

To calculate sentence complexity, we modify a Convolutional Neural Network (CNN) for sentence classification (Kim, 2014) to make continuous predictions. We use aligned sentences from the Newsela corpus (Xu et al., 2015) as training data, labeling each with the complexity level from which it came.[6] As with the word complexity prediction model, we report MSE and Pearson correlation on a held-out test set in Table 2.[7]

We normalize each individual score between 0 and 1, and calculate a final score as follows:

$$score_i = \beta_f f_i + \beta_a a_i + \beta_s s_i \quad (2)$$

We tune these weights (β) on our validation data during experimentation to find the most appropriate combinations of reranking metrics. Examples of improvements resulting from the including each of our contributions are shown in Table 3.

4 Experiments

4.1 Data

We train our models on the Newsela Corpus. In previous work, models were mainly trained on the parallel Wikipedia corpus (PWKP) consisting of paired sentences from English Wikipedia

---

[6] We respect the train/test splits described in Section 4.1.

[7] We report MSE results by level in the appendix.

and Simple Wikipedia (Zhu et al., 2010), or the extended WikiLarge corpus (Zhang and Lapata, 2017). We choose to instead use Newsela, because it was found that 50% of the sentences in Simple Wikipedia are either not simpler or not aligned correctly, while Newsela has higher-quality simplifications (Xu et al., 2015).

As in Zhang and Lapata (2017), we exclude sentence pairs corresponding to levels 4-3, 3-2, 2-1, and 1-0, where the simple and complex sentences are just one level apart, as these are too close in complexity. After this filtering, we are left with 94,208 training, 1,129 validation, and 1,077 test sentence pairs; these splits are the same as Zhang and Lapata (2017). We preprocess our data by tokenizing and replacing named entities using CoreNLP (Manning et al., 2014).

4.2 Training Details

For our experiments, we use Sockeye, an open source Seq2Seq framework built on Apache MXNet (Hieber et al., 2017; Chen et al., 2015). In this model, we use LSTMs with attention for both our encoder and decoder models with 256 hidden units, and two hidden layers. We attempt to match the hyperparameters described in Zhang and Lapata (2017) as closely as possible; as such, we use 300-dimensional pretrained GloVe word embeddings (Pennington et al., 2014), and Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001. We ran our models for 30 epochs.[8]

During training, we use our complexity-weighted loss function, with $\alpha = 2$; for our baseline models, we use cross-entropy loss. At inference time, where appropriate, we set the beam size $b = 100$, and the similarity penalty $\delta = 1.0$. After inference, we set the number of clusters to 20, and we compare two separate reranking weightings: one which uses fluency, adequacy, and simplicity (FAS), where $\beta_f = \beta_a = \beta_s = \frac{1}{3}$; and one which uses only fluency and adequacy (FA), where $\beta_f = \beta_a = \frac{1}{2}$ and $\beta_s = 0$.

4.3 Baselines and Models

We compare our models to the following baselines:

- **Hybrid** performs sentence splitting and deletion before simplifying with a phrase-based machine translation system (Narayan and Gardent, 2014).
- **DRESS** is a Seq2Seq model trained with reinforcement learning which integrates lexical simplifications (Zhang and Lapata, 2017).[9]
- **DMASS** is a Seq2Seq model which integrates the transformer architecture and additional simplifying paraphrase rules (Zhao et al., 2018).[10]

We also present results on several variations of our models, to isolate the effect of each individual improvement. **S2S** is a standard sequence-to-sequence model with attention and greedy search. **S2S-Loss** is trained using our complexity-weighted loss function and greedy search. **S2S-FA** uses beam search, where we rerank all sentences using fluency and adequacy (FA weights). **S2S-Cluster-FA** clusters the sentences before reranking using FA weights. **S2S-Diverse-FA** uses diversified beam search, reranking using FA weights. **S2S-All-FAS** uses all contributions, reranking using fluency, adequacy, and simplicity (FAS weights). Finally, **S2S-All-FA** integrates all modifications we propose, and reranks using FA weights.

5 Results

In this section, we compare the baseline models and various configurations of our model with both standard automatic simplification metrics and a human evaluation. We show qualitative examples where each of our contributions improves the generated simplification in Table 3.

5.1 Automatic Evaluation

Following previous work (Zhang and Lapata, 2017; Zhao et al., 2018), we use SARI as our main automatic metric for evaluation (Xu et al., 2016).[11] Specifically, SARI calculates how often a generated sentence correctly keeps, inserts, and deletes n-grams from the complex sentence, using the reference simple standard as the gold-standard, where $1 \leq n \leq 4$. Note that we do not use

---

[8] All non-default hyperparameters can be found in the Appendix.

[9] For Hybrid and DRESS, we use the generated outputs provided in Zhang and Lapata (2017). We made a significant effort to rerun the code for DRESS, but were unable to do so.

[10] For DMASS, we ran the authors' code on our data splits from Newsela, in collaboration with the first author to ensure an accurate comparison.

[11] To calculate SARI, we use the original script provided by (Xu et al., 2016).

Complex Sentence	Model 1	Model 1 Sentence	Model 2	Model 2 Sentence
Mary travels between two offices.	S2S	Mary is a professor at the park.	S2S-Loss	Mary goes between two offices.
Their fatigue changes their voices, but they're still on the freedom highway.	S2S	Their condition changes their voices, but they're still on the freedom highway.	S2S-FA	Their fatigue changes their voices.
Just until recently, the education system had banned Islamic headscarves in schools and made schoolchildren recite a pledge of allegiance.	S2S-FA	The education system had banned Islamic law.	S2S-Cluster-FA	Only until recently , the education system had banned Islamic hijab in schools.
Police used tear gas, dogs and clubs on the unarmed protesters.	S2S-FA	Police used tear gas and dogs on the unarmed protesters.	S2S-Diverse-FA	They used tear gas and dogs.

Table 3: Example sentences where each component of our model improved the output sentence, compared to a model that does not use that component.

Model	SARI	Oracle
Hybrid	33.27	–
DRESS	36.00	–
DMASS	34.35	–
S2S	36.32	–
S2S-Loss	36.03	–
S2S-FA	36.47	54.01
S2S-Cluster-FA	**37.22**	50.36
S2S-Diverse-FA	35.36	52.65
S2S-All-FAS	36.30	50.40
S2S-All-FA	**37.11**	50.40

Table 4: Comparison of our models to baselines and state-of-the-art models using SARI. We also include oracle SARI scores (Oracle), given a perfect reranker. S2S-All-FA is significantly better than the DMASS and Hybrid baselines using a student t-test ($p < 0.05$).

Model	Len	FKGL	TER	Ins	Edit
Complex	23.1	11.14	0	0	–
Hybrid	12.4	7.82	0.49	0.01	–
DRESS	14.4	7.60	0.44	0.07	–
DMASS	15.1	7.40	0.59	0.28	–
S2S	16.1	7.91	0.41	0.23	–
S2S-Loss	16.4	8.11	0.40	0.31	–
S2S-FA	7.6	6.42	0.73	0.01	7.28
S2S-Cluster-FA	9.1	6.49	0.68	0.05	7.55
S2S-Diverse-FA	7.5	5.97	0.78	0.07	8.22
S2S-All-FAS	9.1	5.37	0.68	0.05	7.56
S2S-All-FA	10.8	6.42	0.61	0.07	7.56
Reference	12.8	6.90	0.67	0.42	–

Table 5: Average sentence length, FKGL, TER score compared to input, and number of insertions. We also calculate average edit distance (Edit) between candidate sentences for applicable models.

BLEU (Papineni et al., 2002) for evaluation; even though it correlates better with fluency than SARI, Sulem et al. (2018) recently showed that BLEU often negatively correlates with simplicity on the task of sentence splitting. We also calculate oracle SARI, where appropriate, to show the score we could achieve if we had a perfect reranking model. Our results are reported in Table 4.

Our best models outperform previous state-of-the-art systems, as measured by SARI. Table 4 also shows that, when used separately, reranking and clustering result in improvements on this metric. Our loss and diverse beam search methods have more ambiguous effects, especially when combined with the former two; note however that including diversity before clustering does slightly improve the oracle SARI score.

We calculate several descriptive statistics on the generated sentences and report the results in Table 5. We observe that our models produce sentences that are much shorter and lower reading level, according to Flesch-Kincaid grade level (FKGL) (Kincaid et al., 1975), while making more changes to the original sentence, according to Translation Error Rate (TER) (Snover et al., 2006). In addition, we see that the customized loss function increases the number of insertions made, while both the diversified beam search and clustering techniques individually increase the distance between sentence candidates.

5.2 Human Evaluation

While SARI has been shown to correlate with human judgments on simplicity, it only weakly cor-

Model	Fluency	Adequacy	Simplicity	All
Hybrid	2.79*	2.76	2.88*	2.81*
DRESS	**3.50**	**3.11****	3.03	**3.21****
DMASS	2.59*	2.15*	2.50*	2.41*
S2S-All-FAS	3.35	2.50*	**3.11**	2.99
S2S-All-FA	3.38	2.66	**3.08**	3.04
Reference	3.82*	3.23*	3.29*	3.45*

Table 6: Average ratings of crowdsourced human judgments on fluency, adequacy and complexity. Ratings significantly different from S2S-All-FA are marked with * ($p < 0.05$); statistical significance tests were calculated using a student t-test. We provide 95% confidence intervals for each rating in the appendix.

relates with judgments on fluency and adequacy (Xu et al., 2016). Furthermore, SARI only considers simplifications at the word level, while we believe that a simplification metric should also take into account sentence structure complexity. We plan to investigate this further in future work.

Due to the current perceived limitations of automatic metrics, we also choose to elicit human judgments on 200 randomly selected sentences to determine the relative overall quality of our simplifications. For our first evaluation, we ask native English speakers on Amazon Mechanical Turk to evaluate the fluency, adequacy, and simplicity of sentences generated by our systems and the baselines, similar to Zhang and Lapata (2017). Each annotator rated these aspects on a 5-point Likert Scale. These results are found in Table 6.[12]

As we can see, our best models substantially outperform the Hybrid and DMASS systems. Note that DMASS performs the worst, potentially because the transformer model is a more complex model that requires more training data to work properly. Comparing to DRESS, our models generate simpler sentences, but DRESS better preserves the meaning of the original sentence.

To further investigate why this is the case, we know from Table 5 that sentences generated by our model are overall shorter than other models, which also corresponds to higher TER scores. Napoles et al. (2011) notes that on sentence compression, longer sentences are perceived by human annotators to preserve more meaning than shorter sentences, controlling for quality. Thus, the drop in human-judged adequacy may be related to our sentences' relatively short lengths.

To test that this observation also holds true for simplicity, we took the candidates generated by our best model, and after reranking them as before, we selected three sets of sentences:

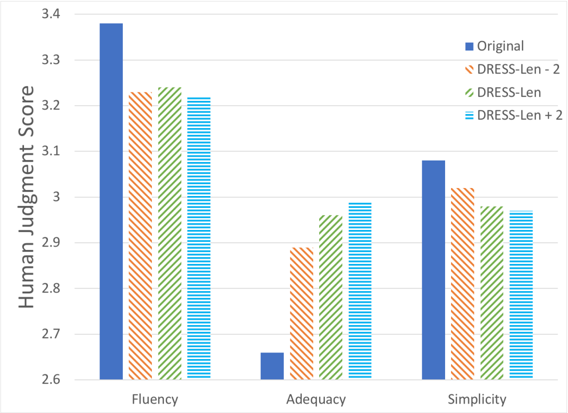

Figure 2: Effect of length on human judgments.

- **MATCH-Dress0**: Highest ranked sentence with length closest to that of DRESS (DRESS-Len); average length is 14.10.
- **MATCH-Dress+2**: Highest ranked sentence with length closest to (DRESS-Len + 2); average length is 15.32.
- **MATCH-Dress-2**: Highest ranked sentence with length closest to (DRESS-Len - 2); average length is 12.61.

The average fluency, adequacy, and simplicity from human judgments on these new sentences are shown in Figure 2, along with those ranked highest by our best model (Original). As expected, meaning preservation does substantially increase as we increase the average sentence length, while simplicity decreases. Interestingly, fluency also decreases as sentence length increases; this is likely due to our higher-ranked sentences having greater fluency, as defined by language model perplexity.

---

[12] We present the instructions for all of our human evaluations in the appendix.

6 Error Analysis

To gain insight in what aspects of the simplification process are challenging to our model, we present the most recurring types of errors from our test set.

6.1 Examples of Error Types

1. Long and complex sentences with multiple clauses
    (a) *Complex*: Turkey has long enshrined the secular ideals of founding father Mustafa Kemal Ataturk, particularly in an education system that until recently banned Islamic headscarves in schools and made schoolchildren begin the day reciting an oath of allegiance to Ataturk's legacy.
    Reference: Schools in Turkey had banned headscarves.
    Simple: They made schoolchildren to Ataturk's history.
    (b) *Complex*: And Wal-Mart, which imports more fruits and vegetables from Mexico than any other U.S. company, announced its effort to force improvements up and down its supply chain.
    Reference: Experts said Wal-Mart is an important company.
    Simple: Wal-Mart used more fruits and vegetables from the company.

2. Need for anaphora resolution
    (a) *Complex*: He is the creative director of Rethink Leisure & Entertainment , which is working on several projects in China and elsewhere in Asia .
    Reference: He is with Rethink Leisure & Entertainment.
    Simple: He is working on several projects in China.
    (b) *Complex*: Teachers there say Richie reads like a high school student.
    Reference: He reads like a high school student.
    Simple: Richie says he is a high school student.

3. Simplifying the wrong part of the sentence
    (a) *Complex*: Parks deliberately maintained her image as shy and proper, said Adrienne Cannon, an expert on African-American history.
    Reference: Adrienne Cannon studies African-American history.
    Simple: She is an expert on African-American history.
    (b) *Complex*: His father owned the home when the lava flowed slowly to the coast.
    Reference: His father still owned the home.
    Simple: The river cut slowly to the coast.

4. Poor substitution due to word embeddings proximity
    (a) *Complex*: Just until recently, the education system had banned Islamic **headscarves** in schools and made schoolchildren begin the day reciting a pledge of allegiance to Ataturk's legacy.
    Reference: Schools in Turkey had banned headscarves.
    Simple: Just until recently, the education officials had banned Islamic **flags**.
    (b) *Complex*: In Beijing kite circles, Fei is widely known as the elder **statesman**.
    Reference: In Beijing, Fei is widely known as an expert.
    Simple: In Beijing, Fei is considered a **doctor**.

5. Training confusion due to misalignments in training corpus
    (a) *Complex*: He heard the applause.
    Reference: The winning word was "magician."
    Simple: But he heard the song.
    (b) *Complex*: More than 300,000 students across the country signed up to participate.
    Reference: Rogers Middle School took part in the program.
    Simple: There were more than 300,000 students.

6. Acceptable simplifications that were not available in the training
    (a) *Complex*: He later tried to buy his freedom.
    Reference: Henson tried to buy his freedom later.
    Simple: The man tried to buy his freedom.
    (b) *Complex*: Middle school was a rough couple of years for Talmus' daughter, Lili Smith.
    Reference: She had a hard time in middle school.
    Simple: School was a rough couple of years.

6.2 Error Discussion

Attempting to rewrite very long and complex sentences resulted to consistent errors, as shown in 1a and 1b. This observation in combination with the examples of mis-alignments in the training corpus (5a and 5b) indicate that we either need to improve the alignments such the model can capture that the simplification process involves in many cases splitting a sentence and then simplifying or train to learn when to split first and then attempt rewriting.

The next two types of errors show failure in capturing discourse level meaning: a) errors due to failed pronoun resolution, shown in 2a and 2b, and b) errors due to the most important part of the sentence being left out, shown in 3b and 3b. In these cases, the sentences were not bad, but the information was assigned to the wrong referent, or important meaning was left out. In 4a and 4b, the substitution is clearly semantically related to the target, but changes the meaning. Finally, there were examples of acceptable simplifications, as in 6a and 6b, that were classified as errors because they were not in the gold data. We provide additional examples for each error category in the appendix.

To improve the performance of future models, we see several options. We can improve the original alignments within the Newsela corpus, particularly in the case where sentences are split. Prior to simplification, we can use additional context around the sentences to perform anaphora resolution; at this point, we can also learn when to perform sentence splitting; this has been done in the Hybrid model (Narayan and Gardent, 2014), but has not yet been incorporated into neural models. Finally, we can use syntactic information to ensure the main clause of a sentence is not removed.

7 Conclusion

In this paper, we present a novel Seq2Seq framework for sentence simplification. We contribute three major improvements over generic Seq2Seq models: a complexity-weighted loss function to encourage the model to choose simpler words; a similarity penalty during inference and clustering post-inference, to generate candidate simplifications with significant differences; and a reranking system to select the simplification that promotes both fluency and adequacy. Our model outperforms previous state-of-the-art systems using SARI, the standard metric for simplification. More importantly, while other previous models generate relatively long sentences, our model is able to generate shorter and simpler sentences, while remaining competitive regarding human-evaluated fluency and adequacy. Finally, we provide a qualitative analysis of where our different contributions improve performance, the effect of length on human-evaluated meaning preservation, and the current shortcomings of our model as insights for future research.

Generating diverse outputs from Seq2Seq models could be used in a variety of NLP tasks, such as chatbots (Shao et al., 2017), image captioning (Vijayakumar et al., 2018), and story generation (Fan et al., 2018). In addition, the proposed techniques can also be extremely helpful in leveled and personalized text simplification, where the goal is to generate different sentences based on who is requesting the simplification.

Acknowledgments

We would like to thank the anonymous reviewers for their helpful feedback on this work. We would also like to thank Devanshu Jain, Shyam Upadhyay, and Dan Roth for their feedback on the post-decoding aspect of this work, as well as Anne Cocos and Daphne Ippolito for their insightful comments during proofreading.

Abstract

Users participate in online discussion forums to learn from others and share their knowledge with the community. They often start a thread with a question or by sharing their new findings on a certain topic. Unlike in Community Question Answering, where questions are mostly factoid based, we find that the threads in a forum are often open-ended (*e.g.*, asking for recommendations from others) without a definitive correct answer. We thus address the task of identifying helpful posts in a forum thread to help users comprehend long-running discussion threads, which often contain repetitive or irrelevant posts. We propose a recurrent neural network based architecture to model (i) the relevance of a post regarding the original post starting the thread, and (ii) the novelty it brings to the discussion, compared to the previous posts in the thread. Experimental results on five different types of online forum datasets show that our model significantly outperforms the state-of-the-art neural network models for text classification.

1 Introduction

Online discussion forums are widely used in many domains such as in generic web content[1], e-health[2], Massive Open Online Courses (MOOCs)[3], and e-commerce, among others. Users participate in these forums to gain knowledge from the collective wisdom of the community. Typically, users start a discussion thread by posting a question or asking others for opinions on a topic. Others then reply to threads relevant to their interests. Importantly, as these forums are indexed by search engines, they need to be discoverable by a wider audience — apart from just registered users — by enabling threads to be found in response to queries.

Due to the open nature of the forums and the various expertise level of users, the posts in the discussion threads vary in helpfulness. To address this, some websites provide actions for users to signal this, as in “Upvote” (`reddit`, `stackoverflow`) and “Highlight” (`coursera`). Such feedback is helpful for identifying important posts among the many. Such feedback rarely comes immediately following new post creation, affecting their visibility to the users (Singh et al., 2017). We can devise technology to proactively identify such helpful posts as they arrive, in a *helpfulness prediction task*, enabling users to efficiently assess relevance.

We observe that there is a key structural difference between online discussion forums and Community Question Answering (CQA) websites. Figure 1 shows the distribution of normalized helpful votes for the top-5 posts across a popular discussion forum (`reddit`), and a CQA website (`stackoverflow`[4]). In CQA, the vote distribution decays exponentially, indicating that usually there is a single correct answer with the largest number of votes (Omari et al., 2016). In contrast, votes for less helpful posts in discussion forums decay at a much lower rate, suggesting that discussion forum threads are more open-ended.

Table 1 shows a sample thread from `reddit` to understand the dynamics of online discussion. We observe the following two major differences compared to threads in CQA domain: (1) The first post (hereafter, *original post*) is not necessarily a question, but can be personal anecdotes or new findings on a certain topic, attracting more discussion. (2) Instead of searching for a single relevant answer as in CQA, discussion forum users find a post helpful

Proceedings of NAACL-HLT 2019, pages 3148–3157
Minneapolis, Minnesota, June 2 - June 7, 2019.

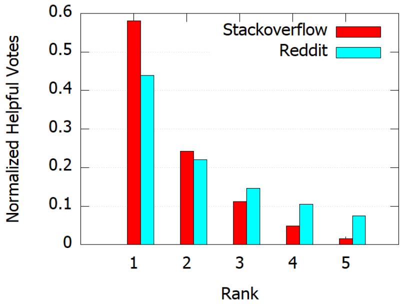

Figure 1: The helpful vote distribution for the top-5 posts across an online discussion forum (`reddit`), and the `stackoverflow` CQA website. The helpful votes decay at a slower rate for `reddit` compared to focused CQA.

Order	Post Text	Helpful?
Original post	I was working yesterday..and my back was bent over and when I got up I felt like I strained my back but now my mind is linking it to my kidney..	Yes
1	I have this and my doc has told me it's muscular and physio might help..	Yes
2	Kidney pain is usually constant and doesn't change when you move, or get better when you change position, from how I understand it..you'll be fine :)	Yes
3	If it happens only when you move there is a big chance it's a muscle spasm, this happens after some physical activities.	No

Table 1: A sample discussion thread from `reddit`. Helpful votes are provided by the website users.

when it introduces some *relevant* (with respect to the original post) and *novel* (*i.e.*, not presented in the earlier posts within the same thread) information. Motivated by these observations, we address helpfulness prediction by considering both the target post and its preceding posts.

We propose a novel neural architecture to predict the helpfulness of a post in a discussion thread. Our approach consists of two components: (1) modeling the *relevance* of a post and (2) determining the *novelty* with respect to the sequence of preceding posts. It combines the output from both components to predict the overall post helpfulness. As recurrent neural networks (RNNs) have shown good performance in sequence modeling tasks (Chung et al., 2014; Sutskever et al., 2014), we apply it to our architecture to model the (i) sequence of words in the post text, and the (ii) sequence of posts in a thread. Our model significantly outperforms other state-of-the-art models across experiments on five varied and large forum datasets. Our main contributions are:

- We reveal the key differences between posts in CQA and online discussion forums;
- We analyze the confounding factors behind the perceived helpfulness of posts in discussion forums. We observe that both *relevance* and *novelty* play important roles in determining the helpfulness of a post;
- We propose a novel neural network architecture to predict the helpfulness by using textual content of a target post as well as sequence of posts preceding it in the thread;
- We compare our model with current neural network classifiers and analyze the factors that influence our model's performance.

2 Related Work

To the best of our knowledge, predicting helpful posts in generic open-ended discussion forums has not been studied before. However, there is significant amounts of related work on similar directions; where researchers evaluate the *quality* (which may not correlate with perceived helpfulness by the community users) of posts in specific domains such as health (Oh et al., 2012; Oh and Worrall, 2013; Beloborodov et al., 2014) and online education (Chandrasekaran et al., 2015; Jenders et al., 2016). External medical resources and thesauri such as UMLS[5] have been used to identify patterns of helpfulness in health (Asghar et al., 2014). In MOOC platforms, apart from the textual content of the forums, additional signals such as user reputation (*e.g.*, average homework scores, number of courses taken) have been used to estimate post quality (Jenders et al., 2016). However, these techniques are tightly coupled with the target domain, and may not be generalizable to new domains.

CQA Answer Quality: Past work has also addressed the evaluation of answer quality in CQA sites (Jeon et al., 2006; Hong and Davison, 2009; Shah and Pomerantz, 2010; **?**; Omari et al., 2016; Li et al., 2015). Typically posed as a classification problem, these use both textual and non-textual feature-based approaches. Since it is quite common for popular questions to attract many potential answers, answer ranking based on perceived quality is another line of approach (Surdeanu et al., 2008; Bian et al., 2008; Wang et al., 2009). Closer to our approach, Omari et al. (2016)

---

[5] `https://www.nlm.nih.gov/research/umls/`

proposed a novelty-based greedy ranking algorithm that depends on a pre-trained parser to identify different propositions, useful for predicting helpfulness. Li et al. (2015) propose a few features for answer quality detection from academic QA sites such as ResearchGate[6]. However this approach does not generalize well since the method uses many website-specific signals such as *reputation scores* for users and their institutions. Additionally, their approach relies on human annotations to identify a few key conversational characteristics in the answers, keeping it from being applied to use cases where scalability and automation are key.

In the CQA answer quality evaluation literature, quality is often measured through the human evaluators' annotations during experimentation (Shah and Pomerantz, 2010; Oh et al., 2012; Omari et al., 2016). However, we are interested in modeling the "helpfulness" for actual discussion forum users (in term of "Upvotes") and not annotators following guidelines to mark answer quality, which might present other forms of bias.

Modeling Novelty in IR, such as search result diversification (Carbonell and Goldstein, 1998; Soboroff and Harman, 2005; Ziegler et al., 2005; Clarke et al., 2008), also constitutes prior art. Carbonell and Goldstein (1998) proposed maximal marginal relevance (MMR) to diversify the set of documents returned for a search query. Similar approaches were also used later in Multi-Document Summarization (MDS) tasks (Nallapati et al., 2017). These approaches address the problem either as a ranking task (ordering search results) or as a subset selection problem (MDS), where all documents are simultaneously made available. In contrast, in our discussion thread scenario, we need to model the discussion posts' sequential nature to understand the context of a later post and, in turn, determine its helpfulness.

Neural Network Based Models have also recently outperformed existing classifiers in many text classification tasks. They have been widely adopted as they induce useful features on their own, given sufficient data. Although there are differences, the problem of answer selection is relevant: the goal is to rank the potential answers to a target question from multiple candidate answers in order of their similarity (Yu et al., 2014; Wang and Nyberg, 2015; Severyn and Moschitti, 2015). However in our case, all posts in a thread are similar to the original post to an extent. Helpful posts are thus more difficult to identify; computing similarity is not viable as a single source solution.

Inspired by all these previous works, we propose a neural architecture to predict the helpfulness of posts in open-ended discussion forums. To make it generic and easily adaptable to multiple domains, we study the problem from a linguistic viewpoint, where we consider only the textual contents of the discussion threads.

3 Methods

We propose a neural network architecture to model post helpfulness (*cf* Figure 2a). Our architecture is end-to-end trainable, adaptable to different domains. The model comprises two components to analyze a target post's thread *relevance* and *novelty* with respect to its past k posts.

3.1 Text Encoder

This component takes a post text p which consists of words $(w_1, w_2, \ldots, w_n)$ as input and encodes it to a tensor $(\mathbf{h}^p)$ in two steps. We first use a word embedding initialized with GloVe[7] to transform all the words from the post text into finite d-dimensional vectors, *i.e.*, $w_i \mapsto \mathbb{R}^d$. Our experimental results show that the coverage of GloVe varies between $68 - 76\%$ on our datasets. To estimate the embeddings for the out-of-vocabulary words and reflect the domain dependence, we keep the embedding vectors trainable. In the second step, the sequence of words are provided to a gated recurrent unit (GRU) layer (Chung et al., 2014) to obtain a sequence of hidden vectors $(\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$, where $\mathbf{h}_i \in \mathbb{R}^g$, and g is the output dimension of the GRU encoded tensor. The latent vector is defined as follows:

$$\mathbf{h}_i = \text{GRU}_{\text{text}}(\mathbf{h}_{i-1}, w_i).$$

The last vector in the sequence, $\mathbf{h}_n$, is considered as the encoded representation of a post text (*cf.* Figure 2c). For a post p, the GRU_{text} encoded representation is denoted as $\mathbf{h}^p$. We use a dropout layer after the GRU to prevent overfitting. In our model, note that there is only a single text encoder; all textual inputs — the target post, original post,

(b) Unrolled Sequence Encoder ($\text{GRU}_{\text{context}}$). (c) Unrolled Text Encoder (GRU_{text}).

and each of the past posts in the thread — are encoded using a single text encoder, since as all of them are essentially text posts of similar nature.

Alternative Architectures. We also tried stacking additional GRUs in our experiments, but we did not observe accuracy improvements. We also tried to replace GRU with LSTM (Long-Short Term Memory) (Hochreiter and Schmidhuber, 1997), resulting in similar performance at the cost of much longer training time due to the larger number of parameters.

3.2 Modeling Post's Relevance

The left component of Figure 2a captures the relevance of a target post with respect to the original post. It takes as input two GRU encoded tensors: one for the target post $\mathbf{h}^t$, the other for the original post $\mathbf{h}^o$. It computes their similarity defined as:

$$\mathbf{r}_t = \mathbf{h}^t \otimes \mathbf{h}^o,$$

where $\otimes$ denotes the element-wise multiplication. We also experimented with element-wise difference and cosine similarity, but found that multiplication works best. Our relevance modeling component is inspired from the architecture for answer sentence selection model (Yu et al., 2014).

3.3 Modeling Post's Novelty

In Figure 2a, the right component models the target post's novelty compared to the past k posts from the same thread. It takes the encoded tensors for the target post $\mathbf{h}^t$ as input, as well as the past k posts $(\mathbf{h}^{t-k}, \mathbf{h}^{t-k+1}, ..., \mathbf{h}^{t-1})$.

We first encode the context of the discussion by modeling the sequence of the past k posts. In order to achieve this, we use another GRU (labeled as Sequence Encoder in Figure 2a) to transform the sequence of k post tensors to a single context tensor $\mathbf{c}^t$ of equal dimension g. Each timestep i of this is defined as follows:

$$\mathbf{c}^t_i = \text{GRU}_{\text{context}}(\mathbf{c}^t_{i-1}, \mathbf{h}^{t-i}).$$

Similar to GRU_{text}, $\mathbf{c}^t_{t-1}$, the last vector in the sequence, is considered as the context representation $\mathbf{c}^t$ (as shown in Figure 2b).

To determine the novelty of the target post, we compute its similarity $\mathbf{n}_t$ with the discussion thread context represented by its context tensor:

$$\mathbf{n}_t = \mathbf{h}^t \otimes \mathbf{c}^t.$$

Importantly, instead of considering all the previous posts in the thread, we limit the context to the past k posts for two reasons:

1. Users may not recall the entire context of discussion while reading a post appearing much later in a long-running thread.

2. Users often arrive at a discussion thread through search engine queries. Since long threads are paginated, a user may arrive on a page in the

middle of the discussion thread, thus also missing the previous context.

We find empirical evidence for these assumptions later in our experiments (see Section 5). In tuning our model, we observed that increasing the context length beyond a threshold does not yield improvements.

3.4 Final Helpfulness Prediction

We combine the relevance tensor ($\mathbf{r}_t$) and novelty tensor ($\mathbf{n}_t$) and feed through a fully connected layer to make the final post helpfulness prediction:

$$\mathbf{x}_t = \mathbf{r}_t \oplus \mathbf{n}_t,$$

$$p(y|\mathbf{x}_t) = sigmoid(\mathbf{W} \cdot \mathbf{x}_t + \mathbf{b}),$$

where $\oplus$ denotes concatenation; $\mathbf{x}_t$ is the concatenated tensor; y is the output label (0 or 1); $\mathbf{W}$ and $\mathbf{b}$ are the weight matrix and bias vector, respectively, learned for the fully connected layer. We use binary cross-entropy loss to train the model, optimizing with Adam (Kingma and Ba, 2014).

Alternative Architectures. We also investigated ensemble architectures. We fed the relevance and novelty tensors through two separate fully connected layers to obtain the binary predictions from both components concurrently, then merged the two predictions via a final fully connected layer for obtaining prediction. This approach fared worse compared to our concatenation-based model, possibly as our final concatenation model can exploit non-linear interactions between both components.

The actual post content is never presented to the fully connected layer so that it generalizes well. The final layer only gets to see the relevance, and novelty vectors, which we believe ameliorates the creation of overfitted (post-based or thread-based) features for the helpfulness prediction task.

4 Experiments

We first describe the datasets, evaluation metrics, and baseline models before our main results. We also conducted additional experiments to answer specific research questions about our model.

4.1 Datasets

We experiment with five real-world online discussion forums (Table 2) to validate model effectiveness. Typical of other research work, we also remove threads that have less than two posts.

1–2. **Reddit** is a popular platform for discussions on a wide-variety of topics on the web. We use a large number of discussion threads from a `reddit` data dump[8]. To diversify the datasets in terms of average thread length, we set different thresholds, and created two datasets: *Reddit_10+* ($\geq$ 10 posts) and *Reddit_3+* ($\geq$ 3 posts). Along with a chronologically ordered set of posts, `reddit` also has “Upvote” counts for every post.

Dataset	# Posts	# Threads	Avg # Posts / Thread	Avg # words / Post
1. Reddit_10+	200,006	9,744	20.52	29.45
2. Reddit_3+	200,016	28,763	6.95	30.58
3. Android Apps	11,643	2,077	5.60	56.53
4. Matrix	10,159	2,484	4.08	65.30
5. Travel	30,116	10,250	2.93	163.43

Table 2: Dataset statistics.

3–4. **Coursera** is a large MOOC platform, providing a discussion forum for the course participants. We select two courses with the largest number of posts: “Matrix-001” and “Android Apps 101-001” from a MOOC dataset (Chandrasekaran et al., 2015). Course participants can “vote” for a post if they find it helpful. We refer to these datasets as *Matrix* and *Android Apps*, hereafter.

5. **Travel Stack Exchange** is one of many QA websites in the Stack Exchange community. We use a data dump[9] of the website and refer to it as *Travel* dataset. In Travel Stack Exchange, a user can “Upvote” a post if she deems it helpful. Although not strictly a discussion forum, the threads in this forum appear to be less objective (by our vote distribution analysis, similar to Figure 1), compared to other CQA sites like `stackoverflow`.

4.2 Post Annotation and Evaluation Metrics

We use the user-provided feedback in form of “mark as helpful”, “like”, “upvote” actions as a proxy of the actual helpfulness of a post. Vote counts vary widely across posts and threads, (*i.e.*, 0 to 3,100 for the `reddit` dataset), making it infeasible to formulate the task as a regression problem. Following by prior published research (Cheng et al., 2014; Lo et al., 2017), we model it as a binary classification problem, and use the 80^{th} percentile expected value of helpful vote count across all the posts as the boundary between the two classes. We assume that a post is

---

[8] `https://files.pushshift.io/reddit/comments/`

[9] `https://archive.org/download/stackexchange/travel.stackexchange.com.7z`

helpful if it has received more helpful votes than the 80^{th} percentile, and *not helpful* otherwise.

Since our goal is to predict the helpful posts and the class distribution is inherently skewed from our definition, we evaluate the model performance in terms of prediction accuracy for only the positive, helpful class. We evaluate using standard precision, recall, and F_1 score across all datasets.

4.3 Baselines

Code for our model is publicly available[10] to aid the reproduction of our results. We experiment with the following state-of-the-art neural text classification methods:

1. BiLSTM (Sun et al., 2017): a stack of two layers of Bidirectional LSTM encoders on post text.

2. Stacked LSTM (Liu et al., 2016): a stack of two layers of LSTM encoders on the post text.

3. LSTM with Attention (Rocktäschel et al., 2016): an LSTM layer with hierarchical attention.

4. Answer Sentence Selection (Yu et al., 2014): a CNN model pioneered in a TREC QA[11] task.

5. Our Model (Relevance based): only the relevance component of our model.

6. Our Model (Novelty based): only the novelty component of our model.

We do not include traditional feature-based models as part of our reported baseline portfolio, as in our study, neural models have outperformed them as well, which is corroborated in recent studies (Kim, 2014). Additionally, such approaches are fragile, as we experiment with datasets from multiple domains with various discussion styles, and extracting hand crafted features for each is non-trivial and labour intensive. As a preliminary experiment, we tried with a traditional bag-of-words based model. However, we do not include it in the baseline portfolio given its poor performance on our datasets.

4.4 Training

We used the Keras[12] library with TensorFlow as the backend for model implementation. We split the dataset 80:10:10 for train, validation, and test, respectively, and perform 5-fold cross validation. We tuned the hyper-parameters via grid search on the validation set for all the models.

The rest of the parameters used follow standard values from the recent literature. We set word embedding dimension (d) to 100, vocabulary size to 100K, hidden dimension of GRU (g) to 128, batch size to 512, the dimension of the final fully connected layer to 128, and use 70% dropout. For the CNN-based Answer Sentence Selection baseline, we tuned the number and size of filters (128 and 3, respectively). The maximum length of post text was set according to average post length (in the training split) for each dataset.

4.5 Results

Table 3 shows the comparison of model performance over the five datasets. We observe that our full model consistently outperforms others in terms of F_1 across all datasets. Our novelty-based model gives the second best score in all datasets except for *Android Apps*. Comparing our novelty-based model against answer selection model, we observe that the helpfulness of a post depends on both its relevance to the original post and the novelty with respect to earlier posts in the same thread. The evaluation scores obtained by the state-of-the-art neural text classification models strongly support this observation. They consistently make less accurate prediction compared to the relevance- and/or novelty-based models. Among them, BiLSTM or LSTM with Attention model achieves the best performance, dependent on the dataset. We discuss the confounding factor affecting performance in Section 5.

We also observe that the prediction is more accurate when there is sufficient context to learn the dynamics of the discussion forums. In *Reddit_10+* and *Reddit_3+*, where both datasets average about 20 and 7 posts per thread respectively, we obtain an F_1 score of 0.40 to 0.51. In the other datasets, where the average thread length is much shorter ($\sim$ 3 to 5), we obtain relatively low F_1 scores of 0.34 to 0.38. Our model is more accurate in `reddit` datasets where threads are longer on average, indicative of more open-ended discussion centered on the original post.

4.6 Case Study

We now highlight a few corner cases successfully handled by our model.

Table 4 shows three target posts along with the original posts and their previous posts from dif-

Table 3: (P)recision, (R)ecall and F$_1$ comparison of model performances across our five datasets representing three domains. Our model outperforms other state-of-the-art neural text classifiers consistently. Ablation study with Answer Selection, Relevance-based, and Novelty-based model shows that modelling both relevance, and novelty is important.

Original Post	**My fiancée and I are looking for a good Caribbean cruise in October and were wondering which islands are best to see and which Cruise line to take?..**	**I've had bouts of heart burn & this time its sticking around for a while. I ate something really spicy on Tuesday night & its Thursday & Im having heart burn on & off... Please help**	**In a few weeks' time, I will be visiting the US for 14 days. Coming from the EU, roaming is very expensive, so I am considering getting a temporary SIM card..**
Past Posts	Friends I am staying with are travelling with Royal Carribean on a cruise in October. They are starting from Miami..	You're probably fine. People get heartburn from time to time.. Eat bland food for a few days and that inflammation should subside..	There are many options you can have as far as mobile phone data prepaid plans are concerned. Since you need coverage along the route..
	The Princess Cruise line has a Caribbean cruise in the fall. It may start in November rather than October but could be suitable for your needs..	Heartburn can last a few days and its not always spicy food that triggers it. I assume youre concerned it might be a heart attack. If that was it you would know it by now.	You may want to check your existing phone plan. For example, quite a few providers in the UK offer free or cheap roaming with data included..
	There are plenty of options for the Caribbean in October regradless of it being in hurricane season..	Heartburn doesn't JUST occur from spicy food. If you're having it over multiple days, it could simply be other food. Fatty foods in particular cause it.	If your main goal is price, MetroPCS has no-contract 30 month plans which have unlimited calling US numbers, unlimited SMS, and unlimited data in the US..
Target Post	If you like to dress up and eat high-end food, the cruise line you want is not the one that caters to honeymooners on a tight budget or to families with small kids. If you like things to be..	Stay calm. Drink lots of water. Do you have an antacid you could take? Try to avoid spicy, acidic, caffeine, alcohol for a while..	`willmyphonework.net` is good for checking a phone's compatibility with the various networks. Suggestion before departure, print-out a list of the carriers your phone will work with hard copy is the way to go here..
Helpful?	Yes	No	No

Table 4: Illustration of different corner cases for helpfulness prediction. The target post needs to be both relevant to the original post, and novel compared to the previous posts in the thread in order to be helpful.

ferent datasets. In the first case, we observe that the target post introduces some relevant and novel information into the thread, and thus our model predicts it as helpful.

In the second example, we find that the target post is quite similar to some of the previous posts. Since it introduces less novelty in the discussion, our model predicts the target post as unhelpful, although relevant to the discussion topic. In the third example, the target post seems to be novel compared to the previous posts but it deviates from discussion topic in the original post. Hence, our model does not predict it as helpful.

These observations indicate that our model treats each of the two qualities of a target post, *i.e.*, relevance with the original post, and novelty compared to the previous discussion individually as necessary but not sufficient conditions. A target post needs both relevance and novelty so that our model predicts it as helpful.

5 Discussion

We now answer the following research questions (RQ) to further analyze prediction of helpful posts:

RQ1: How does the past context length influence model performance? The number of posts across threads varies widely, making it difficult to estimate the optimal value for past context length (k in Section 3.3). To understand the effect of k on model performance, we vary k ranging from 1 to 18 and report F$_1$ for the *Reddit_10+*, and *Reddit_3+* datasets in Figure 3. Interestingly, we observe that, the performance stops improving after a certain number of posts in both cases: k=11 and k=7 for *Reddit_10+*, and *Reddit_3+*, respectively.

Setting too low a k limits the number of past posts the model gets to see, underfitting the data. Large k gives modest performance gains but incurs significant increase in training cost. As discussed in Section 3.3, the entire context might be redundant to determine target posts' helpfulness in long threads.

We believe the context length analysis would be necessary to achieve optimal model performance while exploring other domains.

RQ2: Does the order of contextual posts matter? To investigate whether the order of the past posts matter in determining the helpfulness of a target post, instead of modeling the past posts by GRU$_{\text{context}}$ layer, we just use the average of the

Table 5: F$_1$ obtained by the model variation that uses the average tensor of the past post tensors as the context tensor, compared to our $\text{GRU}_{\text{context}}$ based model.

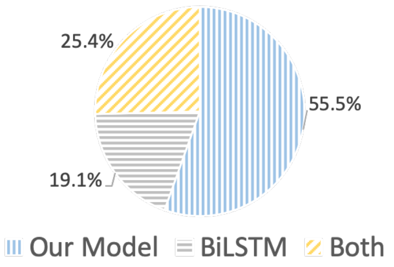

Figure 4: Correct prediction share of helpful posts for Reddit_all. Yellow: both models; blue: only our model; grey: only BiLSTM.

past post tensors to get the context tensor. Table 5 shows the F$_1$ achieved by this variation compared to our model.

We observe that the model performance significantly degrades when the order of the past posts are ignored and represented by an average. Crucially, we find that the datasets with longer threads suffer more compared to the ones with shorter threads. This observation indicates that the sequential nature of discussion is integral to model construction.

RQ3: What factors influence performance among the text classification models and our model? Table 3 shows that BiLSTM achieved better scores compared to the other neural text classification models. To better understand the modeling differences between the BiLSTM and our models, we focus on the cases where one model is correct but not the other (as illustrated for *Reddit_10+* in Figure 4). While both models can predict the correct class in 25.4% cases (in yellow), in the other cases (blue and grey), they differ.

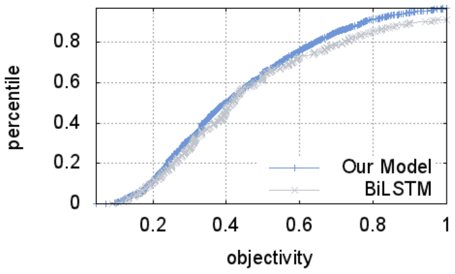

Figure 5: Thread objectivity score CDF. The blue curve shows threads where our model is correct and BiLSTM is not; vice versa for the grey.

We study the objectivity of the posts where such differences were observed. Without loss of generality, we define a metric called thread *objectivity* spread, in terms of the vote shares for the top-5 posts:

$$objectivity = \frac{max(vote(x)) - min(vote(x))}{\sum vote(x)},$$

where $x \in \{\text{top-5 posts}\}$ in the thread and $vote(x)$ gives the helpfulness score of post x. $objectivity$ is unit bound $[0, 1]$. While a high objectivity score indicates skewed helpfulness distribution in a thread, a low score indicates that there are multiple helpful answers in a thread; in other words, the thread is less objective in nature.

We analyze the cumulative distribution functions (CDFs) of objectivity spread scores for all threads belonging to the grey or blue wedge of Figure 4 (*cf.* Figure 5). We observe that the CDF for our model (blue) gives lower objectivity scores with 80^{th} percentile score of 0.64 for our model and 0.72 for BiLSTM, respectively. This indicates that our model performs better when the thread is more open-ended in nature.

6 Conclusion

We studied the problem of predicting helpfulness of posts in open-ended discussion forums. We found key differences in discussion forums compared to traditional CQA platforms: we observe that forum threads are often non-factoid and subjective in nature with many helpful answers. We hypothesize that post helpfulness crucially relies on two factors: (i) its relevance to the discussion thread and (ii) the novelty of the information introduced. We propose a generic and novel neural architecture using GRU encoders to embody this intuition. Our model outperforms state-of-the-art neural text classification baselines over a diverse set of forums representing three distinct domains. Through deeper analysis, we demonstrate that our model is able to encode the sequential nature of contextual posts, and capture the open-ended nature of discussion threads, thus achieving superior performance over other neural approaches.

We plan to apply our work towards building a notification system for incoming helpful posts. In the current work, we addressed the information need aspect present in the discussion forums in general. However, helpfulness might be conflated with other reasons such as humour, sentiment in certain domains. We would like to investigate those aspects in the future.

Abstract

Training data for text classification is often limited in practice, especially for applications with many output classes or involving many related classification problems. This means classifiers must generalize from limited evidence, but the manner and extent of generalization is task dependent. Current practice primarily relies on pre-trained word embeddings to map words unseen in training to similar seen ones. Unfortunately, this squishes many components of meaning into highly restricted capacity. Our alternative begins with sparse pre-trained representations derived from unlabeled parsed corpora; based on the available training data, we select features that offers the relevant generalizations. This produces task-specific semantic vectors; here, we show that a feed-forward network over these vectors is especially effective in low-data scenarios, compared to existing state-of-the-art methods. By further pairing this network with a convolutional neural network, we keep this edge in low data scenarios and remain competitive when using full training sets.

1 Introduction

Modern neural networks are highly effective for text classification, with convolutional neural networks (CNNs) as the de facto standard for classifiers that represent both hierarchical and ordering information implicitly in a deep network (Kim, 2014). Deep models pre-trained on language model objectives and fine-tuned to available training data have recently smashed benchmark scores on a wide range of text classification problems (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2018).

Despite the strong performance of these approaches for large text classification datasets, challenges still arise with small datasets with few, possibly imbalanced, training examples per class. Labels can be obtained cheaply from crowd workers for some languages, but there are a nearly unlimited number of bespoke, challenging text classification problems that crop up in practical settings (Yu et al., 2018). Obtaining representative labeled examples for classification problems with many labels, like taxonomies, is especially challenging.

Text classification is a broad but useful term and covers classification based on topic, on sentiment, and even social status. As Systemic Functional Linguists such as Halliday (1985) point out, language carries many kinds of meanings. For example, words such as *ambrosial* and *delish* inform us not just of the domain of the text (*food*) and sentiment, but perhaps also of the age of the speaker. Text classification problems differ on the dimensions they distinguish along and thus in the words that help in identifying the class.

As Sachan et al. (2018) show, classifiers mostly focus on sub-lexicons; they memorize patterns instead of extending more general knowledge about language to a particular task. When there is low lexical overlap between training and test data, accuracy drops as much as 23.7%. When training data is limited, most meaning-carrying terms are never seen in training, and the sub-lexicons correspondingly poorer. Classifiers must generalize from available training data, possibly exploiting external knowledge, including representations derived from raw texts. For small training sizes, this requires moving beyond sub-lexicons.

Existing strategies for low data scenarios include treating labels as informative (Song and Roth, 2014; Chang et al., 2008) and using label-specific lexicons (Eisenstein, 2017), but neither is competitive when labeled data is plentiful. Instead, we seek classifiers that adapt to both low and high data scenarios.

People exploit parallelism among examples for generalization (Hofstadter, 2001; Hofstadter and

Proceedings of NAACL-HLT 2019, pages 3158–3167
Minneapolis, Minnesota, June 2 - June 7, 2019.

Table 1: **Left**: examples from the Reuters *Grains* class, showing semantic type cohesion (kinds of crops). **Right**: post headers from the *sci.space* newsgroup in 20 Newsgroups, showing topical cohesion (astronomical terms). **Bolded terms** are to draw the reader's attention to parallels among examples.

Sander, 2013). Consider Table 1, which displays five examples from a single class for two tasks. Bolded terms for each task are clearly related, and to a person, suggest abstractions that help relate other terms to the task. This helps with disambiguation: that the word *Pluto* is the planet and not Disney's character is inferred not just by within-example evidence (e.g. *mission*) but also by cross-example presence of *Mars* and *astronauts*.

Cross-example analysis also reveals the amount of generalization warranted. For a word associated with a label, word embeddings give us neighbors, which often are associated with that label. What they do not tell us is the extent this associated-with-same-label phenomenon holds; that depends on the granularity of the classes. Cross-example analysis is required to determine how neighbors at various distances are distributed among labels in the training data. This should allow us to include *barley* and *peaches* as evidence for a class like *Agriculture* but only *barley* for *Grains*.

Most existing systems ignore cross-example parallelism and thus miss out on a strong classification signal. We introduce a flexible method for controlled generalization that selects syntacto-semantic features from sparse representations constructed by Category Builder (Mahabal et al., 2018). Starting with sparse representations of words and their contexts, a tuning algorithm selects features with the relevant kinds and appropriate amounts of generalization, making use of parallelism among examples. This produces task-specific dense embeddings for new texts that can be easily incorporated into classifiers.

Our simplest model, CBC (Category Builder Classifier), is a feed-forward network that uses only CB embeddings to represent a document. For small amounts of training data, this simple model dramatically outperforms both CNNs and BERT (Devlin et al., 2018). When more data is available, both CNNs and BERT exploit their greater capacity and broad pre-training to beat CBC. We thus create CBCNN, a simple combination of CBC and the CNN that concatenates their pre-prediction layers and adds an additional layer. By training this model with a scheduled block dropout (Zhang et al., 2018) that gradually introduces the CBC sub-network, we obtain the benefits of CBC in low data scenarios while obtaining parity with CNNs when plentiful data is available. BERT still dominates when all data is available, suggesting that further combinations or ensembles are likely to improve matters further.

dataset	k	train/test/dev	size range
20NG	20	15076/1885/1885	513/810
reuters	8	6888/862/864	128/3128

attack	2	10000/2000/2000	1126/8874

Table 2: Data sizes, and the disparity between the smallest and the largest class in training data. The k column indicates the number of classes in the task.

2 Evaluation Strategy

Our primary goal is to study classifier performance with limited data. To that end, we obtain learning curves on four standard text classification datasets (Table 2) based on evaluating predictions on the full test sets. At each sample size, we produce multiple samples and run several text classification methods multiple times, measuring the following:

- **Macro-F1 score**. Macro-F1 measures support for all classes better than accuracy, especially with imbalanced class distributions.
- **Recall for the rarest class**. Many measures like F1 and accuracy often mask performance on infrequent but high impact classes, such as detecting toxicity (Waseem and Hovy, 2016))
- **Degenerate solutions**. Complex classifiers with millions of parameters sometimes produce degenerate classifiers when provided very few training examples; as a result, they can skip some output classes entirely.

The datasets we chose for evaluation, while all multi-class, form a diverse set in terms of the number of classes and kinds of cohesion among examples in a single class. The former clearly affects training data needs, while the latter informs appropriate generalization.

- **20 Newsgroups** 20Newsgroups (20NG) contains documents from 20 different newsgroups with about 1000 messages from each. We randomly split the documents into an 80-10-10 train-dev-test split. The classes are evenly balanced.
- **Reuters R8.** The Reuters21578 dataset contains Reuters Newswire articles. Following several authors (Pinto and Rosso, 2007; Zhao et al., 2018, for example), we use only the eight most frequent labels. We begin with a given 80/10/10 split. Given that we focused on single-label classification, we removed items associated with two or more of the top eight labels (about 3% of examples). Classes are highly imbalanced. Of the 6888 training examples, 3128 are labeled *earn*, while only 228 examples are of class *interest* and only 128 are *ship*.
- **Wiki Comments Personal Attack.** The Wikipedia Detox project collected over 100k discussion comments from English Wikipedia and annotated them for presence of personal attack (Wulczyn et al., 2017). We randomly select 10k, 2k, and 2k items as train/dev/test. 11% are attacks.
- **Spam** The SMS Spam Collection v.1 has SMS labeled messages that were collected for mobile phone spam research (Hidalgo et al., 2012). Each of the 5574 messages is labeled as *spam* or *ham*.

3 Identifying Generalizing Features

In this section, we explicate the source of features, discuss the properties relevant to generalization by focusing on one feature in isolation, and present the overall feature selection method. The overview in Figure 1 displays the order of operations: identify *generalizing features* based on the training data (done once), and for each document to be classified, convert it to a vector, where each entry corresponds to a generalizing feature.

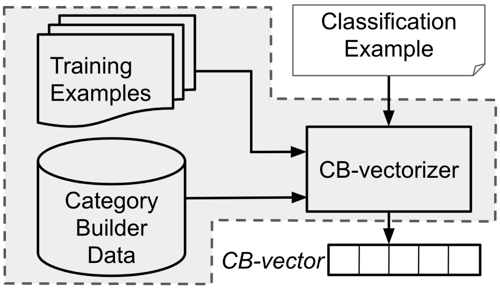

Figure 1: **Shaded Region:** We use Category Builder data (Mahabal et al., 2018) and identify generalizing features in training data, producing a *vectorizer*. This is done once. **Unshaded:** Given a document, the vectorizer produces a dense vector usable in deep networks.

Feature	Prototypical Supports
allergen as X	*pollen, dander, dust mites, soy, perfumes, milk, smoke, mildew*
liter of X	*water, petrol, milk, fluid, beer*
serve with X	*rice, sauce, salad, fries, milk*
flour mixture	*butter mixture, rubber spatula, dredged, creamed, medium speed, sifted, milk*
replacer	*colostrum, calves, whole milk, inulin, pasteurized, weaning*

Table 3: A few features (among hundreds) evoked by *milk*, with top n-grams in their support. **Above dashed line** (F_S) fit in tidy categories (here, *allergen*, *fluid*, and *food* are rough glosses). **Below dashed line** (F_C) are not describable by simple labels—the evoking terms have different parts of speech and instead display *situational coherence*, e.g. association with the process of mixing flour or with animal husbandry (a *replacer* is milk formula for calves).

3.1 Category Builder

Our source of generalizing features is Category Builder (CB) (Mahabal et al., 2018), which constructs a sparse vector space derived from parsed corpora (Erk, 2012). CB constructs features for *n-grams* (not just unigrams) that are the union of syntactic context features F_S and co-occurrence features F_C. Consider *milk*: an F_S feature is $gallon\xrightarrow{prep}of\xrightarrow{pobj}X$ and F_C features include *goat*, *cow*, *drink*, *spill*, etc. Table 3 provides other examples of features evoked by *milk*, along with other n-grams which evoke them. For present purposes, we can treat CB as a matrix with n-grams as rows and features in F_C and F_S as columns. The entries of CB are weights that give the association strength between an n-gram and a feature; these weights are an asymmetric variant of pointwise-mutual information (Mahabal et al., 2018).

3.2 Properties of Generalizing Features

Which features generalize well depends on the granularity of classes in a task. Useful features for generalization strike a balance between *breadth* and *specificity*. A feature that is evoked by many words provides generalization potential because the feature's overall support is likely to be distributed across both the training data and test data. However, this risks over-generalization, so a feature should also be sufficiently specific to be a precise indicator of a particular class.

A key aspect of choosing good features based on a limited training set is to resolve referential ambiguity (Quine, 1960; Wittgenstein, 1953) to the extent supported by the observed uses of the words. To illustrate, consider the *grains* class in the Reuters Newswire dataset. The word *wheat* can evoke the features at different levels of the taxonimical hierarchy: *triticum* (the wheat genus), *poaceae* (grass family), *spermatophyta* (seeded plants), *plantae* (plant kingdom), and *living thing*. The first among these has low breadth and is evoked only by *wheat*. The second is far more useful: specific and yet with a large support, including *maize* and *sorghum*. The final feature is too broad. In general, the most useful features for generalization are the intermediate features, also known as Basic Level Categories (Rosch et al., 1976).

Another important aspect of generalization comprises the *facets* of meaning. For example, the word *milk* has facets relating it to other liquids (e.g., *oil*, *kerosene*), foods (*cheese*, *pasta*), white things (*ivory*), animal products (*honey*, *eggs*), and allergens (*pollen*, *ragweed*). Along these axes, generalization can be more or less conservative; e.g., both *cheese* and *tears of a phoenix* are animal products, but the former is semantically closer to *milk*. Looking back at Table 3, the utility of individual features evoked by *milk* for tasks involving related topics varies; e.g., does the classification problem pertain to *food* or *animal husbandary*?

3.3 Focus on a single feature

A single *generalizing feature* is associated with many n-grams, each of which evokes it (with different strengths). Table 4 displays n-grams that evoke the feature *co-occurrence with **Saturn V***, as discovered by unsupervised analysis of a large corpus of web pages. The table further displays the interaction of this unsupervised feature with supervised data, specifically, with the label *sci.space* in 20NG, when using a size 320 training sample that contain only 18 *sci.space* documents. Counts for some evoking terms are shown within and outside this class, for both training and test data.

		Training		Testing	
n-gram	wt	C	$\overline{C}$	C	$\overline{C}$
apollo	8.93	1	1	5	1
launch pad	8.52	0	0	1	0
rocket	7.32	3	1	8	0
rockets	7.27	2	0	4	1
liftoff	6.92	1	0	1	0
space shuttle	6.27	0	0	4	0
space station	6.19	0	0	4	3
payload	4.23	0	0	5	0
shuttle	2.57	2	0	15	3
kennedy	2.30	1	0	1	4
capacity	1.95	0	1	0	4

Table 4: Some evoking n-grams associated with the CB feature *co-occurrence with **Saturn V*** and pivoting on the class *sci.space*. Counts for n-grams in training (sample size 320) and test data are shown, within *sci.space* (C) and outside ($\overline{C}$). Bolded n-grams are not seen in training but occur in test, providing generalization. The dashed line represents a threshold; higher scoring n-grams are more cohesive, and thresholding can make a feature cleaner by decreasing semantic drift.

Notation. We introduce some notation and explicate with Table 4. We have a labelled collection of training documents T. T_l is the training examples with label l. The *positive support set* $\Psi_l(f,t)$ is the set of n-grams in T_l evoking feature f with weight greater than t, here, $\{$*apollo, rocket, …, shuttle*$\}$ for t=2.3. The *positive support size* $\Lambda_l(f,2.3)$=$|\Psi_l(f,2.3)|$=5 and the *positive support weight* $\lambda_l(f,2.3)$ is the sum of counts of supports of f in l with weight greater than 2.3, here 1+3+2+1+2=9. Analogously the *negative support weight* $\lambda_{\bar{l}}(f,2.3)$ is the sum of counts from outside T_l; here, 1+1=2 since $\{$*apollo, rocket*$\}$ were seen outside *sci.space* once each.

What makes this feature (*words that have co-occurred with Saturn V*) well suited for *sci.space* is that many evoking words here are associated with the label *sci.space*. What confirms the benefit is the limited amount of negative support. Crucially, the bolded terms do not occur in the training data, but do occur in the test data. (We stress that we include these counts here only for this example; our methods do not access the test data for feature selection in our experiments.)

That said, we must limit potential noise from such features, so we seek **thresholded features** $\langle f, t \rangle$, as suggested by the dashed line in Table 4. Items below this line are prevented from evoking f. We choose the highest threshold such that dropped negative support exceeds dropped positive support. This is determined simply by going through all the supports of a feature, sorted by ascending weight, and checking the positive and negative support of all features with smaller versus greater weight given the class. The weight of the feature at this cusp is used as the threshold of the feature for this particular class. This $\langle f, t \rangle$ pair then forms one element of the CB-vector used as a feature for classification.

Given the labeled subsets of T and this feature thresholding algorithm, we produce a vectorizer that embeds documents. The values of a document's embedding *are not* directly associated with any class. Such association happens during training. Although *sci.space* accounts for just 6% of the documents, 75% of documents that contain an n-gram evoking the *Saturn V* feature are in that class. A classifier trained with such an embedding should learn to associate this feature with that class, and an unseen document containing the unseen-in-training term *space shuttle* stands a good chance to be classified as *sci.space*.

The feature displayed in Table 4 is useful for the 20NG problem because it contains a class related to space travel. This feature has no utility in spam classification or in sentiment classification, since, for those problems, seeing *rocket* in one class does not make it more likely that a document containing *space station* belongs to that same class. This example illustrates why a generalization strategy must incorporate both what we can learn from unsupervised data as well as (limited) labeled training data.

3.4 Overall feature selection

We now describe how we use the training data T to produce a set of features-and-threshold pairs; each chosen feature-with-threshold $\langle f, t \rangle$ will be one component in the CB-vectors provide to classifiers. Calculation of features for a single class is a three step process: (i) for each feature f, choose a threshold t (as discussed above) (ii) score the resultant $\langle f, t \rangle$ (iii) filter useless or redundant $\langle f, t \rangle$.

Given a label l and a feature f, we implicitly produce a table of supporting n-grams and their distribution within and outside l (e.g. as in Table 4). This involves computing the precision of a feature at a given threshold value, comparing it to the class probability and deciding whether to keep it.

Recall the positive support $\lambda_l(f, t)$ and negative support $\lambda_{\bar{f}}(f, t)$ defined previously. The **precision** of f at threshold t is $\mu_l(f, t) = \frac{\lambda_l(f,t)}{\lambda_l(f,t)+\lambda_{\bar{l}}(f,t)}$, (this is $\frac{9}{11}$ in the example of Table 4, with t=2.3). However, since we are often dealing with low counts, we smooth the precision toward the empirical class probability of l, $p(l) = \frac{|T_l|}{|T_l|+|T_{\bar{l}}|}$.

$$\tilde{\mu}_l(f, t) = \frac{\lambda_l(f, t) + p(l)\alpha}{\lambda_l(f, t) + \lambda_{\bar{l}}(f, t) + \alpha}$$

The score $S_l(f, t)$ is reduction in error rate of the smoothed precision relative to the base rate:

$$S_l(f, t) = \frac{\tilde{\mu}_l(f, t) - p(l)}{1 - p(l)}$$

We retain a thresholded feature if it is generalizing ($\Lambda_l(\langle f, t \rangle) > 1$), has better-than-chance precision (we use $S_l(\langle f, t \rangle) > 0.01$), and is not redundant (i.e., its positive support has one or more terms not present in positive supports of higher scoring features).

3.5 Creating the CB-vector

Each vector dimension corresponds to some $\langle f, t \rangle$. The evocation level of f is the sum of its evocation for the n-grams in the document d, $e_d(f) = \sum_{w \in d} CB(w, f)$. The vector entry is $\frac{e_d(f)}{t}$ when $e_d(f) >= t$, and is clipped to 0 otherwise.

4 Models

As benchmarks, we use a standard CNN with pretrained embeddings (Kim, 2014) and BERT (Devlin et al., 2018).[1] For CNN, we used 300 filters each of sizes 2, 3, 4, 5, and 6, fed to a hidden layer of 200 nodes after max pooling. Pretrained vectors provided by Google were used.[2] For BERT, we used the `run_classifier` script from GitHub and used the BERT-large-uncased model.

We use the pre-computed vocab-to-context association matrix provided as part of the open

source Categorial Builder repository.[3] This contains 194,051 co-occurrence features (F_C) and 954,276 syntactic features (F_S).

CBC model. The *CB-vector* containing the derived features from the training dataset and Category Builder can be exploited in various ways with existing techniques. The simplest of these is to use a feed-forward network over the *CB-vector*. This model does not encode the tokens or any word order information—information which is highly informative in many classification tasks.

CBCNN model. Inspired by the combination of standard features and deep networks in Wide-and-Deep models (Cheng et al., 2016), we pair the CBC model with a standard CNN, concatenating their pre-prediction layers, and add an additional layer before the softmax prediction. In early experiments, this combined model performed worse than the CNN on larger data sizes, as the network above the CB-vector effectively stole useful signal from the CNN. To ensure that the more complex CNN side of the network had a chance to train, we employed a block dropout strategy (Zhang et al., 2018) with a schedule. During training, with some probability, all weights in the CB-vector are set to 0.5. The probability of hiding decreases from 1 to 0 using a parameterized hyperbolic tangent function $p_k = \frac{2}{e^{Cx}+1}$. Lower values of C lead to slower convergence to zero. The effect is that the CBC sub-network is introduced gradually, allowing the CNN to train while eventually taking advantage of the additional information.

The natural strategy of replacing with 0s (instead of 0.5 as above) was tried and also works, but less well, since the network has no way to distinguish between genuine absence of feature and hiding. In CB-vector, non-zero values are at least 1, and thus 0.5 does not suffer from this problem.

5 Experiments

Our primary goal is to improve generalization for low-data scenarios, but we also want our methods to remain competitive on full data.

5.1 Experimental setup

We compare different models across learning curves of increasing the training set sizes. We use training data sizes of $40, 80, \ldots, 5120$ as well as the entire available training data. For each training size, we produce three independent samples by uniformly sampling the training data and training each model three times at each size. The final value reported is the average of all nine runs. All models are implemented in Tensorflow. Batch sizes are between 5 and 64 depending on training size. Training stops after there is no macro-F1 improvement on development data for 1000 steps.

For evaluation, we focus primarily on macro-F1 and recall of the rarest class. The recall on the rarest class is especially important for imbalanced classification problems. For such problems, a model can obtain high accuracy by strongly preferring the majority class, but we seek models that effectively identify minority class labels. (This is especially important for active learning scenarios, where we expect the CB-vectors to help with in future.)

5.2 Results: low data scenarios

Figure 2 shows learning curves giving macro-F1 scores and rarest class recall for all four datasets. When very limited training data is available, the simple CBC model generally outperforms the CNN and BERT, except for the Spam dataset. The more powerful models eventually surpass CBC; however, the CBCNN model provides consistent strong performance at all dataset sizes by combining the generalization of CBC with the general efficacy of CNNs. Importantly, CBCNN provides massive error reductions with low data for 20NG and R8 (tasks with many labels).

Table 5's left half gives results for all models when using only 320 training examples. For 20NG, CNN's macro-F1 is just 43.9, whereas CBC and CBCNN achieve 61.7 and 62.4—the same as CNN performance with four times as much data. These models outperform CNN on R8 as well, reaching 83.7 vs CNN's 74.1, and also on the Wiki-attack dataset, achieving 80.6 vs CNNs 74.0. BERT fails to produce a solution for the two datasets with >2 labels, but does produce the best result for Spam—indicating an opportunity to more fully explore BERT's parameter settings for low data scenarios and to fruitfully combine CBC with BERT.

Rarest class recall is generally much better with less data when exploiting CB-features. For example, with 320 training examples for R8, CNNs reach 36.2 whereas CBCNN scores 76.2. Prediction quality with few training examples (especially getting good balance across all labels) also inter-

---

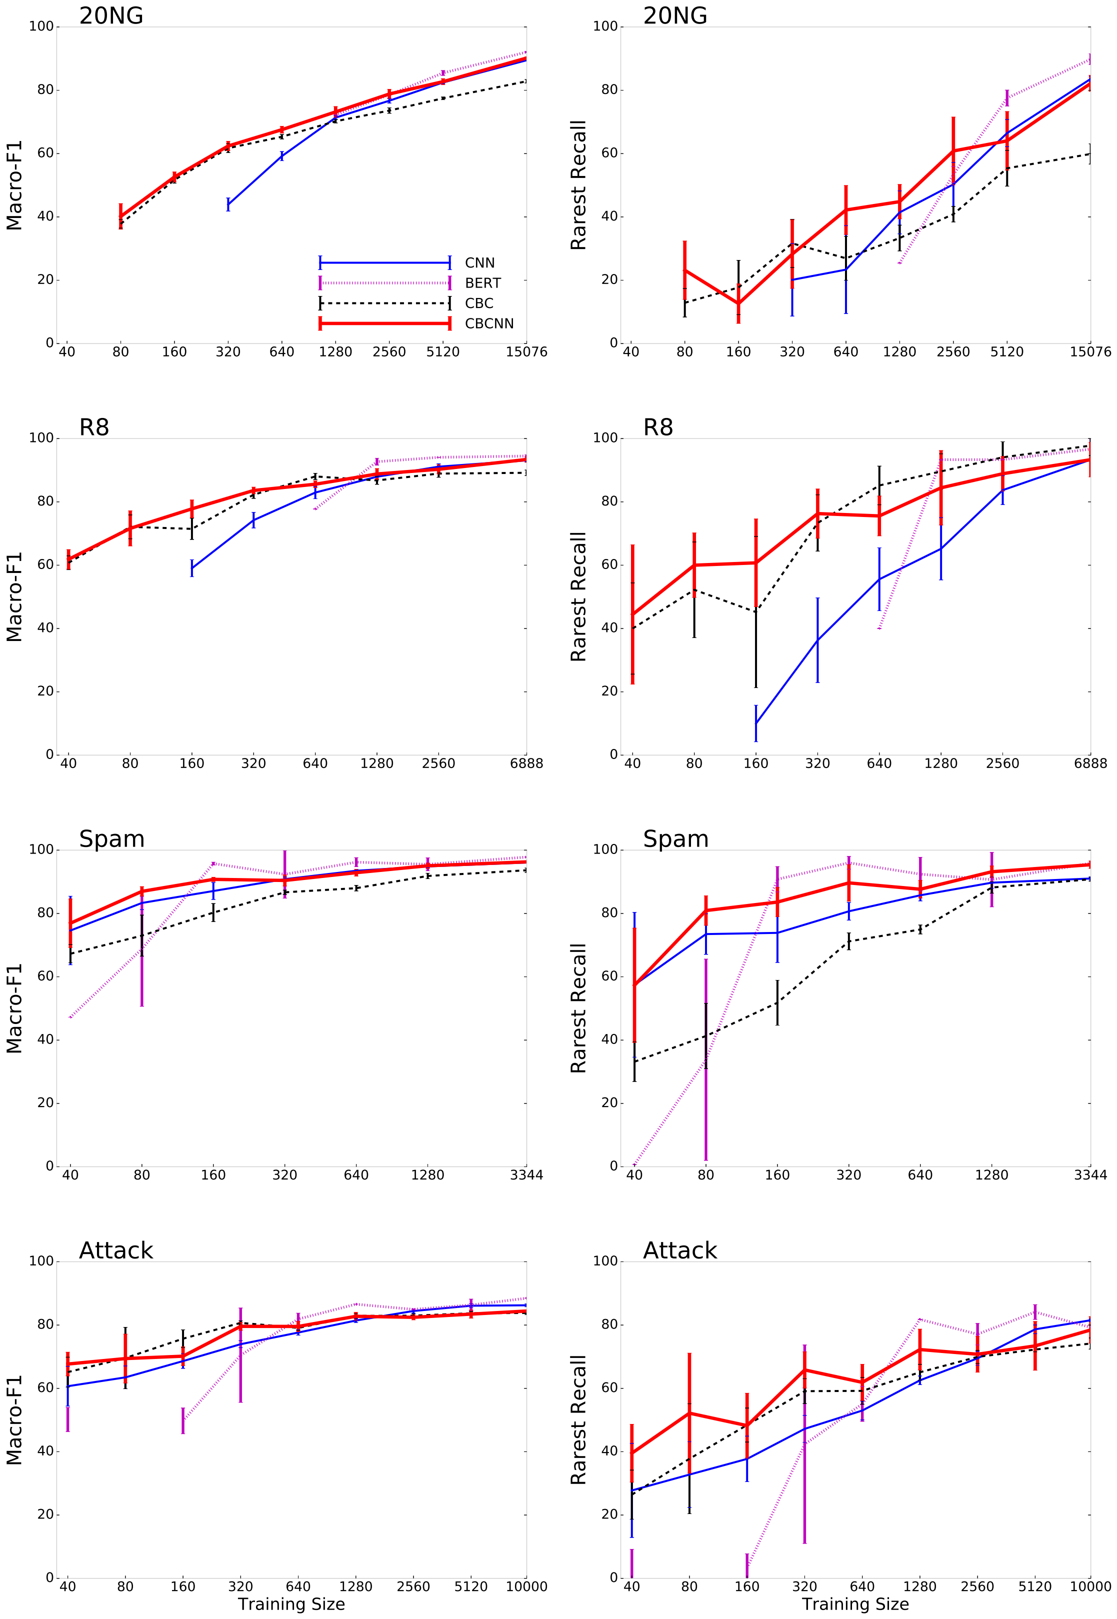

Figure 2: **Left:** F1 score by training size for 20NG, Reuters, SMS Spam, and Wiki-attack. Data is shown for non-degenerate models, and hence CNN and BERT start at higher sizes (see Table 6). **Right:** Recall for the rarest class for the same models.

		320 Training Examples				Full Training Data			
Data	k	CBC	CNN	CBCNN	BERT	CBC	CNN	CBCNN	BERT
20NG	20	61.7	43.9	**62.4**	—	82.9	89.5	90.2	**92.0**
R8	8	82.3	74.2	**83.6**	—	89.2	93.1	93.4	**94.4**
Spam	2	80.3	87.1	90.8	**95.7**	93.7	96.1	96.3	**97.8**
Attack	2	**80.7**	74.0	79.6	70.5	83.8	86.2	84.5	**88.2**

Table 5: Macro-F1 scores on all data sets when using 320 training examples (left) and when using all available training data (right). k is the number of classes. The CBCNN model provides the strongest overall performance across all data sizes. (Note that BERT produces degenerate solutions for the >2 class problems with 320 examples.)

Model	k	CBC	CNN	CBCNN	BERT
20NG	20	80	320	80	1280
R8	8	40	160	40	640
Spam	2	40	40	40	40
Attack	2	40	40	40	40

Table 6: Minimum training size at which a non-degenerate model was produced in any of 9 runs. With more classes, more data is needed by CNN and BERT to produce acceptable models. k is number of classes.

acts with other strategies for dealing with limited resources, such as active learning. For example, Baldridge and Osborne (2008) obtained stronger data utilization ratios with better base models and uncertainty sampling for Reuters text classification: better models pick better examples for annotation and thus require fewer new labeled data points to achieve a given level of performance.

Importantly, the CBC and CBCNN models take far less data to produce non-degenerate models (defined as a model which produces all output classes as predictions). CNN and BERT have a large number of parameters, and using these powerful tools with small training sets produces unstable results. Table 6 gives the minimum training set sizes at which each model produces at least one non-degenerate model. While it might be possible to ameliorate the instability of CNN and BERT with a wider parameter search and other strategies, nothing special needs to be done for CBC. It is likely that an approach which adaptively selects CBC or CBCNN and BERT would obtain the strongest result across all training set sizes.

For each dataset, among the 100 best features chosen (for training size 640), the breakdown of domain features (F_C) versus type features (F_S) is revealing. As expected, domain features are more important in a topical task such as 20NG (71% are F_C features), while the opposite is true for Spam (19%) and a toxicity dataset like Wiki Attack (23%). Reuters shows a fairly even balance between the two types of features (41%): it is useful for R8 to be topically coherent and also to hone in on fairly narrow groups of words that collectively cover a Basic Level Category.

5.3 Results: full data scenarios

Table 5 provides macro-F1 scores for all models when given all available training data. The CBC model performs well, but its (intentional) ignorance of the actual tokens in a document takes a toll when more labeled documents are available. The CNN benchmark, which exploits both word order and the tokens themselves, is a strong performer. The CBCNN model effectively keeps pace with the CNN—improving on 20NG and R8, though slipping on Wiki-Attack. BERT simply crushes all other models when there is sufficient training data, showing the impact of structured pre-training and consistent with performance across a wide range of tasks in Devlin et al. (2018).

6 Conclusion

We demonstrate an effective method for exploiting syntactically derived features from large external corpora and selecting the most useful of those given a small labeled text classification corpus. We show how to do this with the map provided by Category Builder n-grams to features, but other sources of well generalizing features have been exploited for text classification. These include topic models (Blei et al., 2003), ontologies such as WordNet (Bloehdorn and Hotho, 2004) and Wikipedia Category structure (Gabrilovich and Markovitch, 2009). It may be possible to use these other sources exactly as we use CB. Some of these sources have been manually curated, which makes them high quality but limits the size and facets. We have not yet explored their use because CB features seem to cover many of these sources' strengths—for example, F_C features are like topics, and F_S features like nodes in ontologies. Nonetheless, a combination may add value.

Our focus is on data scarce scenarios. However, it would be ideal to derive utility at both the small and large labeled data sizes. This will likely require models that can generalize with contextual features while also exploiting implicit hierarchical organization and order of the texts, e.g. as done by CNNs and BERT. The CBCNN model is one effective way to do this and we expect there could be similar benefits from combining CBC with BERT. Furthermore, approaches like AutoML (Zoph and Le, 2017) would likely be effective for exploring the design space of network architectures for representing and exploiting the information inherent in both signals.

Finally, although we focus on multi-class problems here—each example belongs to a single class—the general approach of selecting features should work for multi-label problems. Our confidence in this (unevaluated) claim stems from the observation that we select features one class at a time, treating that class and its complement as a binary classification problem.

A Appendix

Changes to the Category Builder Matrix

Category Builder uses two matrices: one mapping items to features ($M^{\mathcal{V}\rightarrow\mathcal{F}}$), the other mapping features to items ($M^{\mathcal{F}\rightarrow\mathcal{V}}$). Two are needed since the relationship is asymmetric: the feature *X is a star sign* is more strongly associated with the term *cancer* than vice versa, and the two matrices are thus not exact transposes of each other, although they almost are. For this current work, we just use one matrix, $M^{\mathcal{V}\rightarrow\mathcal{F}}$. For syntactic features F_S, we directly use the Category Builder rows. For F_C features, however, Category Builder replaced the corresponding submatrix in $M^{\mathcal{V}\rightarrow\mathcal{F}}$ with an identity matrix as described in (Mahabal et al., 2018). We obtain that part of the matrix by copying the corresponding rows from $(M^{\mathcal{F}\rightarrow\mathcal{V}})^T$.

This new matrix will be made available as part of the Category Builder project.

Reinforcement Learning Based Text Style Transfer without Parallel Training Corpus

Abstract

Text style transfer rephrases a text from a source style (e.g., informal) to a target style (e.g., formal) while keeping its original meaning. Despite the success existing works have achieved using a parallel corpus for the two styles, transferring text style has proven significantly more challenging when there is no parallel training corpus. In this paper, we address this challenge by using a reinforcement-learning-based generator-evaluator architecture. Our generator employs an attention-based encoder-decoder to transfer a sentence from the source style to the target style. Our evaluator is an adversarially trained style discriminator with semantic and syntactic constraints that score the generated sentence for style, meaning preservation, and fluency. Experimental results on two different style transfer tasks (sentiment transfer and formality transfer) show that our model outperforms state-of-the-art approaches. Furthermore, we perform a manual evaluation that demonstrates the effectiveness of the proposed method using subjective metrics of generated text quality.

1 Introduction

Text style transfer is the task of rewriting a piece of text to a particular style while retaining the meaning of the original text. It is a challenging task of natural language generation and is at the heart of many recent NLP applications, such as personalized responses in dialogue system (Zhou et al., 2017), formalized texts (Rao and Tetreault, 2018), cyberspace purification by rewriting offensive texts (Niu and Bansal, 2018; Santos et al., 2018), and poetry generation (Yang et al., 2018).

Recent works on supervised style transfer with a parallel corpus have demonstrated considerable success (Jhamtani et al., 2017b; Rao and Tetreault, 2018). However, a parallel corpus may not always be available for a transfer task. This has prompted studies on style transfer without parallel corpora. These hinge on the common idea of separating the content from the style of the text (Shen et al., 2017; Fu et al., 2018; Santos et al., 2018). This line of research first encodes the context via a style-independent representation, and then transfers sentences by combining the encoded content with style information. In addition, an appropriate training loss is chosen to change the style while preserving the content. However, these approaches are limited by their use of loss functions that must be differentiable with respect to the model parameters, since they rely on gradient descent to update the parameters. Furthermore, since focusing only on semantic and style metrics in style transfer, they ignore other important aspects of quality in text generation, such as language fluency.

In this paper, we propose a system trained using reinforcement-learning (RL) that performs text style transfer without accessing to a parallel corpus. Our model has a generator-evaluator structure with one generator and one evaluator with multiple modules. The generator takes a sentence in a source style as input and transfers it to the target style. It is an attention-based sequence-to-sequence model, which is widely used in generation tasks such as machine translation (Luong et al., 2015). More advanced model such as graph-to-sequence model can also exploited for this generation task (Xu et al., 2018b). The evaluator consists of a style module, a semantic module and a language model for evaluating the transferred sentences in terms of style, semantic content, and fluency, respectively. Feedback from each evaluator is sent to the generator so it can be updated to improve the transfer quality.

Our style module is a style discriminator built using a recurrent neural network, predicting the likelihood that the given input is in the target style.

Proceedings of NAACL-HLT 2019, pages 3168–3180
Minneapolis, Minnesota, June 2 - June 7, 2019.

We train the style module adversarially to be a target style classifier while regarding the transferred sentences as adversarial samples. An adversarial training renders style classification more robust and accurate. As for the semantic module, we used word movers' distance (WMD), a state-of-the-art unsupervised algorithm for comparing semantic similarity between two sentences (Kusner et al., 2015; Wu et al., 2018b), to evaluate the semantic similarity between input sentences in the source style and the transferred sentences in the target style. We also engaged a language model to evaluate the fluency of the transferred sentences.

Unlike prior studies that separated content from style to guarantee content preservation and transfer strength, we impose explicit semantic, style and fluency constraints on our transfer model. Moreover, employing RL allows us to use other evaluation metrics accounting for the quality of the transferred sentences, including non-differentiable ones.

We summarize our contributions below:

(1) We propose an RL framework for text style transfer. It is versatile to include a diverse set of evaluation metrics as the training objective in our model.

(2) Our model does not rely on the availability of a parallel training corpus, thus addressing the important challenge of lacking parallel data in many transfer tasks.

(3) The proposed model achieves state-of-the-art performance in terms of content preservation and transfer strength in text style transfer.

The rest of our paper is organized as follows: we discuss related works on style transfer in Section 2. The proposed text style transfer model and the reinforcement learning framework is introduced in Section 3. Our system is empirically evaluated on sentiment and formality transfer tasks in Section 4. We report and discuss the results in Section 5 and Section 6. The paper is concluded in Section 7.

2 Related Works

Text style transfer has been explored in the context of a variety of natural language applications, including sentiment modification (Zhang et al., 2018b), text simplification (Zhang and Lapata, 2017), and personalized dialogue (Zhou et al., 2017). Depending on whether the parallel corpus is used for training, two broad classes of style transfer methods have been proposed to transfer the text from the source style to the target style. We will introduce each line of research in the following subsections.

Style transfer with parallel corpus. Style transfer with the help of a style parallel corpus can be cast as a monolingual machine translation task. For this, a sequence-to-sequence (seq2seq) neural network has been successfully applied in a supervised setting. Jhamtani et al. transfer modern English to Shakespearean English by enriching a seq2seq model with a copy mechanism to replicate the source segments in target sentences (Jhamtani et al., 2017a).

Style transfer without parallel corpus. Scarce parallel data in many transfer tasks has prompted a recent interest in studying style transfer without a parallel corpus (e.g., (Zhang et al., 2018a)). Li et al. propose to delete words associated with the source style and replace them with similar phrases associated with the target style. Clearly, this approach is limited to transfers at the lexical level and may not handle structural transfer. Most existing unsupervised approaches share a core idea of disentangling content and style of texts. For a given source sentence, a style-independent content representation is firstly derived. Then, in combination with the target style, the content representation is used to generate the sentence following the target style.

Approaches to extract the content include variational auto-encoders (VAE) and cycle consistency. VAEs are commonly used to learn the hidden representation of inputs for dimensionality reduction, and have been found to be useful for representing the content of the source (Hu et al., 2017; Mueller et al., 2017; Shen et al., 2017; Fu et al., 2018). Cycle consistency is an idea borrowed from image style transfer for content preservation (Zhu et al., 2017). It proposes to reconstruct the input sentence from the content representation, by forcing the model to keep the information of the source sentence (Santos et al., 2018).

The transferred sentences are generated based on the content representation and the target style. One way to achieve this is with the use of a pre-trained style classifier. The classifier scores the transfer strength of the generated sentences and guides the model to learn the target text style (Santos et al., 2018; Prabhumoye et al., 2018). Another way is to learn the style embedding, which can be concatenated with the content embedding as the representation of the target sentence (Fu et al., 2018). The decoder then constructs the sentences from their hidden representations.

We note that previous works rely on gradient descent in their model training, and therefore their training losses (e.g., content and style loss) were limited to functions differentiable with respect to model parameters. Also, very few works consider other aspects of transfer quality beyond the content and the style of the generated sentences. This is in part due to their reliance on a differentiable training objective. We propose an RL-based style transfer system so that we can incorporate more general evaluation metrics in addition to preserving the semantic meaning of content and style transfer strength.

Reinforcement learning. RL has recently been applied to challenging NLP tasks (Yu et al., 2017). RL has advantages over supervised learning in that it supports non-differentiable training objectives and does not need annotated training samples. Benefits of using RL have been demonstrated in image captioning (Guo et al., 2018), sentence simplification (Zhang and Lapata, 2017), machine translation (Wu et al., 2018a) and essay scoring (Wang et al., 2018). A recent work on the task of sentiment transfer applied reinforcement learning to handle its BLEU score-based training loss (a non-differentiable function) (Xu et al., 2018a). Similar to the style transfer works discussed above, it also disentangled the semantics and the sentiment of sentences using a neutralization module and an emotionalization module respectively. Our work is different from these related works in that the semantic preservation and transfer strength are taken care of by the use of discriminators without explicitly separating content and style. An additional aspect that we focus here is the notion of fluency of the transferred sentences, which has not been explored before.

3 Model

Our style transfer system consists of the following modules: a generator, a style discriminator, a semantic module and a language model as shown in Fig. 1. We next describe the structure and function of each component. A closer view of our system is presented in Fig. 2.

Generator. The generator in our system takes a sentence in the source style as input and transfers it to the target style. For this, we use a recurrent encoder-decoder model combined with attention mechanism, which can handle variable-length input and output sequences (Sutskever et al., 2014; Cho et al., 2014). We could also leverage recently proposed more advanced encoder-decoder models (Xu et al., 2018b,c) to exploit rich syntactic information for this task, which we leave it as future work. Both the encoder and the decoder are recurrent neural layers with gated recurrent units (GRU). The encoder takes one word from the input at each time step, and outputs a hidden state vector $\bar{h}_s$ at time s. Similarly, the decoder outputs a hidden representation h_t at time t.

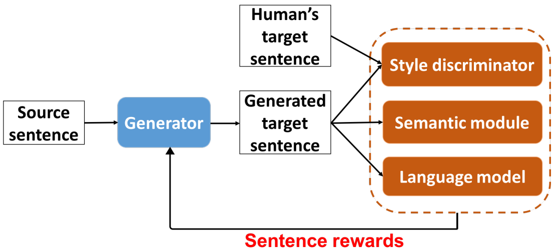

Figure 1: Model overview: the generator transfers the input source sentence to the generated target sentence. The generated sentences are collectively evaluated by the style discriminator, the semantic module and language module respectively. The style discriminator is adversarially trained with both human- and model-generated sentences. These three modules evaluate the generated sentences in terms of transfer strength, content preservation and fluency, and the rewards are sent to train the generator.

Suppose that the input sequence consists of T words $x = \{x_1, \ldots, x_T\}$, and the generated target sentence y is also a sequence of words $\{y_1, \ldots, y_{T'}\}$. We use $\text{vec}(\cdot)$ to denote the embedding of a word.

The gated recurrent unit dynamically updates its state h_t based on its previous state h_{t-1} and current input i_t. Its computation can be abstracted as $h_t = \text{GRU}(h_{t-1}, i_t)$. For the encoder, the input i_t is the embedding of the t-th input source word,

$$\bar{h}_t = \text{GRU}(\bar{h}_{t-1}, \text{vec}(x_t)). \tag{1}$$

For the decoder, the input to the recurrent unit is the embedding of the t-th generated target word.

$$h_t = \text{GRU}(h_{t-1}, \text{vec}(y_t)). \tag{2}$$

An attention mechanism is commonly adopted in text generation, such as machine translation (Bahdanau et al., 2015; Luong et al., 2015). We

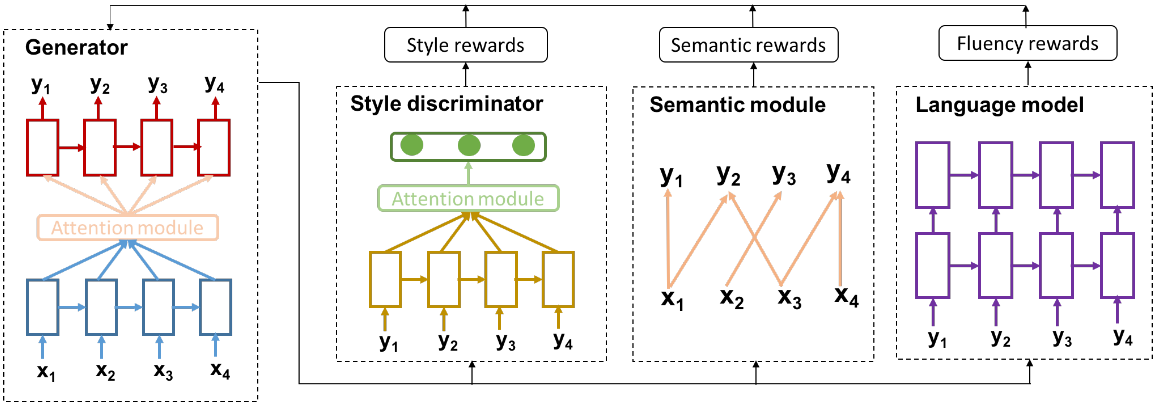

Figure 2: A detailed view of each component in the text style transfer system.

apply the attention mechanism to the decoding step so that the decoder learns to attend to source words and generates words. In this work, we use the attention mechanism similar to that used in (Luong et al., 2015). At the t-th decoding step, the attention $\alpha_t(s)$ is the weight of the s-th encoder state $\bar{h}(s)$.

The encoder hidden states are linearly weighted by the attention as the context vector at time t.

$$c_t = \sum \alpha_t(s)\bar{h}_s. \tag{3}$$

Combining the attention over the source sentence, the decoder produces a new hidden state $\tilde{h}_t$,

$$\tilde{h}_t = \tanh(W_c[c_t; h_t]). \tag{4}$$

The hidden vector $\tilde{h}_t$ is then used to predict the likelihood of the next word in the target sentence over the target vocabulary.

$$\mathbb{P}(y_t|y_{<t}, x) = \text{softmax}(W_s\tilde{h}_t). \tag{5}$$

where W_c and W_s are decoder parameters.

Style discriminator. The style discriminator evaluates how well the generated sentences are transferred to the target style. It is a classifier built on a bidirectional recurrent neural network with attention mechanism. The style discriminator is pre-trained to minimize the cross-entropy loss in the style classification task. This style classifier predicts the likelihood that an input sentence is in the target style, and the likelihood is taken as the style score of a sentence.

The pre-training does not guarantee that the neural network model will learn robust style patterns. So we resort to adversarial training as done in generative adversarial networks (GAN) (Yu et al., 2017; Wang and Lee, 2018). Accordingly, the style discriminator is later adversarially trained to distinguish the original (human-written) sentences from the model-generated ones so that the classifier learns to classify the text style well.

Semantic module. This evaluates how well the content from the input is preserved in the generated sentences. We use word mover's distance (WMD), which is the state-of-the-art approach (known for its robustness and efficiency) to measure the dissimilarity between the input and output sentences based on word embeddings (Kusner et al., 2015; Wu et al., 2018b). We take the negative of the WMD distance and divide it by the sequence length to yield the *semantic score* of a generated sentence. Previous works have also used cycle reconstruction loss to measure content preservation by reconstructing input sentences from generated sentences (Santos et al., 2018).

Language model. The style and the semantic modules do not guarantee the fluency of the transferred sentences. This fluency is achieved using a language model. The language model we use is a two-layer recurrent neural network pre-trained on the corpus in the target style so as to maximize the likelihood of the target sentences (Mikolov et al., 2010; Jozefowicz et al., 2016). The language model estimates the probability of input sentences. We take the logarithm of the probability and divide it by the sequence length as the *fluency score*.

3.1 Reinforcement Learning

The output sentences from the generator are sent to the semantic, style and language model modules for evaluation. These modules give feedback to the generator for the purpose of tuning it and to improve the quality of the generated sentences. We emphasize that despite the fact that our chosen evaluation metrics are not differentiable with respect to the generator parameters, they are still usable here. This is made possible by our use of the RL framework (the REINFORCE algorithm) to update the parameters of the generator (Williams, 1992).

In the RL framework, we define the state and the action for our style transfer task as follows. The state s_t at time t is the input source sequence and the first $t-1$ words that are already generated in the target sequence, i.e., $s_t = (X, Y_{1:t-1})$. The action a_t at time t is the t-th word to be generated in the output sequence, i.e., $a_t = y_t$. Suppose that the target vocabulary is V, and the maximum length of the decoder is T'. The generator G is parameterized with a parameter set θ, and we define the expected reward of the current generator as $J(G_\theta)$. The total expected reward is

$$J(G_\theta) = \sum_{t=1}^{T'} \mathbb{E}_{Y_{1:t-1} \sim G_\theta} [\sum_{y_t \in V} \mathbb{P}_\theta(y_t|s_t) Q(s_t, y_t)], \tag{6}$$

where $\mathbb{P}_\theta(y_t|s_t)$ is the likelihood of word y_t given the current state, and $Q(s_t, y_t)$ is the cumulative rewards that evaluate the quality of the sentences extended from $Y_{1:t}$. Suppose that $r(s_t, y_t)$ is the reward of word y_t at state s_t. The total reward, Q, is defined as the sum of the word rewards.

$$Q(s_t, y_t) = \sum_{\tau=t}^{T'} \gamma^{\tau-t} r(s_\tau, y_\tau), \tag{7}$$

where γ $(0 < \gamma < 1)$, is a discounting factor so that the future rewards have decreasing weights, since their estimates are less accurate.

If we only consider one episode, i.e., $Y_{1:t-1}$ has been given for every y_t, the reward $J(G_\theta)$ can be written as

$$J(G_\theta) = \sum_{t=1}^{T'} \sum_{y_t \in V} \mathbb{P}_\theta(y_t|s_t) Q(s_t, y_t). \tag{8}$$

Sequence sampling. By design, the three evaluation modules in Fig. 1 only evaluate complete sentences instead of single words or partial sentences. This means that we cannot obtain $r(s_t, y_t)$ directly from the evaluation modules at any time instance before the end of the sentence. One way around this problem is rolling out (Yu et al., 2017), where the generator 'rolls out' the given sub-sentence $Y_{1:t}$ at time step t to generate complete sentences by sampling the remaining part of the sentence $\{Y^n_{t+1:T'}\}$.

Previous works have adopted different sampling strategies, including Monte Carlo search, multinomial sampling and beam search. Starting from the given segment $Y_{1:t}$, Monte Carlo search explores the sub-sequence which leads to the best complete sentence (Yu et al., 2017). This leads to a good estimate of the sentence rewards but comes at significant computational cost. In many applications, the other two sampling strategies have been adopted for their efficiency. In multinomial sampling, each word y_τ $(t < \tau \leq T')$ is sampled from the vocabulary according to the likelihood $\mathbb{P}(y_\tau|s_\tau)$ predicted by the generator (ODonoghue et al., 2016; Chatterjee and Cancedda, 2010). The beam search process, on the other hand, keeps track of the k (a user-specified parameter) most likely words at each decoding step rather than just one word (Wu et al., 2018a). While this yields an accurate estimate of the reward for each action, multinomial sampling allows us to explore the diversity of generated texts with a potentially higher reward later on. This is the trade-off between exploitation and exploration in RL.

To balance the estimation accuracy and the generation diversity, we combine the ideas of beam search and multinomial sampling. Given a source sentence, we first generate a reference target sentence $Y^{\text{ref}}_{1:T}$ using beam search. To estimate the reward at each time step t, we draw samples of complete sentences $\{Y^l_{1:T'}\}$ by rolling out the subsequence $Y^{\text{ref}}_{1:t}$ using multinomial sampling. The evaluation scores of the sampled sentences are used as reward $r(y_t, s_t)$. More details about the sampling process are in Appendix.

Reward estimation. We estimate the reward as follows. We draw N samples of complete sentences starting from $Y_{1:t}$: $\{Y^{(n)}_{1:T'}\}^N_{n=1}$. The complete sentences are then fed into the three evaluation modules. Let f_{style} be the style score given by the style module, f_{semantic} be semantic score by the semantic module, and f_{lm} be the fluency score given by the language model.

We score the action y_t at state s_t by the average score of the complete sentences rolled out from $Y_{1:t}$. This action score is defined as the weighted sum of the scores given by the three modules.

$$f(s_t, y_t) = \frac{1}{N} \sum_{n=1}^{N} (\ \alpha \cdot f_{\text{style}}(Y^{(n)}_{1:T'}) + \\ \beta \cdot f_{\text{semantic}}(Y^{(n)}_{1:T'}, Y^{\text{real}}_{1:T'}) + \eta \cdot f_{\text{lm}}(Y^{(n)}_{1:T'})\ ), \tag{9}$$

where the hyperparameters α, β and η are positive.

In our experiments, we set $\alpha = 1.0$, $\beta = 0.5$ and $\eta = 0.5$ heuristically.

Given the scores from the evaluation modules, we define the reward $r(s_\tau, y_\tau)$ of word y_τ at state s_τ as

$$r(s_\tau, y_\tau) = \begin{cases} f(s_\tau, y_\tau) - f(s_{\tau-1}, y_{\tau-1}), & \tau > 1, \\ f(s_1, y_1), & \tau = 1. \end{cases} \tag{10}$$

We then obtain the discounted cumulative reward $Q(s_t, y_t)$ from the rewards $\{r(s_\tau, y_\tau)\}_{\tau > t}$ at each time step using Eq. 7.

The total reward of $J(G_\theta)$ can be derived from the cumulative rewards $\{Q(s_t, y_t)\}$ using Eq. 8. We define the generator loss L_θ as the negative of reward $J(G_\theta)$, $L_G(\theta) = -J(G_\theta)$.

According to Eq. 8, we can find the gradient $\nabla_\theta L_\theta$ of the generator loss as,

$$\nabla_\theta L_G(\theta) = -\sum_{t=1}^{T'} \nabla_\theta \mathbb{P}_\theta(y_t|s_t) Q(s_t, y_t). \tag{11}$$

3.2 Adversarial Training

The style discriminator is pre-trained on corpora in the source and target styles, and is used to evaluate the strength of style transfer. We note that this pre-training may not be sufficient for the style classifier to learn robust patterns and to provide accurate style evaluation. Indeed, in our experiments we found that even though the generator was trained to generate target sentences by maximizing the style rewards, the one-shot pre-training was insufficient to render the sentences in the target style.

Borrowing the idea of adversarial training proposed in GANs, we continuously trained the style discriminator using the generated target sentences. Toward this, we used a combination of a randomly sampled set of human-written target sentences $\{Y^{(k)}_{\text{human}}\}$ and model-generated sentences $\{Y^{(k)}_{\text{model}}\}$. Here the model-generated instances act as adversarial training samples, using which, the style discriminator was trained to distinguish the model outputs from human-written sentences. Let the discriminator D be parameterized by a parameter set ϕ. We define the prediction of the style discriminator, $D(Y)$, as the likelihood that the sentence Y is in the target style. The objective of this adversarial training amounts to minimizing the discriminator loss L_D:

$$L_D(\phi) = \frac{1}{K}\Big(-\sum_{k=1}^{K} \log(1 - D_\phi(Y^{(k)}_{\text{model}})) - \sum_{k=1}^{K} \log D_\phi(Y^{(k)}_{\text{human}}) \Big) . \tag{12}$$

4 Experiments

In this work, we considered two textual style transfer tasks, that of sentiment transfer (**ST**, involving negative and positive sentiments) and formality transfer (**FT**, involving informal and formal styles) using two curated datasets. We experimented with both transfer directions: positive-to-negative, negative-and-positive, informal-to-formal and formal-to-informal.

Dataset. For our experiments with style transfer we used a sentiment corpus and a formality corpus described below.

	Vocabulary	Type	Train	Dev	Test
Sentiment	9,640	Negative	176,878	25,278	50,278
		Positive	267,314	38,205	76,392
Formality	21,129	Informal	50,711	1,019	1,327
		Formal	50,711	1,019	1,019

Table 1: Data sizes of sentiment and formality transfer.

(1) Sentiment corpus. The sentiment corpus consists of restaurant reviews collected from the Yelp website (Shen et al., 2017). The reviews are classified as either negative or positive.

(2) Formality corpus. We use the Grammarly's Yahoo Answers Formality Corpus (GYAFC) (Rao and Tetreault, 2018), which is a collection of sentences posted in a question-answer forum (Yahoo Answers) and written in an informal style. In addition, these sentences have been manually rewritten in a formal style. We used the data from the section *family and relationships*. Note that even though the corpus is parallel, we did not use the parallel information.

Table 1 shows the train, dev and test data sizes as well as the vocabulary sizes of the corpora used in this work.

Model settings. The word embeddings used in this work were of dimension 50. They were first trained on the English WikiCorpus and then tuned on the training dataset. The width of the beam search (parameter k) was 8 during the RL and the inference stage.

Type	Source sentence	Transferred sentence
Negative-to-Positive	Crap fries , hard hamburger buns , burger tasted like crap !	Love you fries, burgers , always fun burger , authentic !
Positive-to-Negative	I was very impressed with this location .	I was very disappointed with this location .
Informal-to-Formal	It defenitely looks like he has feelings for u do u show how u feel u should ! !	It is like he is interested in you you should show how you feel .
Formal-to-Informal	I believe you 're a good man most likely she loves you quite a bit.	I think you 're a good man she kinda loves you .

Table 2: Example transferred sentences.

Pre-training. We pre-trained the generator, the style discriminator and the language model before the reinforcement learning stage. We discuss each of these steps below.

Generator pre-training. We pre-trained the generator to capture the target style from the respective target corpus. This pre-training occurred before setting up the reward from the evaluator to update its parameters in reinforcement learning. During pre-training, we used a set of target instances with a given instance serving as the input as well as the expected output. Using this set we trained the generator in a supervised manner with the cross-entropy loss as the training objective. Pre-training offered two immediate benefits for the generator: (1) the encoder and decoder learned to capture the semantics and the target style from the target corpus; (2) the generator had a good set of initial parameters that led to faster model training. This second aspect is a significant gain, considering that reinforcement learning is more time consuming than supervised learning.

Style discriminator pre-training. The style discriminator in our work was built using a bidirectional recurrent neural network. It was pre-trained using training corpora consisting of sentences in both the source and the target styles. We trained it to classify the style of the input sentences with the cross-entropy classification loss.

Language model pre-training. The language model was a two-layer recurrent neural network. Taking a target sentence $y = \{y_1, \ldots, y_{T'}\}$ as the input, the language model predicted the probability of the t-th word y_t given the previous subsequence $y_{1:t-1}$. The language model was pre-trained on the training corpus in target style to maximize the probability of y_t $(1 \leq t \leq T')$.

Baselines. We considered two state-of-the-art methods of unsupervised text style transfer that use non-parallel training corpus.

(1) Cross alignment model (CA). The CA model assumes that the text in the source and target style share the same latent content space (Shen et al., 2017). The style-independent content representation generated by its encoder is combined with available style information to transfer the sentences to the target style. We used their publicly available model for ST, and trained the model for FT separately with its default parameters.

(2) Multi-decoder seq2seq model (MDS). MDS consists of one encoder and multiple decoders (Fu et al., 2018). Similar to the cross alignment transfer, its encoder learns style-independent representations of the source, and the style specific decoder will rewrite sentences in the target style based on the content representation. We trained the model with its default parameters for both the tasks.

4.1 Evaluation

We used both automatic and human evaluation to validate our system in terms of content preservation, transfer strength and fluency.

4.1.1 Automatic evaluation

Aligning with prior work, we used the automatic metrics of content preservation, transfer and fluency that have been found to be well correlated with human judgments (Fu et al., 2018). For comparison, in Appendix, we also report our style and semantic metrics as provided by the evaluator.

Content preservation. A key requirement of the transfer process is that the original meaning be retained. Here we measure this by an embedding based sentence similarity metric s_{sem} proposed by (Fu et al., 2018). The embedding we used was based on the word2vec (CBOW) model (Mikolov et al., 2013). It was first trained on the English WikiCorpus and then tuned on the training dataset. Previous works used pre-trained GloVe embedding (Pennington et al., 2014), but we note that it does not have embeddings for Internet slang commonly seen in sentiment and formality datasets.

Transfer strength. The transfer strength s_{style} captures the degree to which the style transfer was

Sentiment	Negative-to-Positive				Positive-to-Negative			
Metric	Content	Style	Overall	Perplexity	Content	Style	Overall	Perplexity
CA	**0.894**	0.836	0.432	103.11	0.905	0.836	0.435	185.35
MDS	0.783	0.988	0.437	**98.89**	0.756	0.860	0.402	**156.98**
RLS	0.868	0.98	**0.460**	119.24	0.856	0.992	**0.459**	174.02
Formality	Informal-to-Formal				Formal-to-Informal			
Metric	Content	Style	Overall	Perplexity	Content	Style	Overall	Perplexity
CA	0.865	0.558	0.339	238.05	0.789	0.956	0.432	317.40
MDS	0.519	0.435	0.237	278.65	0.546	0.998	0.353	352.86
RLS	0.885	0.601	**0.358**	**208.33**	0.873	0.982	**0.462**	**267.78**

Table 3: Automatic evaluation of text style transfer systems on sentiment and formality transfer.

carried out and was quantified using a classifier. An LSTM-based classifier was trained for style classification on a training corpus (Fu et al., 2018). The classifier predicts the style of the generated sentences with a threshold of 0.5. The prediction accuracy is defined as the percentage of generated sentences that were classified to be in the target style. The accuracy was used to evaluate transfer strength, and the higher the accuracy is, the better the generated sentences fit in target style.

Overall score. We would like to point out that there is a trade-off between content preservation and transfer strength. This is because the outputs resulting from unchanged input sentences show the best content preservation while having poor transfer strength. Likewise, for given inputs, sentences sampled from the target corpora have the strongest transfer strength while barely preserving any content if at all. To combine the evaluation of semantics and style, we use the overall score s_{overall}, which is defined as a function of s_{sem} and s_{style}: $s_{\text{overall}} = \frac{s_{\text{sem}} * s_{\text{style}}}{s_{\text{sem}} + s_{\text{style}}}$ (Fu et al., 2018).

Fluency. This is usually evaluated with a language model in many NLP applications (Peris and Casacuberta, 2015; Tüske et al., 2018). We used a two-layer recurrent neural network with gated recurrent units as a language model, and trained it on the target style part of the corpus. The language model gives an estimation of perplexity (PPL) over each generated sentence. Given a word sequence of M words $\{w_1, \ldots, w_M\}$ and the sequence probability $p(w_1, \ldots, w_M)$ estimated by the language model, the perplexity is defined as:

$$\text{PPL} = p(w_1, \ldots, w_M)^{-\frac{1}{M}}. \qquad (13)$$

The lower the perplexity on a sentence, the more fluent the sentence is.

4.1.2 Human annotation

Noting the best overall score of our system in both directions of the tasks considered (to be discussed in the section that follows), we performed human annotations for content, style and fluency to validate the automatic scores. We chose a sample of 100 sentences generated by our system for each transfer task and collected three human judgments per sentence in each evaluation aspect. The annotation guidelines were:

Content preservation. Following the annotation scheme adopted by (Rao and Tetreault, 2018), we asked annotators to rate the semantic similarity between the original and transferred sentence on a scale from 1 to 6. Here "1" means completely dissimilar, "2" means dissimilar but on the same topic, "3" means dissimilar while sharing some content, "4" means roughly similar, "5" means almost similar, and "6" means completely similar.

Transfer strength. Annotators were given pairs of original and transferred sentences and were asked to decide which one was more likely to be in the target style. We define transfer strength to be the percentage of transferred sentences that were classified to be in the target style.

Fluency. Similar to the annotation of content, annotators scored sentences for fluency on a scale of 1(*not fluent*) to 6 (*perfectly fluent*).

5 Results

Some example sentences transferred by our system are shown in Table 2. More transferred sentences generated by our system and those by the baseline methods can be found in the Appendix. We first report the results of the automatic evaluation of our proposed system (denoted as "RLS") and the two baselines–the cross alignment model (CA) (Shen et al., 2017) and the multi-decoder seq2seq model (MDS) (Fu et al., 2018)–in Table 3.

Sentiment transfer. We notice that CA was the best in preserving content, MDS generated the most fluent target sentences and our model achieved the best trade-off between meaning and

Metric	Negative-to-positive	Positive-to-negative	Informal-to-formal	Formal-to-informal
Content (1-6)	5.19	5.20	4.96	5.33
Style accuracy	0.90	0.91	0.83	0.86
Fluency (1-6)	5.51	5.61	5.33	5.21

Table 4: Human judgments of transferred sentences

style with the highest overall score. Looking at the Overall score, it is notable that despite the differences in performance between the models studied here, each one performs similarly in both directions. This could be interpreted to mean that with respect to difficulty of transfer, style transfer is equivalent in both the directions for this task.

Formality transfer. For this task, we notice that our model outperforms the baselines in terms of content preservation, transfer strength and fluency with the best Overall score and perplexity. This suggests that our model is better at capturing formality characteristics compared to the baselines. We also note that the style strength of all models for informal-to-formal transfer is significantly lower than that for formal-to-informal transfer. This suggests that the informal-to-formal transfer is harder than the reverse. A plausible explanation is that informal sentences are more diverse and thus easier to generate than formal sentences. For example, informality can be achieved by multiple ways, such as by using an abbreviation (e.g., “u” used as “you”) and adding speech markers (e.g., “hey” and “ummm”), while formality is achieved in a more restricted manner.

Another challenge for informal-to-formal transfer is that informal data collected from online users usually contain non-negligible spelling errors such as “defenetely”, “htink” and “realy”. Words being the smallest semantic units in all the models considered here, these spelling errors could affect the transfer performance.

For each direction of transfer, we average the scores by annotators for each evaluation item, and report the results in Table 4. Our transferred sentences are shown to have good quality in content, style and fluency in subjective evaluations.

6 Discussion

To gain insights into the ways in which our approach performs the intended style transfer, we randomly sampled the generated sentences in the informal-to-formal transfer task. We found that the forms of rewriting can be broadly classified as: lexical substitution, word removal, word insertion and structural change. We show the following examples to these forms of re-writing, where the changed parts are highlighted.

(1) Lexical substitution. The informal sentence “I do **n’t** know what **u** mean” was transferred to “I do **not** know what **you** mean”;

(2) Word removal. The informal sentence “**And** I dont know what I should do” was rewritten as “I do not know what I should do”;

(3) Word insertion. In the example instance “depends on the woman” that was changed to “**It** depends on the woman”, we see that a subject was added to generate a complete formal sentence.

(4) Structural change. A small number of instances were also rewritten by making structural changes. For example, the informal sentence “**Just** tell them , **what are they gonna do** , slap you ??” was transferred to a formal version as “**You should** tell them , **they can not** slap you”. Other ways of style transfer by incorporating evaluation metrics of structural diversity are left for future work.

7 Conclusion

We proposed a reinforcement-learning-based text style transfer system that can incorporate any evaluation metric to enforce semantic, stylistic and fluency constraints on transferred sentences. We demonstrated its efficacy via automatic and human evaluations using curated datasets on two different style transfer tasks. We will explore and incorporate other metrics to improve other aspects of generated texts such as the structural diversity in the future work.

A Appendices

A.1 Sequence Sampling in Reinforcement Learning

The generator G transfers a source sentence X into a sentence in target style. In this work, we use beam search of width k to find a reference target sentence $Y^{\text{ref}}_{1:T'}$. In RL, we need to estimate the reward of each action y_t in the reference sentence

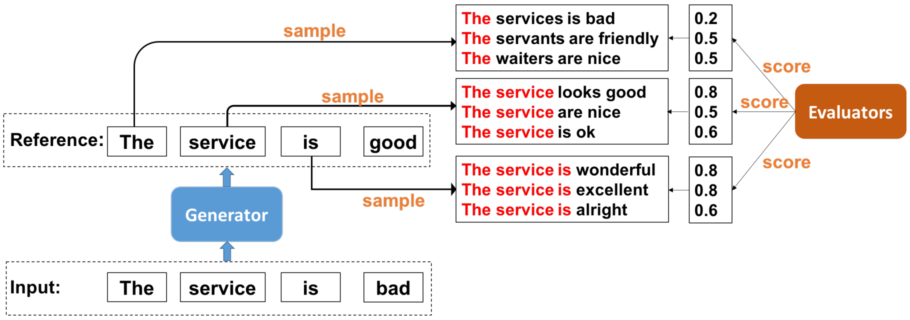

Figure 3: Sequence sampling: red words are sub-sequences in reference target sentence based on which the remaining sub-sequences are sampled. The sampled complete sentences are sent to the evaluator for scoring.

$Y^{\text{ref}}_{1:T'}$. Fig. 3 shows the sampling and scoring process.

Suppose that the reference target sentence $Y^{\text{ref}}_{1:T'}$ is “The service is good”. At the first time step, i.e., when $t = 1$, we start from the sub-sequence $Y^{\text{ref}}_{1:1}$, i.e., the sub-sentence ”The”. We use multinomial sampling to roll out “The” to complete sentences, which are “The service is bad”, “The servants are friendly” and “The waiters are nice” in Fig. 3. These sampled sentences are then sent to the evaluator for scoring in terms of style, content and fluency. Their scores are 0.2, 0.5 and 0.5 respectively, and we average them as the action score $f(y_1, s_1)$ of the first word y_1 at its state s_1. The score $f(y_1, s_1) = 0.4$ is sent back to the generator, which will be used to obtain the reward $r(y_1, s_1)$ as described in Eq. 10. Similarly when $t = 2$, we sample three complete sentences based on the sub-sentence “The service”: “The service looks good”, “The service are nice” and “The service is ok”.

A.2 Experiments

Automatic evaluation metrics. We reported the automatic evaluation results of all text style transfer systems in Table 3, where we used the evaluation metrics adopted by previous works (Fu et al., 2018; Santos et al., 2018). Here we report the style and semantic scores given by the evaluator in our system in Table 5. Recall that semantic score given by our evaluator was the negative of word movers’ distance between the generated sentence and the source sentence divided by the sentence length. The larger the semantic score was, the better the content was preserved in the generated sentence. As for the style evaluation, we used a bidirectional recurrent neural network as style classifier. It predicted the likelihood that an input sentence was in target style, which was taken as the *style score* of the generated sentences. Again, the larger the style score was, the better the generated sentence fitted in target style.

As shown in Table 5, the results given by the semantic and style modules of our evaluator are very similar to those given by Fu et al.. In sentiment transfer task, CA model does best in content preservation and MDS does best in transfer strength. As for FT, our model outperforms the two baselines in terms of semantic and style scores.

Examples and Analysis. We list some example transferred sentences given by our model and two baseline systems in Table 6. In the first example of negative-to-positive transfer, our model adheres to the topic of food service while baselines change to topic of food. Similarly in the first example of positive-to-negative transfer, our model preserves the topic of chicken while CA model talks about pizza and MDS model talks about customer service. Semantic similarity as explicit semantic constraints in our model is shown to be better at preserving the topic of source sentences.

There is still space to improve content preservation in all models. In the second example of informal-to-formal transfer, all transferred sentences miss the segment of “take a deep breathe” in the source sentence. In the second example of formal-to-informal transfer, the three transferred sentences miss part of source information. The source sentence is a rhetorical question, which truly means “people hardly understand the meaning behind their behavior”. This is a hard example, and all models do not capture its semantic meaning accurately.

FT task is more challenging compared with ST given that the sentence structure is more complicated with a larger vocabulary in the formality dataset.

Table 5: Semantic and style scores given by our evaluator on all systems.

	Sentiment				Formality			
	Negative-to-Positive		Positive-to-Negative		Informal-to-Formal		Formal-to-Informal	
Metric	Semantic	Style	Semantic	Style	Semantic	Style	Semantic	Style
CA	**-1.293**	0.806	**-1.346**	0.818	-1.212	0.646	-1.281	0.851
MDS	-1.412	**0.855**	-1.662	0.822	-1.508	0.568	-1.445	**0.878**
RLS	-1.315	0.846	-1.458	**0.847**	**-0.935**	**0.782**	**-0.903**	0.872

Table 6: Example transferred sentences of all systems.

Type	Transferred sentence
Negative-to-positive	Source: I ’ve noticed the food service sliding down hill quickly this year . CA: I have enjoyed the food here and this place is perfect . MDS: Food is the best staff . RLS: I ’ve noticed the food service was perfect this time .
	Source: The chicken tenders did n’t taste like chicken , wtf ? CA: The food tastes good , just like spicy ! MDS: And the food is the food in the food in well . RLS: . The chicken were like chicken, you can find what you want .
Positive-to-negative	Source: I recommend ordering the “ special chicken ” really good ! CA: I would give the pizza ... how they really really good ? MDS: They are the worst customer service . RLS: I would say chicken were very bad .
	Source: My experience was brief , but very good . CA: My experience was ok , but , very good . MDS: Worst , i would never go to going back . RLS: My experience was bad .
Informal-to-formal	Source: Well that is just the way it is i guess . CA: It is the best thing i think that is not . MDS: That is for the way . RLS: It is the way I think .
	Source: Like i said he already knows that you like him , so just take a deep breathe and ask him . CA: I think that she likes you , but perhaps you will get a relationship and and ask her . MDS: If you find him and i think that you have been in a relationship . RLS: I believe he knows that you like him, so go to ask him .
Formal-to-informal	Source: Well, if you are really attracted to this guy, then smile and speak nicely to him . CA: If you to tell her the way that is you and get married . MDS: The way of guys are not if you are not . RLS: Well , if you really like this guy , then smile to him .
	Source: Men are unintelligent! What person understands the meaning behind their behavior ? CA: Men are not of his meaning . MDS: Men are understands all men are not ? RLS: Men are stupid ! Why girl loves the mind ?

Adapting RNN Sequence Prediction Model to Multi-label Set Prediction

Abstract

We present an adaptation of RNN sequence models to the problem of multi-label classification for text, where the target is a *set of labels*, not a sequence. Previous such RNN models define probabilities for sequences but not for sets; attempts to obtain a set probability are after-thoughts of the network design, including pre-specifying the label order, or relating the sequence probability to the set probability in *ad hoc* ways.

Our formulation is derived from a principled notion of set probability, as the sum of probabilities of corresponding permutation sequences for the set. We provide a new training objective that maximizes this set probability, and a new prediction objective that finds the most probable set on a test document. These new objectives are theoretically appealing because they give the RNN model freedom to discover the best label order, which often is the natural one (but different among documents).

We develop efficient procedures to tackle the computation difficulties involved in training and prediction. Experiments on benchmark datasets demonstrate that we outperform state-of-the-art methods for this task.

1 Introduction

Multi-label text classification is an important machine learning task wherein one must predict a set of labels to associate with a given document; for example, a news article might be tagged with labels `sport`, `football`, `2018 world cup`, and `Russia`. Formally, we are given a set of label candidates $\mathcal{L} = \{1, 2, ..., L\}$, and we aim to build a classifier which maps a document x to a set of labels $\mathbf{y} \subset \mathcal{L}$. The label set $\mathbf{y}$ is typically written as a binary vector $\mathbf{y} \in \{0, 1\}^L$, with each bit y_ℓ indicating the presence or absence of a label.

Naively, one could predict each label independently without considering label dependencies. This approach is called Binary Relevance (Boutell et al., 2004; Tsoumakas and Katakis, 2007), and is widely used due to its simplicity, but it often does not deliver good performance. Intuitively, knowing some labels—such as `sport` and `football`—should make it easier to predict `2018 world cup` and then `Russia`. There are several methods that try to capture label dependencies by building a joint probability estimation over all labels $p(\mathbf{y} = (y_1, y_2, ..., y_L)|x)$ (Ghamrawi and McCallum, 2005; Read et al., 2009; Dembczynski et al., 2010; Li et al., 2016). The most popular approach, Probabilistic Classifier Chain (PCC) (Dembczynski et al., 2010) learns labels one-by-one in a predefined fixed order: for each label, it uses one classifier to estimate the probability of that label given all previous labels predictions, $p(y_l|y_1, ..., y_{l-1}, x)$. PCC's well known drawback is that errors in early probability estimations tend to affect subsequent predictions, and can become massive when the total number of label candidates L is large.

Recurrent neural network (RNN) is originally designed to output a sequential structure, such as a sentence (Cho et al., 2014). Recently, RNNs have also been applied to multi-label classification by mapping the label set to a sequence (Wang et al., 2016; Zhang et al., 2016; Jin and Nakayama, 2016; Wang et al., 2017b,a; Chen et al., 2018; Yang et al., 2018). In contrast to PCC where a binary decision is made for each label sequentially, RNN only predicts the positive labels explicitly and therefore its decision chain length is equal to the number of positive labels, not the number of all labels. This makes RNN suffer less from early estimation errors than PCC.

Both PCC and RNN rely heavily on label orders in training and prediction. In multi-label data, the labels are given as sets, not necessarily with natural orders. RNN defines a sequence probability,

Proceedings of NAACL-HLT 2019, pages 3181–3190
Minneapolis, Minnesota, June 2 - June 7, 2019.

while PCC defines set probability. Various ways of arranging sets as sequences have been explored: ordering alphabetically, by frequency, based on a label hierarchy, or according to some label ranking algorithm (Liu and Tsang, 2015). Previous experimental results show that which order to choose can have a significant impact on learning and prediction (Vinyals et al., 2016; Nam et al., 2017; Chen et al., 2018). In the above example, starting label predictions sequence with `Russia`, while correct, would make the other predictions very difficult.

Previous work has shown that it is possible to train an RNN on multi-label data without specifying the label order in advance. With special training objectives, RNN can explore different label orders and converge to some order automatically (Vinyals et al., 2016). In this paper we follow the same line of study: We consider how to adapt RNN sequence model to multi-label set prediction without specifying the label order. Specifically, we make the following contributions:

1. We analyze existing RNN models proposed for multi-label prediction, and show that existing training and prediction objectives are not well justified mathematically and have undesired consequences in practice.

2. We develop efficient approximate training and prediction methods. We propose new training and prediction objectives based on a principled notion of set probability. Our new formulation avoids the drawbacks of existing ones and gives the RNN model freedom to discover the best label order.

3. We crawl two new datasets for multi-label prediction task, and apply our method to them. We also test our method on two existing multi-label datasets. The experimental results show that our method outperforms state-of-the-art methods on all datasets. We release the datasets at `http://www.ccis.neu.edu/home/kechenqin`.

2 Mapping Sequences to Sets

In this section, we describe how existing approaches map sequences to sets, by writing down their objective functions using consistent notations. To review RNN designed for sequences, let $\mathbf{s} = (s_1, s_2, ..., s_T)$ be an input sequence of outcomes, in a particular order, where $s_t \in \{1, 2, ..., L\}$; the order is often critical to the datapoint. An RNN model defines a probability distribution over all possible output sequences given the input in the form $p(\mathbf{s} = (s_1, s_2, ..., s_T)|x) = \prod_{t=1}^{T} p(s_t|x, s_1, s_2, ..., s_{t-1})$. To train the RNN model, one maximizes the likelihood of the ground truth sequence.

At prediction time, one seeks to find the sequence with the highest probability $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}|x)$, and this is usually implemented approximately with a beam search procedure (Lowerre, 1976) (we modified into Algorithm 1). The sequence history is encoded with an internal memory vector h_t which is updated over time. RNN is also often equipped with the attention mechanism (Bahdanau et al., 2014), which in each timestep t puts different weights on different words (features) and thus effectively attends on a list of important words. The context vector c_t is computed as the weighted average over the dense representation of important words to capture information from the document. The context c_t, the RNN memory h_t at timestep t, and the encoding of previous label s_{t-1} are all concatenated and used to model the label probability distribution at time t as $p(s_t|x, s_1, s_2, ..., s_{t-1}) \sim \textit{softmax}(\phi(c_t, h_t, s_{t-1}))$, where ϕ is a non-linear function, and *softmax* is the normalized exponential function.

To apply RNN to multi-label problems, one approach is to map the given set of labels $\mathbf{y}$ to a sequence $\mathbf{s} = (s_1, s_2, ..., s_T)$, on training documents. This is usually obtained by writing the label set in a globally fixed order (e.g. by label frequency), as in PCC. Once the mapping is done, RNN is trained with the standard maximum likelihood objective (Nam et al., 2017):

$$\textit{maximize} \sum_{n=1}^{N} \log p(\mathbf{s}^{(n)}|x^{(n)}) \qquad (1)$$

where $x^{(n)}$ is the n-th document and N is the total number of documents in the corpus.

Vinyals et al. (2016) proposes to dynamically choose during training the sequence order deemed as most probable by the current RNN model:

$$\textit{maximize} \sum_{n=1}^{N} \max_{\mathbf{s} \in \pi(\mathbf{y}^{(n)})} \log p(\mathbf{s}|x^{(n)}) \qquad (2)$$

where the $\pi(\mathbf{y}^{(n)})$ stands for all permutations of the label set $\mathbf{y}^{(n)}$. This eliminates the need to manually specify the label order. However, as noticed

Methods	Training objectives	Prediction objectives
seq2seq-RNN	*maximize* $\sum_{n=1}^{N} \log p(\mathbf{s}^{(n)}\|x^{(n)})$	$\hat{\mathbf{y}} = set(\mathbf{s}^*)$, $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}\|x)$
Vinyals-RNN-max	*maximize* $\sum_{n=1}^{N} \max_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} \log p(\mathbf{s}\|x^{(n)})$	$\hat{\mathbf{y}} = set(\mathbf{s}^*)$, $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}\|x)$
Vinyals-RNN-uniform	*maximize* $\sum_{n=1}^{N} \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} \log p(\mathbf{s}\|x^{(n)})$	$\hat{\mathbf{y}} = set(\mathbf{s}^*)$, $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}\|x)$
Vinyals-RNN-sample	*maximize* $\sum_{n=1}^{N} \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} p(\mathbf{s}\|x^{(n)}) \log p(\mathbf{s}\|x^{(n)})$	$\hat{\mathbf{y}} = set(\mathbf{s}^*)$, $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}\|x)$
set-RNN (ours)	*maximize* $\sum_{n=1}^{N} \log \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} p(\mathbf{s}\|x^{(n)})$	$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} p(\mathbf{y}\|x)$

Table 1: Comparison between previous and our *set-RNN* training and prediction objectives.

by the authors, this objective cannot be used in the early training stages: the early order choice (often random) is reinforced by this objective and can be stuck upon permanently. To address this issue, Vinyals et al. (2016) also proposes two smoother alternative objectives to initialize the model training:

The authors suggest that one first consider many random orders for each label set in order to explore the space:

$$\textit{maximize} \sum_{n=1}^{N} \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} \log p(\mathbf{s}|x^{(n)}) \tag{3}$$

After that, one can sample sequences following the model predictive distribution instead of uniform distribution:

$$\textit{maximize} \sum_{n=1}^{N} \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} p(\mathbf{s}|x^{(n)}) \log p(\mathbf{s}|x^{(n)}) \tag{4}$$

In training, one needs to schedule the transition among these objectives, a rather tricky endeavor. At prediction time, one needs to find the most probable set. This is done by (approximately) finding the most probable sequence $\mathbf{s}^* = \arg\max_{\mathbf{s}} p(\mathbf{s}|x)$ and treating it as a set $\hat{\mathbf{y}} = set(\mathbf{s}^*)$. With a large number of sequences, it is quite possible that the argmax has actually a low probability, which can lead to neglecting important information when we ignore sequences other than the top one.

3 Adapting RNN Sequence Prediction Model to Multi-label Set Prediction

We propose a new way of adapting RNN to multi-label set prediction, which we call *set-RNN*. We appreciate the RNN model structure (Rumelhart et al., 1988) (defines a probability distribution over all possible sequences directly) and introduce training and prediction objectives tailored for sets that take advantage of it, while making a clear distinction between the sequence probability $p(\mathbf{s}|x)$ and the set probability $p(\mathbf{y}|x)$. We define the set probability as the sum of sequences probabilities for all sequence permutations of the set, namely $p(\mathbf{y}|x) = \sum_{\mathbf{s}\in\pi(\mathbf{y})} p(\mathbf{s}|x)$. Based on this formulation, an RNN also defines a probability distribution over all possible sets indirectly since $\sum_{\mathbf{y}} p(\mathbf{y}|x) = \sum_{\mathbf{y}} \sum_{\mathbf{s}\in\pi(\mathbf{y})} p(\mathbf{s}|x) = \sum_{\mathbf{s}} p(\mathbf{s}|x) = 1$. (For this equation to hold, in theory, we should also consider permutations $\mathbf{s}$ with repeated labels, such as $(1, 2, 3, 1)$. But in practice, we find it very rare for RNN to actually generate sequences with repeated labels in our setup, and whether allowing repetition or not does not make much difference.)

In standard maximum likelihood training, one wishes to maximize the likelihood of given label sets, namely, $\prod_{n=1}^{N} p(\mathbf{y}^{(n)}|x^{(n)}) = \prod_{n=1}^{N} \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} p(\mathbf{s}|x^{(n)})$, or equivalently,

$$\textit{maximize} \sum_{n=1}^{N} \log \sum_{\mathbf{s}\in\pi(\mathbf{y}^{(n)})} p(\mathbf{s}|x^{(n)}) \tag{5}$$

3.1 How is our new formulation different?

This training objective (5) looks similar to the objective (3) considered in previous work (Vinyals et al., 2016), but in fact they correspond to very different transformations. Under the maximum likelihood framework, our objective (5) corresponds to the transformation $p(\mathbf{y}|x) = \sum_{\mathbf{s}\in\pi(\mathbf{y})} p(\mathbf{s}|x)$, while objective (3) corresponds to the transformation $p(\mathbf{y}|x) = \prod_{\mathbf{s}\in\pi(\mathbf{y})} p(\mathbf{s}|x)$. The latter transformation does not define a valid probability distribution over $\mathbf{y}$ (i.e., $\sum_{\mathbf{y}} p(\mathbf{y}|x) \neq 1$), and it has an undesired consequence in practical model training: because of the multiplication operation, the RNN model has to assign equally high probabilities to all sequence permutations of the given label set in order to maximize the set probability. If only some sequence permutations receive high probabilities while others receive low probabilities, the set probability computed as the product of sequence probabilities will still be low. In other words, if for each document, RNN finds one good way of ordering relevant labels (such as hierarchically) and allocates most of the probability mass to the sequence in that order, the model still assigns low probabilities to the ground truth label sets and will be penalized heavily. As a consequence the model has little freedom in discovering and concentrating on some natural label order. In contrast, with our proposed training objective, in which the multiplication operation is replaced by the summation operation, it suffices to find only one reasonable permutation of the labels for each document. It is worth noting that different documents can have different label orders; thus our proposed training objective gives the RNN model far more freedom on label order. The other two objectives (2) and (4) proposed in (Vinyals et al., 2016) are less restrictive than (3), but they have to work in conjunction with (3) because of the self reinforcement issue. Our proposed training objective has a natural probabilistic interpretation, and does not suffer from self reinforcement issue. Thus it can serve as a stand alone training objective. Also, using Jensen's inequality, one can show that objective (3) is maximizing a lower bound on the log-likelihood, while objective (5) is maximizing it directly.

3.2 Training by Maximizing Set Probability

Training an RNN model with the proposed objective (5) requires summing up sequence (permutation) probabilities for a set $\mathbf{y}$, where $|\mathbf{y}|$ is the cardinality of the set. Thus evaluating this objective exactly can be intractable. We can approximate this sum by only considering the top K highest probability sequences produced by the RNN model. We introduce a variant of beam search for sets with width K and with the search candidates in each step restricted to only labels in the set (see Algorithm 1 with $ALL = 1$). This approximate inference procedure is carried out repeatedly before each batch training step, in order to find highest probability sequences for all training instances occurring in that batch. The overall training procedure is summarized in Algorithm 2.

3.3 Predicting the Most Probable Set

The transformation $p(\mathbf{y}|x) = \sum_{\mathbf{s} \in \pi(\mathbf{y})} p(\mathbf{s}|x)$ also naturally leads to a prediction procedure, which is different from the previous standard of directly using most probable sequence as a set. We instead aim to find the most likely set $\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} p(\mathbf{y}|x)$, which involves summing up probabilities for all of its permutations. To make it tractable, we propose a two-level beam search procedure. First we run standard RNN beam search (Algorithm 1 with $ALL = 0$) to generate a list of highest probability sequences. We then consider the label set associated with each label sequence. For each set, we evaluate its probability using the same approximate summation procedure as the one used during model training (Algorithm 1 with $ALL = 1$): we run our modified beam search to find the top few highest probability sequences associated with the set and sum up their

Algorithm 1: Beam_Search

```
Input : Instance $x$
        Subset of labels considered $G \subset \mathcal{L}$
        Boolean flag $ALL$: 1 if sequences must contain all $G$ labels; 0 if partial sequences are allowed
Output: A list of top sequences and the associated probabilities
Let $\mathbf{s}_1$,$\mathbf{s}_2$,...,$\mathbf{s}_K$ be the top $K$ sequences found so far. Initially, all $K$ sequences are empty. $\oplus$ means concatenation.
while true do
    // Step 1: Generate Candidate Sequences from each existing sequence $s_k \in K$ and all possible new labels $l \in G$:
    Expand all non-stopped sequences:
    $C = \{\mathbf{s}_k \oplus l | l \in G, STOP \notin s_k\}$
    Include stopped sequences:
    $C = C \cup \{\mathbf{s}_k | STOP \in s_k\}$
    Terminate non-stopped sequences:
    if $ALL == 0$ then
        $C = C \cup \{\mathbf{s}_k \oplus STOP | STOP \notin s_k\}$
    end
    // Step 2: Select highest probabilities sequences from candidate set $C$
    $K$ = topK-argmax$_k\{$prob$[s_k] | s_k \in C\}$
    if all top $K$ sequences end with $STOP$ or contain all labels in $G$ then
        Terminate the algorithm
    end

    end
    Update model parameters by maximizing
    $\sum_{(x^n,\mathbf{y}^n)\in \text{batch}} \log \sum_{\mathbf{s}\in\{\mathbf{s}_1^n,...,\mathbf{s}_K^n\}} p(\mathbf{s}|x^n)$
end
```

Algorithm 3: Prediction Method for set-RNN

```
Input  : Instance $x$
Output: Predicted label set $\hat{\mathbf{y}}$
Obtain $K$ highest probability sequences :
$\{\mathbf{s}_1, ..., \mathbf{s}_K\}$ = Beam_Search(x,$\mathcal{L}$, $ALL = 0$)
Map each sequence $\mathbf{s}_k$ to the corresponding
  set $\mathbf{y}_k$ and remove duplicate sets (if any)
foreach $\mathbf{y}_k$ do
    Get $K$ most probable sequences
      associated with $\mathbf{y}_k$ and their
      probabilities :
    $\{\mathbf{s'}_1, ..., \mathbf{s'}_K, p(\mathbf{s}'_1|x), ..., p(\mathbf{s}'_K|x)\}$=
          = Beam_Search(x,$\mathbf{y}_k$, $ALL = 1$)
    Set probability is approx by summing up :
      $p(\mathbf{y}_k|x) \approx \sum_{\mathbf{s}\in\{\mathbf{s}'_1,...,\mathbf{s}'_K\}} p(\mathbf{s}|x)$
end
$\hat{\mathbf{y}} = argmax_{\mathbf{y}_k}(p(\mathbf{y}_k|x))$
```

probabilities. Among these sets that we have evaluated, we choose the one with the highest probability as the prediction. The overall prediction procedure is summarized in Algorithm 3. As we shall show in case study, the most probable set may not correspond to the most probable sequence; these are certainly cases where our method has an advantage.

Both our method and the competitor state-of-the-art (Vinyals-RNNs) are at most K times slower than a vanilla-RNN, due to the time spent on dealing with K permutations per datapoint. Our proposed method is about as fast as the Vinyals-RNN methods, except for the Vinyals-RNN-uniform which is a bit faster (by a factor of 1.5) because its epochs do not run the additional forward pass.

4 Results and Analysis

4.1 Experimental Setup

We test our proposed set-RNN method on 4 real-world datasets, RCV1-v2, Slashdot, TheGuardian, and Arxiv Academic Paper Dataset (AAPD) (Yang et al., 2018). We take the public RCV1-v2 release[1] and randomly sample 50,000 documents. We crawl Slashdot and TheGuardian documents from their websites[2] and treat the official editor tags as ground truth. We also gather a list of user tags[3] for each document and treat them as additional features. For AAPD dataset, we follow the same train/test split as in (Yang et al., 2018). Table 2 contains statistics of these four datasets. Links to document, official editor tags, and user tags are avaliable at `http://www.ccis.neu.edu/home/kechenqin`.

Data	#Train	#Test	Cardinality	#Labels	Doc length
Slashdot	19,258	4,814	4.15	291	64
RCV1-v2	40,000	10,000	3.17	101	121
TheGuardian	37,638	9,409	7.41	1,527	505
AAPD	53,840	1,000	2.41	54	163

Table 2: Statistics of the datasets.

To process documents, we filter out stopwords and punctuations. Each document is truncated to have maximum 500 words for TheGuardian and AAPD, and 120 for Slashdot and RCV1-v2. Zero padding is used if the document contains less words than the maximum number. Numbers and out-of-vocabulary words are replaced with special tokens. Words, user tags and labels are all encoded as 300-dimensional vectors using WORD2VEC (Mikolov et al., 2013).

We implement RNNs with attention using TENSORFLOW-1.4.0 (Abadi et al., 2016). The dynamic function for RNNs is chosen to be Gated recurrent units (GRU) with 2 layers and at most 50 units in decoder. The size of the GRU unit is 300. We set dropout rate to 0.3, and train the model with Adam optimizer (Kingma and Ba, 2014) with learning rate 0.0005. Beam size is set to be 12 at both training and inference stages. We adopt *label-F1* (average F1 over labels) and *instance-F1*

Table 4: Predicting the most probable sequence vs. predicting the most probable set. Numbers before the arrow: predicting the most probable sequence. Numbers after the arrow: predicting the most probable set. We highlight scores which get significantly improved in bold (improvement is larger than 0.01).

(average F1 over instances) as our main evaluation metrics, as defined below:

$$\text{label-F1} = \frac{1}{L}\sum_{\ell=1}^{L} \frac{2\sum_{n=1}^{N} y_\ell^{(n)} \hat{y}_\ell^{(n)}}{\sum_{n=1}^{N} y_\ell^{(n)} + \sum_{n=1}^{N} \hat{y}_\ell^{(n)}}$$

$$\text{instance-F1} = \frac{1}{N}\sum_{n=1}^{N} \frac{2\sum_{\ell=1}^{L} y_\ell^{(n)} \hat{y}_\ell^{(n)}}{\sum_{\ell=1}^{L} y_\ell^{(n)} + \sum_{\ell=1}^{L} \hat{y}_\ell^{(n)}}$$

where for each instance n, $y_\ell^{(n)} = 1$ if label ℓ is a given label in ground truth; $\hat{y}_\ell^{(n)} = 1$ if label ℓ is a predicted label.

We compare our method with the following methods:

- **Binary Relevance (BR)** (Tsoumakas and Katakis, 2007) with both independent training and prediction;
- **Binary Relevance with support inference (BR-support)** (Wang et al., 2018) which trains binary classifiers independently but imposes label constraints at prediction time by only considering label sets observed during training, namely $\hat{\mathbf{y}} = \arg\max_{\text{observed } \mathbf{y}} \prod_{\ell=1}^{L} p(y_\ell|x)$;
- **Probabilistic Classifier Chain (PCC)** (Dembczynski et al., 2010) which transforms the multi-label classification task into a chain of binary classification problems. Predictions are made with Beam Search.
- **Sequence to Sequence RNN (seq2seq-RNN)** (Nam et al., 2017) which maps each set to a sequence by decreasing label frequency and solves the multi-label task with an RNN designed for sequence prediction (see Table 1).
- **Vinyals-RNN-uniform, Vinyals-RNN-sample, and Vinyals-RNN-max** are three variants of RNNs proposed by (Vinyals et al., 2016). They are trained with different objectives that correspond to different transformations between sets and sequences. See Table 1 for a summary of their training objectives. Following the approach taken by (Vinyals et al., 2016), Vinyals-RNN-sample and Vinyals-RNN-max are initialized by Vinyals-RNN-uniform. We have also tested training Vinyals-RNN-max directly without having Vinyals-RNN-uniform as an initialization, and we name it as **Vinyals-RNN-max-direct**.
- **Sequence Generation Model (SGM)** (Yang et al., 2018) which trains the RNN model

similar to seq2seq-RNN but uses a new decoder structure that computes a weighted global embedding based on all labels as opposed to just the top one at each timestep.

In BR and PCC, logistic regressions with L1 and L2 regularizations are used as the underlying binary classifiers. seq2seq-RNN, PCC, and SGM rely on a particular label order. We adopt the decreasing label frequency order, which is the most popular choice.

4.2 Experimental Results

Table 3 shows the performance of different methods in terms of *label-F1* and *instance-F1*. The SGM results are taken directly from (Yang et al., 2018), and are originally reported only on AAPD dataset in terms of *hamming-loss* and *micro-F1*. Definitions of these two metrics can be found in (Koyejo et al., 2015).

Our method performs the best in all metrics on all datasets (except hamming loss on AAPD, see table 3). In general, RNN based methods perform better than traditional methods BR, BR-support and PCC. Among the Vinyals-RNN variants, Vinyals-RNN-max and Vinyals-sample work the best and have similar performance. However, they have to be initialized by Vinyals-RNN-uniform. Otherwise, the training gets stuck in early stage and the performance degrades significantly. One can see the clear degradation by comparing the Vinyals-RNN-max row (with initialization) with the Vinyals-RNN-max-direct row (without initialization). By contrast, our training objective in set-RNN does not suffer from this issue and can serve as a stable stand alone training objective.

On TheGuardian dataset, set-RNN performs slightly better than seq2seq-RNN in terms of instance-F1, but much better in terms of label-F1. It is known that instance-F1 is basically determined by the popular labels' performance while label-F1 is also sensitive to the performance on rare labels. Figure 1 shows that set-RNN predicts rare labels better than seq2seq-RNN.

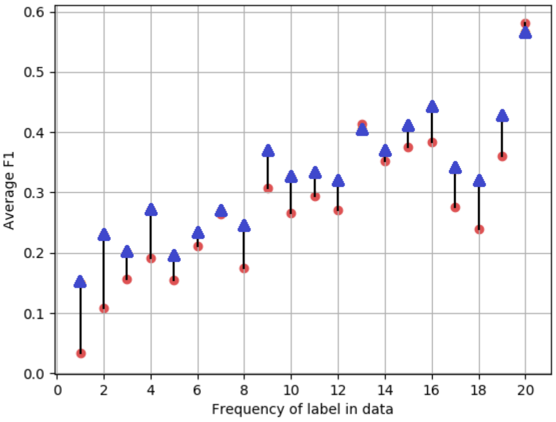

Figure 1: Average F1 over rare labels with the same frequency on TheGuardian dataset. Blue(Δ)=set-RNN, Red($\cdot$)=seq2seq-RNN.

Next we analyze how much benefit our new set prediction strategy brings in. For each RNN-based method, we test two prediction strategies: 1) finding the sequence with the highest probability and outputting the corresponding set (this is the default prediction strategy for all models except set-RNN); 2) outputting the set with the highest probability (this is the default prediction strategy for set-RNN). Table 4 shows how each method performs with these two prediction strategies. One can see that Vinyals-RNN-uniform and set-RNN benefit most from predicting the top set, Vinyals-RNN-sample, Vinyals-RNN-max and Vinyals-RNN-max-direct benefit less, and seq2seq RNN does not benefit at all. Intuitively, for the top-set prediction to be different from the top-sequence prediction, the model has to spread probability mass across different sequence permutations of the same set.

4.3 Analysis: Sequence Probability Dsitribution

Results in Table 4 motivates us to check how sharply (or uniformly) distributed the probabilities are over different sequence permutations of the predicted set. We first normalize these sequence probabilities related to the predicted set and then compute the entropy. To make predictions with different set sizes (and hence different number of sequence permutations) comparable, we further divide the entropy by the logarithm of number of sequences. Smaller entropy values indicate a sharper distributions. The results are shown in Figure 2.

seq2seq-RNN trained with fixed label order and standard RNN objective (1) generates very sharp sequence distributions. It basically only assigns probability to one sequence in the given order. The entropy is close to 0. In this case, predicting the set is no different than predicting the top sequence (see Table 4). On the other extreme is Vinyals-RNN-uniform, trained with objective (3), which spreads probabilities across many se-

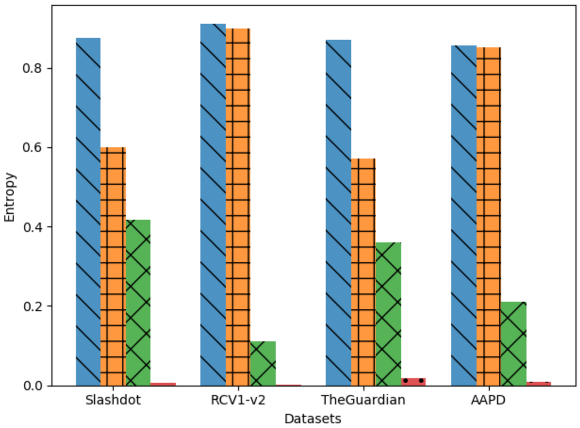

Figure 2: Entropy of sequence probability distribution for each model. Blue(\)=Vinyals-RNN-uniform, Orange(+)=set-RNN, Green(×)=Vinyals-RNN-max, Red(·)=seq2seq-RNN.

quences, and leads to the highest entropy among all models tested (the uniform distribution has the max entropy of 1). From Table 4, we see that by summing up sequence probabilities and predicting the most probable set, Vinyals-RNN-uniform's performance improves. But as discussed earlier, training with the objective (3) makes it impossible for the model to discover and concentrate on a particular natural label order (represented by a sequence). Overall Vinyals-RNN-uniform is not competitive even with the set-prediction enhancement. Between the above two extremes are Vinyals-RNN-max and set-RNN (we have omitted Vinyals-RNN-sample and Vinyals-RNN-max-direct here as they are similar to Vinyals-RNN-max). Both models are allowed to assign probability mass to a subset of sequences. Vinyals-RNN-max produces sharper sequence distributions than set-RNN, because Vinyals-RNN-max has the incentive to allocate most of the probability mass to the most probable sequence due to the max operator in its training objective (2). From Table 4, one can see that set-RNN clearly benefits from summing up sequence probabilities and predicting the most probable set while Vinyals-RNN-max does not benefit much. Therefore, the sequence probability summation is best used in both training and prediction, as in our proposed method.

Comparing 4 datasets in Table 4, we also see that Slashdot and TheGuardian, which have larger label cardinalities (therefore more permutations for one set potentially), benefit more from predicting the most probable set than RCV1 and AAPD, which have smaller label cardinalities.

5 Case Analysis

We further demonstrate how set-RNN works with two examples. In the first example from the RCV1-v2 dataset, the most probable set predicted by set-RNN (which is also the correct set in this example) does not come from the most probable sequence. Top sequences in decreasing probability order are listed in Table 5. The correct label set {forex, markets, equity, money markets, metals trading, commodity} has the maximum total probability of 0.161, but does not match the top sequence.

PROB	SEQUENCE
0.0236	equity, markets, money markets, forex
0.0196	**forex, markets, equity, money markets, metals trading, commodity**
0.0194	**equity, markets, forex, money markets, metals trading, commodity**
0.0159	**markets, equity, forex, money markets, metals trading, commodity**
0.0157	**forex, money markets, equity, metals trading, markets, commodity**
0.0153	**forex, money markets, markets, equity, metals trading, commodity**
0.0148	markets, equity, money markets, forex
0.0143	**money markets, equity, metals trading, commodity, forex, markets**
0.0123	**markets, money markets, equity, metals trading, commodity, forex**
0.0110	**markets, equity, forex, money markets, commodity, metals trading**
0.0107	**forex, markets, equity, money markets, commodity, metals trading**
0.0094	**forex, money markets, equity, markets, metals trading, commodity**

Table 5: The set-RNN predicted set (also the correct set) {forex, markets, equity, money markets, metals trading, commodity} has the max total probability of 0.161, but does not match the top sequence. Sequences for the correct set are in bold.

Next we demonstrate the issue with prescribing the sequence order in seq2seq-RNN with a TheGuardian example[4]. Figure 3 shows the predictions made by seq2seq-RNN and our method. In this particular example the top sequence agrees with the top set in our method's prediction so we can just analyze the top sequence. seq2seq-RNN predicts `Tate Modern` (incorrect but more popular label) while we predict `Tate Britain` (correct but less popular label). The seq2seq predicted sequence is in the decreasing label frequency order while our predicted sequence is not. In the training data, `Exhibition` is more frequent than `Tate Britain` and `Tate Modern`. If we arrange labels by decreasing frequency, `Exhibition` is immediately followed by `Tate Modern` 19 times, and by `Tate Britain` only 3 times. So it is far more likely to have `Tate Modern` than `Tate Britain` after `Exhibition`. However, at the set level, `Exhibition` and `Tate Modern` co-occurs 22 times while `Exhibition` and `Tate Britain`

---

[4] This document can be viewed at `http://www.guardian.co.uk/artanddesign/jonathanjonesblog/2009/apr/08/altermodernism-nicolas-bourriaud`

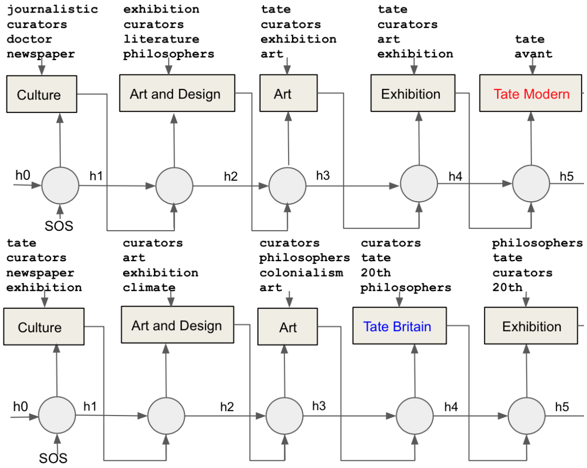

Figure 3: Top: best sequence by seq2seq-RNN; bottom: best sequence by set-RNN. Above models, at each time, we list the top unigrams selected by attention.

co-occurs 12 times, so the difference is not so dramatic. In this case, imposing the sequence order biases the probability estimation and leads to incorrect predictions.

6 Conclusion

In this work, we present an adaptation of RNN sequence models to the problem of multi-label classification for text. RNN only directly defines probabilities for sequences, but not for sets. Different from previous approaches, which either transform a set to a sequence in some pre-specified order, or relate the sequence probability to the set probability in some ad hoc way, our formulation is derived from a principled notion of set probability. We define the set probability as the sum of all corresponding sequence permutation probabilities. We derive a new training objective that maximizes the set probability and a new prediction objective that finds the most probable set. These new objectives are theoretically more appealing than existing ones, because they give the RNN model more freedom to automatically discover and utilize the best label orders.

Abstract

Grapheme to phoneme (G2P) conversion is an integral part in various text and speech processing systems, such as: Text to Speech system, Speech Recognition system, etc. The existing methodologies for G2P conversion in Bangla language are mostly rule-based. However, data-driven approaches have proved their superiority over rule-based approaches for large-scale G2P conversion in other languages, such as: English, German, etc. As the performance of data-driven approaches for G2P conversion depend largely on pronunciation lexicon on which the system is trained, in this paper, we investigate on developing an improved training lexicon by identifying and categorizing the critical cases in Bangla language and include those critical cases in training lexicon for developing a robust G2P conversion system in Bangla language. Additionally, we have incorporated nasal vowels in our proposed phoneme list. Our methodology outperforms other state-of-the-art approaches for G2P conversion in Bangla language.

1 Introduction

Grapheme to phoneme (G2P) conversion provides a mapping between a word and its pronunciation. Such mapping provides opportunity for a non-native person to learn the correct pronunciation of words of a foreign language. Moreover, in modern Text to Speech (TTS) and Automatic Speech Recognition (ASR) systems, G2P conversion is an integral task.

The task of G2P conversion is generally language specific due to language specific conventions, rules, pronunciation constraints, etc. In this paper, we focus on Modern Standard Bangla. An example of G2P conversion in Bangla language: phonetic transcription of অনুশীলন (practice) is /o n u sh i l O n/. (Please refer to Table 1 for our phoneme symbols.)

The simplest means of G2P conversion is to build up a lexicon or dictionary containing the mapping from words to their corresponding pronunciations. However, it fails to provide pronunciations for unknown words and inclusion of newer words increases memory requirement. In another approach (Mosaddeque et al., 2006), there are predefined rules for the conversion of a word to its pronunciation. Though such rule-based approach can work for any word, the system becomes complex when it tries to formulate rules for incorporating all irregularities of pronunciation in a language.

Clearly, these approaches are not feasible for large-scale G2P conversion which is necessary in any modern TTS or ASR system. Data-driven machine learning approaches have great potential in such large-scale G2P conversion (Rao et al., 2015). In such an approach, a machine learning model predicts the phoneme conversion of a grapheme, being trained on a lexicon. A predominant work following such approach in Bangla language is by Google (Gutkin et al., 2016), where they train their system using $37K$ words and achieve word-level accuracy of 81.5%. However, a system trained on their lexicon will face several shortcomings, such as: কাদা(mud) and কাঁদা(to cry) are pronounced differently but will have same phoneme representation in their system as: /k a d a/. Similarly, পরী(fairy) and পড়ি(to read) are pronounced differently but will have same phoneme representation in their system as: /p o r i/. Moreover, G2P system trained on their lexicon performs poorly on our identified critical cases from the most frequent $100K$ words (Table 3).

Being motivated to increase the accuracy of grapheme to phoneme conversion in Bangla language, which will also perform well for critical inputs, we have developed a customized and robust G2P system for Bangla language.

Proceedings of NAACL-HLT 2019, pages 3191–3200
Minneapolis, Minnesota, June 2 - June 7, 2019.

Our major contributions are as follows:

(i) We identify and categorize the critical cases for grapheme to phoneme (G2P) conversion in Bangla language by analyzing the most frequent $100K$ words.

(ii) We enrich the training lexicon for developing a robust G2P conversion system in Bangla language that performs much better for critical cases compared to other state-of-the-art G2P systems.

(iii) We perform phonetic transcriptions considering nasal vowels as separate phonemes.

(iv) We perform extensive simulations on large-scale dataset and show that our methodology outperforms other state-of-the-art approaches for G2P conversion in Bangla language by providing word-level accuracy of 90.2%.

The rest of the paper is organized as follows: we discuss the previous works in Section 2, our phoneme list in Section 3, identification of critical cases and categorization of errors in Section 4, development of our system in Section 5, experimental results in Section 6, and conclusion and future works in Section 7.

2 Previous Works

The research works for G2P in English are quite extensive. Chen (2003) investigate machine learning based systems for G2P in English. They experiment with joint maximum entropy n-gram model, conditional maximum entropy model, etc. Yao and Zweig (2015) utilize bi-directional LSTM (Long Short Term Memory) recurrent neural network for G2P and achieve 5.45% PER on CMU dictionary (air, 2015). Thu et al. (2016) show comparisons among various machine learning algorithms for G2P in Burmese language. Joint sequence n-gram models aim to discover joint vocabulary consisting of graphemes and phonemes through the alignment of graphemes and phonemes. Bisani and Ney (2008) develop a joint-sequence model for G2P. Novak (2012), Novak et al. (2013) are other prominent works working on this model. Neural sequence to sequence models are popular for G2P conversion. Some prominent works on such models are: Caruana (1997), Jiampojamarn et al. (2007), Sutskever et al. (2014), Yao and Zweig (2015), Jiampojamarn et al. (2007), Rao et al. (2015), Yao and Zweig (2015), Schnober et al. (2016), Tsvetkov et al. (2016), He et al. (2016), Wu et al. (2016), Johnson et al. (2016), Toshniwal and Livescu (2016), and Vaswani et al. (2017).

Again, another line of research deals with G2P conversion for more than one language. Such works include: Mana et al. (2001), Kim and Snyder (2012), Deri and Knight (2016), and Milde et al. (2017).

Most of the works related to G2P conversion that are focused on Bangla language, follow rule-based approach. Rule-based approach of Mosaddeque et al. (2006) provides accuracy of 97.01% on a previously seen corpus containing 736 words, but the system's accuracy is 81.95% on an previously unobserved corpus containing 8399 words. This work was extended by Alam et al. (2011) describing 3880 rules with an accuracy of 89.48% on another corpus. Basu et al. (2009) discuss a rule-based approach considering several information: parts-of-speech, subsequent context, etc. Their work describes only 21 rules and provides an accuracy of 91.48% on a corpus of 9294 words. Ghosh et al. (2010) provide a heuristic for G2P that takes into account parts-of-speech, orthographic, and contextual information. Their work provides 70% accuracy on a corpus containing of 755 words. A prominent work for data driven G2P in Bangla language is by Google (Gutkin et al. (2016)). They develop a lexicon and achieve word-level accuracy of 81.5%. Chowdhury et al. (2017) use conditional random field for G2P in Bangla. They report 14.88% phoneme error rate on Google lexicon.

3 Phoneme List

Our Phoneme symbols are provided in Table 1. This table is a good reference for the 47 phoneme symbols that we have followed in this paper and their corresponding International Phonetic Alphabet (IPA) symbols. Throughout the paper, we use these 47 phoneme symbols, not the IPA symbols. There is disagreement between linguists whether nasal vowels should be considered as separate phonemes (Barman, 2009). We added nasal vowels in our phoneme list to differentiate between a word with its nasalized counterpart, such as the word কাঁদা(to cry) and কাদা(mud). Here, /a/, /e/, /u/, /i/, /o/, /O/, /E/, /an/, /en/, /un/, /in/, /on/, /On/, /En/ are normal vowels, /ew/, /ow/, /uw/, /iw/ are weak vowels, and the rest are consonants.

Phoneme	IPA	Phoneme	IPA	Phoneme	IPA	Phoneme	IPA
i	i	On	ɔ̃	D	ɖ	m	m
u	u	an	ã	Dh	ɖʱ	r	r
e	e	k	k	t	t	R	ɽ
o	o	kh	kʰ	th	tʰ	l	l
E	ɛ	g	g	d	d	h	ɦ
O	ɔ	gh	gʱ	dh	dʱ	s	s
a	a	c	ʧ	p	p	sh	ʃ
in	ĩ	ch	ʧʰ	ph	pʰ	iw	i̯
un	ũ	j	dʒ	b	b	ew	e̯
en	ẽ	jh	dʒʱ	bh	bʱ	ow	o̯
on	õ	T	ʈ	N	ŋ	uw	u̯
En	æ̃	Th	ʈʰ	n	n		

Table 1: Our Phoneme Symbols with Their Corresponding IPA Symbols

4 Identification and Categorization of Non-Trivial Cases for Transcription

We envision of developing a robust G2P system that will perform reasonably well on any word in Bangla language. A G2P system that performs well on the most frequent words, should also do well on other words. With this motivation, we focus on increasing accuracy on the most frequent words. Especially, we are concerned about those words that are among the most frequent words but non-trivial or critical for phonetic transcription, i.e., current state-of-the-art methodologies perform poorly on these critical words. We investigate on identifying and categorizing such non-trivial or critical cases so that future research works can give special focus on developing methods for improving phonetic transcriptions of these critical words.

4.1 Identifying the Most Frequent Words

To get a hold of contemporary usage of Bangla language, we do extensive crawling. We crawled 42 websites of various Bangla newspapers, blogs, e-book libraries, wikipedia, etc. covering various domains such as: politics, economics, sports, drama, novel, story, education, entertainment, general knowledge, history, etc. After data cleaning and data normalization, we had about $10M$ sentences. We counted how many times each of the unique words appeared in those sentences. We then consider the most frequent $100K$ words and aim to identify the critical cases for phonetic transcription among these most frequent words.

4.2 Identifying the Critical Cases for Transcription

After changing the Google lexicon (of size $60K$ (around)) according to our phoneme symbols (Table 1), we prepare 4 versions of Google's lexicon of size $12K$, $24K$, $40K$, and $60K$ respectively for identifying the critical cases for phonetic transcription. Algorithm 1 shows prefix comparing algorithm that we use for compressing a phonetic lexicon or dictionary of grapheme sequence to phoneme sequence. The algorithm matches the prefix of consecutive words (grapheme sequence) of a sorted dictionary (sorted according to ascending order of grapheme sequence of a word) and keeps a word (with its corresponding phoneme sequence) only if it does not share its prefix with any other words. We run the algorithm successively 3 times, i.e., we use the destination dictionary of one iteration as the source dictionary of next iteration. Each iteration produces a minimized version of the basic lexicon (Google lexicon). After 3 iterations, the dictionary does not get any more compressed. We find the phonetic transcriptions of each of the $100K$ most frequent words using models trained on each of the 4 versions of Google's lexicon (basic + 3 minimized). So, from 4 models (each model trained on a version of the basic Google lexicon), we get 4 sets of transcriptions for the most frequent $100K$ words. For most of the words (around $70K$ words), we observe that the phonetic transcriptions are exactly same in each of the 4 set. However, for the remaining $30K$ words (29105 words to be exact), we observe that at least one set provides different transcription. We take these $30K$ words to be the critical cases. Our intuition is that if two G2P systems: one trained on a smaller version of the basic lexicon, and another trained on a larger version of the basic lexicon provide the same transcription for a word, then the word is a trivial case for phonetic transcription. We then manually verify the phonetic transcriptions of these $30K$ words taking help from 3 linguists and following Chowdhury (2016), and consider these $30K$ words as critical cases for phonetic transcription.

4.3 Categorizing the Critical Cases

We categorize the critical cases into 7 categories and observe the distribution of the critical transcriptions into these 7 categories. These 7 cate-

Algorithm 1 Algorithm for Compressing a Dictionary or Lexicon

```
$sd$ ← sorted sourceDictionary
$dd$ ← sorted destinationDictionary
$a.grs$ ← grapheme sequence of lexicon entry $a$
add $sd[0]$ to $dd$
$i = 1$
while $i \neq$ length($sd$) do
    $pw = sd[i - 1]$
    $cw = sd[i]$
    if $length(pw.grs) \geq 3$ & $pw.grs$ is prefix of $cw.grs$ then
        continue
    else
        add $cw$ to $dd$
    $i \leftarrow i + 1$
```

gories capture most of the errors. The categories are:

- **Open Close Vowel Confusion:** G2P system provides pronunciation as close vowel that should be pronounced as open vowel ideally, and vice-versa. For example, correct phoneme of ব্যাঙ (frog) is /b E n g/, but if G2P system provides output /b e n g/, then it is an error under this category as in the place of open vowel (here, /E/), G2P system is giving close vowel (here, /e/).
- **Inherent Vowel Confusion:** G2P system does not provide inherent vowel as output where there should be an inherent vowel ideally. For example, correct phoneme of সকাল (morning) is /sh O k a l/, but if G2P system provides output /sh k a l/, then it is an error under this category as the output of G2P does not give inherent vowel (here, /O/).
- **Diphthong Confusion:** G2P system does not provide falling diphthong in output where there should be a falling diphthong ideally. Or, system does not provide rising diphthong in output where there should be a rising diphthong ideally. For example, correct phoneme of সই (friend) is /sh o iw/, but if G2P system provides output /sh o i/, then it is an error under this category as the output of G2P does not capture the falling diphthong (here, /o iw/).
- **s or sh Confusion:** G2P system provides /s/ in phonetic transcription, where there should be /sh/, and vice-versa. For example, correct phoneme sequence of সংগঠন (organization) is /sh O N g O Th o n/, but if G2P system provides output /s O N g O Th o n/, then it is an error under this category as the output of G2P gives /s/ in place of /sh/.
- **s or ch Confusion:** G2P system provides /s/ in phonetic transcription, where there should be /ch/, and vice-versa. For example, correct phoneme sequence of ছাতা (umbrella) is /ch a t a/, but if G2P system provides output /s a t a/, then it is an error under this category as the output of G2P gives /s/ in place of /ch/.
- **Nasal Confusion:** G2P system does not provide any nasal vowel where there should be a nasal vowel, and vice-versa. For example, correct phoneme sequence of চাঁদ (moon) is /c an d/, but if G2P system provides output /c a d/, then it is an error under this category as the output of G2P gives /a/ in place of /an/.
- **Other Vowel Confusion:** G2P system provides completely different vowel than the corresponding vowel that should ideally be in that position of the phoneme sequence. Note that, in the other error categories, for each position in the phoneme sequence, the generated and ideal phonemes were somehow related. But in this category, at a specific position of the phoneme sequence, the generated and ideal phonemes are completely different. For example, correct phoneme sequence of অধ্যবসায় (perseverance) is /o d dh o b O sh a ew/, but if G2P system provides output /o d dh a b O sh a ew/, then it is an error under this category as the output of G2P gives /a/ in place of /o/ (fourth phoneme).

Algorithm 2 compares a machine-generated lexicon with a reference lexicon (manually verified), where both the lexicons have same grapheme sequences, but the corresponding phoneme sequences may be different. This algorithm counts how many errors of each category are there in the machine generated lexicon. The algorithm takes each entry of the generated lexicon and increases the count of the corresponding error category (if an error is present there).

We train attention mechanism based Transformer model on each of the 4 lexicons and get

Algorithm 2 Comparing a Generated Lexicon (gl) with Reference Lexicon (rl)

```
$N \leftarrow$ total number of entries in each lexicon
$A, B, C, D, E, F, G$ are Open Close Vowel, s or sh, s or ch, Nasal, Dipthong, Other Vowel, and Inherent confusions, respectively, all initially zero
$H$ denotes other errors not captured by the 7 categories, initially zero
vl and wl are lists of vowels and weak vowels respectively
$a.phs \leftarrow$ phoneme sequence of lexicon entry $a$
$i \leftarrow 0$
while $i \neq N$ do
    $g = gl[i].phs$
    $r = rl[i].phs$
    $M = \min(length(g), length(r))$
    $j \leftarrow 0$
    while $j \neq M$ do
        $x = g[j]$
        $y = r[j]$
        if $x = y$ then
            continue
        $(x, y) \leftarrow sorted(x, y)$
        $Total\_error = Total\_error + 1$
        if $ocConfusion(x, y)$ then
            $A \leftarrow A + 1$
        else if $(x, y) = (``s", ``sh")$ then
            $B \leftarrow B + 1$
        else if $(x, y) = (``ch", ``s")$ then
            $C \leftarrow C + 1$
        else if $x + ``n" = y$ then
            $D \leftarrow D + 1$
        else if $x$ in wl or $y$ in wl then
            $E \leftarrow E + 1$
        else if $x$ in vl and $y$ in vl then
            $F \leftarrow F + 1$
        else if $removeVowel(g) = removeVowel(r)$ then
            $G \leftarrow G + 1$
        else
            $H \leftarrow H + 1$
        $j \leftarrow j + 1$
    $i \leftarrow i + 1$
```

Algorithm 3 Procedure: ocConfusion (x, y) (Checks if open close vowel confusion)

```
$ocSet \leftarrow [(``O", ``o"), (``E", ``e"),
        (``On", ``on"), (``En", ``en")]$
if $(x, y)$ in $ocSet$ then
    return True
else
    return False
```

Algorithm 4 Procedure: removeVowel (phoneme_sequence)

```
return phoneme_sequence removing all vowels from it
```

4 G2P models. We find the phoneme representation of $30K$ critical cases using each of the 4 G2P models. Using Algorithm 2, we count the errors of each category for each of the 4 models. We report the results in Table 2 and Figure 1. Here, other error denotes the errors that are not captured by these 7 categories. We see from these results that most of the errors are under Open Close vowel, s or sh, Diphthong, and Inherent Vowel confusions.

5 Developing an Improved G2P System for Bangla Language

We develop an improved lexicon and use two machine learning based models trained on our lexicon to develop an improved G2P system for Bangla language.

5.1 Developing an Improved Lexicon

For developing an improved lexicon, we include with Google's lexicon the manually verified $30K$ non-trivial or critical entries. Also, we include the $70K$ entries in which all of the 4 models (trained on each of the 4 versions of Google lexicon) unanimously agreed. After removing the repeated entries with same grapheme sequence, our lexicon consists of around $90K$ entries. In case of repeated entries having same grapheme sequence, we carefully keep only the entry that has been manually verified.

5.2 G2P Models

We use Neural Sequence to Sequence models. In these models, a conditional distribution of a sequence (here, phoneme sequence) is learned conditioned on another sequence (here, grapheme sequence). We train two following Sequence to Sequence models on our lexicon for G2P conversion:

LSTM-RNN: This is a plain Sequence to Sequence model that incorporates an encoder and decoder mechanism. Recurrent Neural Network

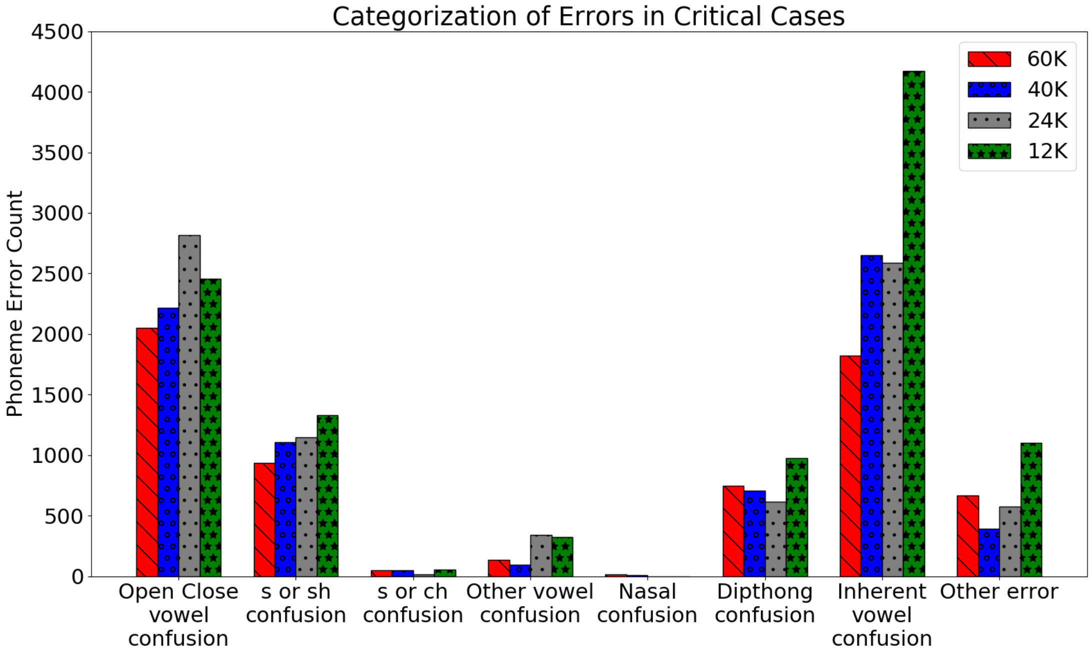

Figure 1: Categorization of errors in critical cases, here each of the $60K, 40K, 24K,$ and $12K$ denotes the model trained on that particular lexicon.

(RNN) is usually utilized in encoder and decoder design. For addressing vanishing gradient problem in RNN, Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is used. We follow Yao and Zweig (2015) for implementation.

Transformer Model: Transformer Model uses attention mechanism. Attention mechanism provides improvement upon plain Sequence to Sequence by easing the flow of information from source sequence to destination sequence. We follow Vaswani et al. (2017) for implementation.

We show the performance of both of these models in Section 6. We observe that Transformer Model provides higher token-level accuracy (lower Word Error Rate) than LSTM-RNN.

6 Experimental Results

We run extensive simulations and use two measures for evaluating the performances of the systems:

Word Error Rate (WER): For calculating Word Error Rate (WER), we use the following formula:

$$\text{WER} = \frac{E}{T}$$

where E denotes the number of words that have disagreement in their generated phoneme sequence and reference phoneme sequence, and T denotes the total number of words.

Phoneme Error Rate (PER): For calculating Phoneme Error Rate (PER), we use the following formula:

$$\text{PER} = \frac{I+S+D}{T}$$

where I, S, D denote respectively the total number of insertion, substitution, and deletion operations needed for all the words to align the generated phoneme sequence with the reference phoneme sequence for each word. T denotes the total number of phonemes present in all the words.

Our best performing model is Transformer Model. We use batch size of 4096. Our neural network has 3 hidden layers, each containing 256 nodes. We use a computer having 8GB RAM, Intel Core i7 CPU, and Nvidia Geforce 1050 GPU for running all of the simulations. For each model, we run the simulations for around $110K$ iterations taking around 5 hours.

6.1 Performance on Critical Cases

We report the experiment results of Google's lexicon on critical cases in Table 3. We do not report our lexicon here as critical cases are already included in our lexicon.

6.2 Performance Comparison In General

For comparing the performances of models trained on our lexicon and Google's lexicon, we randomly

Error Type	**60K**	**40K**	**24K**	**12K**
total error	6415	7222	8087	10400
Open Close Confusion (%)	32.0	30.7	34.8	23.6
Inherent Vowel Confusion (%)	28.4	36.7	32.0	40.1
s or sh confusion (%)	14.6	15.3	14.2	12.8
Dipthong confusion (%)	11.6	9.8	7.6	9.4
Other Vowel Confusion (%)	2.1	1.3	4.2	3.1
s or ch confusion (%)	0.8	0.7	0.2	0.5
Nasal Confusion (%)	0.2	0.1	0	0
Other Error (%)	10.4	5.4	7.1	10.6

Table 2: Error classification of $30K$ critical cases, here each of the four rightmost columns denotes the model trained on that particular lexicon.

Lexicon	**Model**	**WER (%)**	**PER (%)**
Google	LSTM-RNN	25.7	3.26
	Transformer Model	23.6	2.71

Table 3: Performance on Critical Cases

take 9000 entries from our manually verified $30K$ critical cases as test set. We use this test set for evaluating all the models. Though our actual lexicon contains these 9000 entries, we do not keep them in our lexicon while doing the experiments to fairly evaluate the performances of the lexicons. For both lexicons, we keep 90% of the lexicon in train set and remaining 10% in validation set. Table 4 shows the result. Models trained on our lexicon outperforms those trained on Google's lexicon by a significant margin. Moreover, Transformer Model performs better than LSTM-RNN.

Figure 2 and Table 5 categorize the errors of systems trained on 3 types of lexicons (Romanized version of our lexicon is discussed in section 6.3) by using Algorithm 2. Here, we report the results of Transformer Model only as it has been better performing that LSTM-RNN in our experiments. We observe most of the errors are related to Open Close vowel, s or sh, Diphthong, and Inherent Vowel confusions - this finding also conforms to Figure 1 and Table 2, which were error categorization of critical cases.

Lexicon	**Model**	**WER (%)**	**PER (%)**
Google	LSTM-RNN	17.1	2.32
	Transformer Model	14.8	1.88
Our Lexicon	LSTM-RNN	10.5	1.42
	Transformer Model	9.8	1.33

Table 4: Performance Comparison In General

Error Type	**Our Lexicon**	**Romanized Lexicon**	**Google Lexicon**
Total Error	1337	1406	2961
Inherent Vowel Confusion (%)	35.6	34.5	33.8
Open Close Confusion (%)	30.1	30.4	27.9
s or sh confusion (%)	13.3	13.0	12.1
Diphthong confusion (%)	10.7	9.8	13.1
Other Vowel Confusion (%)	1.9	4.3	2.7
s or ch confusion (%)	0.3	0.2	0.2
Nasal Confusion (%)	0.2	0.43	0.6
Other Error (%)	7.9	7.4	9.7

Table 5: Performance comparison on different error categories. Here each of the three rightmost columns denotes the model trained on that particular lexicon.

6.3 Effect of Romanization

For doing experiments on the effect of romanization on G2P conversion, we romanized all grapheme sequences in our lexicon to prepare romanized counterpart of our lexicon. During romanization, each grapheme symbol in Bangla is replaced with a single English letter except that if a consonant grapheme is not followed by a vowel grapheme, "O" was added after the romanized symbol of that consonant as the roman symbol for "অ", which is usually inherently pronounced in such cases. All the symbols used for romanization were completely disjoint to avoid any ambiguity in the lexicon. Figure 3 shows the WER and PER

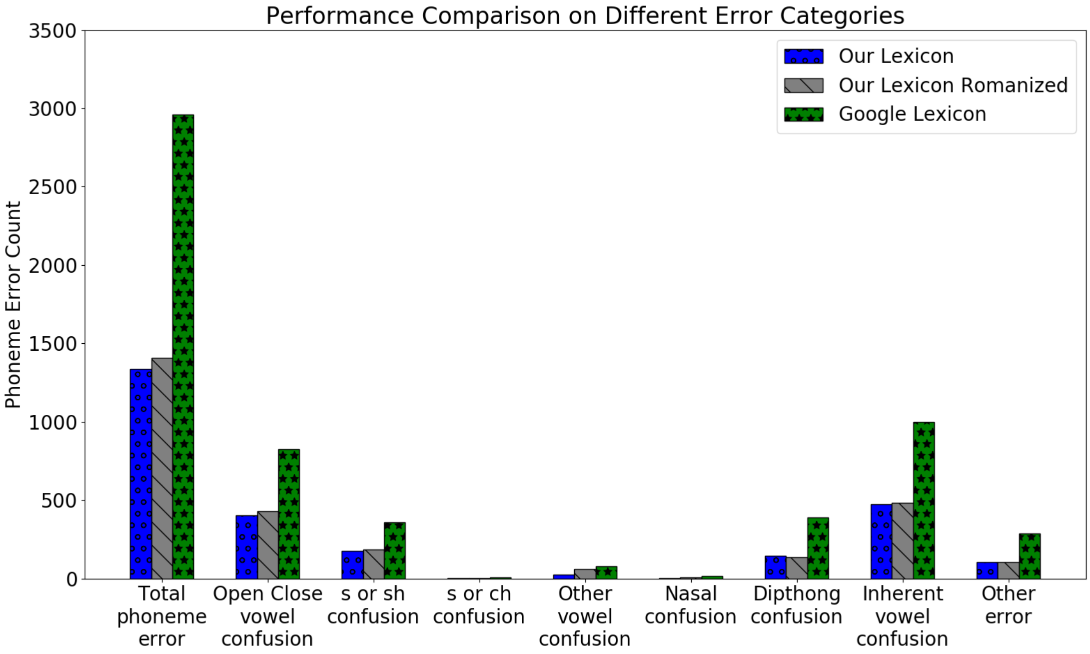

Figure 2: Performance Comparison on Different Error Categories

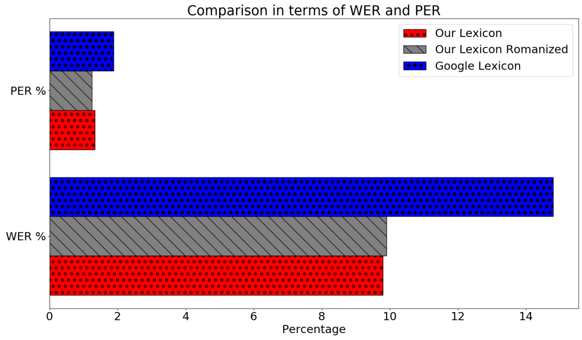

Figure 3: Comparison in terms of WER and PER

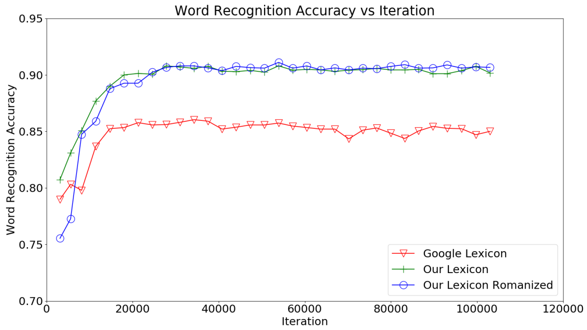

Figure 4: Word Recognition Accuracy vs Iteration

of systems trained on 3 types of lexicons. Here, we report the results of Transformer Model only as it has been better performing than LSTM-RNN in our experiments. Both versions of our lexicon perform better (lower WER and lower PER) than Google's lexicon. Also romanization does not significantly increase or decrease the performance.

Figures 4 and 5 show respectively the Word Recognition Accuracy (1−WER) and Phoneme Recognition Accuracy (1−PER) with respect to number of iterations run during simulation. Both versions of our lexicon perform better (higher Word Recognition Accuracy and higher Phoneme Recognition Accuracy) than Google's lexicon. Figure 6 shows Negative Log Perplexity vs number of iterations. Both versions of our lexicon provide higher negative log perplexity than Google's lexicon.

6.4 Effectiveness of Our Identified Critical Cases

In this section, we want to establish that the improved performance of our lexicon comes not only from the increase in number of training samples, but also due to the fact that the critical cases identified by our novel methodology have been added as training samples. For this, we prepare a new training lexicon by combining a portion of the Google lexicon with a portion of our identified critical cases. As we have kept $9K$ entries from the critical cases as our test set, we take the remaining $21K$ critical cases and combine them with the randomly taken $39K$ entries from Google lexicon to prepare a new lexicon of size $60K$. While taking entries from Google lexicon, we ensure that we do not take any repeated entry that has already been in the critical cases and added to the new lexicon.

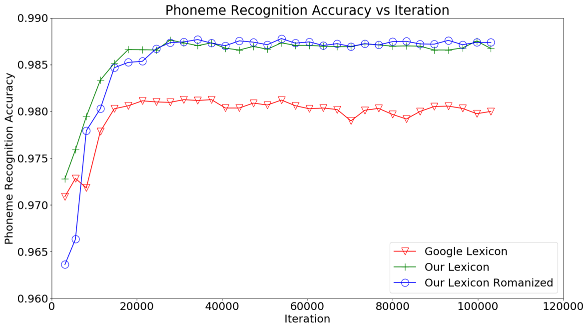

Figure 5: Phoneme Recognition Accuracy vs Iteration

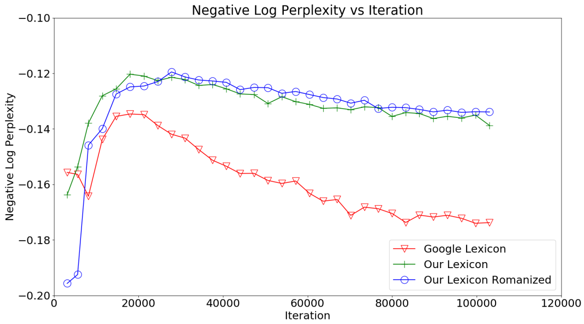

Figure 6: Negative Log Perplexity vs Iteration

Lexicon	**Model**	**WER (%)**	**PER (%)**
Google	LSTM-RNN	17.1	2.32
	Transformer Model	14.8	1.88
New Lexicon	LSTM-RNN	12.6	1.54
	Transformer Model	11.2	1.49

Table 6: Effectiveness of critical cases. Both lexicons are of size $60K$. New Lexicon consists of $21K$ critical cases and $39K$ entries from Google lexicon.

We then compare the performance of this new lexicon with the Google lexicon, both of which are of same size ($60K$), on our test set. The results are in Table 6. The results clearly show that even in the case of same sized lexicons, our identified critical cases can significantly improve the performance as evidenced by the lower WER and lower PER than those for the Google lexicon.

7 Conclusion and Future Works

In this paper, we have identified the critical cases, categorized the errors, and increased the current state-of-the-art accuracy in G2P conversion for Bangla language by developing an improved lexicon. In future, we will do classification of errors using unsupervised clustering approaches. Tables 2 and 5 both show that most of the errors occur in Open Close Vowel, s or sh, Diphthong, and Inherent Vowel confusion categories. In future, we will focus on each category to devise novel methodology for mitigating the errors of that category and in turn further increase the accuracy of G2P system in Bangla.

Abstract

Knowledge Bases (KBs) require constant updating to reflect changes to the world they represent. For general purpose KBs, this is often done through Relation Extraction (RE), the task of predicting KB relations expressed in text mentioning entities known to the KB. One way to improve RE is to use KB Embeddings (KBE) for link prediction. However, despite clear connections between RE and KBE, little has been done toward properly unifying these models systematically. We help close the gap with a framework that unifies the learning of RE and KBE models leading to significant improvements over the state-of-the-art in RE. The code is available at `https://github.com/billy-inn/HRERE`.

1 Introduction

Knowledge Bases (KBs) contain structured information about the world and are used in support of many natural language processing applications such as semantic search and question answering. Building KBs is a never-ending challenge because, as the world changes, new knowledge needs to be harvested while old knowledge needs to be revised. This motivates the work on the Relation Extraction (RE) task, whose goal is to assign a KB relation to a *phrase* connecting a pair of entities, which in turn can be used for updating the KB. The state-of-the-art in RE builds on neural models using distant (a.k.a. weak) supervision (Mintz et al., 2009) on large-scale corpora for training.

A task related to RE is that of Knowledge Base Embedding (KBE), which is concerned with representing KB entities and relations in a vector space for predicting missing links in the graph. Aiming to leverage the similarities between these tasks, Weston et al. (2013) were the first to show that *combining* predictions from RE and KBE models was beneficial for RE. However, the way in which they combine RE and KBE predictions is rather naive (namely, by adding those scores). To the best of our knowledge, there have been no systematic attempts to further unify RE and KBE, particularly during model *training*.

We seek to close this gap with HRERE (Heterogeneous REpresentations for neural Relation Extraction), a novel neural RE framework that learns language and knowledge representations *jointly*. Figure 1 gives an overview. HRERE's backbone is a bi-directional long short term memory (LSTM) network with multiple levels of attention to learn representations of text expressing relations. The knowledge representation machinery, borrowed from **ComplEx** (Trouillon et al., 2016), nudges the language model to agree with facts in the KB. Joint learning is guided by three loss functions: one for the language representation, another for the knowledge representation, and a third one to ensure these representations do not diverge. In effect, this contributes to HRERE's generalization power by preventing over-fitting by either model.

We build on state-of-the-art methods for learning the separate RE and KBE representations and on learning tools that allow us to scale to a moderately large training corpus. (We use a subset of Freebase with 3M entities as our KB.) We validate our approach on an established benchmark against state-of-the-art methods for RE, observing not only that our base model significantly outperforms previous methods, but also the fact that jointly learning the heterogeneous representations consistently brings in improvements. To the best of our knowledge, ours is the first principled framework to combine and jointly learn heterogeneous representations from both language and knowledge for the RE task.

Contributions. This paper describes and evaluates a novel neural framework for jointly learning

Proceedings of NAACL-HLT 2019, pages 3201–3206
Minneapolis, Minnesota, June 2 - June 7, 2019.

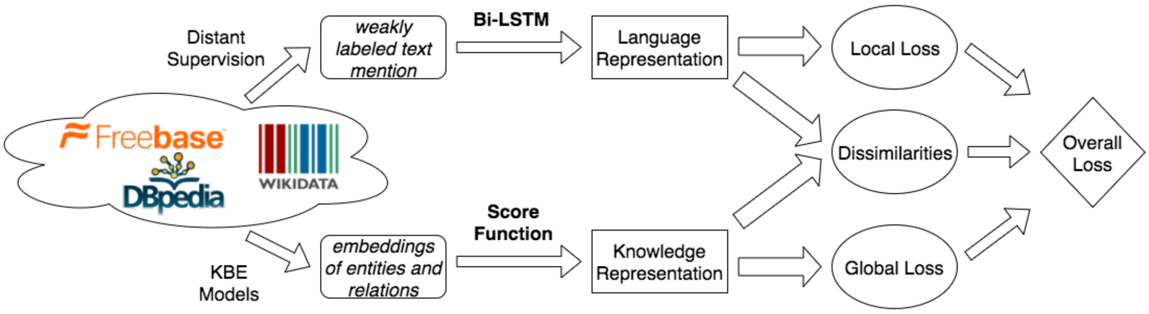

Figure 1: Workflow of the proposed framework.

representations for RE and KBE tasks that uses a cross-entropy loss function to ensure both representations are learned together, resulting in significant improvements over the current state-of-the-art for the RE task.

2 Related Work

Recent neural models have been shown superior to approaches using hand-crafted features for the RE task. Among the pioneers, Zeng et al. (2015) proposed a piecewise convolutional network with multi-instance learning to handle weakly labeled text mentions. Recurrent neural networks (RNN) are another popular architecture (Wu et al., 2017). Similar fast progress has been seen for the KBE task for representing entities and relations in KBs with vectors or matrices. Bordes et al. (2013) introduced the influential translation-based embeddings (TransE), while Yang et al. (2014) leveraged latent matrix factorization in their DistMult method. We build on ComplEx (Trouillon et al., 2016), which extends DistMult into the complex space and has been shown significantly better on several benchmarks.

Weston et al. (2013) were the first to connect RE and KBE models for the RE task. Their simple idea was to train the two models *independently* and only combine them at inference time. While they showed that combining the two models is better than using the RE model alone, newer and better models since then have obviated the net gains of such a simple strategy (Xu and Barbosa, 2018). We propose a much tighter integration of RE and KBE models: we not only use them for prediction, but also *train* them together, thus mutually reinforcing one another.

Recently, many methods have been proposed to use information from KBs to facilitate relation extraction. Sorokin and Gurevych (2017) considered other relations in the sentential context while predicting the target relation. Vashishth et al. (2018) utilized additional side information from KBs for improved RE. However, these methods didn't leverage KBE method to unify RE and KBE in a principled way. Han et al. (2018) used a mutual attention between KBs and text to perform better on both RE and KBE, but their method was still based on TransE (Bordes et al., 2013) which can not fully exploit the advantage of the information from KBs.

3 Background and Problem

The goal in the task of Relation Extraction is to predict a KB relation that holds for a pair of entities given a set of sentences mentioning them (or *NA* if no such relation exists). The input is a KB Ψ with relation set $\mathcal{R}_\Psi$, a set of relations of interest $\mathcal{R}$, $\mathcal{R} \subseteq \mathcal{R}_\Psi$, and an automatically labelled training dataset $\mathcal{D}$ obtained via distant supervision. Given a sentence mentioning entities h, t, the output is a relation $r \in \mathcal{R}$ that holds for h, t or the catch-all relation *NA* if no such r exists.

Knowledge Base and Distant Supervision. As customary, we denote a KB Ψ with relation scheme $\mathcal{R}_\Psi$ as a set of *triples* $\mathcal{T}_\Psi = \{(h, r, t) \in \mathcal{E}_\Psi \times \mathcal{R}_\Psi \times \mathcal{E}_\Psi\}$, where $\mathcal{E}_\Psi$ is the set of entities of interest. Distant supervision exploits the KB to automatically annotate sentences in a corpus containing mentions of entities with the relations they participate in. Formally, a labeled dataset for relation extraction consists of fact triples $\{(h_i, r_i, t_i)\}_{i=1}^N$ and a multi-set of extracted sentences for each triple $\{\mathcal{S}_i\}_{i=1}^N$, such that each sentence $s \in \mathcal{S}_i$ mentions both the head entity h_i and the tail entity t_i.

Problem Statement. Given an entity pair (h, t) and a set of sentences $\mathcal{S}$ mentioning them, the RE task is to estimate the probability of each relation in $\mathcal{R} \cup \{NA\}$. Formally, for each relation r, we want to predict $P(r \mid h, t, \mathcal{S})$.

In practice, the input set of sentences $\mathcal{S}$ can have arbitrary size. For the sake of computational efficiency, we normalize the set size to a fixed number T by splitting large sets and oversampling small ones. We also restrict the length of each sentence in the set by a constant L by truncating long sentences and padding short ones.

4 Methodology

We now go over the details of our framework outlined in Figure 1 for unifying the learning of the language and the knowledge representations used for relation extraction. In a nutshell, we use LSTM with attention mechanisms for language representation and we follow the approach of Trouillon et al. (2016) for KB embedding.

4.1 Language Representation

Input Representation. For each word token, we use pretrained word embeddings and randomly initialized position embeddings (Zeng et al., 2014) to project it into $(d_w + d_p)$-dimensional space, where d_w is the size of word embedding and d_p is the size of position embedding.

Sentence Encoder. For each sentence s_i, we apply a non-linear transformation to the vector representation of s_i to derive a feature vector $z_i = f(s_i; \theta)$ given a set of parameters θ. In this paper, we adopt bidirectional LSTM with d_s hidden units as $f(s_i; \theta)$ (Zhou et al., 2016).

Multi-level Attention Mechanisms. We employ attention mechanisms at both word-level and sentence-level to allow the model to softly select the most informative words and sentences during training (Zhou et al., 2016; Lin et al., 2016). With the learned language representation $\mathbf{s}_L$, the conditional probability $p(r|\mathcal{S}; \Theta^{(L)})$ is computed through a *softmax* layer, where $\Theta^{(L)}$ is the parameters of the model to learn language representation.

4.2 Knowledge Representation

Following the score function ϕ and training procedure of Trouillon et al. (2016), we can get the knowledge representations $e_h, w_r, e_t \in \mathbb{C}^{d_k}$. With the knowledge representations and the scoring function, we can obtain the conditional probability $p(r|(h,t); \Theta^{(G)})$ for each relation r:

$$p(r|(h,t); \Theta^{(G)}) = \frac{e^{\phi(e_h, w_r, e_t)}}{\sum_{r' \in \mathcal{R} \cup \{NA\}} e^{\phi(e_h, w_{r'}, e_t)}}$$

where $\Theta^{(G)}$ corresponds to the knowledge representations $e_h, w_r, e_t \in \mathbb{C}^{d_k}$. Since $NA \notin \mathcal{R}_\Psi$, we use a randomized complex vector as w_{NA}.

4.3 Connecting the Pieces

As stated, this paper seeks an elegant way of connecting language and knowledge representations for the RE task. In order to achieve that, we use separate loss functions (recall Figure 1) to guide the language and knowledge representation learning and a third loss function that ties the predictions of these models thus nudging the parameters towards agreement.

The cross-entropy losses based on the language and knowledge representations are defined as:

$$\mathcal{J}_L = -\frac{1}{N} \sum_{i=1}^{N} \log p(r_i | \mathcal{S}_i; \Theta^{(L)}) \quad (1)$$

$$\mathcal{J}_G = -\frac{1}{N} \sum_{i=1}^{N} \log p(r_i | (h_i, t_i); \Theta^{(G)}) \quad (2)$$

where N denotes the size of the training set. Finally, we use a cross-entropy loss to measure the dissimilarity between two distributions, thus connecting them, and formulate model learning as minimizing $\mathcal{J}_D$:

$$\mathcal{J}_D = -\frac{1}{N} \sum_{i=1}^{N} \log p(r_i^* | \mathcal{S}_i; \Theta^{(L)}) \quad (3)$$

where $r_i^* = \arg\max_{r \in \mathcal{R} \cup \{NA\}} p(r|(h_i, t_i); \Theta^{(G)})$.

4.4 Model Learning

Based on Eq. 1, 2, 3, we form the joint optimization problem for model parameters as

$$\min_{\Theta} \mathcal{J} = \mathcal{J}_L + \mathcal{J}_G + \mathcal{J}_D + \lambda \|\Theta\|_2^2 \quad (4)$$

where $\Theta = \Theta^{(L)} \cup \Theta^{(G)}$. The knowledge representations are first trained on the whole KB independently and then used as the initialization for the *joint* learning. We adopt the stochastic gradient descent with mini-batches and Adam (Kingma and Ba, 2014) to update Θ, employing different learning rates lr_1 and lr_2 on $\Theta^{(L)}$ and $\Theta^{(G)}$ respectively

4.5 Relation Inference

In order to get the conditional probability $p(r|(h,t),\mathcal{S};\Theta)$, we use the weighed average to combine the two distribution $p(r|\mathcal{S};\Theta^{(L)})$ and $p(r|(h,t);\Theta^{(G)})$:

$$\begin{aligned} p(r|(h,t),\mathcal{S};\Theta) &= \alpha * p(r|\mathcal{S};\Theta^{(L)}) \\ &+(1-\alpha) * p(r|(h,t);\Theta^{(G)}). \end{aligned} \tag{5}$$

where α is the combining weight of the weighted average. Then, the predicted relation $\hat{r}$ is

$$\hat{r} = \underset{r \in \mathcal{R} \cup \{NA\}}{\operatorname{argmax}} \; p(r|(h,t),\mathcal{S};\Theta). \tag{6}$$

5 Experiments

Datasets. We evaluate our model on the widely used **NYT** dataset (Riedel et al., 2010) by aligning Freebase relations mentioned in the New York Times Corpus. Articles from years 2005-2006 are used for training while articles from 2007 are used for testing. As our KB, we used a Freebase subset with the 3M entities with highest degree (i.e., participating in most relations). Moreover, to prevent the knowledge representation from memorizing the true relations for entity pairs in the test set, we removed all entity pairs present in the NYT.

Evaluation Protocol: Following previous work (Mintz et al., 2009), we evaluate our model using held-out evaluation which approximately measures the precision without time-consuming manual evaluation. We report both Precision/Recall curves and Precision@N (P@N) in our experiments, ignoring the probability predicted for the *NA* relation. Moreover, to evaluate each sentence in the test set as in previous methods, we append T copies of each sentence into $\mathcal{S}$ for each testing sample.

Word Embeddings: In this paper, we used the freely available 300-dimensional pre-trained word embeddings distributed by Pennington et al. (2014) to help the model generalize to words not appearing in the training set.

Hyperparameter Settings: For hyperparameter tuning, we randonly sampled 10% of the training set as a development set. All the hyperparameters were obtained by evaluating the model on the development set. With the well-tuned hyperparameter setting, we run each model five times on the whole training set and report the average P@N. For Precision/Recall curves, we just select the results from the first run of each model. For training, we set the iteration number over all the training data as 30. Values of the hyperparameters used in the experiments can be found in Table 1.

learning rate on $\Theta^{(L)}$	lr_1	5×10^{-4}
learning rate on $\Theta^{(K)}$	lr_2	1×10^{-5}
size of word position embedding	d_p	25
state size for LSTM layers	d_s	320
input dropout keep probability	p_i	0.9
output dropout keep probability	p_o	0.7
L2 regularization parameter	λ	0.0003
combining weight parameter	α	0.6

Table 1: Hyperparameter setting

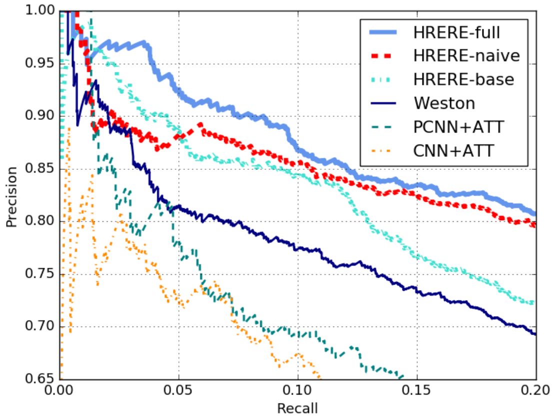

Figure 2: The Precision/Recall curves of previous state-of-the-art methods and our proposed framework.

P@N(%)	10%	30%	50%
Weston	79.3	68.6	60.9
HRERE-base	81.8	70.1	60.7
HRERE-naive	83.6	74.4	65.7
HRERE-full	**86.1**	**76.6**	**68.1**

Table 2: P@N of **Weston** and variants of our proposed framework.

Methods Evaluated. We study three variants of our framework: (1) HRERE-**base**: basic neural model with local loss $\mathcal{J}_L$ only; (2) HRERE-**naive**: neural model with both local loss $\mathcal{J}_L$ and global loss $\mathcal{J}_G$ but without the dissimilarities $\mathcal{J}_D$; (3) HRERE-**full**: neural model with both local and global loss along with their dissimilarities. We compare against two previous state-of-the-art neural models, **CNN+ATT** and **PCNN+ATT** (Lin et al., 2016). We also implement a baseline **Weston** based on the strategy following Weston et al. (2013), namely to combine the scores computed

Relation	Textual Mention	base	naive	full
contains	Much of the **middle east** tension stems from the sense that shiite power is growing, led by **Iran**.	0.311	0.864	**0.884**
place_of_birth	Sometimes I rattle off the names of movie stars from **Omaha**: Fred Astaire, **Henry Fonda**, Nick Nolte . . .	0.109	0.605	**0.646**
country	Spokesmen for **Germany** and Italy in Washington said yesterday that they would reserve comment until the report is formally released at a news conference in **Berlin** today.	0.237	0.200	**0.880**

Table 3: Some examples in NYT corpus and the predicted probabilities of the true relations.

with the methods stated in this paper directly without joint learning.

Analysis. Figure 2 shows the Precision/Recall curves for all the above methods. As one can see, HRERE-**base** significantly outperforms previous state-of-the-art neural models and **Weston** over the entire range of recall. However, HRERE-**base** performs worst compared to all other variants, while HRERE-**full** always performs best as shown in Figure 2 and Table 2. This suggests that introducing knowledge representation consistently results in improvements, which validates our motivating hypothesis. HRERE-**naive** simply optimizes both local and global loss at the same time without attempting to connect them. We can see that HRERE-**full** is not only consistently superior but also more stable than HRERE-**naive** when the recall is less than 0.1. One possible reason for the instability is that the results may be dominated by one of the representations and biased toward it. This suggests that (1) jointly learning the heterogeneous representations bring mutual benefits which are out of reach of previous methods that learn each independently; (2) connecting heterogeneous representations can increase the robustness of the framework.

Case Study. Table 3 shows two examples in the testing data. For each example, we show the relation, the sentence along with entity mentions and the corresponding probabilities predicted by HRERE-**base** and HRERE-**full**. The entity pairs in the sentence are highlighted with bold formatting.

From the table, we have the following observations: (1) The predicted probabilities of three variants of our model in the table match the observations and corroborate our analysis. (2) From the text of the two sentences, we can easily infer that *middle east contains Iran* and *Henry Fonda was born in Omaha*. However, HRERE-**base** fails to detect these relations, suggesting that it is hard for models based on language representations alone to detect implicit relations, which is reasonable to expect. With the help of KBE, the model can effectively identify implicit relations present in the text. (3) It may happen that the relation cannot be inferred by the text as shown in the last example. It's a common wrong labeled case caused by distant supervision. It is a case of an incorrectly labeled instance, a typical occurrence in distant supervision. However, the fact is obviously true in the KBs. As a result, HRERE-**full** gives the underlying relation according to the KBs. This observation may point to one direction of de-noising weakly labeled textual mentions generated by distant supervision.

6 Conclusion

This paper describes an elegant neural framework for jointly learning heterogeneous representations from text and from facts in an existing knowledge base. Contrary to previous work that learn the two disparate representations independently and use simple schemes to integrate predictions from each model, we introduce a novel framework using an elegant loss function that allows the proper connection between the the heterogeneous representations to be learned seamlessly during training. Experimental results demonstrate that the proposed framework outperforms previous strategies to combine heterogeneous representations and the state-of-the-art for the RE task. A closer inspection of our results show that our framework enables both independent models to enhance each other.

Abstract

We propose a new type of representation learning method that models words, phrases and sentences seamlessly. Our method does not depend on word segmentation and any human-annotated resources (e.g., word dictionaries), yet it is very effective for noisy corpora written in unsegmented languages such as Chinese and Japanese. The main idea of our method is to ignore word boundaries completely (i.e., *segmentation-free*), and construct representations for all character n-grams in a raw corpus with embeddings of *compositional* sub-n-grams. Although the idea is simple, our experiments on various benchmarks and real-world datasets show the efficacy of our proposal.

1 Introduction

Most existing word embedding models (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017) take a sequence of words as their input. Therefore, the conventional models are dependent on word segmentation (Yang et al., 2017; Shao et al., 2018), which is a process of converting a raw corpus (i.e., a sequence of characters) into a sequence of segmented character n-grams. After the segmentation, the segmented character n-grams are assumed to be words, and each word's representation is constructed from distribution of neighbour words that co-occur together across the estimated word boundaries. However, in practice, this kind of approach has several problems. First, word segmentation is difficult especially when texts in a corpus are noisy or unsegmented (Saito et al., 2014; Kim et al., 2018). For example, word segmentation on social network service (SNS) corpora, such as Twitter, is a challenging task since it tends to include many misspellings, informal words, neologisms, and even emoticons. This problem becomes more severe in unsegmented languages, such as Chinese and Japanese, whose word boundaries are not explicitly indicated. Second, word segmentation has ambiguities (Luo et al., 2002; Li et al., 2003). For example, a compound word 線形代数学 (linear algebra) can be seen as a single word or sequence of words, such as 線形|代数学 (linear | algebra).

Word segmentation errors negatively influence subsequent processes (Xu et al., 2004). For example, we may lose some words in training corpora, leading to a larger Out-Of-Vocabulary (OOV) rate (Sun et al., 2005). Moreover, segmentation errors, such as segmenting きのう (yesterday) as き|のう (tree | brain), produce false co-occurrence information. This problem is crucial for most existing word embedding methods as they are based on distributional hypothesis (Harris, 1954), which can be summarized as: "*a word is characterized by the company it keeps*" (Firth, 1957).

To enhance word segmentation, some recent works (Junyi, 2013; Sato, 2015; Jeon, 2016) made rich resources publicly available. However, maintaining them up-to-date is difficult and it is infeasible for them to cover all types of words. To avoid the negative impacts of word segmentation errors, Oshikiri (2017) proposed a word embedding method called *segmentation-free word embedding* (`sembei`). The key idea of `sembei` is to directly embed frequent character n-grams from a raw corpus without conducting word segmentation. However, most of the frequent n-grams are non-words (Kim et al., 2018), and hence `sembei` still suffers from the OOV problems. The fundamental problem also lies in its extension (Kim et al., 2018), although it uses external resources to reduce the number of OOV. To handle OOV problems, Bojanowski et al. (2017) proposed a novel *compositional* word embedding method with subword modeling, called *subword-information skip-gram* (`sisg`). The key idea of `sisg` is to extend the notion of vocabulary to include subwords,

Proceedings of NAACL-HLT 2019, pages 3207–3215
Minneapolis, Minnesota, June 2 - June 7, 2019.

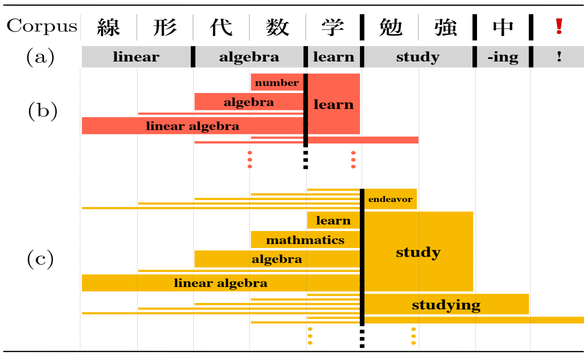

Figure 1: A Japanese tweet with manual segmentation. (a) is the segmentation result of a widely-used word segmenter which conventional word embedding methods are dependent on. (b) and (c) show the embedding targets and their co-occurrence information to be considered in our proposed method `scne` on the boundaries of 数|学 and 学|勉. Unlike conventional word embedding methods, `scne` considers all possible character n-grams on all boundaries (e.g., 線|形, 形|代, 代|数, $\cdots$) in the raw corpus without segmentation.

namely, substrings of words, for enriching the representations of words by the embeddings of its subwords. In `sisg`, the embeddings of OOV (or unseen) words are computed from the embedings of their subwords. However, `sisg` requires word segmentation as a prepossessing step, and the way of collecting co-occurrence information is dependent on the results of explicit word segmentation.

For solving the issues of word segmentation and OOV, we propose a simple but effective unsupervised representation learning method for words, phrases and sentences, called *segmentation-free compositional n-gram embedding* (`scne`). The key idea of `scne` is to train embeddings of character n-grams to compose representations of all character n-grams in a raw corpus, and it enables treating all words, phrases and sentences seamlessly (see Figure 1 for an illustrative explanation). Our experimental results on a range of datasets suggest that `scne` can compute high-quality representations for words and sentences although it does not consider any word boundaries and is not dependent on any human annotated resources.

2 Segmentation-free Compositional n-gram Embedding (`scne`)

Our method `scne` successfully combines a subword model (Zhang et al., 2015; Wieting et al., 2016; Bojanowski et al., 2017; Zhao et al., 2018) with an idea of character n-gram embedding (Oshikiri, 2017; Kim et al., 2018). In `scne`, the vector representation of a target character n-gram is defined as follows. Let $x_1 x_2 \cdots x_N$ be a raw unsegmented corpus of N characters. For a range $i, i+1, \ldots, j$ specified by index $t = (i,j)$, $1 \leq i \leq j \leq N$, we denote the substring $x_i x_{i+1} \cdots x_j$ as $\boldsymbol{x}_{(i,j)}$ or $\boldsymbol{x}_t$. In a training phase, `scne` first counts frequency of character n-grams in the raw corpus to construct n-gram set V by collecting M-most frequent n-grams with $n \leq n_{\max}$, where M and $n_{\max}$ are hyperparameters. For any target character n-gram $\boldsymbol{x}_{(i,j)} = x_i x_{i+1} \cdots x_j$ in the corpus, `scne` constructs its representation $v_{\boldsymbol{x}_{(i,j)}} \in \mathbb{R}^d$ by summing the embeddings of its sub-n-grams as follows:

$$v_{\boldsymbol{x}_{(i,j)}} = \sum_{s \in S(\boldsymbol{x}_{(i,j)})} z_s,$$

where $S(\boldsymbol{x}_{(i,j)}) = \{\boldsymbol{x}_{(i',j')} \in V \mid i \leq i' \leq j' \leq j\}$ consists of all sub-n-grams of target $\boldsymbol{x}_{(i,j)}$, and the embeddings of sub-n-grams $z_s \in \mathbb{R}^d$, $s \in V$ are model parameters to be learned. The objective of `scne` is similar to that of Mikolov et al. (2013),

$$\sum_{t \in \mathcal{D}} \left\{ \sum_{c \in \mathcal{C}(t)} \log \sigma\left(v_{\boldsymbol{x}_t}^\top u_{\boldsymbol{x}_c}\right) + \sum_{\tilde{s} \sim P_{\text{neg}}}^{k} \log \sigma\left(-v_{\boldsymbol{x}_t}^\top u_{\tilde{s}}\right) \right\},$$

where $\sigma(x) = \frac{1}{1+\exp(-x)}$, $\mathcal{D} = \{(i,j) \mid 1 \leq i \leq j \leq N, j-i+1 \leq n_{\text{target}}\}$, and $\mathcal{C}((i,j)) = \{(i',j') \mid \boldsymbol{x}_{(i',j')} \in V, j' = i-1 \text{ or } i' = j+1\}$. $\mathcal{D}$ is the set of indexes of all possible target n-grams in the raw corpus with $n \leq n_{\text{target}}$, where n_{target} is a hyperparameter. $\mathcal{C}(t)$ is the set of indexes of contexts of the target $\boldsymbol{x}_t$, that is, all character n-grams in V that are adjacent to the target (see Figures 1 and 2). The negative sampling distribution P_{neg} of $\tilde{s} \in V$ is proportional to its frequency in the corpus. The model parameters $z_s, u_{\tilde{s}} \in \mathbb{R}^d$, $s, \tilde{s} \in V$, are learned by maximizing the objective. We set $n_{\text{target}} = n_{\max}$ in our experiments.

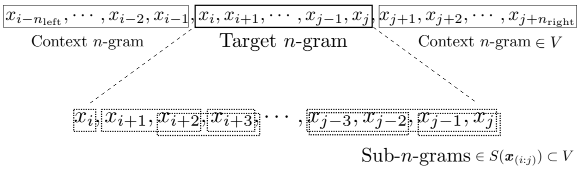

Figure 2: A graphical illustration of the proposed model trying to compute a representation for a character n-gram $\boldsymbol{x}_{(i,j)}$. The co-occurrence of $\boldsymbol{x}_{(i,j)}$ and its neighbouring context n-grams are used to train embeddings of *compositional* n-grams.

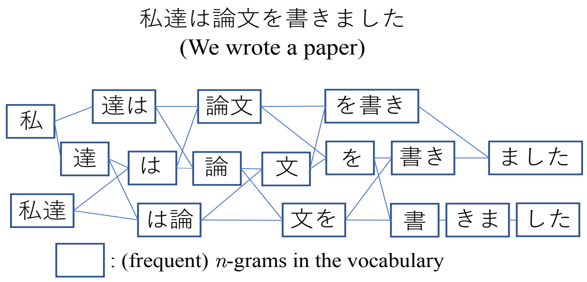

Figure 3: An example of a frequent n-gram lattice.

Although we examine frequent n-grams for simplicity, incorporating supervised word boundary information or *byte pair encoding* into the construction of *compositional* n-gram set would be an interesting future work (Kim et al., 2018; Sennrich et al., 2016; Heinzerling and Strube, 2018).

2.1 Comparison to Oshikiri (2017)

To avoid the problems of word segmentation, Oshikiri (2017) proposed *segmentation-free word embedding* (`sembei`) (Oshikiri, 2017) that considers the M-most frequent character n-grams as individual words. Then, a *frequent n-gram lattice* is constructed, which is similar to a word lattice used in morphological analysis (see Figure 3). Finally, the pairs of adjacent n-grams in the lattice are considered as target-context pairs and they are fed to existing word embedding methods, e.g., `skipgram` (Mikolov et al., 2013). Although `sembei` is simple, the frequent n-gram vocabulary tends to include a vast amount of non-words (Kim et al., 2018). Furthermore, its vocabulary size is limited to M, hence, `sembei` can not avoid the undesirable issue of OOV. The proposed `scne` avoids these problems by taking all possible character n-grams as embedding targets. Note that the target-context pairs of `sembei` are fully contained in those of `scne` (see Figure 1).

2.2 Comparison to Kim et al. (2018)

To overcome the problem of OOV in `sembei`, Kim et al. (2018) proposed an extension of `sembei` called *word-like n-gram embedding* (`wne`). In `wne`, the n-gram vocabulary is filtered to have more vaild words by taking advantage of a supervised probabilistic word segmenter. Although `wne` reduce the number of non-words, there is still the problem of OOV since its vocabulary size is limited. In addition, `wne` is dependent on word segmenter while `scne` does not.

2.3 Comparison to Bojanowski et al. (2017)

To deal with OOV words as well as rare words, Bojanowski et al. (2017) proposed *subword information skip-gram* (`sisg`) that enriches word embeddings with the representations of its subwords, i.e., sub-character n-grams of words. In `sisg`, a vector representation of a target word is encoded as the sum of the embeddings of its subwords. For instance, subwords of length $n = 3$ of the word *where* are extracted as `<wh, whe, her, ere, re>`, where "<","\>" are special symbols added to the original word to represent its left and right word boundaries. Then, a vector representation of *where* is encoded as the sum of the embeddings of these subwords and that of the special sequence `<where>`, which corresponds to the original word itself. Although `sisg` is powerful, it requires the information of word boundaries as its input, that is, semantic units need to be specified when encoding targets. Therefore, it cannot be directly applied to unsegmented languages. Unlike `sisg`, `scne` does not require such information. The proposed `scne` is much simpler, but due to its simpleness, the embedding target of `scne` should contains many non-words, which seems to be a problem (see Figure 1). However, our experimental results show that `scne` successfully captures the semantics of words and even sentences for unsegmented languages without using any knowledge of word boundaries (see Section 3).

3 Experiments

In this section, we perform two intrinsic and two extrinsic tasks at both word and sentence level, focusing on unsegmented languages. The implementation of our method is available on GitHub[1].

3.1 Common Settings

Baselines: We use `skipgram` (Mikolov et al., 2013), `sisg` (Bojanowski et al., 2017) and `sembei` (Oshikiri, 2017) as word embedding baselines. For sentence embedding, we first test simple baselines obtained by averaging the word vectors over a word-segmented sentence. In addition, we examine several recent successful sentence embedding methods, `pv-dbow`, `pv-dm` (Le and Mikolov, 2014) and `sent2vec` (Pagliardini et al., 2018) in an extrinsic task. Note that both `scne` and `sembei` have embeddings of frequent character n-grams as their model parameters, but

---

[1] `www.github.com/kdrl/SCNE`

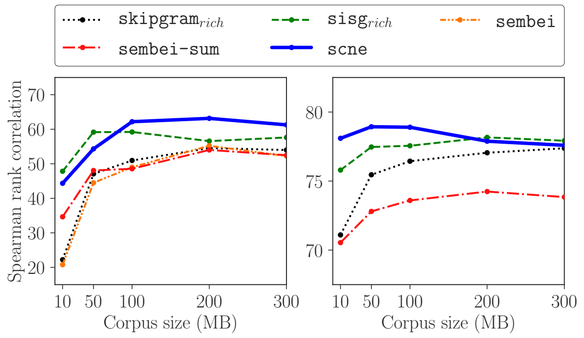

Figure 4: Word (left) and sentence (right) similarity tasks on portions of Chinese Wikipedia corpus.

the differences come from training strategies, such as embedding targets and the way of collecting co-occurrence information (see Section 2.1 for more details). For contrasting scne with sembei, we also propose a variant of sembei (denoted by sembei-sum) as one of baselines, which composes word and sentence embeddings by simply summing up the embeddings of their sub-n-grams which are learned by sembei.

Hyperparameters Tuning: To see the effect of rich resources for the segmentation-dependent baselines, we employ widely-used word segmenter with two settings: Using only a basic dictionary (*basic*) or using a rich dictionary together (*rich*). The dimension of embeddings is 200, the number of epochs is 10 and the number of negative samples is 10 for all the methods. The n-gram vocabulary size $M = 2 \times 10^6$ is used for sisg, sembei and scne. The other hyperparameters, such as learning rate and $n_{\max}$, are carefully adjusted via a grid search in the validation set. In the word similarity task, 2-fold cross validation is used for evaluation. In the sentence similarity task, we use the provided validation set. In the downstream tasks, vector representations are combined with a supervised logistic regression classifier. We repeat training and testing of the classifier 10 times, while the prepared dataset is randomly split into train (60%) and test (40%) sets at each time, and the hyperparameters are tuned by 3-fold cross validation in the train set. We adopt mean accuracy as the evaluation metric. See Appendix A.1 for more experimental details.

3.2 Word and Sentence Similarity

We measure the ability of models to capture semantic similarity for words and sentences in Chinese; see Appendix A.2 for the experiment in Japanese. Given a set of word pairs, or sentence pairs, and their human annotated similarity scores, we calculated Spearman's rank correlation between the cosine similarities of the embeddings and the scores. We use the dataset of Jin and Wu (2012) and Wang et al. (2017) for Chinese word and sentence similarity respectively. Note that the conventional models, such as skipgram, cannot provide the embeddings for OOV words, while the *compositional* models, such as sisg and scne, can compute the embeddings by using their sub-word modeling. In order to show comparable results, we use the null vector for these OOV words following Bojanowski et al. (2017).

	skipgram$_{rich}$	sisg$_{rich}$	sembei	sembei-sum	**scne**
Wiki.	51.0	59.2	49.0	48.6	**62.2**
SNS	41.3	47.0	38.9	41.5	**60.0**
Diff.	-9.7	-12.2	-10.1	-7.1	-2.2

Table 1: Spearman rank correlations of the word similarity task on two different Chinese corpora. Best scores are boldface and 2nd best scores are underlined.

Results: To see the effect of training corpus size, we train all models on portions of Wikipedia[2]. The results are shown in Figure 4. As it can be seen, the proposed scne is competitive with or outperforms the baselines for both word and sentence similarity tasks. Moreover, it is worth noting that scne provides high-quality representations even when the size of training corpus is small, which is crucial for practical real-world settings where rich data is not available. For a next experiment to see the effect of noisiness of training corpus, we test both noisy SNS corpus and the Wikipedia corpus[3] of the same size. The results are reported in Table 1. As it can be seen, the performance of segmentation-dependent methods (skipgram, sisg) are decreased greatly by the noisiness of the corpus, while scne degrades only marginally. The other two segmentation-free methods (sembei, sembei-sum) performed poorly. This shows the efficacy of our method in the noisy texts. On the other hand, in preliminary experiments on English (not shown), scne did not get better results than our segmentation-dependent baselines and it will be a future work to incorporate easily obtainable word boundary information into scne for segmented languages.

---

[2] We use 10, 50, 100, 300MB of Wikipedia from the head.

[3] We use 100MB of Sina Weibo posts for Chinese SNS corpus and 100MB of Chinese Wikipedia corpus.

3.3 Noun Category Prediction

As a word-level downstream task, we conduct a noun category prediction on Chinese, Japanese and Korean[4]. Most settings are the same as those of Oshikiri (2017). Noun words and their semantic categories are extracted from Wikidata (Vrandečić and Krötzsch, 2014) with a predetermined semantic category set[5], and the classifier is trained to predict the semantic category of words from the learned word representations, where unseen words are skipped in training and treated as errors in testing. To see the effect of the noisiness of corpora, both noisy SNS corpus and Wikipedia corpus of the same size are examined as training corpora[6].

Results: The results are reported in Table 2. Since the set of covered nouns (i.e., non-OOV words) depends on the methods, we calculate accuracies in two ways for a fair comparison: Using all the nouns and using the intersection of the covered nouns. `scne` achieved the highest accuracies in all the settings when using all the nouns, and also performed well when using the intersection of the covered nouns, especially for the noisy corpora.

3.4 Sentiment Analysis

As a sentence-level evaluation, we perform sentiment analysis on movie review data. We use 101k, 56k and 200k movie reviews and their scores respectively from Chinese, Japanese and Korean movie review websites (see Appendix A.1.6 for more details). Each review is labeled as positive or negative by its rating score. Sentence embedding models are trained using the whole movie reviews as training corpus. Among the reviews, 5k positive and 5k negative reviews are randomly selected, and the selected reviews are used to train and test the classifiers as explained in Section 3.1.

Results: The results are reported in Table 3. The accuracies show that `scne` is also very effective in the sentence-level application. In this experiment, we observe that the larger $n_{\max}$ contributes to the performance improvement in sentence-level application by allowing our model to capture composed representations for longer phrases or sentences.

4 Conclusion

We proposed a simple yet effective unsupervised method to acquire general-purpose vector representations of words, phrases and sentences seamlessly, which is especially useful for languages whose word boundaries are not obvious, i.e., unsegmented languages. Although our method does not rely on any manually annotated resources or word segmenter, our extensive experiments show that our method outperforms the conventional approaches that depend on such resources.

Acknowledgments

We would like to thank anonymous reviewers for their helpful advice. This work was partially supported by JSPS KAKENHI grant 16H02789 to HS and 18J15053 to KF.

---

[4] Although Korean has spacing, word boundaries are not obviously determined by space.

[5] {food, song, music band name, manga, fictional character name, television series, drama, chemical compound, disease, taxon, city, island, country, year, business enterprise, public company, profession, university, language, book}

[6] For each language, we use 100MB of Wikipedia and SNS data as training corpora. For the SNS data, we use Sina Weibo for Chinese and Twitter for the rest.

A Appendices

A.1 Experimental Details

A.1.1 Hyperparameters Tuning

For `skipgram`, we performed a grid search over $(h, \gamma) \in \{1, 5, 10\} \times \{0.01, 0.025\}$, where h is the size of context window and γ is the initial learning rate. For `sisg`, we performed a grid search over $(h, \gamma, n_{\text{min}}, n_{\text{max}}) \in \{1, 5, 10\} \times \{0.01, 0.025\} \times \{1, 3\} \times \{4, 8, 12\}$, where h is the size of context window, γ is the initial learning rate, n_{min} is the minimum length of character n-gram and n_{max} is the maximum length of character n-gram. For `pv-dbow`, `pv-dm` and `sent2vec`, we performed a grid search over $(h, \gamma) \in \{5, 10\} \times \{0.01, 0.05, 0.1, 0.2, 0.5\}$, where h is the size of context window and γ is the initial learning rate. For `sembei` and `scne`, we used the initial learning rate 0.01 and $n_{\text{min}} = 1$. The maximum length of n-gram to consider n_{max} is grid searched over $\{4, 6, 8\}$ in the word and sentence similarity tasks. In the noun category prediction task, we used $n_{\text{max}} = 8$ for `sembei` and the n_{max} of `scne` is grid searched over $\{4, 6, 8\}$. For sentiment analysis task, we tested both $n_{\text{max}} = 8$ and $n_{\text{max}} = 16$ for `sembei` and `scne` to see the effect of large n_{max}. After carefully monitoring the loss curve and the performance in the word and sentence similarity tasks, we set the number of epochs 10 for all methods. In preliminary experiments, we also tested the number of epochs 20 for the word-segmentation-dependent baselines but there were no significant differences. In the two supervised downstream tasks, the learned vector representations are combined with the logistic regression classifier. The parameter C, which is the inverse of regularization strength of the classifier, is adjusted via a grid search over $C \in \{0.1, 0.5, 1, 5, 10\}$. Again, as explained in the main paper, the hyperparamters are grid searched on the determined validation set for all experiments.

A.1.2 Implementations

Here we provide the list of implementations of baselines which are used in our experiments. For `skipgram`[7], `sisg`[8], `sembei`[9], and `sent2vec`[10], we use the official implementations provided by the authors. Meanwhile, as for `pv-dbow` and `pv-dm`, we employ a widely-used implementation of Gensim library[11].

A.1.3 Word Segmenters and Word Dictionaries for Unsegmented Languages

Below we list the word segmentation tools and word dictionaries which are used in our experiments. We employed a widely-used word segmentation tool for each language.

For Chinese language, we used jieba[12] with its

[9] `https://github.com/oshikiri/w2v-sembei`

[10] `https://github.com/epfml/sent2vec`

[11] `https://radimrehurek.com/gensim/models/doc2vec.html`

[12] `https://github.com/fxsjy/jieba`

default dictionary[13] or with an extended dictionary[14], which fully supports both traditional and simplified Chinese characters.

For Japanese, we used MeCab[15] with its default dictionary called IPADIC[15] along with specially designed neologisms-extended dictionary called mecab-ipadic-NEologd[16]. Note that, because this extended dictionary *mecab-ipadic-NEologd* is specially designed to include many neologisms, there is a significant word coverage improvement by using this word dictionary as it can be seen in the Japanese noun category prediction task in the main paper.

For Korean, we used mecab-ko[17] with its default dictionary called mecab-ko-dic[18] along with another extended dictionary called NIADic[19].

A.1.4 Training Corpora

We prepared Wikipedia corpora and SNS corpora for Chinese, Japanese and Korean for our experiments. For the Wikipedia corpora, we used the first 10, 50, 100, 200 and 300MB of texts from the publicly available Wikipedia dumps[20]. The texts are extracted by using WikiExtractor tool[21]. For Chinese SNS corpus, we used 100MB of Leiden Weibo Corpus (van Esch, 2012) from the head. For Japanese and Korean SNS corpora, we collected Japanese and Korean tweets using Twitter Streaming API. We removed usernames and URLs from the SNS corpora. There were many informal words, emoticons and misspellings in the SNS corpora. We preserved them without preprocessing to see the effect of the noisiness of training corpora in our experiments.

A.1.5 Preprocess of Wikidata

For the noun category prediction task, we extracted noun words and their semantic categories from Wikidata (Vrandečić and Krötzsch, 2014) following Oshikiri (2017). We determined the semantic category set used in our experiments as follows: First, we collected Wikidata objects that have Chinese, Japanese, Korean and English labels. Next, we sorted the categories by the number of noun words, and removed categories (e.g., *Wikimedia category* or *Wikimedia template*) that do not represent any semantic category. We also removed out several categories that contain too many noun words (e.g., *human*) or too few noun words (e.g., *academic discipline*). Since there were several duplicated labels for different Wikidata objects, the number of nouns for each language is slightly different. Each category has at least 0.1k words and no more than 5k words. The numbers of extracted noun words that are used in our experiments were 22,468, 22,396 and 22,298 for Chinese, Japanese and Korean, respectively.

	skipgram$_{rich}$	sisg$_{rich}$	sembei	sembei-sum	**scne**
Wiki.	8.3	15.4	4.0	9.3	**24.1**
SNS	5.3	12.7	2.8	9.3	**23.0**
Diff.	-3.0	-2.7	-1.2	-0.0	-1.1

Table 4: Spearman rank correlations of the word similarity task on two different Japanese corpora.

A.1.6 Movie Review Datasets

In the main paper, three movie review datasets are used to evaluate the quality of sentence embeddings. We used 101,114, 55,837 and 200,000 movie reviews and their rating scores from Yahoo奇摩電影[22], Yahoo!映画[23] and Naver Movies[24] for Chinese, Japanese and Korean, respectively.

A.2 Additional Experiment on Japanese

In this section, we show the results of Japanese word similarity experiments. We use the datasets of Sakaizawa and Komachi (2018). It contains 4427 pairs of words with human similarity scores. We omit sentence similarity task since there is no public widely-used benchmark dataset for Japanese yet. Following the main paper, given a set of word pairs and their human annotated similarity scores, we calculated Spearman's rank correlation between the cosine similarities of the embeddings and the human scores. We use 2-fold

cross validation for hyperparameters tuning. The same grid search is performed as explained in Section A.1.1. To see the effect of the noisiness of training corpora, we use two Japanese corpora, 100MB of Wikipedia corpus and 100MB of noisy SNS corpus (Twitter), which are also used in the Japanese noun category prediction task in the main paper. As seen in Table 4, the experiment results for Japanese are similar to those of Chinese in the main paper.

Exploiting Noisy Data in Distant Supervision Relation Classification

Abstract

Distant supervision has obtained great progress on relation classification task. However, it still suffers from noisy labeling problem. Different from previous works that underutilize noisy data which inherently characterize the property of classification, in this paper, we propose RCEND, a novel framework to enhance Relation Classification by Exploiting Noisy Data. First, an instance discriminator with reinforcement learning is designed to split the noisy data into correctly labeled data and incorrectly labeled data. Second, we learn a robust relation classifier in semi-supervised learning way, whereby the correctly and incorrectly labeled data are treated as labeled and unlabeled data respectively. The experimental results show that our method outperforms the state-of-the-art models.

1 Introduction

Relation classification plays a crucial role in natural language processing (NLP) tasks, such as question answering and knowledge base completion (Xu et al., 2016; Han et al., 2018a). The goal of relation classification is to predict relations of the target entity pair given a plain text. Traditional supervised learning methods (Zelenko et al., 2002; Bunescu and Mooney, 2005; Zhou et al., 2005) heavily rely on large scale annotated data which is time and labor consuming. Mintz et al. (2009) proposed distant supervision (DS) to automatically generate training data for relation classification based on the assumption that if two target entities have a relation in knowledge base (KB), sentences containing this entity pair might express the relation. For example, if a relational fact <Apple, *founder*, Steve Jobs> exists in KB, distant supervision will assign *founder* as the label of all sentences that contain "Apple" and "Steve Jobs" together.

Sentence	DS	Gold
S1:**Al Gore** was waiting to board a commercial flight from **Nashville** to Miami...	LivedIn	NA
S2:There were also performers who were born in **Louisiana** , including **Lucinda Williams**...	LivedIn	BornIn
S3:**Boggs** was married, had three young children and lived in **Brewster**	NA	LivedIn

Table 1: Examples of noisy labeling problem in distant supervision relation classification. S1 and S2 are heuristically labeled as *LivedIn* by DS, but neither of them mention the relation while S2 mentions the *BornIn* relation. S3 expresses the *LivedIn* relation but it is mislabeled as *NA* since no relation of the entity pair exist in KB.

However, it suffers from noisy labeling problem due to the irrelevance of aligned text and incompleteness of KB, which consists of **false positives** and **false negatives**. The false positives means that not all sentences containing two entities mention the relation in KB, such as S1 and S2 in Table 1. And the false negatives are sentences are mislabeled as no relation (*NA*) due to the absence of relational fact in KB even though they express the target relation, such as S3 in Table 1.

In order to reduce the impact of noisy data, previous works (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016; Han et al., 2018b) adopt Multi-Instance Learning (MIL) for relation classification. Recent studies (Feng et al., 2018; Qin et al., 2018b,a) introduce reinforcement learning (RL) and adversarial learning to filter out incorrectly labeled sentences and achieve significant improvements. However, there are two remaining challenges of noisy labeling problem.

- Most of these approaches focus on solving the false positives but overlook false nega-

Proceedings of NAACL-HLT 2019, pages 3216–3225
Minneapolis, Minnesota, June 2 - June 7, 2019.

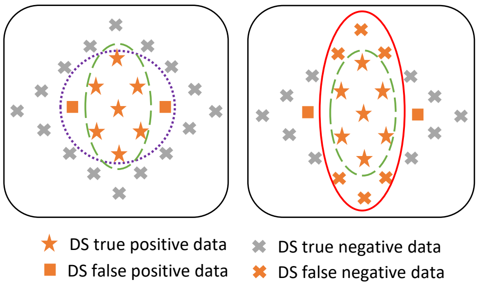

Figure 1: Illustration of false positive and false negative cases

tives. As illustrated in Figure 1, they concentrate on discovering the false positive instances[1] which are suppressed or removed at last and obtain a better decision boundary (green dashed line) than without consideration of false positive instances. Nevertheless, there are still a lot of false negative instances expressing similar semantic information with positive data. These instances also provide evidence for the target relation. The incorrect labels will weaken the discriminative capability of available features and confuse the model if they stay the same. However, when we remedy the label correctly, we indeed possess the optimal decision boundary (red solid line).

- There lacks an effective method to fully utilize noisy data of distant supervision. (Xu et al., 2013; Liu et al., 2017) apply methods such as pseudo-labels to directly correct the label of noisy data and Luo et al. (2017) design a dynamic transition matrix to model noise patterns. They still suffer from the drawback of error propagation during training.

To tackle the above challenges, we propose a novel framework exploiting noisy data to enhance distant supervision relation classification. We design an instance discriminator with reinforcement learning to recognize both false positive and false negative instances simultaneously, and further split the noisy dataset into two sets, representing correctly labeled and incorrectly labeled data respectively. Additionally, we learn a robust relation classifier applying a semi-supervised learning method, whereby the correctly and incorrectly labeled data are regarded as labeled and unlabeled data. On the one hand, we mitigate the side effect of incorrectly labeled data by recognizing them and treating them as unlabeled data. On the other hand, taking full advantage of the incorrectly labeled data in semi-supervised learning way facilitates robust property of model and improves generalization performance. Our contributions in this work are three-fold:

- We propose a deep reinforcement learning framework to discriminate both false-positive and false-negative instances simultaneously.
- We introduce a semi-supervised learning method to fully exploit the noisy data in distant supervision relation classification.
- We conduct experiments on a widely used benchmark dataset and the results show that our method achieves significant improvements as compared with strong baselines.

2 Related work

Many efforts based on supervised learning (Zelenko et al., 2002; Bunescu and Mooney, 2005; Zhou et al., 2005) have been devoted to relation classification. As is well-known, achieving a good performance while applying supervised learning paradigm requires a large amount of high-quality annotated data. To address the issue of data sparsity, Mintz et al. (2009) propose distant supervision to automatically annotate large scale training data, which inevitably results in noisy labeling problem.

To tolerate noisy instances in positive examples, most early approaches employ multi-instance learning framework, including multi-instance single-label learning (Riedel et al., 2010) and multi-instance multi-label learning (Hoffmann et al., 2011; Surdeanu et al., 2012). Recently, deep learning has also been introduced to propose an end-to-end convolutional neural network for relation classification (Zeng et al., 2014). In the sentences bag of one entity pair, Zeng et al. (2015) select the most reliable sentence, and Lin et al. (2016) propose attention schemes to de-emphasize unreliable sentences. Han et al. (2018b) incorporate hierarchical information of relations to enhance the attention scheme. But they fail to handle the issue where all sentences in one bag are mislabeled.

Feng et al. (2018); Qin et al. (2018b,a) further achieve improvement by using reinforcement

---

[1] In this paper, instance is the same as sentence

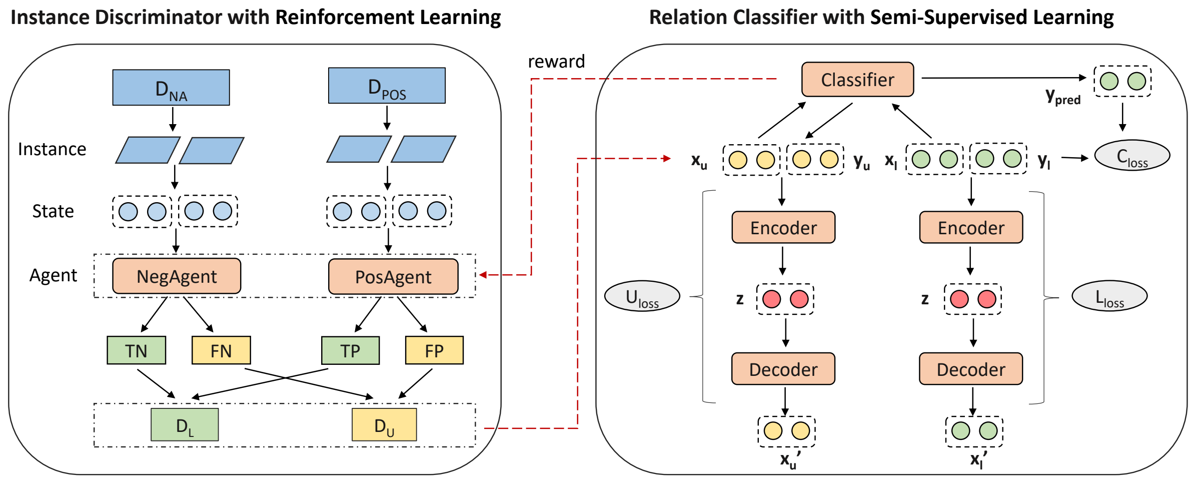

Figure 2: The framework of train process. Instance discriminator, consisting of PosAgent and NegAgent, aims to recognize false-positive (FP) and false-negative (FN) instances from positive dataset ($\mathcal{D}_{\text{POS}}$) and NA dataset ($\mathcal{D}_{\text{NA}}$) respectively. Afterward, true-positive (TP) and true-negative (TN) instances are split into labeled data ($\mathcal{D}_l$) while FP and FN instances are split into unlabeled data ($\mathcal{D}_u$). We adopt SemiVAE, which consists of an encoder, a decoder and a classifier, to train a robust relation classifier with semi-supervised learning utilizing the above data $\mathcal{D}_l$,$\mathcal{D}_u$. More details are introduced in Section 3.2 and 3.3.

learning and adversarial learning to explicitly remove incorrectly labeled sentences. However, they neglect the useful inherent information of those sentences which should be replaced correctly. In other words, they remove the noise rather than utilize it in the right way.

Furthermore, Xu et al. (2013) correct false negative instances by using pseudo-relevance feedback to expand the origin knowledge base. Liu et al. (2017) apply a dynamic soft-label instead of the immutable hard label produced by DS during the training process. Luo et al. (2017) design a transition matrix which characterizes the underlying noise pattern to correct noisy labels. They utilize the noisy data and address the false negative problem to some extent, but they still suffer from the drawback that errors may be propagated because the model is unable to correct its own mistakes.

In this work, we propose a unified framework for learning a discriminator to recognize both false-positive and false-negative instances with reinforcement learning, and utilizing the incorrectly labeled data as unlabeled data in semi-supervised learning way.

3 Methodology

In this section, we introduce our framework and the details of instance discriminator and relation classifier as follows.

3.1 Framework

In MIL paradigm, the entire instances are split into multiple entity-pair bags $\{B_{h_i,t_i}\}_{i=1}^{k}$. The sentences in $B_{h,t}$ mention both head entity h and tail entity t. Here we denote dataset as $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{n}$, where x_i is a sentence associated with the corresponding entity pair, y_i is a noisy relation label produced by distant supervision and n is the total number of sentences contained in each bag. As mentioned above, *NA* is a special relation which indicates the sentence does not express any relations in the KB. We define other relations in the KB as positive relations. Accordingly, we split the dataset into $\mathcal{D}_{\text{POS}}$ and $\mathcal{D}_{\text{NA}}$.

In the scenario of distant supervision, an ideal model is not only capable of capturing valid supervision information about correctly labeled data with less noise, but also leveraging information contained in incorrectly labeled data by correcting the noisy label implicitly.

As a result, we solve the task of distant supervision relation classification in two steps. As depicted in Figure 2, we design an instance discriminator to heuristically recognize false positive and false negative instances from the noisy distantly-supervised dataset with reinforcement learning. The correctly labeled instances discovered by the discriminator are split into labeled data while the incorrectly labeled ones are split into unlabeled data. The details of the instance discriminator will be introduced in Section 3.2. After scanning the entire noisy dataset, we train a robust classifier with semi-supervised learning utilizing above labeled data and unlabeled data. The details of the relation classifier will be introduced in Section 3.3. Meanwhile, the relation classifier provides rewards to the instance discriminator for updating parameters of its policy function.

3.2 Instance discriminator

We regard recognizing incorrectly labeled instances as a reinforcement learning problem. The instance discriminator acts as an agent interacting with the environment that consists of a noisy dataset and a relation classifier. The agent is parameterized with a policy network $\pi(a|s;\theta)$ which gives the probability distribution of action a at each state s and receives reward r from the relation classifier to update parameters θ. Note that *NA* indicates that there is no relation between two entities or that the relation is of no interest. The relation *NA* is very ambiguous since instances have no unified pattern. Thus we cannot decide whether a sentence belongs to *NA* only by the fact that it does not express any other positive relation. Under this consideration, we adopt two agents, PosAgent and NegAgent, to recognize false positive and false negative instances respectively. The definitions of the components in RL are introduced as follows.

State The state includes the semantic and syntactic information of current sentence and the relation label given by DS. We use a piecewise convolutional neural network (PCNN) (Zeng et al., 2015) to convert each sentence into real-valued vector $\boldsymbol{x}$ and build a class representation matrix $\boldsymbol{M}$ to represent each relation type. As we decide whether the current sentence is correctly labeled according to the similarity between the semantic meanings of sentence and relation, we only take the current sentence into consideration without sentences in early states. For PosAgent, state $\boldsymbol{s}_p$ is the concatenation of the current sentence vector $\boldsymbol{x}$ and corresponding relation embedding. For NegAgent, we represent state $\boldsymbol{s}_n$ by the vector of relational scores based on the representation of the current sentence $\boldsymbol{x}$.

$$\begin{aligned} \boldsymbol{s}_p &= [\boldsymbol{x}; \boldsymbol{M}_{[y]}] \\ \boldsymbol{s}_n &= \boldsymbol{M}\boldsymbol{x} + \boldsymbol{b} \end{aligned} \tag{1}$$

where y is relation label of the current sentence. $\boldsymbol{b} \in \mathbb{R}^{n_r}$ is a bias vector and n_r is the number of class.

Action We desire the agent to distinguish whether the current sentence is mislabeled or not. Therefore, the action of our agent is defined as $a_i \in \{0, 1\}$, where 0 indicates the sentence is incorrectly labeled and 1 indicates the sentence is correctly labeled.

Reward The reward function can reflect the advantage of redistributing the noisy data. As previously mentioned, the actions of our agent redistribute noisy data into labeled data and unlabeled data, corresponding to correctly labeled and incorrectly labeled instances. Therefore, the average likelihood of labeled data will be larger than unlabeled data when the agent makes correct actions. We define the difference of likelihood between them as the reward to evaluate the performance of our policy. Consequently, the reward is defined as follows:

$$r = \lambda(\frac{1}{|L|}\sum_{x \in L} p_\phi(y|x) - \frac{1}{|U|}\sum_{x \in U} p_\phi(y|x)) \tag{2}$$

where L and U is the subset of labeled data and unlabeled data respectively, and y is the relation label given by DS. $p_\phi(y|x)$ is calculated by the relation classifier from the semi-supervised learning framework. λ is used to scale the difference to a rational numeric range.

Training the Policy-based Agent

The objective of the agent is to maximize the expected reward of the actions sampled from the probability distribution. Given a mini-batch data B, following the policy, our agent produces a set of probability distributions of actions $\pi(a_i|s_i;\theta)$. Based on the actions, the agent achieves a performance-driven reward r. We use a policy gradient strategy to compute the gradient and update our agent referring to the policy gradient theorem (Sutton et al., 1999) and the REINFORCE algorithm (Williams, 1992). The parameters of the policy network are updated according to the following gradient:

$$\theta \leftarrow \theta + \alpha \sum_{i=1}^{|B|} \nabla_\theta r \log \pi(a_i|\boldsymbol{s}_i;\theta) \tag{3}$$

As the goal of our agent is to determine whether an annotated sentence expresses target relation with weak supervision, we need a relation classifier to compute the reward for updating the policy network. We first pre-train our classifier on the entire dataset with supervised learning until rough convergence. Then we pre-train the policy network by receiving rewards from the pre-trained classifier with the parameters frozen. The pre-training strategy is necessary as it saves time that would otherwise be spent training the model by trial and error. It is also widely used by other related works (Silver et al., 2016; Bahdanau et al., 2016). The training procedure for instance discriminator is summarized in Algorithm 1.

3.3 Relation Classifier

In order to reach the maximum utilization of noisy data, we train our relation classifier with semi-supervised learning. Below, we introduce PCNN and SemiVAE, the method we adopt for semi-supervised learning.

PCNN

We take the widely used CNN architecture (PCNN) (Zeng et al., 2015; Lin et al., 2016) to encode input sentences into low-dimensional vectors and predict their corresponding relation labels.

Given a sentence containing an entity pair, we represent the i-th word as $\boldsymbol{v}_i$ by concatenating its word embedding $\boldsymbol{w}_i$ and position embedding $\boldsymbol{p}_i$ which encodes the relative distances from it to two entities ($\boldsymbol{v}_i \in \mathbb{R}^d, w_i \in \mathbb{R}^{d_w}, p_i \in \mathbb{R}^{d_p}, d = d_w + d_p$).

Afterward, the convolution layer applies a kernel of the window size l to slide over the input sequence $\{\boldsymbol{v}_1, \boldsymbol{v}_2, ..., \boldsymbol{v}_m\}$ and output the d_h-dimensional hidden embeddings $\boldsymbol{h}$, where $\boldsymbol{h} \in \mathbb{R}^{m \times d_c}$ and d_c is the number of feature maps.

Then, piecewise max-pooling is used to divide the hidden embeddings into three parts $\{\boldsymbol{h}^1, \boldsymbol{h}^2, \boldsymbol{h}^3\}$ by the position of head and tail entities. We perform max-pooling on each part respectively and get final embedding $\boldsymbol{x}$ by concatenating the pooling results, where $\boldsymbol{x} \in \mathbb{R}^{d_s} (d_s = d_c \times 3)$.

$$\boldsymbol{x} = [\max(\boldsymbol{h}^1); \max(\boldsymbol{h}^2); \max(\boldsymbol{h}^3)] \tag{4}$$

Finally, we formalize the probability of predicting y given sentence $\boldsymbol{x}$ as follows:

$$\begin{aligned} \boldsymbol{o} &= \boldsymbol{M}\boldsymbol{x} + \boldsymbol{b}, \\ p_\phi(y|\boldsymbol{x}) &= \frac{\exp{(o_y)}}{\sum_{k=1}^{n_r} \exp{(o_k)}} \end{aligned} \tag{5}$$

where $\boldsymbol{M} \in \mathbb{R}^{n_r \times d_s}$ is the class embeddings of each relation and $\boldsymbol{b} \in \mathbb{R}^{n_r}$ is a bias vector.

Semi-supervised VAE

SemiVAE, a semi-supervised learning method based on variational inference, is introduced and developed by (Kingma et al., 2014; Xu et al., 2017). The inference model consists of three components as follows. An encoder network $p_\varphi(z|x, y)$ encodes data x and label y into a latent variable z. The decoder network $p_\psi(x|z, y)$ is used to estimate the probability of generating x given z and categorical label y. Finally, classifier $p_\phi(y|x)$ predict the corresponding label y of x. We model both encoder and decoder by multilayer perceptron (MLP) and employ the PCNN model as the classifier in SemiVAE.

For the case of labeled data (x_l, y_l), the evidence lower bound is:

$$\begin{aligned} \log p_\psi(x_l, y_l) \geq & \mathbb{E}_{p_\varphi(z|x_l,y_l)}[\log p_\psi(x'_l|y_l, z)] \\ & + \log p_\psi(y_l) - D_{KL}(p_\varphi(z|x_l, y_l)||p(z)) \\ & = -\mathcal{L}(x_l, y_l) \end{aligned} \tag{6}$$

where first term represent the expectation of the conditional log-likelihood on latent variable z and the last term is Kullabck-Leibler divergence between the prior distribution $p(z)$ and the latent posterior $p_\phi(z|x_l, y_l)$.

For the case of unlabeled data x_u, the unobserved label y_u is obtained from the classifier in the inference model. The variational lower bound is:

$$\begin{aligned} \log p_\psi(x_u) \geq & \sum_y p_\phi(y_u|x_u)(-\mathcal{L}(x_u, y_u)) + \mathcal{H}(p_\phi(y_u|x_u)) \\ & = -\mathcal{U}(x_u) \end{aligned} \tag{7}$$

where $\mathcal{H}$ denotes the entropy of $p_\phi(y_u|x_u)$.

Since the classifier $p_\phi(y|x)$ is unable to learn directly from labeled data, a classification loss is introduced as:

$$\mathcal{C} = \mathbb{E}_{(x,y) \in D_l}[-\log p_\phi(y|x)] \tag{8}$$

To maximize the evidence lower bound of both labeled data and unlabeled data and minimize the classification loss, the objective is defined as:

$$\mathcal{J} = \sum_{(x,y) \in \mathcal{D}_l} \mathcal{L}(x, y) + \sum_{x \in \mathcal{D}_u} \mathcal{U}(x) + \beta \mathcal{C} \tag{9}$$

where $\mathcal{D}_l$ and $\mathcal{D}_u$ are labeled and unlabeled data respectively, β is a factor used to scale the classification loss of labeled data.

Algorithm 1 Reinforcement Learning Algorithm for Instance Discriminator.

```
Input: Origin dataset $\mathcal{D}_{\text{POS}} = \{(x_i, y_i)\}_{i=1}^{n}$.
    ( To be clear, we demonstrate the training procedure of PosAgent. NegAgent is trained in the same way. )
Output: Labeled data $\mathcal{D}_l$ , unlabeled data $\mathcal{D}_u$.
Initialize parameters of policy network as $\theta$.
for step $t = 1 \to T$ do
    Partition $\mathcal{D}_{\text{POS}}$ into minibatches of size $b_s$
    for minibatch $B \subset \mathcal{D}_{\text{POS}}$ do
        $B = \{(x_j, y_j)\}_{j=1}^{b_s}$
        Sample actions for each sentence in $B$: $a_j \sim \pi(a_j|s_j; \theta)$
        if $a_j == 0$ then
            Add $x_j$ to $\mathcal{D}_u$
        else
            Add $(x_j, y_j)$ to $\mathcal{D}_l$
        end if
        Calculate reward $r$ by Eq.(2)
        Update $\theta$ by Eq.(3)
    end for
end for
```

Algorithm 2 Semi-supervised Learning Algorithm for Relation Classifier.

```
Input: Labeled data $\mathcal{D}_l$, unlabeled data $\mathcal{D}_u$.
Initialize parameters of relation classifier as $\phi$.
for epoch $i = 1 \to N$ do
    Sample m data pair $(x_l, y_l)$ from $\mathcal{D}_l$
    Sample m data $x_u$ from $\mathcal{D}_u$ and predict their corresponding unobserved label $y_u$ via $p_\phi(y|x)$
    Update $\phi$ by Eq.(9)
end for
```

After our reinforcement learning process, we obtain an instance discriminator which possesses the capability of recognizing incorrectly labeled instances from the noisy dataset. Additionally, the entire DS dataset $\mathcal{D}$ is split into labeled data $\mathcal{D}_l$ and unlabeled data $\mathcal{D}_u$. Therefore, we utilize the above data to train SemiVAE model and obtain a robust relation classifier which explicitly learns from correctly labeled data and correct incorrectly labeled data implicitly. The training procedure for relation classifier is summarized in Algorithm 2.

4 Experiment

4.1 Datasets and Evaluation

We evaluate our model on a widely used dataset that is generated by aligning entity pairs from Freebase with New York Times corpus(NYT)[2] and developed by (Riedel et al., 2010). Entity mentions are recognized by the Stanford named entity recognizer (Finkel et al., 2005). The relation facts in Freebase are divided into two parts for training and testing respectively. The sentences from the corpus of the years 2005-2006 are used as the training instances, and sentences from 2007 are used as the testing instances. There are 52 positive relations and a special relation *NA*.

Batch size b_s	160
Word Dimension d_w	50
Position Dimension d_p	5×2
Convolution Filter Dimension d_c	230
Convolution Window Size l	3
Latent Variable Dimension d_z	100
Dropout p	0.5
Regulator λ, β	100, 2

Table 2: Hyperparameter settings

Following previous works, we evaluate our model on the held-out evaluation, which compares relation facts extracted from the test corpus with those in Freebase. We adopt aggregated precision/recall curves and precision@N (P@N) to illustrate the performance of our model.

4.2 Parameter Settings

We adopt the Adam (Kingma and Ba, 2014) optimizer to optimize our instance discriminator and relation classifier with learning rate 0.0001 and 0.001 respectively. We also apply dropout to prevent overfitting. More detailed hyperparameter settings are presented in Table 2.

4.3 Overall Evaluations Results

We adopt the following baselines with which we compare our model:

- **Mintz** (Mintz et al., 2009) is the original distantly supervised model. **MultiR** (Hoffmann et al., 2011) and **MIML**(Surdeanu et al., 2012) handle overlapping relation problem with graphical model in multi-instance and multi-instance multi-label framework. All above models are based on handcrafted feature.

- **PCNN+ONE** (Zeng et al., 2015) and **PCNN+ATT** (Lin et al., 2016) are both robust models to solve noisy labeling problem

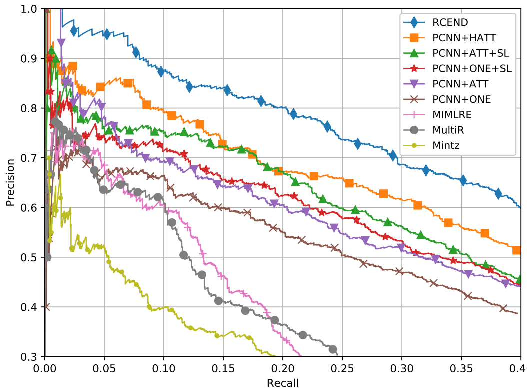

Figure 3: Precision-recall curves of our model and baselines.

P@N	100	200	300	Mean
PCNN+ONE	72.3	69.7	64.1	68.7
PCNN+ATT	76.2	73.1	67.4	72.2
PCNN+ONE+SL	84.0	81.0	74.0	79.7
PCNN+ATT+SL	87.0	84.5	77.0	82.8
PCNN+HATT	88.0	79.5	75.3	80.9
RCEND	**95.0**	**87.5**	**84.4**	**88.9**

Table 3: Top-N precision (P@N) of our model and baselines

based on the at-least-one assumption and selective attention. **PCNN+HATT** (Han et al., 2018b) is a attention-based method which employs hierarchical attention to exploit correlations among relations.

- **PCNN+ONE+SL** and **PCNN+ATT+SL**(Liu et al., 2017) use a soft-label method to alleviate the negative impact of the noisy labeling problem.

We compare our model with aforementioned baselines and the results are shown in Figure 3. From the overall result we can see that: (1) All feature-based models preform poorly as their features are derived from NLP tools, which will generate errors that propagate through in model. (2) PCNN+ONE and PCNN+ATT boost the performance because they reduce noise in the bag of entity pair by selecting the most confident sentence or de-emphasize the incorrectly labeled sentences with an attention mechanism. (3) When PCNN+ONE and PCNN+ATT use soft labels, they achieve an improvement. This indicates correcting the noisy label is helpful to relation classification in MIL scheme. (4) PCNN+HATT further enhances the performance as it incorporates hierarchical information of relations to improve the attention mechanism. (5) Our method RCEND achieves the best precision over the entire recall range compared with all baselines. The performance achieves further improvement when we regard the incorrectly labeled sentences as unlabeled data and adopt a semi-supervised learning method to train our model. It shows that exploiting noisy data with our method is beneficial to promote distant supervision relation classification.

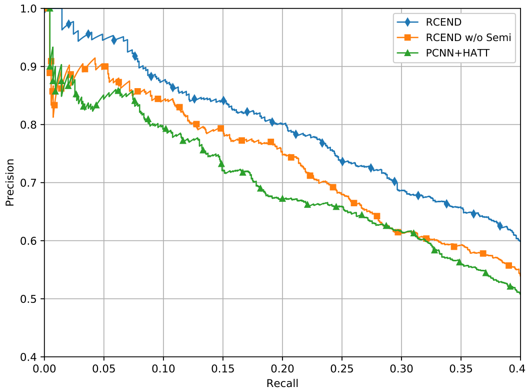

Figure 4: Precision-recall curves of our model with different settings.

P@N	100	200	300	Mean
RCEND	**95.0**	**87.5**	**84.4**	**88.9**
RCEND w/o Semi	90.0	84.6	79.1	84.6
RCEND(P)	87.1	82.1	80.1	83.3
RCEND(N)	89.1	85.1	81.1	85.1

Table 4: Top-N precision (P@N) of our model with different settings.

We also report the result of Precisions@N (100, 200, 300) in Table 3. We can see that our method outperforms the baselines on the precision values of top N triples extracted.

4.4 Impact of Unlabeled Data

To further verify the impact of the unlabeled data, we conduct experiments with both utilization and non-utilization of unlabeled data. The results are presented in Figure 4. Note that, the method RCEND w/o Semi is similar to the method proposed by (Feng et al., 2018), which only removes the incorrectly labeled sentences but does not fully utilize them. We can see that it achieves higher precision over the entire level of recall compared to PCNN+HATT, the best noise-tolerate method in MIL scheme, which shows that removing noise is better than dealing with them with soft attention weights. However, it is still unable to surpass our method. In Table 4, our method also shows notable improvement over RCEND w/o Semi. This demonstrates that fully utilizing noisy data is more advantageous than reducing them.

Type	Sentence	Predict	DS
FN	C1: [**Oliver O'Grady**] is now a silver-haired , twinkly-eyed resident of [**Ireland**] , where Ms. Berg often films him in parks ...	Nationality	NA
	C2: ... said [**John Allison**] , editor of [**Opera**] magazine , based in London.	EmployedBy	NA
	C3: [**Jean-Pierre Bacri**] is a famous writer , who is too self-centered to care about his lonely , overweight , 20-year-old daughter , [**Lolita Marilou Berry**]...	ChildrenOf	NA
FP	C4: they wanted to interview [**Bill Cosby**] after they met with a former Temple University employee who has accused him of groping her in his home in suburban [**Philadelphia**]	LivedIn	BornIn
	C5: "Without the fog , [**London**] wouldn't be a beautiful city."the French painter Claude Monet wrote to his wife , Alice , during one of his long visits to [**England**] from France.	NA	Capital
	C6: MTV Goes to Africa MTV opened its first local music channel in Africa this week , a step touted by the singer [**Lebo Mathosa**] , above , at an MTV event in [**Johannesburg**].	NA	DieIn

Table 5: Examples for case study. The first three sentences are examples of false negative case and the final three are examples of false positive case.

This can be partially explained due to the label rectification of the incorrectly labeled data during semi-supervised learning with correctly labeled data which improves the generalization performance.

4.5 Impact of False Positives and False Negatives

The goal of this experiment is to inspect whether the relation classifier is enhanced more through the utilization of false negatives or through the utilization of false positives. As depicted in Figure 5, RCEND(P) only recognizes the false positive sentences in $\mathcal{D}_{\text{POS}}$ by PosAgent and regards them as unlabeled data. Likewise, RCEND(N) only discovers and utilizes false negative sentences. RCEND(P) and RCEND(N) behave similarly and achieve further improvement when utilizing both false-positive and false-negative sentences, which implies that both of them are important and promote the ability of our relation classifier. And the results in Table 4 also show utilizing false negative data performs slightly better than false positives since false negative data might be predicted as positive relation and increase samples of the target relation to learn a more accurate decision boundary.

4.6 Case Study

We sample some examples of incorrectly labeled data which are regarded as unlabeled data during training. In Table 5, it can be seen that our discriminator recognizes both false positive and false negative instances. For example, though the fact (John Allison, *EmployedBy*, Opera) is absent in the KB due to the incompleteness of the KB, C2 expresses *EmployedBy* relation and provides evidence of target relation. Additionally, C4 is mislabeled as *BornIn* due to the relational fact (Bill Cosby, *BornIn*, Philadelphia), even though it mentions *LivedIn* relation. Further more, they are all predicted correctly by our relation classifier in the end which shows that our model indeed captures the valid information of noisy data and exploits them to enhance its ability.

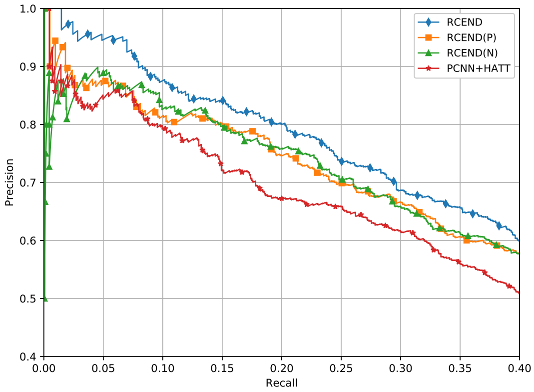

Figure 5: Precision-recall curves of our model with different settings.

5 Conclusion

In this paper, we proposed RCEND to fully exploit valid information of the noisy data in distant supervision relation classification. The instance discriminator is trained with reinforcement learning, which aims to recognize the instances mislabeled by distant supervision. We treat the correctly labeled instances as labeled data and incorrectly labeled ones as unlabeled data. Afterward, we adopt a semi-supervised learning method to learn a robust relation classifier to utilize the data. In this way, not only can our model reduce the side effect of noisy labels, but also adequately take advantage of valid information contained in noisy data. Experiments demonstrate that our model outperforms state-of-the-art baselines.

Abstract

In this paper we present a method to learn word embeddings that are resilient to misspellings. Existing word embeddings have limited applicability to malformed texts, which contain a non-negligible amount of out-of-vocabulary words. We propose a method combining FastText with subwords and a supervised task of learning misspelling patterns. In our method, misspellings of each word are embedded close to their correct variants. We train these embeddings on a new dataset we are releasing publicly. Finally, we experimentally show the advantages of this approach on both intrinsic and extrinsic NLP tasks using public test sets.

1 Introduction

Word embeddings constitute a building block of many practical applications across NLP and related disciplines. Techniques such as Word2Vec (Mikolov et al., 2013a,b) and GloVe (Pennington et al., 2014) have been extensively used in practice. One of their drawbacks, however, is that they cannot provide embeddings for words that have not been observed at training time, i.e. *Out-Of-Vocabulary* (OOV) words. In real-world tasks, the input text is often generated by people and misspellings, a common source of OOV words, are frequent (e.g. (Cucerzan and Brill, 2004) report that misspellings appear in up to 15% of web search queries). As a consequence, the quality of downstream applications of word embeddings in real-world scenarios diminishes.

Simply allowing the inclusion of misspellings into corpora and vocabularies in existing methodologies might not provide satisfactory results. The sparsity of misspellings would most likely prevent their embeddings from demonstrating any interesting properties. Trying to balance the representation of misspellings with the representation of correctly spelled variants in training data by artificially introducing misspelled variants for every word in the corpus would on the other hand cause up to an exponential growth in the size of the training data, making training of the models infeasible.

To address this deficiency, we propose Misspelling Oblivious (word) Embeddings (**MOE**), a new model combining FastText (Bojanowski et al., 2017) with a supervised task which embeds misspellings close to their correct variants. We carry out experiments on well established tasks and on their variants adapted to the misspellings problem. We also propose new methods of evaluating embeddings specifically designed to capture their quality on misspelled words. We train **MOE** embeddings on a new dataset we are releasing publicly. Finally, we experimentally show the advantages of this approach on both intrinsic and extrinsic NLP tasks using public test sets. Summarizing, we propose the following contributions:

- a novel problem and a non-trivial solution to building word embeddings resistant to misspellings;
- a novel evaluation method specifically suitable for evaluating the effectiveness of **MOE**;
- a dataset of misspellings [1] to train **MOE**.

The reminder of this paper is structured as follows. Section 2 gives an overview of the word embeddings literature. In Section 3.1 we introduce Word2Vec and FastText models. We introduce the **MOE** model in Section 3.2. Section 4 contains the descriptions of datasets we trained on and section 5 contains the description of experiments we conducted and their results. In Section 6 we present our conclusions and plans for further research.

2 Related Work

One of the first works to introduce the concept of a distributed representation for symbolic data was (Hinton, 1986). Later, the Information Retrieval community proposed techniques of embedding words into a vector space. Latent Semantic Indexing (Deerwester et al., 1990) was one of the most influential works in this area. (Bengio et al., 2003) introduced the first neural language model which jointly learned word embeddings. Although such a language model was outperforming the baselines, it was not practical because of long training time requirements. (Collobert and Weston, 2008) proposed new neural architectures for word embeddings and showed that pre-trained word embeddings can be very valuable for some downstream NLP tasks. Word2Vec (Mikolov et al., 2013b,a) got very popular both because of its effectiveness and its ability to train models on very large text corpora efficiently. (Levy and Goldberg, 2014) showed that Word2Vec's skip-gram with negative sampling model (SGNS) is implicitly equivalent to word co-occurrence matrix factorization. Besides neural approaches, (Pennington et al., 2014) proposed an SVD based architecture which gained a lot of attention because it allowed to effectively consider the popularity of each word in the model definition.

FastText (Bojanowski et al., 2017) is a popular, recent proposal in the area of word embeddings. FastText introduces subword-level features to the Word2Vec framework which enables building embeddings for OOV words (see details in Section 3.1). An alternative approach, also capable of yielding representations for OOV words, is MIMIK (Pinter et al., 2017). MIMICK learns a function from input words to embeddings by minimizing the distance between embeddings produced by a char-based approach and the pre-trained embeddings. As opposed to **MOE**, MIMICK does not support misspellings explicitly and it requires a set of pre-trained embeddings as input. We consider MIMICK to be a viable alternative to FastText which deserves future work exploring its performance on misspelled text.

3 Misspelling Oblivious Embeddings

3.1 The FastText Model

Our current work can be viewed as a generalization of FastText, which, in turn, extends the the skip-gram with negative sampling (SGNS) architecture, proposed as a part of the Word2Vec framework. In this section we will briefly discuss major additions to SGNS introduded by FastText.

Let V be a vocabulary of words and $T = w_1, w_2, \ldots, w_{|T|}$ be a text corpus, represented as a sequence of words from V. We define the context of a word $w_i \in V$ as $C_i = \{w_{i-l}, \ldots, w_{i-1}, w_{i+1}, \ldots, w_{i+l}\}$ for some l set as a hyperparameter. In the SGNS model, a word w_i is represented by a single embedding vector $\mathbf{v}_i$ equivalent to the input vector of a simple feed-forward neural network, trained by optimizing the following loss function:

$$L_{W2V} := \sum_{i=1}^{|T|} \sum_{w_c \in C_i} [\ell(s(w_i, w_c)) + \sum_{w_n \in N_{i,c}} \ell(-s(w_i, w_n))] \tag{1}$$

where ℓ denotes the logistic loss function $\ell(x) = log(1 + e^{-x})$ and $N_{i,c}$ is a set of negative samples drawn for the current word w_i and its context $w_c \in C_i$. s is the scoring function, which for SGNS is defined as the the dot product $\mathbf{v}_i^T \mathbf{u}_c$, where $\mathbf{u}_c$ is an output vector associated with the word w_c and $\mathbf{v}_i$ is an input vector associated with the word w_i. Therefore, $s\left(w_i, w_c\right) = \mathbf{v}_i^T \mathbf{u}_c$.

In FastText, we additionally embed subwords (also referred to as character n-grams) and use them to construct the final representation of w_i. Formally, given hyperparameters m and M denoting a minimum and a maximum length of an n-gram respectively, the FastText model embeds all possible character n-grams of the word such that $m \leq n \leq M$. E.g. given $m = 3$, $M = 5$ and the word *banana*, the set of n-grams we consider is $ban, ana, nan, bana, anan, nana, banan, anana$. Now, let $\mathcal{G}_{w_i}$ denote the set of all n-grams of a word $w_i \in V$ plus the word itself (e.g. $\mathcal{G}_{\text{banana}}$ is the set defined in the example above plus the word *banana* itself). Given $\mathcal{G}_{w_i}$, FastText scoring function for a word w_i and a context w_c is defined as follows:

$$s_{FT}(w_i, w_c) := \sum_{\mathbf{v}_g, g \in \mathcal{G}_{w_i}} \mathbf{v}_g{}^T \mathbf{u}_c \tag{2}$$

Therefore, the representation of w_i is expressed through the sum of the representations of each of the n-grams derived from w_i plus the representation of w_i itself. FastText optimizes the loss function in Eq.1, but uses the scoring function s_{FT} defined in Eq.2. An extensive experimentation has shown that FastText improves over the original Word2Vec skip-gram model. The loss function of FastText will be referred to as L_{FT} throughout the rest of this work.

3.2 The MOE Model

As was shown empirically in the FastText paper, the n-grams which impact the final representation of a word the most in FastText correspond to morphemes. Based on this observation, we hypothesize that although FastText can capture morphological aspects of text, it may not be particularly resistant to misspellings which can occur also withing the dominant morphemes. In this section, we present the architecture of our model - **MOE** or Misspelling Oblivious (word) Embeddings. **MOE** holds the fundamental properties of FastText and Word2Vec while giving explicit importance to misspelled words.

Loss Function. The loss function of **MOE** is a weighted sum of two loss functions: L_{FT} and L_{SC}. L_{FT} is the loss function of FastText which captures semantic relationships between words. L_{SC} or the spell correction loss aims to map embeddings of misspelled words close to the embeddings of their correctly spelled variants in the vector space. We define L_{SC} as follows:

$$L_{SC} := \sum_{(w_m,w_e)\in M} [\ell(\hat{s}(w_m, w_e)) + \sum_{w_n \in N_{m,e}} \ell(-\hat{s}(w_m, w_n))] \tag{3}$$

where M is a set of pairs of words (w_m, w_e) such that $w_e \in V$ is the expected (correctly spelled) word and w_m is its misspelling. $N_{m,e}$ is a set of random negative samples from $V \setminus \{w_m, w_e\}$. L_{SC} makes use of the logistic function $\ell(x) = log(1 + e^{-x})$ introduced in Section 3.1. The scoring function $\hat{s}$ is defined as follows:

$$\hat{s}(w_m, w_e) = \sum_{\mathbf{v}_g, g\in\hat{\mathcal{G}}_{w_m}} \mathbf{v}_g{}^T \mathbf{v}_e \tag{4}$$

where $\hat{\mathcal{G}}_{w_m} := \mathcal{G}_{w_m} \setminus \{w_m\}$. Therefore, the scoring function is defined as the dot product between the sum of input vectors of the subwords of w_m and the input vector of w_e. Formally, the term $\ell(\hat{s}(w_m, w_e))$ enforces predictability of w_e given w_m. Intuitively, optimizing L_{SC} pushes the representation of a misspelling w_m closer to the representation of the expected word w_e. It is also worth mentioning that embeddings for w_m and w_e share the same parameters set. The complete loss function of **MOE**, L_{MOE}, is defined as follows:

$$L_{MOE} := (1 - \alpha)L_{FT} + \alpha\frac{|T|}{|M|}L_{SC} \tag{5}$$

Optimizing the loss functions L_{FT} and L_{SC} concurrently is not a straightforward task. This is because two different loss functions iterate over two different datasets: the text corpus T, and the misspellings dataset M. The optimization process should be agnostic to the sizes of T and M in order to prevent results from being severely affected by those sizes. Therefore, we scale L_{SC} with the coefficient $|T|/|M|$. This way the importance of a single Stochastic Gradient Descent (SGD) update for L_{FT} becomes equivalent to a single SGD update for L_{SC}. Moreover, α is the hyperparameter which sets the importance of the spell correction loss L_{SC} with respect to L_{FT} thus making **MOE** a generalization of FastText.

4 Data

As mentioned in Section 3.2, **MOE** jointly optimizes two loss functions, each of which iterates over a separate dataset - a corpus of text for the FastText loss L_{FT} and a set of pairs (misspelling, correction) for the spell correction loss L_{SC}. In this section, we will briefly discuss how we obtain each of these datasets.

4.1 English text corpus

We use an English Wikipedia dump[2] as the text corpus T to optimize L_{FT}. The baseline FastText model is also trained on this dataset. Matt Mahoney's perl script[3] is used for pre-processing the raw Wikipedia dump. After pre-processing, the training corpus consists of $|T|= 4,341,233,424$ words. When generating the vocabulary V based on the corpus, we apply a frequency threshold of 5. After deduplication and thresholding, the size of the vocabulary for our corpus is $|V|= 2,746,061$ words. We also apply progressive subsampling of

---

[2] `dumps.wikimedia.org`

[3] `http://mattmahoney.net/dc/textdata`

frequent words in order to not assign too much importance to highly frequent words.

4.2 Misspelled data generation

The misspellings dataset M consists of a set of pairs (w_m, w_e), where $w_e \in V$ represents a (presumably correctly spelled) word from the vocabulary and w_m is a misspelling of w_e. Given the size of V, we opt for generating misspellings in an automated fashion, using an in-house misspellings generation script. The script is based on a simple error model, which captures the probability of typing a character p_m when a character p_e is expected (note that it's possible to have $p_m == p_e$), given a context of previously typed characters. The script is capable of generating misspellings of targeted edit distance for an input word w_i. In the reminder of this section, we'll discuss details of the script implementation.

Error model. In order to create the error model, we first mine query logs of a popular search engine[4] and identify cases where a query was manually corrected by a searcher. We then pivot on the modified character and for each such modification we save a triplet (c, p_m, p_e), where p_m is the pivot character before modification, p_e is the the target character after modification and c represents up to 3 characters preceding the pivot in the original query. E.g. given a query *hello worjd* corrected to *hello world*, we would generate four triplets: $[(wor, j, l), (or, j, l), (r, j, l), (\epsilon, j, l))]$, where ϵ represents an empty word. Similarly, we create triplets by pivoting on characters which have not been modified. After processing all available logs, we count each unique triplet. For each unique pair (c, p_m) of a context and a pivot, we then create a *target list* consisting of all possible targets p_e, each associated with its probability calculated based on counts. We then sort each target list in the order of decreasing probability.

Injecting misspellings. Let's consider a word $w_i \in V$ that we want to misspell. For each character $p \in w_i$, we take it's longest possible context c (up to 3 characters) and we look up the *target list* corresponding to (c, p). We then proceed along the *target list*, summing up the probabilities of subsequent targets until the sum is greater or equal to a randomly selected target probability $tp \in [0.0, 1.0]$. We then choose the corresponding target t as a replacement for p (note that in the majority of the cases $t == p$). We repeat this process for every word from V.

In order to respect real distributions of words in the text corpus T, we set the number of misspellings generated for each word $w_i \in V$ to be equal to the square root of the number of appearances of w_i in T. The total size of misspellings dataset generated in this fashion is $|M| = 20,068,964$ pairs. We make the dataset of misspellings publicly available at `https://bitbucket.org/bedizel/moe`.

5 Experiments

In this section, we describe the experimental set up used for training our models and the experiments we conducted.

5.1 Experimental setup

We use FastText[5] as a baseline for comparison since it can generate embeddings for OOV words which makes it potentially suitable for dealing with misspellings. We train the baseline model using the default hyperparameters provided by the authors. We consider character n-grams of lengths between $m = 3$ and $M = 6$, and we use 5 negative samples for each positive sample. Training **MOE** requires optimizing two loss functions L_{FT} and L_{SC} jointly. For optimizing L_{FT}, we use the same parameters as in the baseline. Additionally, to optimize L_{SC}, we experiment with 5 negative samples per positive sample. We sweep over a range of values for the coefficient combining the two losses: $\alpha \in \{0.01, 0.05, 0.1, 0.5, 0.25, 0.5, 0.75, 0.95, 0.99\}$. Both FastText and **MOE** are trained using Stochastic Gradient Descent with a linearly decaying learning rate for 5 epochs to learn vectors with 300 dimensions. We evaluate the performance of **MOE** on the following tasks: (intrinsic) Word Similarity, Word Analogy and Neighborhood Validity; (extrinsic) POS Tagging of English sentences.

We report the overlap between the misspellings seen at training time and misspellings present in tests in Table 1.

5.2 Intrisic Evaluation

We evaluate MOE on two classic intrinsic tasks, namely Word Similarity and Word Analogy and

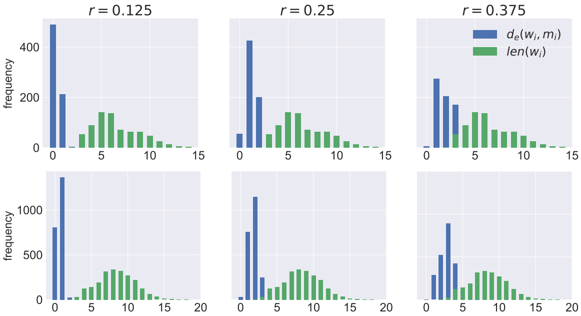

Figure 1: Distribution of edit distances $d_e(w_i, m_i)$ and lenghts of words $len(w_i)$ for WS353 variants (Top) and RW variants (Bottom).

on a novel intrinsic task evaluating the distance between vector embeddings of misspellings and their correctly spelled variants.

Word Similarity. In the word similarity task, we evaluate how well embeddings generated by **MOE** can capture the semantic similarity between two words. For this purpose, we use two datasets: (i) *WS353* (Finkelstein et al., 2001), and (ii) *Rare Words (RW)* (Luong et al., 2013). Both datasets contain pairs of words w_a, and w_b annotated with a real value in the range $[0, 10]$ representing the degree of similarity between w_a and w_b as perceived by human judges.

In order to evaluate how resilient our method is to spelling errors, for each pair of words (w_a, w_b) in the dataset, we provide a respective pair of misspellings (m_a, m_b). The misspellings are mined from search query logs of a real-world online search service. When desired misspellings are not available in the logs, we synthetically generate them using the same script we used to generate the set M (see Section 4 for details). We create 3 misspelled variants of both WS353 and RW datasets. In each variant we limit the ratio between the edit distance (Levenshtein, 1966) of the word and the misspelling $d_e(w_i, m_i)$ and the length of the word by a constant r, where $r \in \{0.125, 0.250, 0.375\}$, with $r = 0$ representing the original dataset. More precisely for each r we look for a misspelling which satisfies the following condition $d_e(w_i, m_i) = \lfloor r * len(w_i) \rfloor$. Effectively, if a word is too short to satisfy the condition, we preserve the original word (then $w_i = m_i$). Histograms in Figure 1 show the actual distribution of edit distances and lengths of words. As expected, edit distance increases steeply with the increase of r value. Edit distances are higher for the RW dataset since in average the length of words in RW is higher than on average length of words in WS353. Also, we observe that for $r = 0.125$, a significant portion of the words is not changed.

We conduct experiments for different values of the hyperparameter α which sets the trade-off between L_{FT} and L_{SC}, i.e. the importance assigned to semantic loss and misspelling loss. In the experiments, results corresponding to $\alpha = 0$ represents our baseline, FastText, since for $\alpha = 0$ the loss L_{MOE} is equal to L_{FT}.

We measure the Spearman's rank correlation (Spearman, 1904) between the distance of an input pair of words and the human judgment score both for the original and the misspelled pair. Figure 2 demonstrates the results of the word similarity task on the WS353 dataset. We observe that **MOE** is improving over FastText for WS353 variants with $r = 0.25$, and $r = 0.375$, and degrading performance when $r = 0$, and $r = 0.125$, where the majority of the words is not changed (see Figure 1 for the edit distance distribution). As we expected, larger values of α, corresponding to more attention given to misspellings during training, result in improvements for highly misspelled datasets.

For the RW dataset (Figure 2), we observe that for all the values of r, **MOE** improves over the FastText baseline when we set $\alpha = 0.05$. More specifically, when $r \in \{0, 0.125\}$ and when $\alpha <\approx 0.1$, the proposed method improves over the baseline. When the amount of misspellings is higher, i.e., $r \in \{0.25, 0.375\}$, **MOE** improves the results over the baseline for all of the α values. These results suggest that FastText may be a good baseline for dealing with low edit distance misspellings, however our model is better at capturing semantic relationships on higher edit distance misspellings. This is in line with our hypothesis presented in

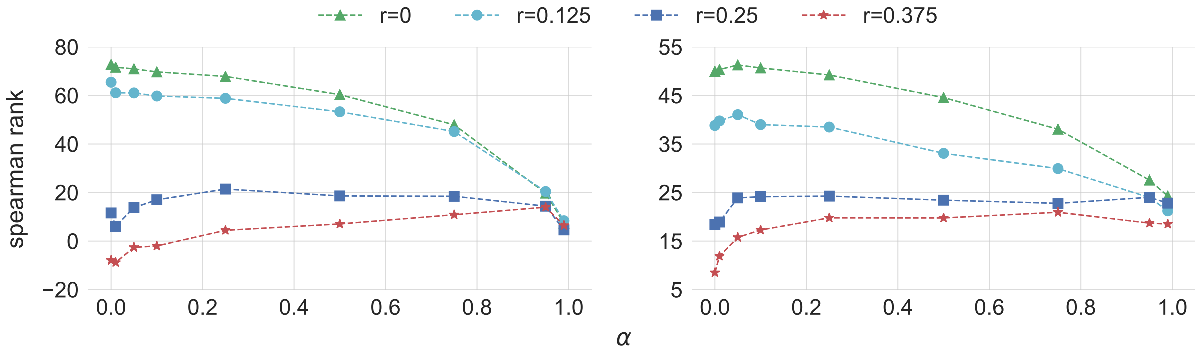

Figure 2: Experimental results for word similarity task for WS353 (Left) and RW (Right). $\alpha = 0$ values represent our baseline, FastText.

Section 3.2.

Word Analogy. In addition to the word similarity, we also test the performance of **MOE** on the popular word analogy task introduced by (Mikolov et al., 2013a). This task attempts to measure how good the embeddings model is at preserving relationships between words. A single test sample from the word analogy dataset consists of four words A, B, C, D, forming two pairs - A, B and C, D, remaining in analogous relationships ("A is to B like C is to D"). There are two types of relationships: (i) *syntactic*, related to the structure of words; and (ii) *semantic*, related to their meanings. *banana, bananas, cat, cats* is an example of a syntactic test sample. In both pairs the fact that the second word is a plural version of the first constitutes a relationship between them. *Athens, Greece, Berlin, Germany* is an example of a semantic test sample. The relationship which is being tested in this case is that between the capital of a country and the country itself.

In addition to analyzing the canonical variant of the word analogies test, we also introduce a modification which is suitable specifically to the misspellings use-case. Given a line A, B, C, D from the original analogies dataset, we misspell the first pair of words, obtaining a line A', B', C, D, where A' is a misspelling of A and B' is a misspelling of B. We want to test if the misspelled pair A', B' preserves the relationship of the pair C, D. When generating misspellings we use a procedure similar to the one used for word similarities. We create one variant of the misspelled dataset, constraining the edit distance to $r = 0.25$.

Experimental results for the canonical version of the word analogy task, presented in Figure 3, show that **MOE** performs worse than FastText on the semantic analogy task. On the other hand, **MOE** performs better than the baseline on the syntactic analogies task. The results for the misspelled variant of the task show that, the overall performance of both the baseline and **MOE** is worse than on the canonical variant. For low values of $\alpha \in \{0.01, 0.05\}$, **MOE** outperforms the baseline on the semantic task, achieving an over 67% better score than FastText for $\alpha = 0.01$. **MOE** outperforms the baseline on the syntactic task for all tested values of α, improving by over 80% for $\alpha = 0.75$. For $\alpha = 0.01$, which achieved the best semantic result, the improvement on the syntactic task is over 33%.

The trends that we observe both in the canonical and the misspelled variant of the word analogies task seem to validate our choice of the loss function for the **MOE** model. It is clear that the FastText component of the loss is indispensable to learn the semantic relationships between words. In fact, it is the only component of the loss function which attempts to learn these relationships. Therefore, decreasing it's importance (by increasing the value of α) is reflected by a decay in the semantic analogies score. The spell-correction component of the loss function, on the other hand, leverages the relationship between correctly spelled words and their misspellings. As a side effect, it also adds additional subword information into the model. This explains our good performance on the syntactic analogies task. As our results on the misspelled variant of the task show, we improve over the baseline in understanding analogies on the misspelled words, which was one of the design principles for **MOE**.

Neighborhood Validity. One of the explicit objectives of **MOE** is to embed misspellings close to their correct variants in the vector space. In order to validate this hypothesis, we check where in the neighborhood of a misspelling the correct word is situated. Formally, for a pair (w_m, w_e) of a misspelling and its correction, we pick k nearest neighbors of the misspelling w_m in the embedding space using cosine similarity as a distance metric. We then evaluate the position of the correct word w_e within the neighborhood of w_m using two metrics:

- We use *MRR* (Voorhees et al., 1999) to score the neighborhood of the embeddings of misspellings (we assign a score of 0 if the correct word is not present).
- We also compute the *neighborhood coverage* defined as the percentage of misspellings for which the neighborhood contains the correct version.

The test set contains $5,910$ pairs (w_m, w_e) sampled from a collection of data coming from a real-world online service[6]. Figure 4 shows experimental results for Neighbor Validity task. We remind that $\alpha = 0$ denotes the FastText baseline.

The test results confirm our hypothesis. We observe that MRR increases when more importance is given to the L_{SC} component of the loss for any size of the neighborhood $k \in \{5, 10, 50, 100\}$. A similar trend can be observed for the neighborhood coverage task. We conclude that, on average, we're more likely to surface the correction using **MOE** than with FastText. What is more, whenever we are able to surface the correct version of a misspelled word, its position in the ranking is higher for **MOE** than for the FastText baseline.

5.3 Extrinsic Evaluation

POS Tagging. Finally, we evaluate **MOE** on a Part-of-Speech (POS) tagging task[7]. To assess the impact of misspellings we artificially inject misspellings in the dataset. We train **MOE** on three different dataset variants: a non-misspelled dataset, to verify that **MOE** does not jeopardize the performance on correct words; a dataset where 10% of words contain a misspelling, to simulate a realistic environment where some of the words are misspelled; and finally on a dataset where 100% of words contain misspellings, to simulate a highly distorted environment. We use a state-of-the-art POS tagger (Ma and Hovy, 2016) consisting of a Conditional Random Fields (CRF) model where embeddings of the words in a sentence constitute observations and the tags to assign constitute the latent variables. This model adds a dependency on both layers of a Bi-LSTM component to the tag variables in the CRF. We evaluate the F1 score of the system for the three dataset variants we describe above. We test two different representations as input to the CRF: FastText (our baseline), and **MOE** embeddings. Our results are reported in Table 2.

We make the following observations based on the results of our experiments. Firstly, in the two extreme cases of the 100% misspelled test and correct training and the correct test and 100% misspelled training, **MOE** improves the F1 by 2 and 3.5 points respectively with respect to the FastText baseline. When the test data is 100% misspelled, **MOE** always beats the baseline by up to 2.3 points of F1. Also, in this case the loss in F1 with respect to the case where both the training and the test are

Table 2: Performance on POS tagging task for UPOS tags using CRF. The models were trained on 100 epochs with an early stop (small difference on validation error) mechanism enabled. Considering F1 score, we evaluate on 2 variants of test data: Original (correctly spelled) on the right hand side of the table and 100% misspelled on the left hand side.

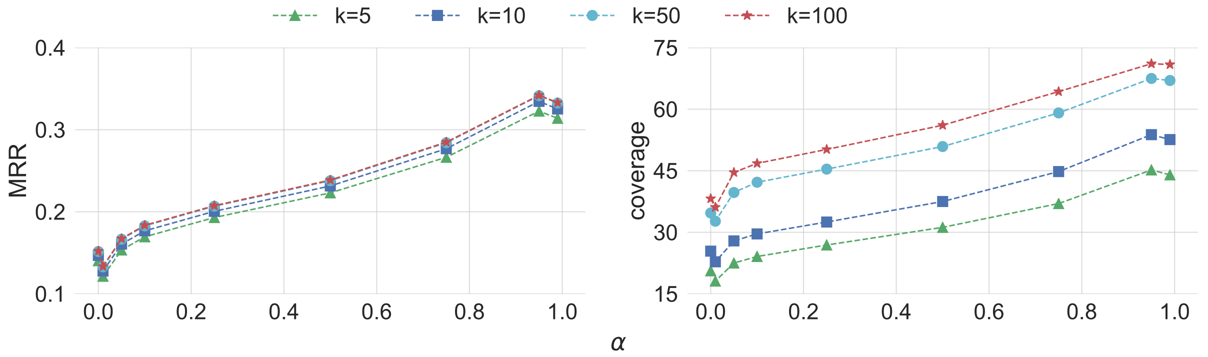

Figure 4: Experimental results for the Neighborhood Validity task. $\alpha = 0$ values represent our baseline, FastText. On the left hand side we present the resulting MRR scores. On the right hand size we present the results for the neighborhood coverage.

correct is much less then when the training data does not contain misspellings. To be remarked is the F1 score difference in the more realistic case consisting of training data that is 10% misspelled. In this case **MOE** attains a sensitive improvement of 2.3% points of F1. Finally, **MOE** does not reduce the effectiveness of the CRF POS Tagger with respect to the FastText baseline when neither the training nor the test set are misspelled. All in all, we have shown that **MOE** does not affect the effectiveness of the POS Tagger in the case of correctly misspelled words and improves sensitively the quality of the POS tagger on misspellings.

6 Conclusion and Future Work

One of the most urgent issues of word embeddings is that they are often unable to deal with malformed words which is a big limitation in the real-world applications. In this work, we proposed a novel model called **MOE**, which aims to solve a long-standing problem: generating high quality, semantically valid embeddings for misspellings.

In the experiments section, in the neighborhood validity task, we show that **MOE** maps embeddings of misspellings close to embedding of the corresponding correctly spelled word. Moreover, we show that **MOE** is performing significantly better than the FastText baseline for the word similarity task when misspellings are involved. For the canonical versions of the word similarity tasks, where misspellings are not involved, we show that **MOE** doesn't worsen the quality significantly for the WS353 dataset and improves over baseline for the RW dataset. In the word analogy task, **MOE** is able to preserve the quality of the semantic analogies similar to the baseline, while improving on the syntactic analogies. In the variant of the test where misspellings are involved, **MOE** outperforms the baseline on both semantic and syntactic questions. Finally, we have shown that **MOE** does not affect the effectiveness of the POS Tagger in the case of correctly spelled words and improves sensitively the quality of the POS tagger on misspellings.

In the future, we will test different ways of training embeddings for misspellings including the extension of the same technique to multi-lingual embeddings. We are going to test deep architectures to combine the n-grams in misspellings to better capture various interdependencies of n-grams and correct versions of words. Finally, we will assess the robustness of both character-based (Kim et al., 2016) and context-dependent embeddings (Devlin et al., 2018), (Peters et al., 2018) with respect to misspellings.

Abstract

We address relation extraction as an analogy problem by proposing a novel approach to learn representations of relations expressed by their textual mentions. In our assumption, if two pairs of entities belong to the same relation, then those two pairs are analogous. Following this idea, we collect a large set of analogous pairs by matching triples in knowledge bases with web-scale corpora through distant supervision. We leverage this dataset to train a hierarchical siamese network in order to learn entity-entity embeddings which encode relational information through the different linguistic paraphrasing expressing the same relation. We evaluate our model in a one-shot learning task by showing a promising generalization capability in order to classify unseen relation types, which makes this approach suitable to perform automatic knowledge base population with minimal supervision. Moreover, the model can be used to generate pre-trained embeddings which provide a valuable signal when integrated into an existing neural-based model by outperforming the state-of-the-art methods on a downstream relation extraction task.

1 Introduction

The task of identifying semantic relationships between entities in unstructured textual corpora, namely Relation Extraction (RE), is often a prerequisite for many other natural language understanding tasks, e.g. automatic knowledge base population, question answering, etc. RE is commonly addressed as a classification task (Bunescu et al., 2005), where a model is trained to classify relation mentions in text among a predefined set of relation types. For instance, given the sentence "Robert Plant is the singer of the band Led Zeppelin", an effective RE system might extract the triple `memberOf`(ROBERT PLANT, LED ZEPPELIN), where `memberOf` is a relation label expressed by the linguistic context *"is the singer of the band"*.

Since a given relation can be expressed using different textual patterns surrounding entities, the state-of-the-art RE models which follow this approach need a considerable amount of examples for each relation to reach satisfactory performance. Distant supervision (Mintz et al., 2009) instead uses training examples from a knowledge base, guaranteeing a large amount of (popular) relation examples without human intervention, which can be used effectively by neural networks (Lin et al., 2016; Glass et al., 2018). However, even with this technique, approaching RE as a classification task presents several limitations: (1) distant supervision models are not accurate in extracting relations with a long-tailed distribution, because they typically have a small set of instances in knowledge bases; (2) in most domains, relation types are very specific and only a few examples of each relation are available; (3) these models cannot be applied to recognize new relation types not observed during training.

In this paper, we address RE from a different perspective by reducing it to an analogy problem. Our assumption states that if two pairs of entities, (A, B) and (C, D), have at least one relation in common r, then those two pairs are analogous. Viceversa, solving proportional analogies, such as $A : B = C : D$, consists of identifying the implicit relations shared between two pairs of entities. For example, ROME:ITALY=PARIS:FRANCE is a valid analogy because `capitalOf` is a relation in common.

Based on this idea, we propose an end-to-end neural model able to measure the degree of analogical similarity between two entity pairs, instead of predicting a confidence score for each relation type. An entity pair is represented through its

Proceedings of NAACL-HLT 2019, pages 3235–3245
Minneapolis, Minnesota, June 2 - June 7, 2019.

mentions in a textual corpus, sequences of sentences where entities in the pair co-occur. If a mention represents a specific relation type, then this relationship is expressed by the linguistic context surrounding the two entities. E.g., “Rome is the capital of Italy” or “The capital of France is Paris” referring to the example above. Thus, given two analogous entity pairs represented by their textual mentions sets as input, the model is trained to minimize the difference between the representations of relations having the same linguistic patterns. In other words, the model learns the different paraphrases expressing the same relation. In our research hypothesis, a model trained in such way is able to recognize analogies between unseen entity pairs belonging to new unseen relation types by: (1) generalizing over the sequence of words in the mentions; (2) projecting the sequence of words in the mentions into a vector space representing relational semantics. This approach poses several research questions: (RQ1) How to collect and organize a dataset for training? (RQ2) What kinds of models are effective for this task? (RQ3) How should the model be evaluated?

Knowledge bases, such as Wikidata or DBpedia, consist of large relational data sources organized in the form of triples, `predicate`(SUBJECT, OBJECT). We exploit this information to build a reliable set of analogous facts used as ground truth. Then, we adopt distant supervision to retrieve relation mentions in web-scale textual corpora by matching the subject-object entities which co-occur in the same sentences (Riedel et al., 2010; ElSahar et al., 2018; Glass and Gliozzo, 2018a). Through this technique we can train our model on millions of analogy examples without human supervision.

Since our goal is to train a model able to compute the relational similarity given two sets of textual mentions, we use siamese networks to learn discriminative features between those two instances (Hadsell et al., 2006). This kind of neural network has been used in both computer vision (Koch et al., 2015) and natural language processing (Mueller and Thyagarajan, 2016; Neculoiu et al., 2016) in order to map two similar instances close in a feature space. However, in our setting each instance consists of a set of mentions, therefore it is inherently a multi-instance learning task[1]. We propose a hierarchical siamese network with an attention mechanism at both word level (Yang et al., 2016) and at the set level (Ilse et al., 2018) in order to select the textual mention which better describes the relation. To the best of our knowledge, this is the first application of a siamese network by pairing sets of instances, so it can be considered a novelty of this work.

We evaluate the generalization capability of our model in recognizing unseen relation types through an one-shot relational classification task introduced in this paper. We train the parameters of the model on a subset of most frequent relations of one of three different distantly supervised datasets used in our experiments. Then, we evaluate it on the long-tailed relations of each dataset. During the test phase, only a single example for each unseen relation is provided. This example is not used to update the parameters of the model as in a classification task, but rather to produce the vector representation of the relation itself. Entity pairs having mention sets close to this representation are more likely to be analogous. The experiments show promising results of our approach on this task, compared with the recent deep models commonly used for encoding textual representations (Conneau et al., 2017). However, when the number of the unseen relation types increases, the performance of our model become far from the results obtained in the one-shot image classification (Koch et al., 2015), opening an interesting challenge for future work.

Finally, our model shows a transfer capability in other tasks through the use of its pre-trained vectors. Indeed, a branch of the hierarchical siamese network can be used to generate entity-entity representations given sets of mentions as input, that we call *analogy embeddings*. In our experiments, we integrate those representations into an existing end-to-end model based on convolutional networks (Glass and Gliozzo, 2018b), outperfoming the state-of-the-art systems on two shared datasets commonly used for distantly supervised relation extraction.

Relation Extraction Several approaches have been proposed in the literature to address the problem of extracting relations from text with minimal supervision.

The bootstrapping method (Agichtein and Gra-

---

[1] Due to the weak supervision, the whole set of mentions is labeled, but each individual mention in the set is unlabeled.

vano, 2000) collects the textual patterns between a few example pairs of entities iteratively, and uses them to retrieve other pairs of entities from a corpus. This method is limited by the semantic drift issue since wrong patterns might be collected.

OpenIE (Mausam et al., 2012) is an unsupervised method for extracting triples from text, where the relations are linguistic phrases. The lack of a canonical form for the extracted relations makes this approach not suitable to populate knowledge bases with a fixed schema.

Universal schema (Riedel et al., 2013) addresses RE by combining the OpenIE and knowledge base relations through a matrix factorization technique typically adopted in the collaborative filtering approach of recommendation systems. The column-less (Toutanova et al., 2015) and row-less (Verga and McCallum, 2016) extensions of this method can handle unseen entity pairs and textual relations when combined (Verga et al., 2017).

The one-shot RE has been addressed by (Yuan et al., 2017), who adopt a siamese network to extract fine-grained relations which typically have few training examples. This model has two main limitations. Firstly, it works only by pairing two single mentions and is not able to handle a whole set of mentions referring to a relation instance. Our hierarchical siamese network overcomes this issue by using an attention mechanism at both word and mention level. Moreover, their one-shot evaluation mainly focuses on extracting the same relation types seen during training. Instead, the goal of our one-shot task is to evaluate the transfer capability in extracting unseen relation types across domains using a single pre-trained model.

Recently, (Levy et al., 2017) propose to reduce RE slot-filling to a question answering problem. The main idea is to build a set of question-answer pairs for the relations in knowledge bases and train a reading comprehension model using this dataset. This approach shows promising zero-shot capability in extracting unseen relation types. However, the schema querification phase requires a crowd-sourcing effort. Our method uses distant supervision, so it does not need any kind of manual annotations.

Word Analogy The analogy problem, from a computational linguistic perspective, was originally addressed by (Turney, 2006) who investigate several similarity measures for solving word analogy questions in the Scholastic Aptitude Test dataset. The authors provide an interesting argument regarding the different types of similarities, attributional and relational, and their use in solving word analogies. Attributional similarity, typical of the word vector space models, is useful for synonym detection, word sense disambiguation and so on. Instead, relational similarity is suitable for understanding analogies between two pairs of words. Our neural-based analogy approach is inspired by this finding.

Recently, word analogies, namely the proportional analogy between two word pairs such as $a : b = c : d$, have been used by (Mikolov et al., 2013; Pennington et al., 2014) to show the capability of word embeddings to discover linguistic regularities in word contexts using vector offsets (e.g. $king - man + woman = queen$). The works in (Gladkova et al., 2016; Vylomova et al., 2016) explore the use of word vectors to model the semantic relations. The proportional analogy is also adopted by (Liu et al., 2017) as analogical inference in order to learn multi-relational embeddings which are evaluated on knowledge base completion benchmarks.

However, in order to apply word embedding models to proportional analogy, the model must have seen the words during training. This approach is unsuitable for computing the analogy between out-of-vocabulary words. Our approach overcomes this limitation, since it works by considering the contexts where the entities occur.

3 Learning Relations by Analogy

Given two pairs of entities, (A, B) and (C, D), their semantic relations can be expressed by their mentions in text, $(A, B) = \{S_i\}$ and $(C, D) = \{S_j\}$. Specifically, $\{S_i\}$ and $\{S_j\}$ are the sets of sentences where (A, B) and (C, D) co-occur in the same set. Two pairs of entities are analogous, $A : B = C : D$, iff their mentions sets, or part of them, express the same relation r. Knowledge bases, such as Wikidata, contain millions of trusted facts in form of triples, $r(A, B)$, namely pairs of entities in known relationships. We leverage these relational data sources as ground truth in order to collect a set of proportional analogy statements. Then, we build a dataset through the distant supervision technique by retrieving the mentions sets from web-scale corpora.

Our idea is to train a neural network to solve

Figure 1: Learning relations by analogy through matching the facts from knowledge bases with textual corpora.

the analogy problem between any two entity pairs in this dataset, as long as they are described by the textual contexts where they co-occur. In other words, this task is reduced to a binary classification of determining whether the relational similarity between the representations of two sets of mentions exceeds a threshold. The network is trained by feeding two sets of mentions related to two different pairs, and it is optimized to return a positive label if the two entity pairs are analogous, namely they share at least one relation, or a negative label otherwise.

Figure 1 provides an example of this process. For the relation `memberOf`, the entity pairs (ROBERT PLANT, LED ZEPPELIN) and (DAVID GILMOUR , PINK FLOYD) are sampled. The two entity pairs are converted into their respectively mentions sets gathered from a textual corpus, such as Wikipedia. Since these two entity pairs are analogous, the network is optimized to learn the representations of the two textual contexts to be close into the feature space. In fact, the first sentences of both pairs represent the concept of membership of a band, even if they are expressed using different words. Based on our assumption, the aim is to learn how to encode the relational representations through the different paraphrases of the same relation. However, the model also needs negative examples during the training phase. We randomly select an entity pair from a different relation for each positive example, such as (ROBERT PLANT, LED ZEPPELIN) and (PARIS, FRANCE). Since we cast the problem as a binary classification task, we create a balanced dataset of positive and negative examples.

Siamese neural networks (Bromley et al., 1993) are well suited to this task because they are specifically designed to compute the similarity between two instances. A siamese network has symmetric twin sub-networks which share the same parameters, but are joined by an energy function at the head. Weight sharing forces the two similar instances to be mapped to very close locations in feature space because both of the sub-networks are optimized using the same function. In computer vision, siamese architectures based on convolutional neural networks (Hadsell et al., 2006; Koch et al., 2015; Vinyals et al., 2016) have shown promising performance in learning highly discriminative features by pairing images that belong to the same class. Likewise, our hypothesis is that a siamese network trained by matching two distinct mentions sets that share the same relation is able to learn how to map patterns of words across the sentences containing the two pairs of entities so as to capture the semantics of the relation. For instance, given the example in Figure 1 an effective siamese network should determine that the patterns for *"is the lead singer"* and *"was the guitarist"* express the same relation, `memberOf`.

To train a siamese network based on our approach, we have to face the following challenges: (1) the language may be highly variable and the same relation expressed in a multitude of different ways; (2) the mentions set of an entity pair consists of several sentences, each of which might express different relations, hence this is a multi-instance learning problem; (3) distant supervision could provide a wrong labeling, namely sentences which do not express any specific relations.

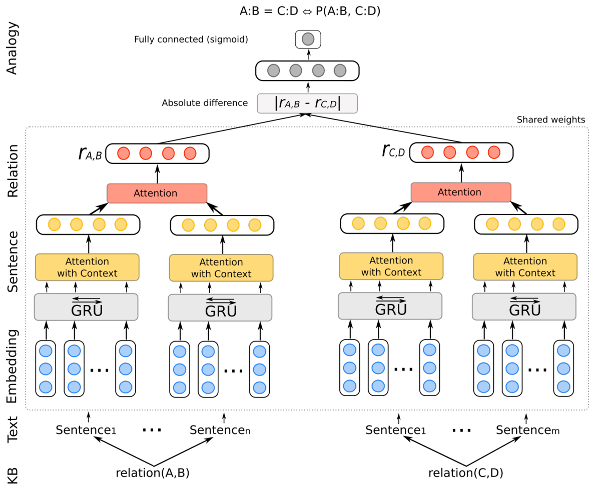

Figure 2: Hierarchical siamese network.

4 Hierarchical Siamese Network

To face these challenges, we propose a Hierarchical Siamese Network (HSN) architecture as shown in Figure 2. In the following paragraphs, we describe the details of each component.

Input Representation The HSN takes as input two entity pairs represented by their mentions sets. Since the twin sub-networks of the HSN are the same, we focus only on one of these. Given a triple $r(A, B)$ from a knowledge base, the relation r can be expressed through the set of sentences in a textual corpus where the the two entities co-occur: $r(A, B) = \{S_1, S_2, \ldots, S_n\}$, with $S_i = \{w_{i1}, w_{i2}, \ldots, w_{ik}\}$, where w_{ij} represents the j-th word in the sentences S_i, $\forall i \in 1 \leq i \leq n$ and $\forall j \in 1 \leq i \leq k$. The purpose of a sub-network is to learn a low-rank vector representation $r_{A,B}$ for the relation r expressed by the pair (A, B). This is done by hierarchically composing the word and sentence representations.

Gated Recurrent Unit for Sentence Encoder Given a sentence $S_i = \{w_{i1}, w_{i2}, \ldots, w_{ik}\}$, we map each one-hot word representation of w_{ij} into its word embedding $x_{ij} = Ew_{ij}$, where $E^{d,|V|}$ is a matrix of real-valued vectors of size d, and V is a (fixed) vocabulary. Word embeddings are designed to encode syntactic and semantic features of words and can be randomly initialized or pre-trained on large corpora. We use pre-trained GloVe (Pennington et al., 2014) embeddings for our purposes. We encode the whole sentence S_i into a low-rank representation by composing its constituent word embeddings. An effective way to perform such an encoding is using recurrent neural networks (RNN) which are able to compose word embeddings by taking into account their positions in the sentence conditioned on the previous words. For our model, this capability is critical in order to detect sequences of words which express a particular relation, such as *"is the capital of"*. We use a bidirectional GRU (Bahdanau et al., 2014) to gather the information from both directions for words. Formally, given $\overrightarrow{h_{ij}} = \overrightarrow{GRU}(x_{ij})$ and $\overleftarrow{h_{ij}} = \overleftarrow{GRU}(x_{ij})$, the hidden state $h_{ij} = [\overrightarrow{h_{ij}}, \overleftarrow{h_{ij}}]$ is a new dense representation of w_{ij} which encodes also the information of the whole sentence.

Word Attention with Context Vector However, only certain words in a sentence express the semantics of a relation, therefore we need a strategy to automatically identify them during the training. For example, the words *"singer"* and *"guitarist"* at both sides of Figure 1 are good candidates to express the relation `member`. We use the attention mechanism with a context vector proposed in (Yang et al., 2016) to reward such words which are important to the meaning of a relation and then aggregate their information in the sentence representation. In detail, $s_i = \sum_k \alpha_{ik} h_{ik}$, where $\alpha_{ij} = \frac{exp(u_{ij}^T u_w)}{\sum_k exp(u_{ik}^T u_w)}$, and $u_{ij} = tanh(W_w h_{ij} + b_w)$. The vector s_i represents the sentence S_i and is computed as the weighted sum of the GRU-based word vectors h_{ij} using the normalized attention weights α_{ij}. The parameters for the attention mechanism are the weights and biases W_w, b_w and u_w, the context vector, a global fixed vector which, independently from a specific word, represents a kind of query which helps to inform what is the most informative word for each analogy. The context vector u_w essentially works like a memory mechanism, as described in (Sukhbaatar et al., 2015; Kumar et al., 2016).

Attention for Multi-instance Relation Representation Once all sentences in the mentions set are encoded, the aim of the last layer of a sub-network is to produce the vector $r_{A,B}$ which represents the pair (A, B). However, while weak supervision guarantees a large amount of training data without any human intervention, wrongly labeled sentences inevitably occur. For instance, the S2 of the pair on the right side in the Figure 1 does not express the relation `member` precisely, therefore a wrong bias could propagate during the training phase. This issue is typically addressed through a multi-instance setting, where a model should identify the correct instance(s) from a bag. Recently, end-to-end neural architectures have been proposed to address this multi-instance classification problem (Wang et al., 2018; Feng and Zhou, 2017) by proposing several ways to aggregate the unlabeled instances, such as taking their average. Our goal is to have a model which is able to properly select the most relevant sentences by ascribing different weights to the encoded sentences. For this purpose, we adopt an attention mechanism at the sentence level. It is important to point out that the sentences in the mentions set do not have any temporal relationship, therefore we adapt the standard attention strategies as described in (Ilse et al., 2018). In detail, $r_{A,B} = \sum_i \alpha_i s_i$ is the embedding of the relation r given the pair (A, B), with $\alpha_i = \frac{exp(u_i^T u_s)}{\sum_k exp(u_k^T u_s)}$, $u_i = tanh(W_s s_i + b_s)$, where W_s and u_s are parameters.

Merging Layer and Training Strategy There are several ways to merge the output of the two sub-networks in order to learn the analogical similarity between them. For instance, (Hadsell et al., 2006) propose a contrastive loss with the aim of decreasing the distance between two instance representations. However, we adopt the strategy proposed in (Koch et al., 2015), in which the metric distance is induced by a fully-connected layer with a sigmoidal output unit on the absolute difference between the representations output by twin networks. Thus, given $r_{A,B}$ and $r_{C,D}$ the two relation embeddings which encode the whole mentions sets of the two entity pairs, we can compute the degree of analogy between them with $p = \sigma(W_r(|r_{A,B} - r_{C,D}|))$, where the parameters W_r measure the importance of each element of the difference vector, and they are learned in a end-to-end fashion, together with the relation representations. We build a training set by pairing the mentions sets of the entity-entity pairs from a KB, following the idea discussed in the next section. Thus, we can reduce the analogy task to a binary classification problem, so that $p = P((A, B), (C, D); \Theta)$ is equal to 1 if $A : B = C : D$, 0 otherwise. We learn Θ (all the parameters of HSN) using a gradient-based method which minimizes a cross-entropy loss function with the L2 regularization.

Table 1: Statistics of the distantly supervised datasets.

5 Experiments

Once the analogy model is trained, it has two different capabilities. First, the whole HSN architecture can be used as a binary classifier in order to infer if two entity pairs, expressed by their mentions sets, are analogous. Second, we can use its subnetwork before the merge layer as a feature extractor to generate entity-entity vectors given sets of sentences as input which can be used as pretrained analogy embeddings in other tasks. We evaluate our model on the one-shot relational classification and distantly supervised relation extraction benchmarks.

5.1 Datasets

In the entire experimental protocol we exploit three different datasets (see the supplemental material for details). **T-REX** (ElSahar et al., 2018) is a large scale alignment dataset between Wikipedia abstracts and Wikidata triples, having 685 unique relations. **NYT-FB** (Riedel et al., 2010) is a standard benchmark for distantly supervised relation extraction. The text of New York Times was processed with a named entity recognizer and the identified entities linked by name to Freebase. **CC-DBP** (Glass and Gliozzo, 2018a) is a web-scale KB population benchmark. It combines the text of Common Crawl with the entity-relation-entity triples from 298 frequent relations in DBpedia. Mentions of DBpedia entities are located in text by matching the preferred label. This task is similar to NYT-FB, but it has a much larger number of relations, triples and textual contexts. The statistics of the three datasets are summarized in Table 1. Aside from the difference in size and KB adopted, it worth noting also the difference in terms of corpus style of these datasets. For instance, T-REX has well-written textual mentions, because the sentences are extracted from Wikipedia. Conversely, CC-DBP and NYT-FB contain dirtier sentences which mean a high probability of incurring wrong labeling.

5.2 Training and Implementation Details

For both benchmarks, we use the same analogy model trained only once on a subset of the relations in T-REX. In detail, we discard all relations having less than 20 entity pairs, collecting 482 relations. We sort the relations by the number of instances, and we took the most frequent 60% of them to train the HSN. We use the remaining 20% of the relations for validation and the least frequent 20% as a corpus to implement one of the three one-shot classification tasks. For the validation and test partitions we randomly select only 20 entity pairs for each relation. This becomes a useful test set for the one-shot validation. To train the HSN, we select a balanced number of positive and negative examples out of the training split based on these rules: (1) for each relation, we randomly extract a set of 20 entity pairs; (2) out of this set, we generated all possibile combinations, $\binom{20}{2} = 190$, as positive pairing examples; (3) for each combination, we create a negative example by randomly selecting an entity pair from another relation. After these steps, we collect a bucket of 109,820 proportional analogy training examples.

We iterate this process throughout the training phase by selecting a different buckets at each iteration to prevent overfitting. The training is monitored by computing the binary accuracy over a fixed validation set, consisting of 36,480 analogy examples, built by adopting the same criteria described above. We initialize our word embedding layer with the pre-trained GloVe vectors consisting of 6B tokens with 50 dimensions. The word embedding weights are not updated during training. The number of mentions for each entity pair is fixed to 3, based on their average on T-REX (see Table 1).

5.3 One-shot Relational Classification

Task Given an unseen entity pair (A^t, B^t) and its mentions set $\langle A^t, B^t \rangle$, the one-shot relation classification task is to categorize this test pair (A^t, B^t) into one of N relation types, with the restriction that for each relation type $r_i, \forall i \in N$, we are given only one entity pair (A^i, B^i) together with its mentions set $\langle A^i, B^i \rangle$ as training. We can cast the one-shot classification in terms of a relational similarity as follows:

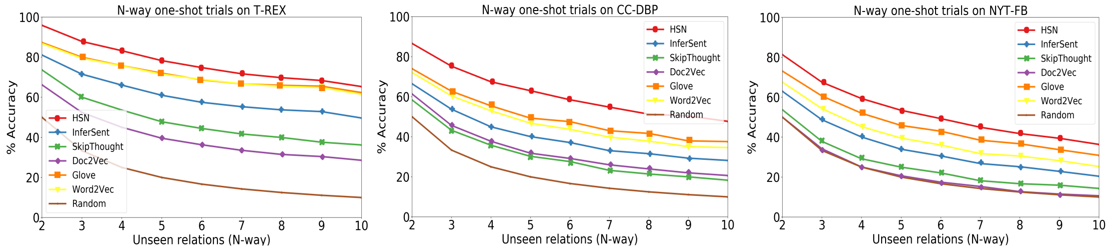
$$r_i = \arg\max_i sim_M(\langle A^t, B^t \rangle, \langle A^i, B^i \rangle) \quad (1)$$

where sim_M is a similarity score, using the method M, which measures the analogy between the train and test entity pairs through their mentions sets. We implemented sim_{HSN} using the HSN trained as described above. The two mentions sets are given as input to the network and their similarity is computed using the sigmoidal output of the last layer.

Baselines A method M should be robust in facing the *unseen* entity pairs used for testing. Training a standard RE model using just one example cannot provide a suitable baseline. Furthermore, since the two new entities that we want to classify might not be present in an existing knowledge graph, we could not apply relational embeddings (Bordes et al., 2013) as well. Thus, the use of the contexts surrounding the two entities in the mentions sets to compute the relational similarity score is needed. In other words, we cast the task of one-shot relational classification to a problem of measuring textual (i.e. mentions) similarity with the aim to prove that our pre-trained siamese model is able to grasp the semantics of relations better than the other pre-trained text representation models.

We implemented five baselines commonly used to encode textual representations. First, we use the pre-trained Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) embeddings. The score is given by the cosine similarity between the bag-of-means for the two entity pairs, averaging the word vectors in the mentions sets. We also adopt Doc2Vec (Le and Mikolov, 2014) to derive entity pair vectors, and comparing them using cosine similarity. For each entity pair, a pseudo-document embedding is created by concatenating its mentions sets. Finally, we compare HSM with the pre-trained Skip-Thought (Kiros et al., 2015) and InferSent (Conneau et al., 2017) sentence encoders, which are the state-of-the-art in computing textual similarity. An entity pair vector is obtained by averaging the embeddings of each sentence in the mentions set.

One-shot trials We follow the experimental setup described in (Koch et al., 2015) to create our one-shot benchmark. For each dataset, we select the 20% of less frequent relations sorted by the number of entity pairs, having at least 20 instances. Therefore, we collect three different one-shot test sets of 92, 55 and 11 unseen relation types for T-REX, CC-DBP and NYT-FB,



(a) T-REX (b) CC-DBP (c) NYT-FB

Figure 3: One-shot relational classification results for N-way unseen relation types.

respectively. The reason behind this criteria is to prevent the overlap of the semantic relation types between the train data and the different one-shot test sets. In fact, frequent relations, such as `location` or `birthPlace`, are common in all three datasets, and they are used to train our HSN. Moreover, using the long-tailed relations, such as `portOfRegistry`, we emulate a scenario where only a small set of relation examples are available, making more challenging the task. To evaluate the one-shot capabilities on N-way classes: (1) N different relation types are selected; (2) we sample one(shot) entity pair example for each of the selected N relation types; (3) we choose another entity pair used as test example from one of the N relation types. All the selections in these three steps are random. If the relation type returned by the Eq. 1 is equal to the relation type of the selected test example, then the one-shot trial is correct, otherwise it is incorrect. We repeated this operation k times for N from 2 to 10, for each of the three datasets. We choose k equal to 10,000, so that the random baseline converges to $100/N$, in order to create an unbiased testbed.

Results and Discussion The results are reported in Figure 3. Our model outperforms all the baselines on the test split of T-REX, reaching an accuracy range from 95.87% to 65.33% for N-way one-shot trials. This behavior remains constant also for the other two datasets, showing the solidity of HSN even though it has been trained on a different corpus using relations from an another ontology. This result confirms that our model is able to generalize on the linguistic contexts expressing relations, as well as the capability to learn how to transfer this information to other relations not observed before. The supplemental file reports some one-shot trial examples.

The lower accuracy on CC-DBP and NYT-FB might be caused by the different style of the corpora (Wikipedia vs. Web pages). Indeed, the test set of T-REX is build using the same corpus which HSN is trained on. The Wikipedia abstracts consist of well-written contents, typically the definition of one of the two entities in the pairs. Thus, T-REX can be considered an easier dataset compared with the other two.

Surprisingly, the average vectors using Word2Vec and GloVe obtain remarkable performance compared to state-of-the-art sentence encoders. This might be due to the way how these sentence models are trained. For instance, InferSent is trained using a natural language inference dataset, which might be not suitable to learn representations which represent relations in text. Instead, HSN is trained and optimized to learn and encode relational representations. However, this aspect deserves to be dealt with more deeply, as does the comparison of HSN on the shared textual similarity benchmarks; we think this is a clear path for future research.

5.4 Transfer Learning in Relation Extraction

We also evaluate the ability of the analogy model to provide low-rank representations for entity pairs which are useful for more traditional relation extraction tasks, where a corpus of text has to be processed and relevant relations in a predefined schema have to be recognized.

Table 2: Three examples of relational similarity between two pairs of entities computed by our HSN. For each example, we report the unseen relation type, the mentions related to each pair, and the similarity score. We report only the mention having the highest attention weight. The examples show the ability of the analogy model in providing a high score to two mentions which represent the same relation, even if they are expressed using different textual contexts.

To this aim, we use the sub-network of our HSN before the merge layer, and we feed the mentions set of each entity pair of instances as found in the corpus to generate an analogy embedding as a vector of features. In detail, given a set of mentions referring to an entity pair (A, B) as input, the pre-trained HSN generates an embedding $r_{A,B}$ (see Figure 2) which represents the relation between those two entities. Then, we concatenate these embeddings to the penultimate layer of a relation extraction model, PCNN-KI (Glass and Gliozzo, 2018b), based on a convolutional neural network, which is the state-of-the-art for this benchmark. The final fully-connected layer uses the representation from HSN in combination with its own learned multi-instanced vector representation to predict a confidence score for each relation. During the training of this joint model, PCNN-KI+Analogy, we freeze our analogy embeddings in order to avoid the loose the *knowledge transfer* capability.

As for the one-shot setting described before, we use the same pre-trained the HSN on the T-REX and we used it as a feature extractor for entity pairs in both train-test standard splits of NYT-FB, as used in (Zeng et al., 2015; Lin et al., 2016). Figure 4 reports the results of our evaluation. The model which uses the features generated by HSN largely improve the performances of PCNN-KI, despite the HSN is trained on a different corpus and using a different KB. In the same chart, we also report a compared evaluation for other approaches proposed in the literature for the NYT-FB benchmark: PCNN+ATT (Lin et al., 2016), CNN+ATT (Zeng et al., 2015), MIML-RE (Surdeanu et al., 2012), Hoffmann (Hoffmann et al., 2011), Mintz (Mintz et al., 2009).

We run the evaluation also on CC-DBP, a larger dataset for distantly supervised RE, using the same train-test setting adopted in (Glass and Gliozzo, 2018b). As done for the NYT-FB dataset, we incorporate the analogy embeddings generated by the same HSN trained on the T-REX. The results confirm the improvements obtained by PCNN-KI model if it integrates our pre-trained embeddings (Table 3).

	AUC	F1
PCNN-KI	0.437	0.468
PCNN-KI+Analogy	**0.500**	**0.504**

Table 3: AUC and F1 results on CC-DBP.

6 Conclusion and Future Work

In this paper, we proposed a novel approach to learn representations of relations in text. Alignments between knowledge bases and textual corpora are used as ground truth in order to collect a set of analogies between entity pairs. We designed a hierarchical siamese network trained to recognize those analogies. The experiments showed the two main advantages of our approach. First, the model can generalize on new unseen relation types, obtaining promising results in one-shot learning compared with the state-of-the-art sentence encoders. Second, the model can generate low-rank representations can help existing neural-based models designed for other tasks. As future work, we plan to continue our investigation by extending the method with other ideas. For instance, the use of positional embeddings, as well as the use of placeholders replacing the entities in the textual mentions are promising future directions. Finally, we plan also to explore the use of analogy embeddings in other tasks, such as question answering and knowledge base population.

Abstract

Because large, human-annotated datasets suffer from labeling errors, it is crucial to be able to train deep neural networks in the presence of label noise. While training image classification models with label noise have received much attention, training text classification models have not. In this paper, we propose an approach to training deep networks that is robust to label noise. This approach introduces a non-linear processing layer (*noise model*) that models the statistics of the label noise into a convolutional neural network (CNN) architecture. The noise model and the CNN weights are learned jointly from noisy training data, which prevents the model from overfitting to erroneous labels. Through extensive experiments on several text classification datasets, we show that this approach enables the CNN to learn better sentence representations and is robust even to extreme label noise. We find that proper initialization and regularization of this noise model is critical. Further, by contrast to results focusing on large batch sizes for mitigating label noise for image classification, we find that altering the batch size does not have much effect on classification performance.

1 Introduction

Deep Neural Networks (DNNs) have led to significant advances in the fields of computer vision (He et al., 2016), speech processing (Graves et al., 2013) and natural language processing (Kim, 2014; Young et al., 2018; Devlin et al., 2018). To be effective, supervised DNNs rely on large amounts of carefully labeled training data. However, it is not always realistic to assume that example labels are clean. Humans make mistakes and, depending on the complexity of the task, there may be disagreement even among expert labelers. Further, samples drawn from the class conditional densities with overlapping supports gives rise to the label noise in training datasets. To support noisy labels in data, we need new training methods that can be used to train DNNs directly from the corrupted labels to significantly reduce human labeling efforts. Zhu and Wu (2004) perform an extensive study on the effect of label noise on classification performance of a classifier and find that noise in input features is less important than noise in training labels.

In this work, we add a *noise model* layer on top of our target model to account for label noise in the training set, following (Jindal et al., 2016; Sukhbaatar et al., 2014). We provide extensive experiments on several text classification datasets with artificially injected label noise. We study the effect of two different types of label noise; *Uniform label flipping (Uni)*, where a clean label is swapped with another label sampled uniformly at random; and *Random label flipping (Rand)* where a clean label is swapped with another label from the given number of labels sampled randomly over a unit simplex.

We also study the effect of different initialization, regularization, and batch sizes when training with noisy labels. We observe that proper initialization and regularization helps the noise model learn to be robust to even extreme amounts of noise. Finally, we use low-dimensional projections of the features of the training examples to understand the effectiveness of the noise model.

The rest of the paper is organized as follows. Section 2 discusses the various approaches in literature to handle label noise. In Section 3, we describe the problem statement along with the proposed approach. We describe the experimental setup and datasets in Section 4. We empirically evaluate the performance of the proposed approach along with the discussion in Section 5 and finally conclude our work in Section 6.

Proceedings of NAACL-HLT 2019, pages 3246–3256
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related Work

Learning from label noise is a widely studied problem in the classical machine learning setting. Earlier works (Brodley and Friedl, 1999; Rebbapragada and Brodley, 2007; Manwani and Sastry, 2013) consider learning from noisy labels for a wide range of classifiers including SVMs (Natarajan et al., 2013) and fisher discriminants (Lawrence, 2001). Traditional approaches handle label noise by detecting and eliminating the corrupted labels. More details about these approaches can be found in (Frénay and Verleysen, 2014).

Recently, DNNs have made huge gains in performance over traditional methods on large datasets with very clean labels. However large real-world datasets often contain label errors. A number of works have attempted to address this problem of learning from corrupted labels for DNNs. These approaches can be divided into two categories; attempts to mitigate the effect of label noise using auxiliary clean data, and attempts to learn directly from the noisy labels.

Presence of auxiliary clean data: This line of research exploits a small, clean dataset to correct the corrupted labels. For instance, Li et al. (2017) learn a teacher network with clean data to re-weight a noisy label with a soft label in the loss function. Similarly, Veit et al. (2017) use the clean data as a label correction network. One can use this auxiliary source of information to do inference over latent clean labels (Vahdat, 2017). Further, Yao et al. (2018) models the auxiliary trustworthiness of noisy image labels to alleviate the effect of label noise. Though these methods show very promising results, the absence of clean data in some situations might hinder the applicability of these methods.

Learning directly from noisy labels: This research directly learns from the noisy labels by designing a robust loss function, or by modeling the latent labels. For instance, Reed et al. (2014), apply bootstrapping to the loss function to have consistent label prediction for similar images. Similarly, Joulin et al. (2016) alleviate the label noise effect by adequately weighting the loss function using the sample number. Jiang et al. (2017) propose a sequential meta-learning model that takes in a sequence of loss values and outputs the weights for the labels. Ghosh et al. (2017) further explores the conditions on loss functions such that the loss function is noise tolerant.

A number of approaches learn the transition from latent labels to the noisy labels. For example, Mnih and Hinton (2012) propose a noise adaptation framework for symmetric label noise. Based on this work, several other works (Sukhbaatar et al., 2014; Jindal et al., 2016; Patrini et al., 2017; Han et al., 2018) account for the label noise by learning a noisy layer on top of a DNN where the learned transition matrix represents the label flip probabilities. Similarly, Xiao et al. (2015) propose a probabilistic image conditioned noise model. Azadi et al. (2015) proposed an image regularization technique to detect and discard the noisy labeled images. Other approaches include building two parallel classifiers (Misra et al., 2016) where one classifier deals with image recognition and the other classifier models humans reporting bias.

All of these approaches have targeted image classification. In this work, we propose a framework for learning from noisy labels for text classification using a DNN architecture. Similar to (Sukhbaatar et al., 2014; Jindal et al., 2016; Patrini et al., 2017), we append a non-linear processing layer on top of this architecture to model the label noise. This layer helps the base architecture to learn better representations, even in the presence of label noise. We empirically show that, for better classification performance, the knowledge of noise transition matrix is not needed. Instead, the process forces the DNN to learn better sentence representations.

3 Problem Statement

In a supervised text classification setting where $\mathbf{x}_i \in \mathbf{R}^d$ is a d-dimensional word embedding of the ith word in a sentence of length l (padded wherever necessary), we represent the sample as a temporal embedding matrix $\mathbf{X} \in \mathbf{R}^{d\times l}$ which belongs to one of the K classes. Let the noise-free training set be denoted by

$$\mathcal{D} = \{(\mathbf{X}_1, y_1), (\mathbf{X}_2, y_2), \cdots, (\mathbf{X}_n, y_n)\},$$

where $y_i \in \{1, \ldots, K\}$ represents the category of ith sample, n is the total number of training samples, and there is an unknown joint distribution $p(\mathbf{X}, y)$ on the sample/label pairs. This temporal representation of a sample $\mathbf{X}$ is fed as input to a classifier on the training set $\mathcal{D}$ with sample categories y. However, as mentioned in Section 2, we cannot access the true noise-free samples labels and instead, observe noisy labels corrupted by an unknown noise distribution. Let this *noisy* training set be denoted by

$$\mathcal{D}' = \{(\mathbf{X}_1, y_1'), (\mathbf{X}_2, y_2'), \cdots, (\mathbf{X}_n, y_n')\},$$

where y_i' represents the corrupted label for the sentence $\mathbf{X}_i$. In this work, we suppose the label noise is *class-conditional*, where the noisy label y_i' depends only on the true label y_i, but not on the input $\mathbf{X}_i$ or any other labels y_j or y_j'. Under this model, the label noise is characterized by the conditional distribution

$$p(y' = i | y = j) = \Phi_{ij},$$

which we describe via the $K \times K$ column-stochastic matrix Φ_{ij}, parameterized by a matrix $\mathbf{Q} = \{\Phi_{ij}\}$.

In our experiments, we artificially inject label noise into the training and validation sets. We fix the noise distribution Φ_{ij} and, for a training sample, we generate a noisy label by drawing i.i.d from this noise distribution Φ_{ij}. However, we do not alter the test labels.

Though the proposed approach works for any noise distribution, for this study, we focus on two different types of label flip distributions. We use a noise model parameterized by the overall probability of a label error, denoted by $0 \leq p \leq 1$. For a noise level p, we set the noise distribution matrix

$$\Phi = (1-p)\mathbf{I} + \frac{p}{K}\mathbf{II}^K, \tag{1}$$

and we call it *Uniform label flip noise model*. Here, $\mathbf{I}$ represents the identity matrix and $\mathbf{II}$ denotes the all-ones matrix. Similarly, we describe the *random label flip noise model* as

$$\Phi = (1-p)\mathbf{I} + p\Delta, \tag{2}$$

where $\mathbf{I}$ is the identity matrix, and Δ is a matrix with zeros along the diagonal and remaining entries of each column are drawn uniformly and independently from the $K-1$-dimensional unit simplex. The label error probability for each class is p, while the probability distribution *within* the erroneous classes is drawn uniformly at random.

Our objective is to train a classifier on the noisy labeled sample categories on the training set $\mathcal{D}'$ such that it jointly makes accurate predictions of the true label y and learns the noise transition matrix simultaneously, given $\mathbf{X}$. For the noisy dataset $\mathcal{D}'$, it is straightforward to train a classifier that predicts the *noisy* labels using conditional distribution for the noisy labeled input sentence $\mathbf{X}$:

$$p(y' = \hat{y}'|\mathbf{X}) = \sum_i \Big(p(y' = \hat{y}'|y = \hat{y}_i) \\ p(y = \hat{y}_i|\mathbf{X})\Big). \tag{3}$$

One can learn the classifier associated with $p(y' = \hat{y}'|x)$ via standard training on the noisy set $\mathcal{D}'$. To predict the clean labels by learning the conditional distribution $p(y = \hat{y}_i|x)$ requires more effort, as we cannot extract the "clean" classifier from the noisy classifier when the label noise distribution is unknown.

3.1 Proposed Framework

We refer to the DNN model without the final layer as the *base model* or network *without noise model (WoNM)*. This model, along with the non-linear layer, is trained via back-propagation on the noisy training dataset. The non-linear processing layer in the *noise model* transforms the base model outputs to match the noisy labels during the forward pass better and presents the denoised labels to the base model during the backward pass. The noise layer is parameterized by a square matrix $\Psi \in \mathbf{R}^{K\times K}$). At test time, we remove this learned noise model and use the output of the base model as final predictions.

We refer to the base model parameters as Θ. The base model outputs a probability distribution over the number of K categories denoted as $p\left(y = \hat{y}_i|\mathbf{X};\Theta\right) \forall i \in \{1, 2, \cdots, K\}$. During the forward pass the noise model transforms this output to obtain the noisy labels as

$$p\left(y'|\mathbf{X};\Theta,\Psi\right) = \sigma\left(\Psi \times p\left(y|\mathbf{X};\Theta\right)\right), \tag{4}$$

where $\sigma(\cdot)$ represents the usual softmax operator. Note that both the equations (3) and (4) compute the probability distribution over noisy labels – our noise model does not learn a noise transition matrix. However, we assert that the knowledge of exact noise statistics is neither necessary nor sufficient for the better prediction results.

We learn the base model parameters Θ and the noise model parameters Ψ by maximizing the log likelihood (4) over all of the training samples, minimizing the *cross-entropy* loss:

$$\begin{aligned}\mathcal{L}(\Theta, \Psi; \mathcal{D}') &= -\frac{1}{n}\sum_{i=1}^{n}\log\left[p\left(y'|\mathbf{X}_i;\Theta,\Psi\right)\right] \\ &= -\frac{1}{n}\sum_{i=1}^{n}\log\left[\sigma\left(\Psi \times p\left(y|\mathbf{X}_i;\Theta\right)\right)\right]_{y_i}\end{aligned} \quad (5)$$

Similar to (Sukhbaatar et al., 2014), we initialize the noise model weights to the identity matrix. Since DNNs have high capacity, we may encounter the situation when the base model itself absorbs all the label noise and, thus, the noise model does not learn anything at all. In order to avoid this situation, and to prevent overfitting, we apply l_2 regularization to the noise model. However, we want the noise model to overfit the label noise. In the experiment section, we observe that with proper regularization and weight initialization the noise model absorbs most of the label noise. Finally, we train the entire network according to the following loss function:

$$\mathcal{L} = -\frac{1}{n}\sum_{i=1}^{n}\log\left[\sigma\left(\Psi \times p\left(y|\mathbf{X}_i;\Theta\right)\right)\right]_{y_i} + \frac{1}{2}\lambda||\Psi||_2^2. \quad (6)$$

Here, λ is a tuning parameter and we validate the value of λ by repeating the experiment multiple times with multiple λ values over different datasets and choose the one with better classification performance on the validation set for the respective datasets. A value of $\lambda = 0.01$ works best.

4 Datasets and Experimental Setup

In this section, we empirically evaluate the performance of the proposed approach for text classification and compare our results with the other methods.

4.1 General Setting

In all the experiments, we use a publicly-available deep learning library *Baseline* – a fast model development tool for NLP tasks (Pressel et al., 2018). For all the different datasets, we choose a commonly-used, high-performance model from (Kim, 2014) as a base model. To examine the robustness of the proposed approach, we intentionally flip the class labels with 0% to 70% label noise, in other words: $p \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7\}$, and observe the effect of different types of label flipping, such as uniform (*Uni*) and random (*Rand*) label flipping, along with instance-dependent label noise. For all the experiments, we use early stopping based on validation set accuracy where the class labels in validation are also corrupted.

	Dataset	K	L	N	T	Type
Text Data	SST-2	2	19	76961	1821	Balanced
	TREC	6	10	5000	500	Not Balanced
	AG-News	4	38	110K	10K	Balanced
	DBpedia	14	29	504K	70K	Balanced

Table 1: Summary of text classification datasets; K: denotes the number of classes, L: represents the average length of sentence, N: denotes the number of training samples, T: represents the number of test samples, Type: describes whether the dataset is balanced.

We indicate the performance of a standard deep network *Without Noise model (WoNM)* on the noisy label dataset. We also plot the results for the stacked *Noise Model Without Regularization (NMWoRegu)* and stacked *Noise Model With Regularization (NMwRegu)*. Unless otherwise stated, in all the deep networks with the stacked noise model, we initialize the noise layer parameters as an identity matrix. We further analyze the effect of the noise layer initialization on the overall performance. We define *TDwRegu* as the stacked noise model with regularization, initialized with true injected noise distribution and *RandwRegu* as the stacked noise model with regularization, initialized randomly. We run all experiments five times and report the mean accuracy.

4.2 Datasets

Here, we describe all the text classification datasets used to evaluate the performance of the proposed approach. The base model architecture is the same for all datasets. For each set, we tune the number of filter windows and filter lengths using the development set. Along with the description, we also provide the hyper-parameters we selected for each. Table 1 summarizes the basic statistic of the datasets.

1. SST-2[1] (Socher et al., 2011): Stanford Sentiment Treebank dataset for predicting the sentiment of movie reviews. The classification task involves detecting positive or negative reviews. Using the base model with

Table 2: Test performance for different text classification datasets

clean labels we obtain classification accuracy of 87.27%. For this dataset, the base model network architecture consists of an input and embedding layer + $[3, 4, 5]$ feature windows with 100 feature maps each and dropout rate 0.5 with batch size 50.

2. TREC[2] (Voorhees and Tice, 1999): A question classification dataset consisting of fact based questions divided into broad semantic categories. We use a six-class version of TREC dataset. For this dataset, the base model network architecture consists of an input and embedding layer + $[3]$ one feature windows with 100 feature maps and dropout rate 0.5 with batch size 10.

3. Ag-News[3] (Zhang et al., 2015): A large-scale, four-class topic classification dataset. It contains approx 110K training samples. For this dataset, the base model network architecture consists of Input layer + Embedding layer + $[3, 4, 5]$ feature windows with 200 feature maps and dropout rate 0.5 with batch size 100.

4. DBpedia[3] (Zhang et al., 2015): A large scale 14-class topic classification dataset containing $36K$ training samples per category. For this dataset, the base model network architecture consists of Input layer + Embedding layer + $[1, 2, 3, 4, 5, 7]$ feature windows with 400 feature maps each and dropout rate 0.5 with batch size 1024.

[3] `http://www.di.unipi.it/~gulli/AG_corpus_of_news_articles.html`

For all the datasets, we use Rectified Linear Units (ReLU) and fix the base model architecture. We use early stopping on dev. sets for all the datasets. We run all the experiments 5 times and report the average classification accuracy in Table 2. We train all the networks end-to-end via stochastic gradient descent over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012) except for the DBpedia, where we use SGD. In order to improve base model performance, we initialize the word embedding layer with the publicly available *word2vec* word vectors (Mikolov et al., 2013) for all the datasets except for DBpedia, where we use *GloVe* embeddings (Pennington et al., 2014).

5 Results and Discussion

We evaluate the performance of our model in Table 2 for each datasets in the presence of uniform and random label noise and compare the performance with the base model (*WoNM*) as our baseline. For all datasets, the proposed approach is significantly better than the baseline for both random and uniform label noise. For all datasets, we observe a gain of approximately 30% w.r.t the baseline in the presence of extreme label noise. We do observe a drop in classification accuracy as we increase the percentage of label noise but even at the extreme label noise our method outperformed the baseline method. Interestingly, if we assume an oracle to determine prior knowledge of true noise distribution (*TDwRegu01*), it does not necessarily improve classification performance, especially for multi-class classification problems. For binary classification, using the SST-2 dataset, we did observe that the noise model initialized with the true noise distribution works better than all the other models. In addition to this, we also observe a slight performance gain for the proposed approach over the baseline with clean labels – perhaps due to label noise inherent in the datasets.

5.1 Effect of Different Regularizers

The *NMwRegu01* performs better in all cases for both types of label noise. We plot the weight matrix learned by all the noise models in all the noise regimes. For brevity, we only plot the weight matrix for AG-News datasets with 30% label noise in Fig.1. We find that l_2 regularization diffuses the diagonal weight elements and learns more smoothed off-diagonal elements which resemble the corresponding input label noise distribution in Fig. 1d. This also means that, without regularization, the noise model has less ability to diffuse the diagonal elements which leads to poor classification performance. Therefore, we use a regularizer (l_2) to diffuse the diagonal entries.

In some cases, especially for low label noise, we find the l_2 regularization with a small penalty works better than a large penalty since, for low label noise, learning a less diffuse noise is beneficial. The proposed approach scales to a large number of label categories, as evident from the experiments on DBpedia dataset in the last row of Table .2.

5.2 Effect of Different Scaling Factors on Noise Layer Initialization

We initialize the noise model weights as identity matrices with gain equal to the number of classes (gain = K) for all experiments. We observe the effect of different gain values on the overall performance of the proposed network in Fig. 2 where on x-axis we vary the scaling factor – a function of number of classes in the dataset. We plot the classification performance for the DBpedia dataset with 50% random noise. For each noise model in Fig. 2a, we find that setting the gain to K works best and any other gain results in poor performance.

In Fig. 2b we plot the Frobenius norm of the learned noise model weights with respect to the different gain values. We find that, using the high gain initialization, the model learns a high noise model norm, resulting in poor classification performance. This finding provides support to the claim in (Liao et al., 2018) that “higher layer norm leads to highest test errors.”

5.3 Effect of Batch Size

We also observe the effect of different batch sizes on performance as described in (Rolnick et al., 2017). For all datasets, we do observe small performance gains for highly non-uniform noisy labels, for instance 70%, in Fig. 3 row 2. However, for uniform label flips, we do not observe performance gains with increasing batch size.

	TRB			TRPr		
Data(N%)	WoNM	Noisy	True	NMwRegu01	Noisy	True
SST2 (40%)	70.24	70.95	79.24	82.32	73.90	83.25
AG (70%)	59.70	52.44	79.18	90.33	86.27	89.4
AG (60%)	83.25	68.8	88.28	90.45	87.77	90.78
TREC (40%)	66.80	63.4	79.0	73.40	69.6	83.2
TREC (20%)	83.6	80.0	86.0	87.40	83.6	90.0

Table 3: SVM Classification

5.4 Instance Dependent Label Noise

We further investigate the performance of the proposed approach on instance-dependent label noise by flipping each class labels with different noise percentages as shown in Fig. 4a. For brevity, we present results on AG-News dataset in Fig. 4. On this type of label noise, the performance of the proposed approach is far better than the baseline with a performance improvement of $\sim 6\%$. The noise model learned by the proposed approach is shown in Fig. 4b and we show the normalized weight matrix in Fig. 4c. We observe that the learned noise model is able to capture the input label noise statistics and is highly correlated to the input noise distribution with Pearson Correlation Coefficient 0.988.

5.5 Understanding Noise Model

In order to further understand the noise model, we first train the base model and the proposed model on noisy labels. Afterward, we collect

[Best viewed in color]

the last fully-connected layer's activations for all the training samples and treat them as the learned feature representation of the input sentence. We get two different sets of feature representations, one corresponding to the base model (*TRB*), and the other corresponding to the proposed model (*TRPr*). Given these learned feature representations – the artificially injected noisy labels and the true labels of the training data – we learn two different SVMs for each model, with and without noise. For the base model, for both SVMs, we use TRB representation as inputs and train the first SVM with the true labels as targets and the second SVM with the unreliable labels as targets. Similarly, we train two SVMs for the proposed model. After training, we evaluate the performance of all the learned SVMs on clean test data in Table 3, where the 1st column represents the corresponding model performance, "Noisy" and "True" column represents the SVM performance when trained on noisy and clean labels, respectively. We run these experiments for different datasets with different label noise.

The SVM, trained on TRB and noisy labels, is very close to the base model performance (3). This suggests that the base model is just fitting the noisy labels. On the other hand, when we train an SVM on the TRPr representations with true labels as targets, the SVM achieves the proposed model performance. This means that the proposed approach helps the base model to learn better feature representations even with the noisy targets, which suggest that this noise model is learning a label denoising operator.

We analyze the representation of training samples in feature domain by plotting the t-SNE embeddings (Van Der Maaten, 2014) of the TRB and TRPr. For brevity, we plot the t-SNE visualizations for TREC dataset with 50% label noise in Fig. 5 .

For each network, we show two different t-SNE plots. For example in Fig. 5a we plot two rows of t-SNE embeddings for the proposed model. In the first row of Fig. 5a, each training sample is represented by its corresponding true label, while in the second row (the noisy label plot) each training sample is represented by its corresponding noisy label. We observe that, as the learning process progresses, the noise model helps the base model to cluster the training samples in the feature domain. With each iteration, we can see the formation of clusters in Row 1. However, in Row 2, when the noisy labels are superimposed, the clusters are not well separated. This means that the noise model denoises the labels and presents the true labels to the base network to learn.

In Fig. 5b, we plot two rows of t-SNE embeddings of the TRB representations. It seems that the network directly learns the noisy labels. This provides further evidence to support (Zhang et al., 2016)'s finding that the deep network memorizes data without knowing of true labels. In Row 2 of Fig. 5b, we can observe that the network learns noisy features representations which can be well clustered according to given noisy labels.

6 Conclusion

In this work, we propose a framework to enable a DNN to learn better sentence representations in the presence of label noise for text classification tasks. To model the label noise, we append a nonlinear noise model on top of the standard DNN architecture. With proper initialization and regularization, the noise model is able to absorb most of the label noise and helps the base model to learn better sentence representations.

Understanding Learning Dynamics Of Language Models with SVCCA

Naomi Saphra and **Adam Lopez**
Institute for Language, Cognition, and Computation
University of Edinburgh
`n.saphra@ed.ac.uk` `alopez@ed.ac.uk`

Abstract

Research has shown that neural models implicitly encode linguistic features, but there has been no research showing *how* these encodings arise as the models are trained. We present the first study on the learning dynamics of neural language models, using a simple and flexible analysis method called Singular Vector Canonical Correlation Analysis (SVCCA), which enables us to compare learned representations across time and across models, without the need to evaluate directly on annotated data. We probe the evolution of syntactic, semantic, and topic representations and find that part-of-speech is learned earlier than topic; that recurrent layers become more similar to those of a tagger during training; and embedding layers less similar. Our results and methods could inform better learning algorithms for NLP models, possibly to incorporate linguistic information more effectively.

1 Introduction

Large neural networks have a notorious capacity to memorize training data (Zhang et al., 2016), but their high accuracy on many NLP tasks shows that they nonetheless generalize. One apparent explanation for their performance is that they learn linguistic generalizations even without explicit supervision for those generalizations—for example, that subject and verb number agree in English (Linzen et al., 2016); that derivational suffixes attach to only specific parts of speech (Kementchedjhieva and Lopez, 2018); and that short segments of speech form natural clusters corresponding to phonemes (Alishahi et al., 2017). These studies tell us that neural models learn to implicitly represent linguistic categories and their interactions. But *how* do they learn these representations?

One clue comes from the inspection of multilayer models, which seem to encode lexical categories in lower layers, and more contextual categories in higher layers. For example, Blevins et al. (2018) found that a word's part of speech (POS) is encoded by lower layers, and the POS of its syntactic parent is encoded by higher layers; while Belinkov et al. (2018) found that POS is encoded by lower layers and semantic category is encoded by higher layers. More generally, the most useful layer for an arbitrary NLP task seems to depend on how "high-level" the task is (Peters et al., 2018). Since we know that lower layers in a multi-layer model converge to their final representations more quickly than higher layers (Raghu et al., 2017), it is likely that models learn local lexical categories like POS earlier than they learn higher-level linguistic categories like semantic class.

How and when do neural representations come to encode specific linguistic categories? Answers could explain why neural models work and help us improve learning algorithms. We investigate how representations of linguistic structure are learned over time in neural language models (LMs), which are central to NLP: on their own, they are used to produce contextual representations of words for many tasks (e.g. Peters et al., 2018); while *conditional* LMs power machine translation, speech recognition, and dialogue systems. We use a simple and flexible method, Singular Vector Canonical Correlation Analysis (SVCCA; Raghu et al., 2017), which allows us to compare representations from our LM at each epoch of training with representations of other models trained to predict specific linguistic categories. We discover that lower layers initially discover features shared by all predictive models, but lose these features as the LM explores more specific clusters. We demonstrate that different aspects of linguistic structure are learned at different rates within a single recurrent layer, acquiring POS tags early but continuing to learn global topic information later in training.

2 Methods

Our experiments require a LM, tagging models, and a method to inspect the models: SVCCA.

2.1 Language model

We model the probability distribution over a sequence of tokens $x_1 \dots x_{|x|}$ with a conventional two-layer LSTM LM. The pipeline from input x_t at time step t to a distribution over x_{t+1} is described in Formulae (1)–(4). At time step t, input word x_t is embedded as (1) h_t^e, which is input to a two-layer LSTM, producing outputs (2) h_t^1 and (3) h_t^2 at these layers, along with cell states c_t^1 and c_t^2. A softmax layer converts h_t^2 to a distribution from which (4) $\hat{x}_{t+1}$ is sampled.

$$\begin{aligned} h_t^e &= \text{embedding}(x_t) && (1) \\ h_t^1, c_t^1 &= \text{LSTM}_1(h_t^e, h_{t-1}^1, c_{t-1}^1) && (2) \\ h_t^2, c_t^2 &= \text{LSTM}_2(h_t^1, h_{t-1}^2, c_{t-1}^2) && (3) \\ \hat{x}_{t+1} &\sim \text{softmax}(h_t^2) && (4) \end{aligned}$$

Each function can be thought of as a *representation* or *embedding* of its discrete input; hence h_t^e is a representation of x_t, and—due to the recursion in (2)—h_t^1 is a representation of $x_1 \dots x_t$.

2.2 Tagging models

To inspect our language model for learned linguistic categories, we will use a collection of tagging models, designed to mimic the behavior of our language model but predicting the next *tag* rather than the next word. Given $x_1 \dots x_{|x|}$, we model a corresponding sequence of tags $y_1 \dots y_{|x|}$ using a one-layer LSTM. (Our limited labeled data made this more accurate on topic tagging than another two-layer LSTM, so this architecture does not directly parallel the LM.)

$$\begin{aligned} h_t^{e\prime} &= \text{embedding}'(x_t) && (5) \\ h_t^{1\prime}, c_t^{1\prime} &= \text{LSTM}'(h_t^{e\prime}, h_{t-1}^{1}{}', c_{t-1}^{1}{}') && (6) \\ \hat{y}_{t+1} &\sim \text{softmax}'(h_t^{1\prime}) && (7) \end{aligned}$$

We will also discuss *input taggers*, which share this architecture but instead sample y_t, the tag of the most recently observed word.

2.3 SVCCA

SVCCA is a general method to compare the correlation of two vector representations. Let d_A and d_B be their dimensions. For N data points we have two distinct views, given by matrices $A \in \mathcal{R}^{N \times d_A}$ and $B \in \mathcal{R}^{N \times d_B}$. We project these views onto a shared subspace in two steps:

1. Use Singular Value Decomposition (SVD) to reduce matrices A and B to lower dimensional matrices A' and B', respectively. This is necessary because many dimensions in the representations are noisy, and in fact cancel each other out (Frankle and Carbin, 2018). SVD removes dimensions that were likely to be less important in the original representations from A and B, and in keeping with Raghu et al. (2017), we retain enough dimensions to keep 99% of the variance in the data.

2. Use Canonical Correlation Analysis (CCA) to project A' and B' onto a shared subspace, maximizing the correlation of the projections. Formally, CCA identifies vectors w, v to maximize $\rho = \frac{<w^\top A', v^\top B'>}{\|w^\top A'\| \|v^\top B'\|}$. We treat these w, v as new basis vectors, computing the top d_C (a hyperparameter) such basis vectors to form projection matrices $W \in \mathcal{R}^{d_C \times d_{A'}}, V \in \mathcal{R}^{d_C \times d_{A'}}$. The resulting projections WA' and VB' map onto a shared subspace where the representations of each datapoint from A' and B' are maximally correlated.

Intuitively, the correlation ρ will be high if both representations encode the same information, and low if they encode unrelated information. Figure 1 illustrates how we use SVCCA to compare representation h_t^2 of our language model with the recurrent representation of a tagger, $h_t^{1\prime}$. In practice, we run over all time steps in a test corpus, rather than a single time step as illustrated.

3 Experimental Setup

We trained our LM on a corpus of tokenized, lowercased English Wikipedia (70/10/20 train/dev/test split). To reduce the number of unique words in the corpus, we excluded any sentence with a word type appearing fewer than 100 times. Words appearing fewer than 100 times in the resulting training set are replaced with an unknown token. The resulting training set has over 227 million tokens of 20K types.

We train for 50 epochs to maximize cross-entropy, using a batch size of 40, dropout ratio of 0.2, and sequence length of 35. The optimizer is standard SGD with clipped gradients at 0.25,

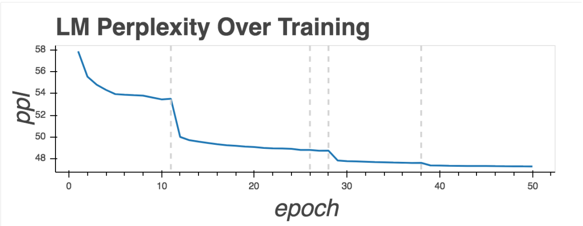

Figure 2: Test performance of the LM. Vertical dotted lines indicate when the optimizer rescales the step size.

with the learning rate quartered when validation loss increases. The result of training is shown in Figure 2, which illustrates the dips in loss when learning rate changes. All experiments on the LM throughout training are conducted by running the model at the end of each epoch in inference mode over the test corpus.

3.1 Taggers

To understand the representations learned by our LM, we compare them with the internal representations of tagging models, using SVCCA. Where possible, we use coarse-grained and fine-grained tagsets to account for effects from the size of the tagset. Table 1 illustrates our tagsets.

POS tagging For syntactic categories, we use POS tags, as in Belinkov et al. (2017). As a coarse-grained tagset, we use silver Universal Dependency Parse (UDP) POS tags automatically added to our Wikipedia corpus with spacy.[1] We also use a corpus of fine-grained human annotated Penn Treebank POS tags from the Groningen Meaning Bank (GMB; Bos et al., 2017).

Semantic tagging We follow Belinkov et al. (2018) in representing word-level semantic information with silver SEM tags (Bjerva et al., 2016). SEM tags disambiguate POS tags in ways that are relevant to multilingual settings. For example, the comma is not assigned a single tag as punctuation, but has distinct tags according to its function: conjunction, disjunction, or apposition. The 66 fine-grained SEM tag classes fall under 13 coarse-grained tags, and an ‘unknown’ tag.

Global topic For topic, we classify each word of the sequence by its source Wikipedia article; for example, every word in the wikipedia article on Trains is labeled “Trains”. This task assesses whether the network encodes the global topic of the sentence.

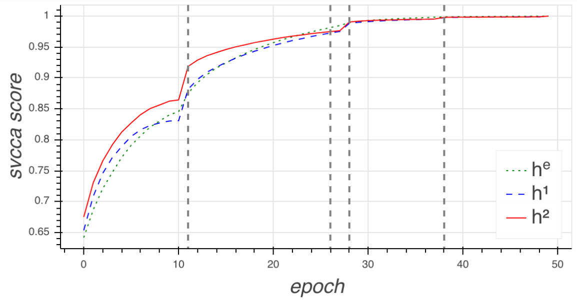

Figure 3: SVCCA score between representations at each epoch and from the final trained LM.

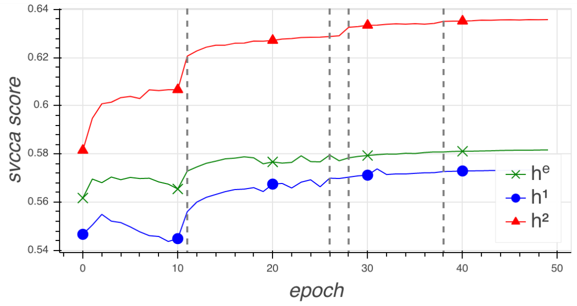

Figure 4: SVCCA score between the LM at each epoch and a LM with different initialization.

UDP silver POS and topic information use the same corpus, taken from the 100 longest articles in Wikipedia randomly partitioned in a 70/10/20 train/dev/test split. Each token is tagged with POS and with the ID of the source article. The corpus is taken from the LM training data, which may increase the similarity between the tag model and LM. Because both tag predictors are trained and tested on the same domain as the LM, they can be easily compared in terms of their similarity to the LM representation. Though the SEM corpus and the PTB corpus are different domains from the Wikipedia training data, we compare their activations on the same 191K-token 100-article test corpus.

Table 2 describes the training and validation corpus statistics for each tagging task. Note that topic and UDP POS both apply to the same en-wikipedia corpus, but PTB POS and SEM use two different unaligned sets from the GMB corpus.

4 Experiments, Results, and Analysis

A benefit of SVCCA is its flexibility: it can compute the correlation of a hidden representation to any other vector. Raghu et al. (2017) used it to understand learning dynamics by comparing a learned representation to snapshots of the same representation at different epochs during training. We use a similar experiment to establish the basic learning dynamics of our model. In our shallow 2-level model, activations at h^1 converge slightly after h^2 (Figure 3). This differs from the results of Raghu et al. (2017), who found that a 5-layer stacked LSTM LM exhibits faster convergence at lower layers, but this difference may be attributed to our much larger training data, which gives our model sufficient training data at early epochs.

Empirical upper bounds. Our main experiments will test the rate at which different linguistic categories are learned by different layers, but to interpret the results, we need to understand the behaviour of SVCCA for these models. In theory, SVCCA scores can vary from 0 for no correlation to 1 for perfect correlation. But in practice, these extreme cases will not occur. To establish an *empirical* upper bound on correlation, we compared the similarity at each epoch of training to the frozen final state of a LM with identical architecture but different initialization, trained on the same data (Figure 4).[2] The correlations increase over time as expected, but to a maximum near 0.64; we don't expect correlations between our LM and other models to exceed this value. We explore corresponding lower bounds in our main experiments below.

Correlations between different layers. Next we examine the correlation between different layers of the same model over time (Figure 5). We observe that, while over time correlation increases, in general closer layers are more similar, and they are less correlated than they are with the same layer of a differently initialized model. This supports the idea that we should compare recurrent layers with recurrent layers because their representations play similar roles within their respective architectures.

SVCCA vs. Diagnostic classifiers A popular method to analyze learned representations is to use a *diagnostic classifier* (Belinkov et al., 2017; Hupkes et al., 2018) or probe (Conneau et al., 2018), a separate model that is trained to predict a linguistic category of interest, y_t, from an arbitrary hidden layer h_t. Diagnostic classifiers are widely used (Belinkov et al., 2018; Giulianelli et al., 2018).

---

[2] This experiment is similar to the comparisons of randomly initialized models by Morcos et al. (2018).

Table 2: Tag predictor and tagger statistics. Accuracy and perplexity on $t+1$ are from the target tag predictor, on t are from the input tagger. Metrics obtained when training on randomly shuffled labels are provided as a low baseline. Accuracy is on the test set from the training domain (GMB or Wikipedia).

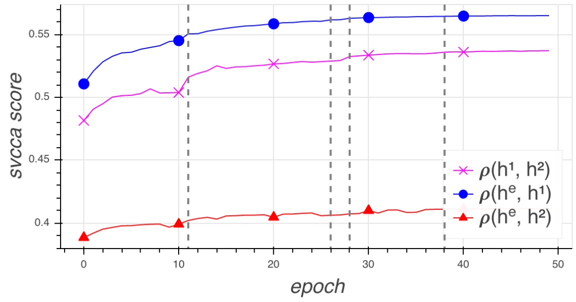

Figure 5: SVCCA score between different layers of the LM at each epoch. For example, $\rho(h^2, h^1)$ compares the activations h^2 with the activations h^1.

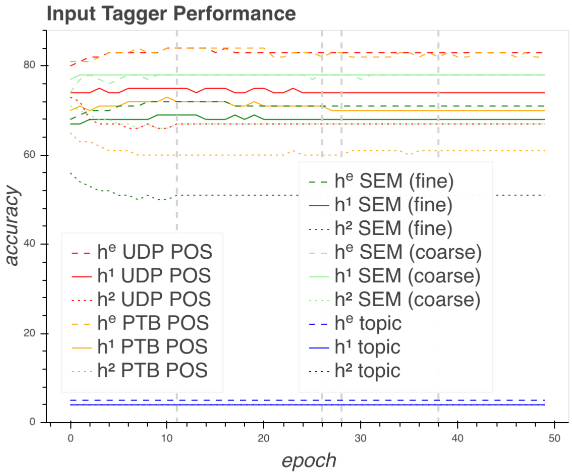

Figure 6: Learning dynamics interpreted with diagnostic classifiers labeling input word tag y_t.

But if a diagnostic classifier is trained on enough examples, then random embeddings as input representations often outperform any pretrained intermediate representation (Wieting and Kiela, 2019; Zhang and Bowman, 2018). This suggests that diagnostic classifiers may work simply by memorizing the association between an embedding and the most frequent output category associated with that embedding; since for many words their category is (empirically) unambiguous, this may give an inflated view of just how much a model “understands” about that category.

Our use of SVCCA below will differ from the use of diagnostic classifiers in an important way. Diagnostic classifiers use the intermediate representations of the LM as inputs to a tagger. A representation is claimed to encode, for example, POS if the classifier accurately predicts it—in other words, whether it can *decode* it from the representation. We will instead evaluate the *similarity* between the representations in an LM and in an independently-trained tagger. The intuition behind this is that, if the representation of our LM encodes a particular category, then it must be similar to the representation of model that is specifically trained to predict that category. A benefit of the approach is that similarity can be evaluated on *any* dataset, not only one that has been labeled with the linguistic categories of interest.

Another distinction from the typical use of diagnostic classifiers is that probes are usually used to decode tag information about the context or most recent *input* from the hidden state at the current step. Because the hidden representation at time t is meant to encode predictive information about the target word at time $t+1$, we treat it as encoding a prediction about the tag of the *target* word.

To understand the empirical strengths and weaknesses of these approaches, we compare the use of SVCCA and diagnostic classifiers in understanding learning dynamics. In other words, we ask: is our first conceptual shift (to SVCCA) necessary? To test this, we use the same model as Belinkov et al. (2017), which classifies an arbitrary representation using a ReLU followed by a softmax layer. To be consistent with Belinkov et al. (2017), we use y_t as their target label. We repeat their method in this manner (Figure 6) as well as applying our second modification, in which we instead target the label y_{t+1} (Figure 7).

We found the correlations to be relatively stable over the course of training. This is at odds with

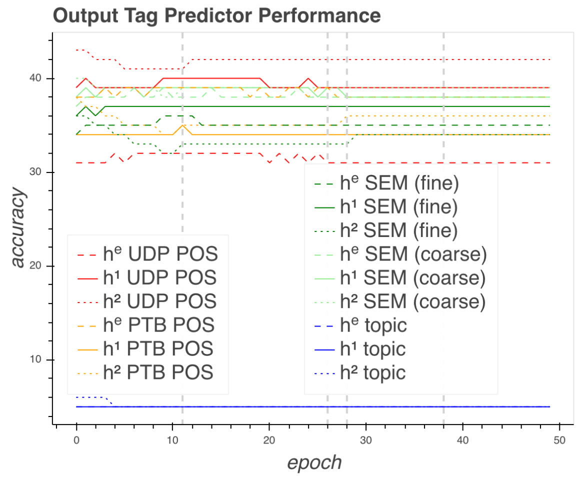

Figure 7: Learning dynamics interpreted with diagnostic classifiers labeling target word tag y_{t+1}.

the results in Figures 2 and 3, which suggest that representations change substantially during training in ways that materially affect the accuracy of the LM. This suggests that diagnostic classifiers are not illustrating improvements in word representations throughout training, and we conclude that they are ineffective for understanding learning dynamics. Our remaining experiments use only SVCCA.

4.1 SVCCA on Output Tag Prediction

We applied SVCCA to each layer of our LM with the corresponding layer of each tag predictor in order to find the correlation between the LM representation and the tag model representation at each level (Figure 8). To establish empirical lower bounds on correlation, we also trained our taggers on the same data with randomly shuffled labels, as in Zhang et al. (2016). These latter experiments, denoted by the dotted lines of Figure 8, show how much of the similarity between models is caused by their ability to memorize arbitrary associations. Note that the resulting scores are nonzero, likely because the linguistic structure of the input shapes representations even when the output is random, due to the memorization phase of training (Shwartz-Ziv and Tishby, 2017).

The strongest similarity at recurrent layers belongs to the most local property, the UDP POS tag. Both coarse- and fine-grained semantic tags, which rely on longer range dependencies, fall below UDP POS consistently. Topic, which is global to an entire document, is the least captured and the slowest to stabilize. Indeed, correlation with true

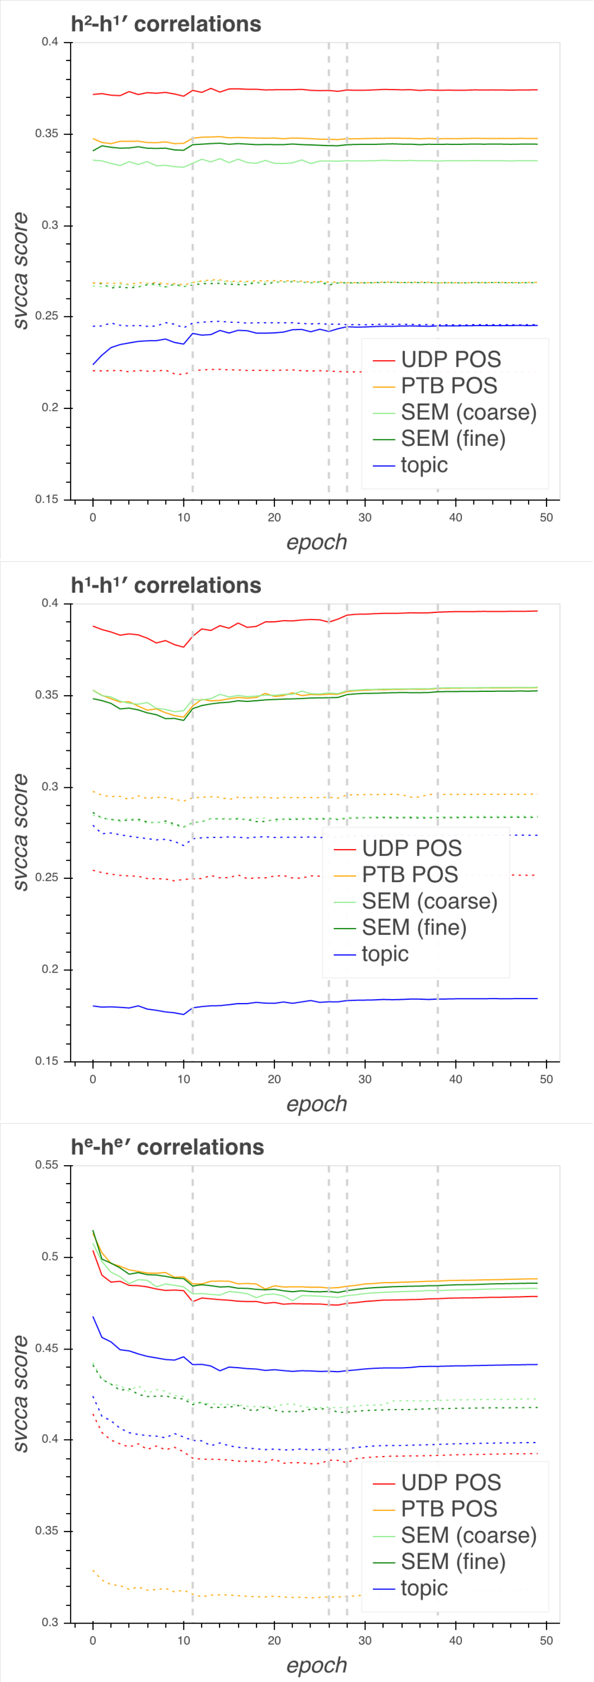

Figure 8: SVCCA correlation scores between the LM predicting x_{t+1} and the tag model predicting y_{t+1}. At the end of each epoch, we compare the current LM with the final tag model. Dotted lines use shuffled tags. Gray vertical lines mark when the step size is rescaled.

topic falls consistently *below* the score for a model trained on randomized topic tags, implying that early in training the model has removed the context necessary to identify topic (below even the inadequate contextual information memorized by a model with random labels), which depends on the general vocabulary in a sentence rather than a local sequence. Over time correlation rises, possibly because the model permits more long-distance context to be encoded. Khandelwal et al. (2018) found that LSTMs remember content words like nouns for more time steps than they remember function words like prepositions and articles. We hypothesize that the LM's slower stabilization on topic is related to this phenomenon, since it must depend on content words, and its ability to remember them increases throughout training.

The encoder layer exhibits very different patterns. Because the representation produced by the encoder layer is local to the word, the nuances that determine how a word is tagged in context cannot be learned. The encoder layers are all highly similar to each other, which suggests that the unigram representations produced by the encoder are less dependent on the particular end task of the neural network. Similarity between the encoders declines over time as they become more specialized towards the language modeling task. This decline points to some simple patterns which are learned for all language tasks, but which are gradually replaced by representations more useful for language modeling. This process may even be considered a naturally occurring analog to the common practice of initializing the encoder layer as word embeddings pretrained an unrelated task such as skipgram or CBOW (Mikolov et al., 2013). It seems that the 'easy' word properties, which immediately improve performance, are similar regardless of the particular language task.

At h^1, the correlation shows a clear initial decline in similarity for all tasks. This seems to point to an initial representation that relies on simple shared properties, which in the first stage of training is gradually dissolved before the layer begins to converge on a structure shared with each tag predictor. It may also be linked to the information bottleneck learning phases explored by Shwartz-Ziv and Tishby (2017). They suggest that neural networks learn by first maximizing the mutual information between the input and internal representation, then minimizing the mutual information between the internal representation and output. The network thus initially learns to effectively represent the input, then compresses this representation, keeping only the elements relevant to the output.[3] If the LM begins by maximizing mutual information with input, because the input is identical for the LM and tag models it may lead to these similar initial representations, followed by a decline in similarity as the compression narrows to properties specific to each task.

4.2 SVCCA on Input Tagging

Our second conceptual shift is to focus on output tag prediction—asking what a representation encodes about the *next* output word, rather than what it has encoded about words it has already observed in the input. What effect does this have? Since we already studied output tags in the previous set of experiments, here we consider input tags, in the style of most diagnostic classifier analysis (Figure 9). The learning dynamics are similar to those for tag prediction, but the UDP POS tagger decreases dramatically in all correlations while the GMB-trained taggers[4] often increase slightly. While the shapes of the lines are similar, UDP POS no longer consistently dominates the other tasks in recurrent layer correlation. Instead, we find the more granular PTB POS tags lead to the most similar representations.

5 Discussion and Conclusions

We find clear patterns in the encoding of linguistic structure with SVCCA, in contrast to the weaker results from a less responsive diagnostic classifier. Because SVCCA proves so much more sensitive than the diagnostic classifiers currently in use, we believe that future work on measuring the encoding of linguistic structure should use the similarity of individual modules from independently trained tag predictors rather than the performance of tag predictors trained on a particular representation.

This system should also be of interest because it is efficient. To train a diagnostic classifier, we must run a forward pass of the LM for each forward pass of the auxiliary model, while SVCCA only requires the LM to run on the test set. A fur-

---

[3] This memorization–compression learning pattern parallels the memorization–generalization of the first half of the U-shaped curve exhibited by human children learning irregular word forms. Kirov and Cotterell (2018) observe similar patterns when artificially modeling inflection.

[4] PTB POS, SEM (fine), and SEM (coarse)

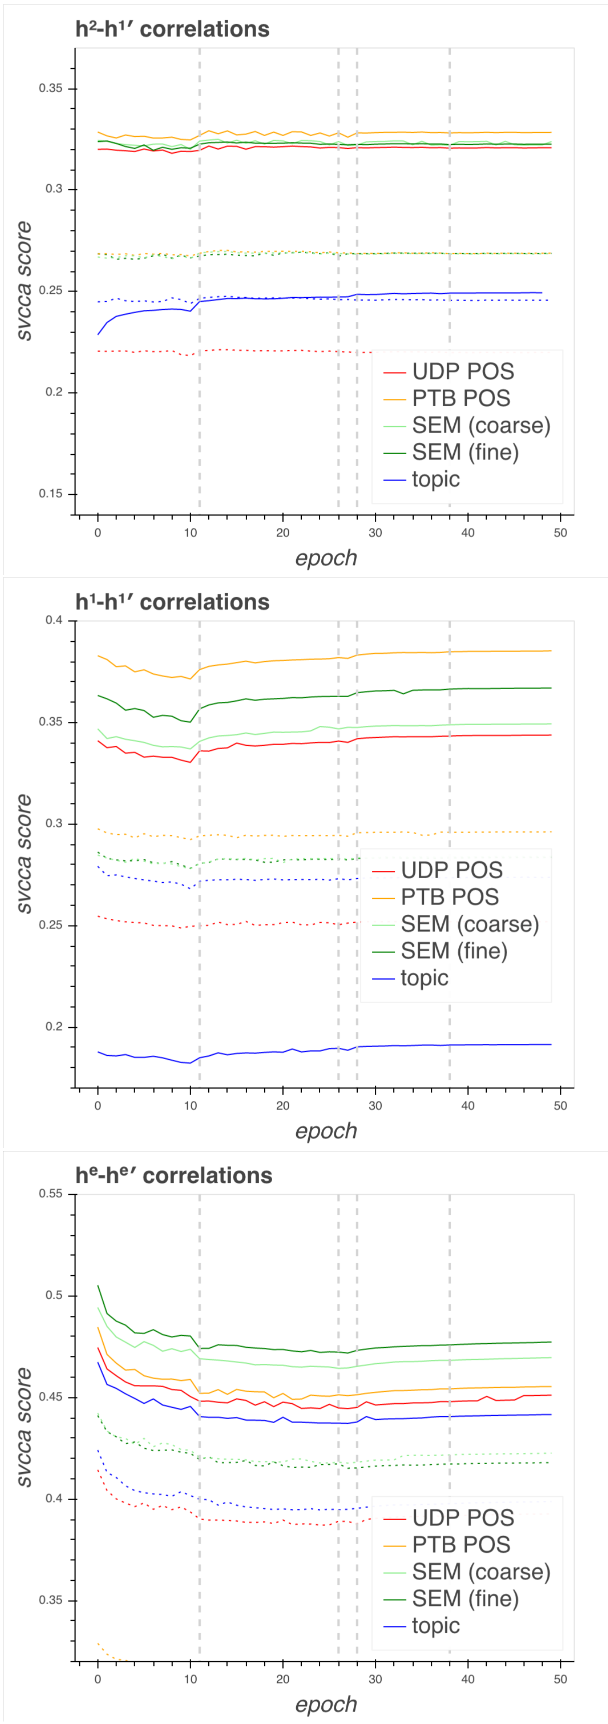

Figure 9: SVCCA correlation scores between LM activations when predicting x_{t+1} and tagger activations when labeling y_t. Dotted lines use shuffled tags. Gray vertical lines mark when the step size is rescaled.

ther efficiency gain is particular to studying learning dynamics: we train only one tagger and compare it to different versions of the LM over training, but for standard probing, we must train a new version of each layer's tagger at each epoch. Our SVCCA experiments in Figure 8 ran in hours, while the diagnostic classifier experiments in Figure 7 ran for days.

Our method holds another, more subtle advantage. Our analysis provides an alternative view of what it means for a model to *encode* some linguistic trait. The literature on analyzing neural networks includes a broad spectrum of interpretations about what it means to encode a property. At one end of the spectrum lies the purely informational view (e.g., mutual information; Noshad and Hero III, 2018). Mutual information is a very flexible view, but it requires us to compute theoretical information content, which in practice can only be estimated. Furthermore, information can be represented without being used, as shown by Vanmassenhove et al. (2017), who found that NMT systems often predicted tense according to a diagnostic classifier but did not produce the correct tense as output. The other end of the spectrum is focused on the structure of the representation space (e.g., the features and the property in question are linearly similar; Alishahi et al., 2017). Analyzing structural similarity should remedy the shortcomings of the informational view, but most intermediate representations are not targeted to extract the property in question through a linear transformation, and failing to be interpretable through such simple extraction should not be equated to a failure to encode that property.

Most of the literature on analyzing representations, by probing with a more complex architecture, seeks the flexibility of mutual information with the concreteness and tractability of the structural view – but instead obscures the strict information view without offering interpretable information about the structure, because the architecture of a diagnostic classifier affects its performance. It should not be surprising that representational quality as measured by such systems is a poor indicator of translation quality (Cífka and Bojar, 2018). SVCCA, in contrast, is a structural view that does not directly compare an activation that targets word prediction with a particular tag, but instead compares that activation with one targeting the prediction of the tag.

Let us consider a specific common probing method. What do we learn about the LM when a feedforward network cannot extract tag information directly from the embedding layer, but can from a recurrent layer? It may be tempting to conclude that tag information relies heavily on context, but consider some alternative explanations. If the embedding encodes the tag to be interpreted by a recurrent layer, a feedforward network may not be capable of representing the function to extract that tag because it does not have access to a context vector for aiding interpretation of the hidden layer. Perhaps its activation functions cover a different range of outputs. By directly comparing LSTM layers to LSTM layers and embedding layers to embedding layers, we respect the shape of their outputs and the role of each module within the network in our analysis.

The results of our analysis imply that early in training, representing part of speech is the natural way to get initial high performance. However, as training progresses, it increasingly benefits the model to represent categories with longer-range dependencies, such as topic.

6 Future Work

One direction for future work is exploring how generalization interacts with the correlations between LMs and tag predictors. It may be that a faithful encoding of a property like POS tag indicates that the LM is relying more on linguistic structure than on memorizing specific phrases, and therefore is associated with a more general model.

If these measurements of structure encoding are associated with more general models, we might introduce regularizers or other modifications that explicitly encourage correlation with a tagging task.

Combes et al. (2018) identified the phenomenon of *gradient starvation*, meaning that while frequent and unambiguous features are learned quickly in training, they slow down the learning of rarer features. For example, artificially brightening images according to their class leads to a delay in learning to represent the more complex natural class features. Although it is tempting to claim that semantic structure is learned using syntactic structure as natural scaffolding, it is possible that the simple predictive power of POS is acting as an attractor and starving semantic features that are rarer and more ambiguous. A possible direction for future work would be to explore which of these explanations is true, possibly by decorrelating particular aspects of linguistic structure from language modeling representations.

The techniques in this paper could be applied to better understand the high performance of a system like ELMo (Peters et al., 2018). Different layers in such a system are useful for different tasks, and this effect could be understood in terms of the gradual divergence between the layers and their respective convergence to representations geared toward a single task.

A Performance Out Of Domain

Because SEM tags and PTB POS tags were both trained on the GMB corpus, we present the SVCCA similarities on an in-domain GMB test corpus as well as the Wikipedia test corpus used elsewhere in the paper. The results are in Figures 10-11. In general correlations are higher using the original tagging domain, but not enough to contradict our earlier analysis. The shapes of the curves remain similar.

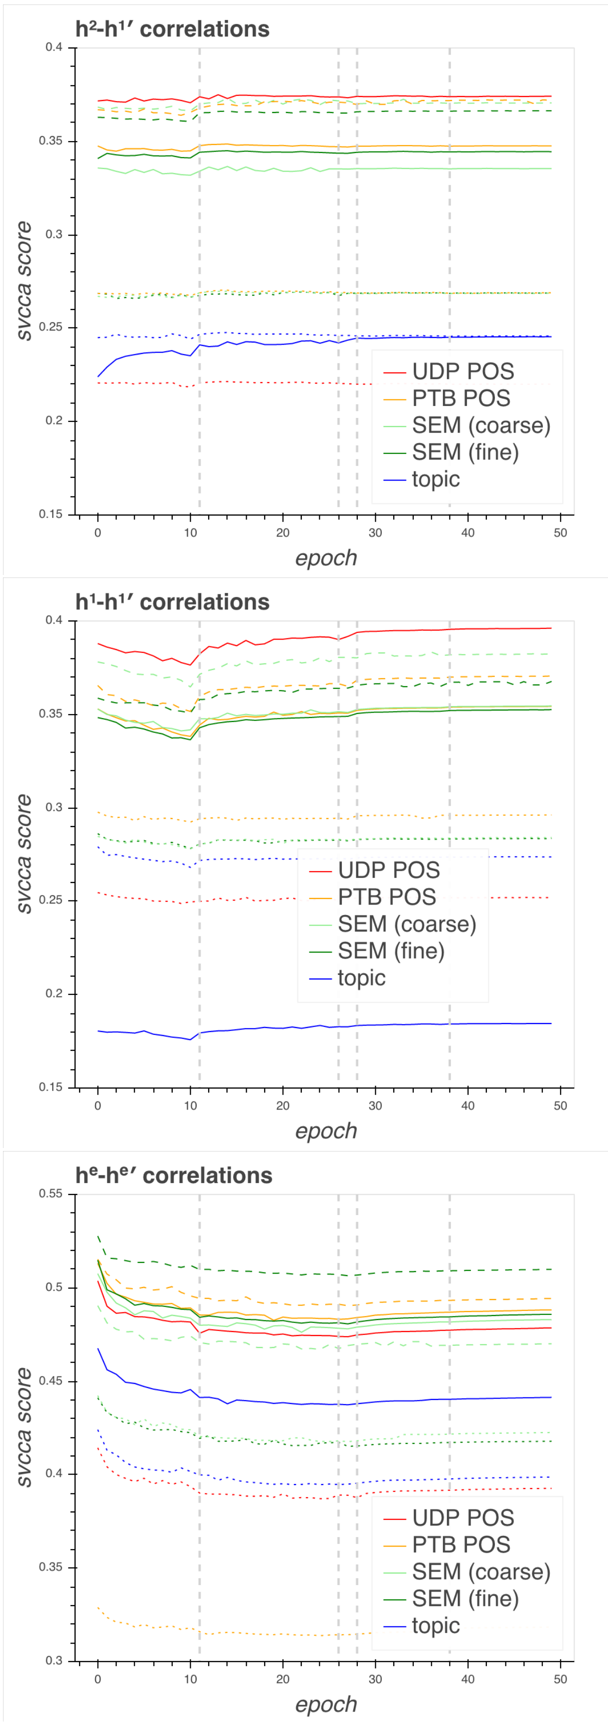

Figure 10: SVCCA correlation scores between LM and y_{t+1} tag predictor. Dotted lines use models trained on randomly shuffled the data. Dashed lines use GMB domain test data.

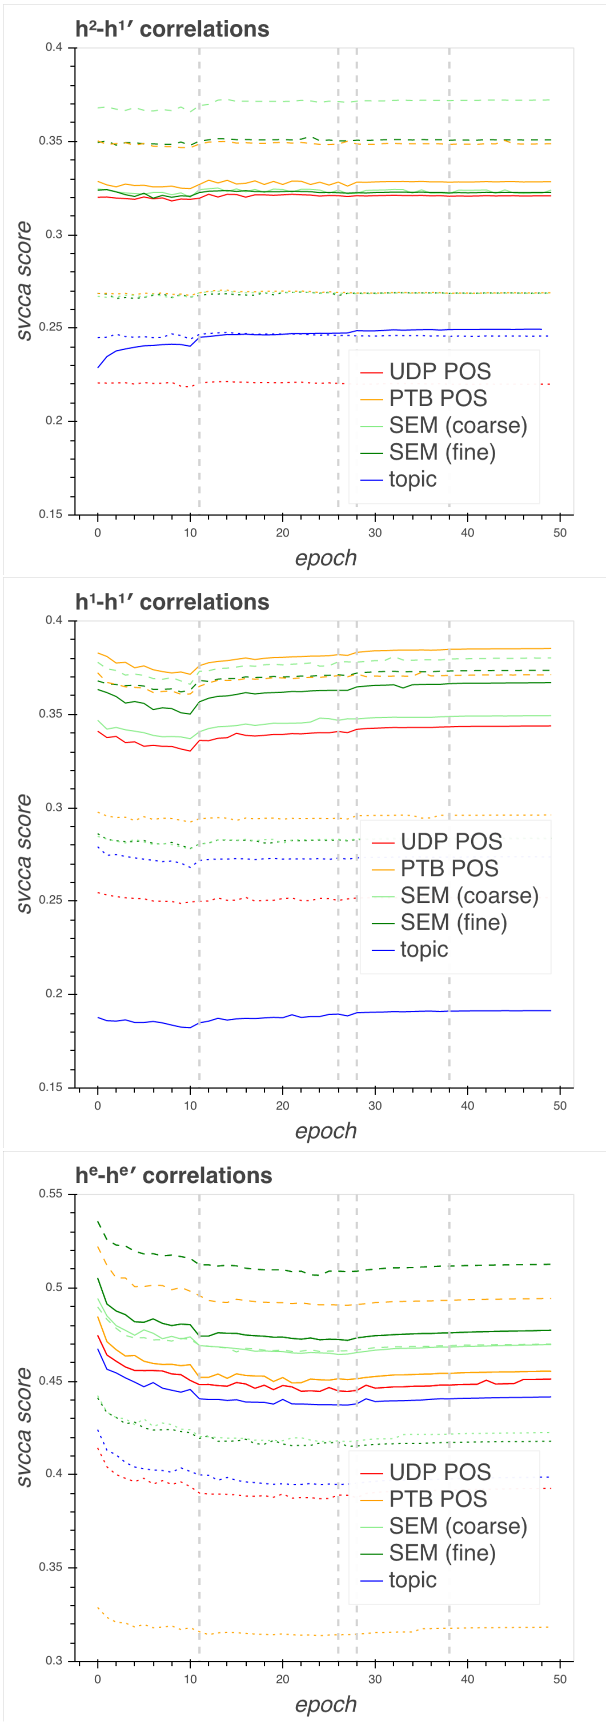

Figure 11: SVCCA correlation scores between LM and y_t tagger. Dotted lines use models trained on randomly shuffled the data. Dashed lines use GMB domain test data.

Using Large Corpus N-gram Statistics to Improve Recurrent Neural Language Models

Abstract

Recurrent neural network language models (RNNLM) form a valuable foundation for many NLP systems, but training the models can be computationally expensive, and may take days to train on a large corpus. We explore a technique that uses large corpus n-gram statistics as a regularizer for training a neural network LM on a smaller corpus. In experiments with the Billion-Word and Wikitext corpora, we show that the technique is effective, and more time-efficient than simply training on a larger sequential corpus. We also introduce new strategies for selecting the most informative n-grams, and show that these boost efficiency.

1 Introduction

Recurrent neural network models of language (RNNLMs) form a foundation for many natural language processing systems. However, the networks can be expensive to train: training a single model over several million tokens can take hours, and searching through the large hyperparameter space of RNNLMs often entails training and testing hundreds of different models. This makes it burdensome to experiment with new RNNLM architectures on large corpora, or to train RNNLMs for new textual domains.

RNNLMs are typically trained on sequential text. In this paper, we investigate how to efficiently augment the training of RNNLMs by regularizing the models to match n-gram statistics taken from a much larger corpus. The motivation is that large-corpus n-gram statistics may be informative to an RNNLM trained on a smaller sequential corpus, but unlike RNNLM training, n-gram statistics are inexpensive to compute even over large corpora. Moreover, the statistics only need to be computed once and can be re-used for training many different smaller-corpus RNNLMs.

Naively, regularizing an RNNLM to match a given set of n-gram statistics is non-trivial, because the marginal probabilities that n-gram statistics represent are not parameters of the RNNLM. In recent work, Noraset et al. (2018) showed that it was possible to regularize an RNNLM to match given n-gram statistics by training the network, when started from a zero state, to match each n-gram probability. However, the regularization approach in that work had tractability limitations—the time cost of the regularization was sufficiently high that using it was inferior to simply training the RNNLM on more sequential text.

In this paper, we present an efficient n-gram regularization technique and show that the technique can improve RNNLM training. Our method has three distinctions from previous work that provide efficiency. First, we prioritize regularizing only the n-grams that are most likely to improve the model, by focusing on cases where the RNNLM's sequential training corpus diverges significantly from the n-gram statistics. Secondly, we regularize the entire output softmax of the RNN to match given conditional n-gram statistics, which means we can impose a large number of statistical constraints using only one softmax evaluation. Finally, we use an ensemble of multiple loss functions in our regularizer, which provides an additional boost. In experiments, we show how n-gram regularization with these enhancements results in better models using the same amount of training time, compared to standard sequential training. We also plan to release our code base and to the research community.[1]

2 Methods

RNNLMs are trained to optimize a loss function L_d, which is defined as the average negative log-likelihood of a training corpus. We regularize the RNNLM to match n-gram statistics by introduc-

Proceedings of NAACL-HLT 2019, pages 3268–3273
Minneapolis, Minnesota, June 2 - June 7, 2019.

ing another penalty term L_p to the loss function that captures how well the model matches n-gram statistics, giving a combined loss L:

$$L = L_d + \alpha L_p,$$

where α is a hyperparameter to control the regularization strength. We use the term *large corpus* to refer to the text utilized to compute the n-gram statistics. We expect the large corpus to be multiple orders of magnitude larger than the *small corpus* utilized for computing the RNN's sequential loss L_d. In the rest of this section, we first define what we mean by conditional n-gram statistics, and then present our regularization methods.

2.1 Conditional N-gram Statistics

An order-N n-gram is a sequence of N words. For a given corpus $\boldsymbol{c}$, we denote the kth distinct order-N n-gram $w_{k1}, w_{k2}, ..., w_{kN}$ as $\mathbf{w}_k^N$, and denote the corresponding order $N-1$ n-gram formed by the first $N-1$ words as $\mathbf{w}_k^{N-1}$. Here, in order to eliminate ambiguity, the notation $N-1$ is exclusively used to represent the prefix. For instance, $\mathbf{w}_k^3$ is the k-th trigram, while $\mathbf{w}_k^{4-1}$ is the trigram prefix of the k-th 4-gram. We define conditional n-gram statistics as the empirical conditional probabilities of observing each next word w_{kN} given the previous $N-1$ gram $\mathbf{w}_k^{N-1}$ for all ks :

$$\hat{P}(w_{kN}|\mathbf{w}_k^{N-1}) = \frac{count(\mathbf{w}_k^N)}{count(\mathbf{w}_k^{N-1})}, \forall \mathbf{w}_k^N \in \Omega(\boldsymbol{c}),$$

where w_{kN} and $\mathbf{w}_k^{N-1}$ are the Nth word and the corresponding previous $N-1$ gram of $\mathbf{w}_k^N$ respectively, and $\Omega(\boldsymbol{c})$ is the set of all unique $\mathbf{w}_k^N$s contained in the corpus $\boldsymbol{c}$. For a given RNNLM, the model conditional probability for some n-gram $\mathbf{w}_k^N$ is defined as:

$$P_\theta(w_{kN}|\mathbf{w}_k^{N-1}) = \mathbb{E}_h(P_\theta(w_{kN}|\mathbf{w}_k^{N-1}, h)),$$

where h is the model's hidden state prior to encountering the N-gram. However, it is difficult to express that expectation in terms of the model parameters, so we adopt the approach from Noraset et al. (2018), which has shown preliminary evidence of forming an effective regularizer:

$$\mathbb{E}_h(P_\theta(w_{kN}|\mathbf{w}_k^{N-1}, h)) \approx P_\theta(w_{kN}|\mathbf{w}_k^{N-1}, h_0),$$

where h_0 is a zero hidden state.

2.2 Conditional N-gram Regularization

We propose three forms of regularization loss functions that penalize the divergence of the model's conditional probabilities from the conditional n-gram statistics.

2.2.1 Mean Squared Log Probability Ratio

We denote our first penalty as L_p^{sq}, defined as:

$$L_p^{sq} = \frac{1}{\|R\|} \sum_{\mathbf{w}_k^N \in R} \left(log \frac{\hat{P}(w_{kN}|\mathbf{w}_k^{N-1})}{P_\theta(w_{kN}|\mathbf{w}_k^{N-1})} \right)^2,$$

where R is a set of n-grams $\mathbf{w}_k^N$ to regularize, and $\hat{P}$ and P_θ are conditional n-gram statistics and model conditional probabilities as defined in Section 2.1. This penalty is similar to that of (Noraset et al., 2018). However, instead of computing the loss with multiple forward passes for different $\mathbf{w}_k^N$s that have the same $\mathbf{w}_k^{N-1}$, we propose to only perform one forward pass for each $\mathbf{w}_k^{N-1}$, and regularize all subsequent Nth words. This makes our loss much more computationally efficient. As this penalty only accounts differences in point-wise probabilities for specific words w_N, it can be used for partially specified distributions where we only know the desired probabilities for some Nth words in a given context, but not the entire distribution.

2.2.2 Mean Kullback–Leibler Divergence

We denote our second penalty as L_p^{KL}, defined as:

$$P_{\mathbf{w}_k^{N-1}} = \hat{P}(w|\mathbf{w}_k^{N-1}), Q_{\mathbf{w}_k^{N-1}} = P_\theta(w|\mathbf{w}_k^{N-1})$$
$$L_p^{KL} = \frac{1}{\|R\|} \sum_{\mathbf{w}_k^{N-1} \in R} D_{KL}(P_{\mathbf{w}_k^{N-1}} || Q_{\mathbf{w}_k^{N-1}}),$$

where here R is a set of prefixes $\mathbf{w}_k^{N-1}$ to regularize. This penalty regularizes all possible subsequent words w_N, thus it only works for fully-specified reference distributions.

2.2.3 Combined Penalty

Because the above two penalty functions differ, we hypothesize that they may be complementary and propose a *combined* penalty $L_p^c = L_p^{sq} + L_p^{KL}$.

2.3 N-gram Selection Strategy

Note that we do one forward pass for each unique $\mathbf{w}_k^{N-1}$, so only the number of distinct prefixes $\mathbf{w}_k^{N-1}$ will significantly affect the computational cost of our regularization methods. Naively regularizing all unique prefixes in a large corpus usually requires a large number of forward passes, which could be expensive. We hypothesize that some prefixes are more useful than others, so we attempt to select the ones that will improve the model the most. We propose to select prefixes $\mathbf{w}_k^{N-1}$ that maximize the **E**xpected **L**og-likelihood **C**hange (ELC), defined as:

$$ELC(\mathbf{w}_k^{N-1}) = \sum \hat{P}(\mathbf{w}_k^N) log \frac{\hat{P}(w_{kN}|\mathbf{w}_k^{N-1})}{P_\theta(w_{kN}|\mathbf{w}_k^{N-1})}.$$

Ideally, P_θ would reflect the statistics of the RNNLM, updated during training, but these are expensive to obtain. Thus we propose to train a inexpensive n-gram model (Chen and Goodman, 1999) on the sequential corpus to serve as P_θ, and we use that to select a fixed set of n-grams to regularize.

3 Experiments

We now present our experiments measuring the effectiveness of conditional n-gram regularization.

3.1 Data and Settings

We experiment on a medium-size (2 layers with 650 hidden states) LSTM language model (Zaremba et al., 2014) over two corpora: Wikitext (Merity et al., 2016) and Google Billion-Word (Chelba et al., 2013) (1B). We adopt weight tying (Inan et al., 2016) and variational dropout (Gal and Ghahramani, 2016). All models are trained by SGD for 30 epochs with batch size 64 and truncated backpropagation (Mikolov et al., 2011) with 35 time steps. The learning rate starts at 20 and then is reduced to 5 at epoch 20. For the 1B corpus, we follow the same procedure in Yang et al. (2017) to generate training, validation and test sets, except that we use only the top 50K vocabulary terms. For the Wikitext corpus, we adopt the Wikitext-2 vocabulary. All of the RNNLM sequential training sets are small subsets sampled from the Wikitext-103 and 1B training corpora.

For each dataset, we use the whole training set as the large corpus for building our reference conditional n-gram statistics. In this study, we only consider conditional trigram regularization for all experiments. The regularization takes additional time during training. To enable a fair experiment, we equalize the training time between regularized models and the baselines, by providing the baselines with more sequential training data than the regularized models. The three proposed penalties are almost equally fast, thus they can be compared against the same baseline. Unlike RNNs, there are no hyperparameter settings or decisions involved in computing the n-gram counts, so this can be done once and re-used across the many RNN training runs that adequate hyperparameter search for RNNs often entails. Moreover, counting n-grams is fast. We approximate that it takes about one minute to obtain n-gram statistics from the Wikitext-103 training corpus, for example. Thus, we set up our experiments to equalize neural network training time, and we ignore the small one-time cost of computing n-gram statistics.

We fix the number of bigrams per batch to be 500, and employ the proposed strategy to select the top X most informative bigrams (X depends on the number of batches in sequential data). Finally, instead of tuning the regularization strength hyperparameter α for each setting, we fix α to be 1.0, 0.75 and 0.5 for the three sequential data sizes based on the heuristic that larger sequential data may need less regularization. More carefully tuning the regularization strength might yield somewhat better results for our methods. Also, using different regularization strengths in the combined penalty might further improve results.

3.2 Results

In Table 1, we compare the performance of our proposed methods against equal-time controlled baselines under different token sizes for both the Wikitext and 1B data sets. In the table, the numbers in the column headings indicate the token count of the sequential corpus used to train the regularized methods. The baselines train on larger corpora, to ensure an equal-time setting as described above. All regularized models outperform their baseline counterparts for all token sizes. Among them, the models regularized by the combined penalty consistently perform best. This illustrates that conditional n-gram regularization is effective at incorporating large-corpus statistics to improve an RNNLM trained on a relatively small corpus. Performing regularization using the combined selection strategy yields more accurate models compared to simply training on a larger sequential corpus.

In Figure 1, we plot validation perplexities after each training epoch for models trained on the 5M-token 1B corpus, against an equal-time baseline. The plot shows that the relative performance of the methods remains similar across training epochs.

Methods	Wikitext			Google 1B		
	500K	1M	2M	2.5M	5M	10M
baseline	161	110	76	110	90	81
sq_log	122	91	72	98	86	80
KL	137	100	77	100	86	78
combined	**112**	**86**	**69**	**94**	**83**	**77**

Table 1: Test perplexities of different methods and sequential training token sizes. sq_log: mean squared log probability ratio penalty. KL: mean Kullback-Leibler divergence penalty. Models with the combined penalty achieve the lowest perplexities.

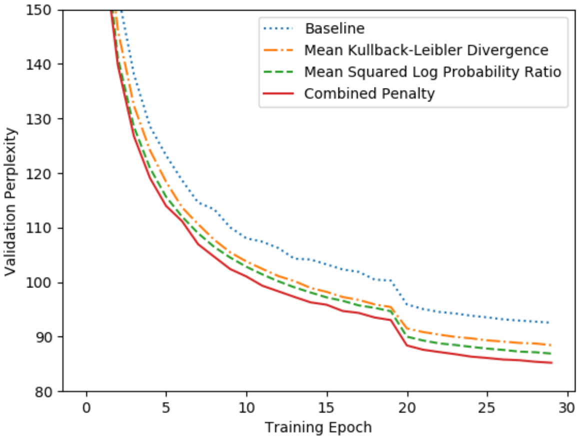

Figure 1: Validation Perplexities on the 5M-token 1B Dataset. The combined penalty performs best.

3.3 Analysis

In Table 2, we demonstrate how the number of regularized bigrams affects the performance. Here, the regularized models always train on wikitext-2 as a sequential corpus, and the baseline trains on larger corpora as the fractions of bigrams increases. The regularized model achieves 66 test perplexity on Wikitext-2 corpus, which is about 2.7 points worse than a state of the art mixture of softmax model (Yang et al., 2017) even though our model has fewer parameters (25M vs. 35M). Including more bigrams helps lower the perplexity, while it also demands extra computational time. ELC performs best when using less than 20% of the bigrams. Regularizing randomly selected n-grams does not outperform the equal-time baseline, indicating that not all n-grams are equally useful. In order to be time efficient, it is important to select informative n-grams, and ELC is an effective measure of informativeness.

% of total bigrams	baseline	random	ELC
0%	86	86	86
5%	76	83	**69**
10%	71	77	**67**
20%	**66**	71	67
40%	**61**	68	66

Table 2: Test perplexities of RNNLMs trained on Wikitext-2 regularized with different numbers of bigrams using the combined penalty. Baseline indicates an equal-time controlled baseline, random is a regularized model with bigrams selected randomly, and ELC indicates our proposed strategy.

In Table 3, we consider ensembling a standard RNN with a KN-smoothed trigram model. This achieves a ppl of 65, but requires 51M more parameters, whereas our regularization with the n-grams achieves most of the perplexity improvement at the cost of zero additional parameters. Further, somewhat surprisingly we find that an ensemble of our regularized RNNLM with the n-gram model achieves much better perplexity of 59.

Models	Test PPL
Unregularized RNNLM	86
Unregularized RNNLM + Trigram KN	65
Regularized RNNLM	67
Regularized RNNLM + Trigram KN	**59**

Table 3: Test perplexities of RNN-LMs trained with and without regularization on the Wikitext-2 corpus, ensembled with a KN-smoothed trigram model trained on the Wikitext-103 corpus.

Another possible way of efficiently utilizing a large corpus would involve training a Word2vec model on the large corpus, and using the pre-trained embeddings within a RNNLM trained on a small corpus. This approach can utilize larger corpora since training a Word2vec model is much faster than training a RNNLM. However, in our preliminary experiments with this approach, we did not observe any improvement when using word embeddings trained on a large corpus. Further experiments with variants of this approach are an item of future work.

4 Related Work

Chelba et al. (2017) trained large-order n-gram models using a recurrent neural network trained over limited context to produce the conditional probability estimates. Our regularizer is trained in a similar way, but by contrast we are focused on how the regularizer can be used in concert with standard sequential RNNLM training to improve the training procedure. We introduce n-gram selection techniques and distinct loss functions that increase the effectiveness of the combined training. Ganchev et al. (2010) presents a posterior regularization method for restricting posterior distributions of probabilistic models with latent variables to obey predefined constraints using the EM algorithm. This approach shares our goal of imposing constraints on probabilistic models, but we focus on RNNLMs, which do not estimate distributions over latent state variables and are not trained using EM. Finally, Mikolov et al. (2011), Józefowicz et al. (2016) and Chelba et al. (2013) trained ensembles of RNNLMs and KN-smoothed n-gram models, and showed that one can obtain a better model when ensembling RNNLMs with n-gram models. Our experiments show that compared to ensemble methods, conditional n-gram regularization achieves similar results at the cost of zero additional parameters, and can perform even better when combined with ensembling.

5 Conclusion and Future Work

In this paper, we have proposed methods to utilize using large corpus n-gram statistics to regularize RNNLMs trained on a smaller corpus. Our experiments demonstrate that the proposed regularization penalties are effective in improving model performance, and can be more time efficient than training RNNLMs on a larger sequential corpus. Selecting informative n-grams is shown to be important. In future work, we would like to obtain a better theoretical understanding of why starting the RNNLM from a zero state forms an effective n-gram regularizer. We would also like to extend our regularization approach to BiLSTMs (Peters et al., 2017) and Transformers (Alec Radford and Sutskever, 2018; Devlin et al., 2018).

Abstract

Distributed representations of sentences have become ubiquitous in natural language processing tasks. In this paper, we consider a continual learning scenario for sentence representations: Given a sequence of corpora, we aim to optimize the sentence encoder with respect to the new corpus while maintaining its accuracy on the old corpora. To address this problem, we propose to initialize sentence encoders with the help of corpus-independent features, and then sequentially update sentence encoders using Boolean operations of *conceptor* matrices to learn corpus-dependent features. We evaluate our approach on semantic textual similarity tasks and show that our proposed sentence encoder can continually learn features from new corpora while retaining its competence on previously encountered corpora.

1 Introduction

Distributed representations of sentences are essential for a wide variety of natural language processing (NLP) tasks. Although recently proposed sentence encoders have achieved remarkable results (e.g., (Yin and Schütze, 2015; Arora et al., 2017; Cer et al., 2018; Pagliardini et al., 2018)), most, if not all, of them are trained on *a priori* fixed corpora. However, in open-domain NLP systems such as conversational agents, oftentimes we are facing a dynamic environment, where training data are accumulated sequentially over time and the distributions of training data vary with respect to external input (Lee, 2017; Mathur and Singh, 2018). To effectively use sentence encoders in such systems, we propose to consider the following *continual sentence representation learning task*: Given a sequence of corpora, we aim to train sentence encoders such that they can continually learn features from new corpora while retaining strong performance on previously encountered corpora.

Toward addressing the continual sentence representation learning task, we propose a simple sentence encoder that is based on the summation and linear transform of a sequence of word vectors aided by matrix conceptors. Conceptors have their origin in reservoir computing (Jaeger, 2014) and recently have been used to perform continual learning in deep neural networks (He and Jaeger, 2018). Here we employ Boolean operations of conceptor matrices to update sentence encoders over time to meet the following desiderata:

1. *Zero-shot learning*. The initialized sentence encoder (no training corpus used) can effectively produce sentence embeddings.
2. *Resistant to catastrophic forgetting*. When the sentence encoder is adapted on a new training corpus, it retains strong performances on old ones.

The rest of the paper is organized as follows. We first briefly review a family of linear sentence encoders. Then we explain how to build upon such sentence encoders for continual sentence representation learning tasks, which lead to our proposed algorithm. Finally, we demonstrate the effectiveness of the proposed method using semantic textual similarity tasks.[1]

Notation We assume each word w from a vocabulary set V has a real-valued word vector $v_w \in \mathbb{R}^n$. Let $p(w)$ be the monogram probability of a word w. A corpus D is a collection of sentences, where each sentence $s \in D$ is a multiset of words (word order is ignored here). For a collection of vectors $Y = \{y_i\}_{i \in I}$, where $y_i \in \mathbb{R}^l$

for i in an index set I with cardinality $|I|$, we let $[y_i]_{i\in I} \in \mathbb{R}^{l\times|I|}$ be a matrix whose columns are vectors $y_1, \cdots, y_{|I|}$. An identity matrix is denoted by $\mathbf{I}$.

2 Linear sentence encoders

We briefly overview "linear sentence encoders" that are based on linear algebraic operations over a sequence of word vectors. Among different linear sentence encoders, the smoothed inverse frequency (SIF) approach (Arora et al., 2017) is a prominent example – it outperforms many neural-network based sentence encoders on a battery of NLP tasks (Arora et al., 2017).

Derived from a generative model for sentences, the SIF encoder (presented in Algorithm 1) transforms a sequence of word vectors into a sentence vector with three steps. First, for each sentence in the training corpus, SIF computes a weighted average of word vectors (line 1-3 of Algorithm 1); next, it estimates a "common discourse direction" of the training corpus (line 4 of Algorithm 1); thirdly, for each sentence in the testing corpus, it calculates the weighted average of the word vectors and projects the averaged result away from the learned common discourse direction (line 5-8 of Algorithm 1). Note that this 3-step paradigm is slightly more general than the original one presented in (Arora et al., 2017), where the training and the testing corpus is assumed to be the same.

```
Algorithm 1: SIF sentence encoder.
Input : A training corpus $D$; a testing corpus $G$; parameter $a$, monogram
        probabilities $\{p(w)\}_{w\in V}$ of words
1 for sentence $s \in D$ do
2     $q_s \leftarrow \frac{1}{|s|}\sum_{w\in s}\frac{a}{p(w)+a}v_w$
3 end
4 Let $u$ be the first singular vector of $[q_s]_{s\in D}$.
5 for sentence $s \in G$ do
6     $q_s \leftarrow \frac{1}{|s|}\sum_{w\in s}\frac{a}{p(w)+a}v_w$
7     $f_s^{\text{SIF}} \leftarrow q_s - uu^\top q_s$.
8 end
Output: $\{f_s^{\text{SIF}}\}_{s\in G}$
```

Building upon SIF, recent studies have proposed further improved sentence encoders (Khodak et al., 2018; Pagliardini et al., 2018; Yang et al., 2018). These algorithms roughly share the core procedures of SIF, albeit using more refined methods (e.g., softly remove more than one common discourse direction).

3 Continual learning for linear sentence encoders

In this section, we consider how to design a linear sentence encoder for continual sentence representation learning. We observe that common discourse directions used by SIF-like encoders are estimated from the training corpus. However, incrementally estimating common discourse directions in continual sentence representation learning tasks might not be optimal. For example, consider that we are sequentially given training corpora of `tweets` and `news article`. When the first `tweets` corpus is presented, we can train a SIF sentence encoder using `tweets`. When the second `news article` corpus is given, however, we will face a problem on how to exploit the newly given corpus for improving the *trained* sentence encoder. A straightforward solution is to first combine the `tweets` and `news article` corpora and then train a new encoder from scratch using the combined corpus. However, this paradigm is not efficient or effective. It is not efficient in the sense that we will need to re-train the encoder from scratch every time a new corpus is added. Furthermore, it is not effective in the sense that the common direction estimated from scratch reflects a compromise between tweets and news articles, which might not be optimal for either of the stand-alone corpus. Indeed, it is possible that larger corpora will swamp smaller ones.

To make the common discourse learned from one corpus more generalizable to another, we propose to use the conceptor matrix (Jaeger, 2017) to characterize and update the common discourse features in a sequence of training corpora.

3.1 Matrix conceptors

In this section, we briefly introduce matrix conceptors, drawing heavily on (Jaeger, 2017; He and Jaeger, 2018; Liu et al., 2019). Consider a set of vectors $\{x_1, \cdots, x_n\}$, $x_i \in \mathbb{R}^N$ for all $i \in \{1, \cdots, n\}$. A conceptor matrix is a regularized identity map that minimizes

$$\frac{1}{n}\sum_{i=1}^{n}\|x_i - Cx_i\|_2^2 + \alpha^{-2}\|C\|_{\text{F}}^2. \qquad (1)$$

where $\|\cdot\|_{\text{F}}$ is the Frobenius norm and α^{-2} is a scalar parameter called *aperture*. It can be shown that C has a closed form solution:

$$C = \frac{1}{n}XX^\top(\frac{1}{n}XX^\top + \alpha^{-2}I)^{-1}, \qquad (2)$$

where $X = [x_i]_{i\in\{1,\cdots,n\}}$ is a data collection matrix whose columns are vectors from $\{x_1, \cdots, x_n\}$. In intuitive terms, C is a soft projection matrix on the linear subspace where the typical components of x_i samples lie. For convenience in notation, we may write $C(X, \alpha)$ to stress the dependence on X and α.

Conceptors are subject to most laws of Boolean logic such as NOT $\neg$, AND $\wedge$ and OR $\vee$. For two conceptors C and B, we define the following operations:

$$\neg C := \mathbf{I} - C, \qquad (3)$$

$$C \wedge B := (C^{-1} + B^{-1} - \mathbf{I})^{-1} \qquad (4)$$

$$C \vee B := \neg(\neg C \wedge \neg B) \qquad (5)$$

Among these Boolean operations, the OR operation $\vee$ is particularly relevant for our continual sentence representation learning task. It can be shown that $C \vee B$ is the conceptor computed from the union of the two sets of sample points from which C and B are computed. Note that, however, to calculate $C \vee B$, we only need to know two matrices C and B and do not have to access to the two sets of sample points from which C and B are computed.

3.2 Using conceptors to continually learn sentence representations

We now show how to sequentially characterize and update the common discourse of corpora using the Boolean operation of conceptors. Suppose that we are sequentially given M training corpora $D^1, \cdots, D^M$, presented one after another. Without using any training corpus, we first initialize a conceptor which characterizes the corpus-independent common discourse features. More concretely, we compute $C^0 := C([v_w]_{w\in Z}, \alpha)$, where $[v_w]_{w\in Z}$ is a matrix of column-wisely stacked word vectors of words from a stop word list Z and α is a hyper-parameter. After initialization, for each new training corpus D^i ($i = 1, \cdots, M$) coming in, we compute a new conceptor $C^{\text{temp}} := C([q_s]_{s\in D^i}, \alpha)$ to characterize the common discourse features of corpus D^i, where those q_s are defined in the SIF Algorithm 1. We can then use Boolean operations of conceptors to compute $C^i := C^{\text{temp}} \vee C^{i-1}$, which characterizes common discourse features from the new corpus as well as the old corpora. After all M corpora are presented, we follow the SIF paradigm and use C^M to remove common discourse features from (potentially unseen) sentences. The above outlined conceptor-aided (CA) continual sentence representation learning method is presented in Algorithm 2.

Algorithm 2: CA sentence encoder.

```
Input : A sequence of $M$ training corpora
        $\mathcal{D} = \{D^1, \cdots, D^M\}$; a testing
        corpus $G$; hyper-parameters $a$ and $\alpha$;
        word probabilities $\{p(w)\}_{w\in V}$; stop
        word list $Z$.
1  $C^0 \leftarrow C([v_w]_{w\in Z}, \alpha)$ .
2  for corpus index $i = 1, \cdots, M$ do
3      for sentence $s \in D^i$ do
4          $q_s \leftarrow \frac{1}{|s|}\sum_{w\in s}\frac{a}{p(w)+a}v_w$
5      end
6      $C^{\text{temp}} \leftarrow C([q_s]_{s\in D^i}, \alpha)$
7      $C^i \leftarrow C^{\text{temp}} \vee C^{i-1}$
8  end
9  for $s \in G$ do
10     $q_s \leftarrow \frac{1}{|s|}\sum_{w\in s}\frac{a}{p(w)+a}v_w$
11     $f_s^{\text{CA}} \leftarrow q_s - C^M q_s$
12 end
Output: $\{f_s^{\text{CA}}\}_{s\in G}$
```

A simple modification of Algorithm 2 yields a "zero-shot" sentence encoder that requires only pre-trained word embeddings and no training corpus: we can simply skip those corpus-dependent steps (line 2-8) and use C^0 in place of C^M in line 11 in Algorithm 2 to embed sentences. This method will be referred to as "zero-shot CA."

4 Experiment

We evaluated our approach for continual sentence representation learning using semantic textual similarity (STS) datasets (Agirre et al., 2012, 2013, 2014, 2015, 2016). The evaluation criterion for such datasets is the Pearson correlation coefficient (PCC) between the predicted sentence similarities and the ground-truth sentence similarities. We split these datasets into five corpora by their genre: news, captions, wordnet, forums, tweets (for details see appendix). Throughout this section, we use publicly available 300-

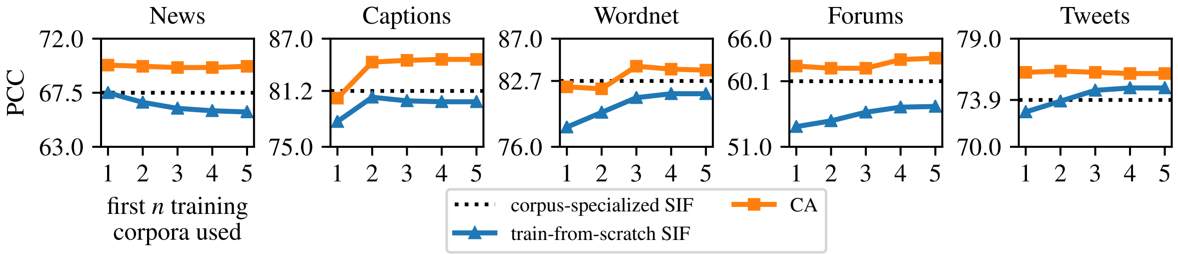

Figure 1: PCC results of STS datasets. Each panel shows the PCC results of a testing corpus (specified as a subtitle) as a function of increasing numbers of training corpora used. The setup of this experiment mimics (Zenke et al., 2017, section 5.1).

	News	Captions	WordNet	Forums	Tweets
av. train-from-scratch SIF	66.5	79.7	80.3	55.5	74.2
zero-shot CA	65.6	79.8	82.5	61.5	75.2
av. CA	**69.7**	**83.8**	**83.2**	**62.5**	**76.2**

Table 1: Time-course averaged PCC of train-from-scratch SIF and conceptor-aided (CA) methods, together with the result of zero-shot CA. Best results are in boldface and the second best results are underscored.

dimensional GloVe vectors (trained on the 840 billion token Common Crawl) (Pennington et al., 2014). Additional experiments with Word2Vec (Mikolov et al., 2013), Fasttext (Bojanowski et al., 2017), Paragram-SL-999 (Wieting et al., 2015) are in the appendix.

We use a standard continual learning experiment setup (cf. (Zenke et al., 2017, section 5.1)) as follows. We sequentially present the five training datasets in the order[2] of news, captions, wordnet, forums, and tweets, to train sentence encoders. Whenever a new training corpus is presented, we train a SIF encoder from scratch[3] (by combining all available training corpora which have been already presented) and then test it on each corpus. At the same time, we incrementally adapt a CA encoder[4] using the newly presented corpus and test it on each corpus. The lines of each panel of Figure 1 show the test results of SIF and CA on each testing corpus (specified as the panel subtitle) as a function of the number of training corpora used (the first n corpora of news, captions, wordnet, forums, and tweets for this experiment). To give a concrete example, consider the blue line in the first panel of Figure 1. This line shows the test PCC scores (y-axis) of SIF encoder on the news corpus when the number of training corpora increases (x-axis). Specifically, the left-most blue dot indicates the test result of SIF encoder on news corpus when trained on news corpus itself (that is, the first training corpus is used); the second point indicates the test results of SIF encoder on news corpus when trained on news and captions corpora (i.e., the first *two* training corpora are used); the third point indicates the test results of SIF encoder on news corpus when trained on news, captions, and wordnet corpora (that is, the first *three* training corpora are used), so on and so forth. The dash-lines in panels show the results of a corpus-specialized SIF, which is trained and tested on the same corpus, i.e., as done in (Arora et al., 2017, section 4.1). We see that the PCC results of CA are better and more "forgetting-resistant" than train-from-scratch SIF throughout the time course where more training data are incorporated. Consider, for example, the test result of news corpus (first panel) again. As more and more training corpora are used, the performance of train-from-scratch SIF drops with a noticeable slope; by contrast, the performance CA drops only slightly.

As remarked in the section 3.2, with a simple modification of CA, we can perform zero-shot sentence representation learning without using any training corpus. The zero-shot learning results are

---

[2] The order can be arbitrary. Here we ordered the corpora from the one with the largest size (news) to the smallest size (tweets). The results from reversely ordered corpora are reported in the appendix.

[3] We use $a = 0.001$ as in (Arora et al., 2017). The word frequencies are available at the GitHub repository of SIF.

[4] We used hyper-parameter $\alpha = 1$. Other parameters are set to be the same as SIF.

presented in Table 1, together with the time-course averaged results of CA and train-from-scratch SIF (i.e., the averaged values of those CA or SIF scores in each panel of Figure 1). We see that the averaged results of our CA method performs the best among these three methods. Somewhat surprisingly, the results yielded by zero-shot CA are better than the averaged results of train-from-scratch SIF in most of the cases.

We defer additional experiments to the appendix, where we compared CA against more baseline methods and use different word vectors other than GloVe to carry out the experiments.

5 Conclusions and future work

In this paper, we formulated a continual sentence representation learning task: Given a consecutive sequence of corpora presented in a time-course manner, how can we extract useful sentence-level features from new corpora while retaining those from previously seen corpora? We identified that the existing linear sentence encoders usually fall short at solving this task as they leverage on "common discourse" statistics estimated based on a priori fixed corpora. We proposed two sentence encoders (CA encoder and zero-shot CA encoder) and demonstrate their the effectiveness at the continual sentence representation learning task using STS datasets.

As the first paper considering continual sentence representation learning task, this work has been limited in a few ways – it remains for future work to address these limitations. First, it is worthwhile to incorporate more benchmarks such as GLUE (Wang et al., 2019) and SentEval (Conneau and Kiela, 2018) into the continual sentence representation task. Second, this work only considers the case of linear sentence encoder, but future research can attempt to devise (potentially more powerful) non-linear sentence encoders to address the same task. Thirdly, the proposed CA encoder operates at a corpus level, which might be a limitation if boundaries of training corpora are ill-defined. As a future direction, we expect to lift this assumption, for example, by updating the common direction statistics at a sentence level using Autoconceptors (Jaeger, 2014, section 3.14). Finally, the continual learning based sentence encoders should be applied to downstream applications in areas such as open domain NLP systems.

Relation Discovery with Out-of-Relation Knowledge Base as Supervision

Abstract

Unsupervised relation discovery aims to discover new relations from a given text corpus without annotated data. However, it does not consider existing human annotated knowledge bases even when they are relevant to the relations to be discovered. In this paper, we study the problem of how to use out-of-relation knowledge bases to supervise the discovery of unseen relations, where out-of-relation means that relations to discover from the text corpus and those in knowledge bases are not overlapped. We construct a set of constraints between entity pairs based on the knowledge base embedding and then incorporate constraints into the relation discovery by a variational auto-encoder based algorithm. Experiments show that our new approach can improve the state-of-the-art relation discovery performance by a large margin.

1 Introduction

Relation extraction has been widely used for many applications, such as knowledge graph construction (Dong et al., 2014), information retrieval (Liu et al., 2014), and question answering (Ravichandran and Hovy, 2002). Traditional supervised approaches require direct annotation on sentences with a relatively small number of relations (Roth and Yih, 2002; Kambhatla, 2004).[1] With the development of large-scale knowledge bases (KBs) such as Freebase (Bollacker et al., 2008), relation extraction has been extended to larger scales comparable to KBs using the distant supervision (Mintz et al., 2009). However, when the training corpus does not support the annotated relations showing in the KB, such approach could fail to find sufficient training examples. Distant supervision assumption can be violated by up to 31% for some relations when aligning to NYT corpus (Riedel et al., 2010). More importantly, either traditional supervised learning or distantly supervised learning cannot discover new relations unseen in the training phase.

Unsupervised relation discovery tries to overcome the shortcomings of supervised or distantly supervised learning approaches. Existing approaches either extract surface or syntactic patterns from sentences and use relation expressions as predicates (which result in many noisy relations) (Etzioni et al., 2004; Banko et al., 2007), or cluster the relation expressions based on the extracted triplets to form relation clusters (Yao et al., 2011, 2012; Marcheggiani and Titov, 2016). However, these approaches do not use existing high-quality and large-scale KBs when they are relevant to the relations to be discovered.

In this paper, we consider a new relation discovery problem where both the training corpus for relation clustering and a KB are available, but the relations in the training corpus and those in the KB are not overlapped. As shown in Figure 1, in the KB, we have entities `Pink Floyd`, `Animals`, etc., with some existing relations *notable_work* and *has_member* in the KB. However, when doing relation discovery, we can only get supporting sentences that suggest new relations *based_on* and *influenced_by*. This is a common and practical problem since predicates in KBs are limited to the annotator defined relations while the real relations in the world are always open and creative.

It is challenging when there is no overlapped relation between target relation clusters and the KB because in this case the KB is not a direct supervision. But if target relation clusters and the KB share some entities, we can use the shared entities as a bridge to introduce indirect supervision for the relation discovery problem. Specifically, we build constraints between pairs of tuples based on the

---

[1] We distinguish a relation (e.g., a predicate in a knowledge base) from the relation expression (e.g., the text surface between entities in a sentence) throughout the paper.

Amused to Death was inspried by Neil Postman's book **Amusing Ourselves to Death**.

Loosely based on George Orwell's **Animal Farm**, **Animals** describe various classes in society as different kinds of animals

Postman distinguishes the **Orwellian** vision of the future, from that offered by Aldous Huxley in Brave New World.

Figure 1: An illustration of our new relation discovery setting. The konwledge base contains relations *notable_work* and *has_member*. However, the training corpus to perform relation discovery only contains new relations *based_on* and *influenced_by*.

KB. For example, in Figure 1, when we cluster the *based_on* relation, we can evaluate the similarity between the tuple (`Animals`, `Animal Farm`) and the tuple (`Amused to Death`, `Amusing Ourselves to Death`) based on the KB. If the KB tells us these two pairs of tuples are close to each other, then we put a constraint to force our relation clustering algorithm to group them together.

We use the discrete-state variational autoencoder (DVAE) framework (Marcheggiani and Titov, 2016) as our base relation discovery model since this framework is flexible to incorporate different features and currently the state-of-the-art. We use KB embedding (Bordes et al., 2013) to obtain entity embeddings in the KB and use entity embeddings to evaluate the similarity between a pair of tuples. Then constraints are constructed and incorporated into the DVAE framework in a way inspired by the must-link and cannot-link based constrained clustering (Basu et al., 2004). We show that with no overlapped relations between the KB and the training corpus, we can improve the relation discovery by a large margin.

Our contributions are summarized as follows.

- We study a new prevalent but challenging task of relation discovery where the training corpus and the KB have no overlapped relation.
- We propose a new kind of indirect supervision to relation discovery which is built based on pairwise constraints between two tuples.
- We show promising results using existing relation discovery datasets to demonstrate the effectiveness of our proposed learning algorithm for the new relation discovery task.

The code we used to train and evaluate our models is available at `https://github.com/HKUST-KnowComp/RE-RegDVAE`.

2 Problem Definition

We use $\mathcal{X}$ to denote the set of all training sentences. $\mathcal{V}$ is the set of named entities that are recognized by an NER system in $\mathcal{X}$, and (e_1, e_2) is the pair of first and second entities in a given sentence $x \in \mathcal{X}$. $\mathcal{R}_\mathcal{X}$ is the set of relation labels for $\mathcal{X}$. In addition, there exists an external knowledge base $\mathcal{G}(\mathcal{E}_\mathcal{G}, \mathcal{T}_\mathcal{G})$, consisting of a set of entities $\mathcal{E}_\mathcal{G}$ and relations $\mathcal{R}_\mathcal{G}$ and triplets $\mathcal{T}_\mathcal{G}$ where a triplet consists of two entities with their relation.

Our model is a relation extractor to predict the underlying semantic relation $r \in \mathcal{R}_\mathcal{X}$ given sentences $\mathcal{X}$, with the help of $\mathcal{G}(\mathcal{E}_\mathcal{G}, \mathcal{T}_\mathcal{G})$. In particular, we focus on the challenging scenario where $\mathcal{R}_\mathcal{X} \cap \mathcal{R}_\mathcal{G} = \emptyset$.

3 Model

In this section, we first review the discrete-state variational autoencoder (DVAE) in §3.1. Then we introduce our new framework in §3.2.

3.1 DVAE for Relation Discovery

Assuming that we perform generative modeling, where each latent relation r follows a uniform prior distribution $p_u(r)$, we follow (Marcheggiani and Titov, 2016) to optimize a pseudo-likelihood:

$$\mathcal{L}(\theta) = \log \sum_{r \in \mathcal{R}_{\mathcal{X}}} p(e_i, e_{-i} | r, \theta) p_u(r) \tag{1}$$

$$\approx \sum_{i=1}^{2} \log \sum_{r \in \mathcal{R}_{\mathcal{X}}} p(e_i | e_{-i}, r, \theta) p_u(r), \tag{2}$$

where e_i and e_{-i} are entities, $i \in \{1, 2\}$ and e_{-i} denotes the complement $\{e_1, e_2\} \setminus \{e_i\}$. $p(e_i|e_{-i}, r, \theta)$ is the probability of one entity given another entity as well as the relation, where θ denotes the set of parameters. Note that this probability p is defined on the triplet (e_1, r, e_2) which is universal across different sentences containing the two entities.

The pseudo-likelihood $\mathcal{L}(\theta)$ can be lower-bounded based on Jensen's inequality through a variational posterior $q(r|x, \psi)$:

$$\begin{aligned}\mathcal{L}(\theta, \psi) = & \sum_{i=1}^{2} \sum_{r \in \mathcal{R}_{\mathcal{T}}} q(r|x, \psi) \log p(e_i | e_{-i}, r, \theta) \\ & + \alpha H \left[q(r|x, \psi) \right],\end{aligned} \tag{3}$$

where $q(r|x, \psi)$ predicts the relation based on the whole sentence x as an input and ψ as the set of parameters. H is the entropy to regularize the probability distribution q, and α is the hyper-parameter to balance the regularization strength.

This model consists of two components, an encoder $q(r|x, \psi)$ which encodes sentence features into a relation distribution, and a decoder $p(e_i|r, e_{-i}, \theta)$ which predicts an entity given the relation cluster and another entity. Both are modeled by softmax functions:

$$q(r|x, \psi) = \frac{\exp\left(\mathbf{w}_r^{\intercal} \mathbf{g}(x)\right)}{\sum_{r' \in \mathcal{R}_{\mathcal{X}}} \exp\left(\mathbf{w}_{r'}^{\intercal} \mathbf{g}(x)\right)}, \tag{4}$$

$$p(e_i | e_{-i}, r, \theta) = \frac{\exp\left(\phi(e_i, e_{-i}, r, \theta)\right)}{\sum_{e'_i \in \mathcal{V}} \exp\left(\phi(e'_i, e_{-i}, r, \theta)\right)}, \tag{5}$$

where $\psi = \{\mathbf{w}_r | r \in \mathcal{R}_{\mathcal{X}}\}$ and $\mathbf{g}(x)$ is a vector representation of sentence x, which can be high-dimensional one-hot feature encodings or low-dimensional sentence embeddings encoded by deep neural networks. $\phi(e_1, e_2, r, \theta)$ can be a general scoring function defined over triplets. We use the instantiation with the best performance shown by (Marcheggiani and Titov, 2016), which is a combination of bilinear model and selectional preference model:

$$\phi(e_1, e_2, r, \theta) = \mathbf{e}_1^{\intercal} \mathbf{C}_r \mathbf{e}_2 + [\mathbf{e}_1, \mathbf{e}_2]^{\intercal} \mathbf{r} \tag{6}$$

where $\theta = \{\mathbf{C}_r, \mathbf{r}, \mathbf{e}_i | r \in \mathcal{R}_{\mathcal{T}}, e_i \in \mathcal{V}\}$, $\mathbf{C}_r$ is a matrix, $\mathbf{r}$ is a vector for the relation r, $\mathbf{e}_1$ and $\mathbf{e}_2$ are the vectors for head and tail entities respectively, and $[\mathbf{e}_1, \mathbf{e}_2]$ is the concatenation of the vector representations of the two entities.

The DVAE model directly optimizes the variational lower bound by doing gradient ascent for θ and ψ jointly. Both encoder $q(r|x, \psi)$ and decoder $p(e_i|r, e_{-i}, \theta)$ are implemented as neural networks. Standard training techniques and tricks can be applied.

3.2 Knowledge Base Constraint

Our KB constraint framework can be summarized as a two-step procedure: KB constraints construction and regularization for the learning model. In the constraints construction step, a set of sentences is formed as a query to KB and retrieves a set of constraints back. Then in the regularization step, we apply the constraint to regularize posterior distributions of the relation extractor.

Conceptually, given a set of sentences $\mathcal{X}$, we want to bias the learning result: After the entities are linked to the KB, if KB inference indicates that some pairs should be in a relation based on a set of rules Υ, then the extractor should be constrained to output it. This constraint can be encoded into a feature function $Q(\mathcal{X})$ = "entity pairs in the same relation based on Υ" and put into the posterior regularization framework (Gillenwater et al., 2011). However, the computational complexity of the feature function is exponential since we need to traverse the KB to find Υ. We instead consider the must-link and cannot-link constraints (Basu et al., 2004), indicating respectively that a pair of sentences should be or should not be labeled as the same relation. For each pairwise constraint, the model assigns an associated cost of violating that constraint for the model regularization.

3.2.1 KB Constraints Construction

From the perspective of KB, a must-link constraint on sentences (x_1, x_2) exists if two pairs of entities $(p_1, p_2) = [(e_{1,1}, e_{1,2}), (e_{2,1}, e_{2,2})]$ are similar given the KB, where $(e_{i,1}, e_{i,2})$ is the entity pair

Euclidean L_2 distance	$d_{Euc}\left(q_1(r), q_2(r)\right) = \sqrt{\sum_r \lvert q_1(r) - q_2(r)\rvert^2}$
Kullback-Leibler (KL) divergence	$d_{KL}(q_1(r), q_2(r)) = \sum_r q_1(r) \log\left(\frac{q_1(r)}{q_2(r)}\right)$
Jensen-Shannon (JS) divergence	$d_{JS}(q_1(r), q_2(r)) = \frac{1}{2}\sum_r q_1(r) \log\left(\frac{2q_1(r)}{q_1(r)+q_2(r)}\right) + \frac{1}{2}\sum_r q_2(r) \log\left(\frac{2q_2(r)}{q_1(r)+q_2(r)}\right)$

Table 1: Cluster regularization with different distance or divergences.

belongs to sentence x_i. This motivates us to define a similarity score for a pair of entity pairs. Instead of modeling the common relation paths or logic rules, which is computationally infeasible, we compare them in the latent embedding space. In particular, we model the KB using the TransE (Bordes et al., 2013) model, where a relation is interpreted as a translation from the head entity to the tail entity, with a score function, $\mathbf{e}_1 + \mathbf{r} = \mathbf{e}_2$ for each gold triplet (e_1, r, e_2) in the KB. This operation is fast and the latent embeddings are expressive in many cases. Then we can reason the latent relation representation of a particular pair in vector space by $\mathbf{r}_i = \mathbf{e}_{i,2} - \mathbf{e}_{i,1}$, without the need for extra parameters. Here $\mathbf{r}_i$ is not necessarily a real relation between two entities in the KB but just reflects the geometric property. The penalty for violating a must-link constraint between a pair of sentences with a high KB score should be higher than those with low KB scores. This further inspires us to define a soft constraint penalty based on the similarity of latent KB relations.

Here, we use the adjusted cosine similarity (Sarwar et al., 2001) between two latent relations as a must-link confidence score

$$s^+(x_1, x_2) = [\cos(\mathbf{e}_{1,2} - \mathbf{e}_{1,1}, \mathbf{e}_{2,2} - \mathbf{e}_{2,1})]^+_{\gamma^+} \tag{7}$$

where $[x]^+_{\gamma^+} = x$ if $x > \gamma^+$ otherwise 0, $\gamma^+ \in [0, 1]$ is a threshold we defined to control the must-link scope, $e_{i,j}$ is named entity in x_i and $\mathbf{e}_{i,j}$ is its embedding. The similarity between $\mathbf{e}_{1,2} - \mathbf{e}_{1,1}$ and $\mathbf{e}_{2,2} - \mathbf{e}_{2,1}$ evaluates whether two sentences indicate similar relations according to the KB embedding.

We also define the cannot-link in a similar way, where two sentences cannot be in the same cluster with a confidence

$$s^-(x_1, x_2) = [\cos(\mathbf{e}_{1,2} - \mathbf{e}_{1,1}, \mathbf{e}_{2,2} - \mathbf{e}_{2,1})]^-_{\gamma^-} \tag{8}$$

where $[x]^-_{\gamma^-} = x$ if $x < -\gamma^-$ otherwise 0, and $\gamma^- \in [0, 1]$ is a threshold we defined to control the cannot-link scope. We simply set $\gamma^+ = \gamma^- = \gamma$.

3.2.2 Clustering Regularization

For each pair of sentences (x_1, x_2), the relation extractor will predict a clustering posterior $q_i(r|x_i, \psi)$, $i = 1, 2$, which can be computed based on Eq. (4). We regularize the clustering result on the probability distance between sentence pairs, using either Euclidean L_2 distance, Kullback-Leibler (KL) divergence, or Jensen-Shannon (JS) divergence. The computation of the distance or divergences can be found in Table 1.

Then the soft constraints introduced in §3.2.1 are applied on the corresponding distance to calculate the regularization terms:

$$D^+(x_1, x_2) = -d_*\left(q_1(r), q_2(r)\right) s^+(x_1, x_2), \tag{9}$$

$$D^-(x_1, x_2) = d_*\left(q_1(r), q_2(r)\right) |s^-(x_1, x_2)|, \tag{10}$$

for must and cannot links respectively, where d_* can be d_{Euc}, d_{KL}, or d_{JS}. Taking must-link constraint as an example, if the posterior distributions $q_1(r|x_1, \psi)$ and $q_2(r|x_2, \psi)$ are different from each other but KB suggests that these two sentences should be in the same cluster where $s^+(x_1, x_2)$ is large, then $d_*\left(q_1(r), q_2(r)\right)$ being large means there is a large cost when q_1 and q_2 being different. Then in the training phase, we want to reduce this cost given the constraint.

The constraints above are defined in a $|\mathcal{X}| \times |\mathcal{X}|$ space. It is almost impossible to enumerate all of the constraints. To make it trainable, we instead gather the constraints within a mini-batch. Since in different training epochs we randomly permute the training samples, it is possible to touch many pairs of sentences in practice.

3.3 Learning

The model parameters only exist in original autoencoder components (i.e., ψ and θ), which can be jointly optimized by maximizing the following objective function with L_2 regularization:

$$\begin{aligned}\mathcal{L}(\theta,\psi) = &\sum_{x\in X}\sum_{i=1}^{2}\sum_{r\in R_T} q(r|x,\psi)\log p(e_i|e_{-i},r,\theta)\\ &+\sum_{x\in X}\alpha H\left[q(r|x,\psi)\right]\\ &+\sum_{X_i\sim X}\sum_{(x_1,x_2)\in X_i}\beta D(x_1,x_2)\\ &+\lambda\|(\psi,\theta)\|_2,\end{aligned} \tag{11}$$

where α, β, γ, and λ are hyper-parameters to control the regularization strength. D can be D^+ or D^- depending on the cosine similarity between pairs. In practice, we apply annealing method over α in an exponential way:

$$\alpha_t = \alpha_0 \exp(-\eta t) \text{ and } \eta = \frac{\log(\alpha_0/\alpha_T)}{T},$$

where α_0 is the initial value, and α_T is the final value, t and T are the current and total training steps respectively. This method enables the extractor to explore more possibilities first and finally converge to a stable distribution.

It is difficult to directly compute the partition function in Eq. (5), as it requires to sum over $|\mathcal{V}|$. We use the same negative sampling method as (Marcheggiani and Titov, 2016) to substitute $\log p(e_i|e_{-i},r,\theta)$ in Eq. (11) with:

$$\begin{aligned}\log p(e_i|e_{-i},r,\theta) \approx &\log\sigma(\phi(e_i,e_{-i},r,\theta))\\ &+\sum_{e^{\text{neg}}\in\mathcal{N}}\log\sigma\left(-\phi(e^{\text{neg}},e_i,r,\theta)\right),\end{aligned}$$

where $\mathcal{N}$ is the set of randomly sampled entities in $\mathcal{V}$ and σ is the sigmoid function.

4 Experiments

In this section, we show the experimental results.

4.1 Dataset and Preprocessing

We evaluate our model in the context of unsupervised relation discovery and compare to the baseline model, DVAE (Marcheggiani and Titov, 2016) which is the current state-of-the-art of relation discovery. Distant supervision assumes that the relations should be aligned between the KB and the training text corpus, which is not available in our setting.

We tested our model on three different subsets of New York Times corpus (NYT) (Sandhaus and Evan, 2008).

	Data	**NYT122**	**NYT71**	**NYT27**
Text	# sentences	67,123	14,210	87,144
	# facts	9,207	2,274	8,559
	# entity pairs	20,939	3,539	36,714
	# entities	5,865	2,489	4,803
	# relations	122	71	27
KB	# triplets	401,490	456,146	439,507
	# entity pairs	331,008	373,875	354,960
	# entities	14,907	14,933	14,911
	# relations	705	1,009	1,031

Table 2: Statistics of datasets. # facts in the text corpus is the number of sentences with relation labels.

- The first one is widely used in unsupervised settings, which was developed by Yao et al. (2011) and has also been used by Marcheggiani and Titov (2016). This dataset contains articles 2000 to 2007, with named entities annotated and features processed (POS tagging, NER, and syntactic parsing). We use this dataset to compare with previous work directly (Marcheggiani and Titov, 2016).

- The second and third ones are usually applied by supervised models. So when they generated the data, they tended to focus on relations with more supporting sentences. The second one was developed by Zeng et al. (2017). The data is built by aligning Wikidata (Vrandečić, 2012) relations with NYT corpus, as a result of 99 possible relations. It is built to contain more updated facts and richer structures of relations, e.g., a larger number of relation/relation paths. We use this dataset to amplify the effects coming from relation paths in KB, as the data was used to train a path-based relation extraction model.

- The third one was developed by Riedel et al. (2010) and has also been used by Lin et al. (2016). This dataset was generated by aligning Freebase (Bollacker et al., 2008) relations with NYT in 2005-2007, and with 52 possible relations. We use this data to test the clustering result with a narrow relation domain.

We align these datasets against FB15K, which is a randomly sampled subset of Freebase developed by Bordes et al. (2013). For each of the datasets above, we hold out the triplets in FB15K that contains relations in corresponding text data, so that we ensure that KB cannot give any direct supervision on any relation labels. We then discard named

Table 3: Comparison results on NYT122 with different prediction and regularization strategies (using encoder or decoder).

entities in text corpus if they are not shown in KB, so that we can directly test the influence of our KB constraint model. Finally, we only keep a single label for each sentence, and e_1, e_2 follow the occurrence order in the sentence. The resulting datasets contain 122, 71, and 27 relation labels respectively, so we name them as NYT122, NYT71, and NYT27. The statistics of the three datasets are shown in Table 2. For NYT71 and NYT27, we perform the same feature extraction as NYT122 shown in (Marcheggiani and Titov, 2016).

4.2 Implementation Details

All the model parameters are initialized randomly. The number of negative samples is set to 5, mini-batch size is set to 100 with 80 epochs. We optimize all the models using AdaGrad (Duchi et al., 2011) with initial learning rate at 0.5. For NYT122, we induce 40 relations clusters, with $\alpha_0 = 4$, $\alpha_T = 10^{-5}$, $\beta = 0.6$, and $\gamma = 0.9$. For NYT71, we induce 30 relations clusters, with $\alpha_0 = 2$, $\alpha_T = 10^{-4}$, $\beta = 0.8$, and $\gamma = 0.95$. For NYT27, we induce 20 relations clusters, with $\alpha_0 = 2$, $\alpha_T = 10^{-4}$, $\beta = 0.8$, and $\gamma = 0.3$. We train TransE as our KB embedding model with 50 dimensions and 1,000 epochs.

We report the average and standard deviation based on five different runs. We randomly split the data into validation:test=4:6. All the model selections were based on validation sets, and final evaluation results will be only based on test sets.

4.3 Evaluation and Discussion

As the scoring function, we use the B^3F_1 (Bagga and Baldwin, 1998) which has also been used by our baseline (Marcheggiani and Titov, 2016), and Normalized Mutual Information (NMI) (Strehl and Ghosh, 2002) metrics. Both are standard measures for evaluating clustering tasks.

Regularization and Prediction Strategies. We first report our results on NYT122 using different regularization and prediction settings, as this dataset was used by our baseline model DVAE.

Note that both encoder and decoder components can make relation predictions. In fact, the way of using encoder $q(r|x, \psi)$ for each sentence is straightforward. Then based on the encoder, we predict relation on the basis of single occurrence of entity pair. When using the decoder, we need to re-normalize $p(e_i|r, e_{-i}, \theta)$ as $p(r|e_1, e_2, \theta)$ to make predictions. Based on the decoder, we make predictions for each unique entity pair. As a consequence, our constraints can be imposed on both encoder and decoder. The way of computing decoder probability distribution is the same as making predictions. So in this experiment, we report both results.

The results are shown in Table 3. From the table, we can see that regularization with Euclidean distance performs the best compared to KL and JS. Moreover, the regularization over encoder is better than the regularization over decoder. This may be because the way that we put constraints only over sampled sentences in a batch may hurt the regularization of decoder, since sampled unique pairs may be less than sample sentences. If we look at results comparing original DVAE prediction based on the encoder and the decoder, both result in similar F1 and NMI numbers. Thus, we can only conclude that currently in the way we do sampling, constraining over encoder is a better choice.

Comparison on Different Datasets. We also compare our algorithm on the three datasets with different baseline settings. In order to evaluate our model rigorously, besides the original DVAE model, we compare two additional augmented baseline models with the same hyper-parameter setting: DVAE with TransE embeddings appended to encoder input features (DVAE+E) and DVAE

with decoder entity vectors replaced by pre-trained KB embeddings (DVAE+D). For our method, we report RegDVAE with the best setting where we use Euclidean distance based constraints to regularize the encoder. Moreover, we report a setting with fixed embeddings in the decoder as the ones obtained from TransE (RegDVAE+D). This also makes sense since even though the TransE embeddings are not trained with the observation of the same relations as the text corpus, the embeddings already contain much semantic information about entities. Then by fixing the embeddings of entities in the decoder, we can significantly reduce the number of parameters that need to be trained. The results are shown in Table 4. As we can see that, RegDVAE+D can outperform the original DVAE by 8∼23 points on F1. DVAE+D is also good but may fail when there are a lot of out-of-sample entities in the training corpus.

Hyper-parameter Sensitivity. We have three hyper-parameters in our algorithm: α_0 for the regularization of encoder entropy, β for the regularization with our constraints, and γ for the threshold of KB based cosine similarities. Here, we test β and γ, since the sensitivity result of α_0 is the same as the original DVAE work (Marcheggiani and Titov, 2016). The sensitivity of β is shown in Figure 2(a). The results are good in a wide range from $\beta = 0.5$ to $\beta = 2$. The sensitivity of γ is shown in Figure 2(b). It reveals some interesting patterns. At the beginning when γ is small, it hurts the performance. After γ getting greater than 0.7, it improves the performance, which means that only very similar relations indicated by KB embeddings are useful relations as constraints. In addition, $\gamma = 1$ (meaning only finding identical relations) is worse than $\gamma = 0.9$, which means we indeed find some relations in our KB so that different triplets will be constrained.

KB Relation Overlap. Although we assume that there is no overlapped relation between the KB and the training text corpus, in practice, we may find a lot of applications that the relations are partially observed in KB. Thus, we also test a setting when the KB has different proportions of overlapped relations with training text corpus. In this case, we train different KB embeddings for different percentages of overlapped relations, and then apply the embeddings into the constraints. The results are shown in Figure 2(c). As we can see, in general, more overlapped relations will result in better performance. The best number can be better than the number without overlapped relation by about two points. This again verifies that the KB embedding is very robust and represent the semantic meanings of entities even with part of the

Contextual Sentence	Cluster	Similarity
. . . **Spain** will become the third country in **Europe**. . .	12	0.926
Portugal, with all that talent, goes home to **Europe**. . .	12

relations observed (Bordes et al., 2013).

Case Study. We also show some examples of entity pair similarities in Table 5. From the Table we can see that our target relation cluster is */location/contained_by*. In the first example, the similarity between entity pairs (`Spain, Europe`) and (`Portugal, Europe`) are high, which indicates the same cluster of pairs of sentences. The same constraint is applied in the second example, although there's no direct connection between (`Brazil, Latin America`), (`Argentina, Latin America`).

5 Related Work

Supervised and Distantly Supervised Relation Extraction. Traditional supervised relation extraction focuses on a limited number of relations (Roth and Yih, 2002; Kambhatla, 2004; Chan and Roth, 2010). Distant supervision uses KBs to obtain a lot of automatically annotated data (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Xu et al., 2013a; Zhang et al.; Zeng et al., 2015; Lin et al., 2016; Zeng et al., 2017). There are two important assumptions behind these models, namely multi-instance learning (Riedel et al., 2010) and multi-instance multi-label learning (Hoffmann et al., 2011; Surdeanu et al., 2012). Our setting is similar to multi-instance learning but we assume there is no overlapped relation between KB and training text corpus. Universal schema (Riedel et al., 2013; Verga et al., 2016; Toutanova et al., 2015; McCallum et al., 2017) can also exploit KB to help extract relations. It needs a lot of entity pairs in text to co-occur with KB triplets, which is under the same setting with distant supervision. Those surface patterns are pre-extracted and shown in the training phase, which makes it also a weakly supervised learning method.

Unsupervised Relation Extraction. Open Domain Information Extraction (Open-IE) assumes that every relation expression can represent a unique relation (Etzioni et al., 2004; Banko et al., 2007; Fader et al., 2011; Mausam et al., 2012; Xu et al., 2013b; Angeli et al., 2015). On the other hand, relation clustering approaches group all the related relation expressions to represent a relation (Lin and Pantel, 2001; Mohamed et al., 2011; Takamatsu et al., 2011; Yao et al., 2011, 2012; Nakashole et al., 2012a,b; Marcheggiani and Titov, 2016). Our setting is based on (Marcheggiani and Titov, 2016) but we also introduce KB as a different kind of weak and indirect supervision.

Knowledge Base Representation. Embedding based knowledge base representation learning methods (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Trouillon et al., 2016) represent entities and relations as vectors, denoted as $\mathbf{e}$ and $\mathbf{C}_r$ respectively such that for a distances function f, the value $f(\mathbf{e}_1, \mathbf{C}_r, \mathbf{e}_2)$ is maximized for all (e_1, r, e_2) facts. Among all these methods, TransE model has a favorable property that the translation operation can be easily recovered by entity vectors ($\mathbf{r}_{1,2} = \mathbf{e}_1 - \mathbf{e}_2$). With its simplicity and high performance, TransE is enough for demonstration. Though our method is not restricted to the representation form of KB, we leave it for future evaluation.

Constraints can be made more explainable by paths finding. For instance, the Path Ranking Algorithm (PRA) (Lao and Cohen, 2010; Lao et al., 2011) uses random walk to perform multi-hop reasoning based on logic rules. Later on, reinforcement Learning (Toutanova et al., 2015; Xiong et al., 2017; Das et al., 2017; Chen et al., 2018) is used to search for paths more effectively. Though heuristics are used to further reduce the number of mined relations, it is still very costly to find the paths for KB with hundreds of relations, if not impossible.

Constraint Modeling. Originated from semi-supervised learning (Chapelle et al., 2006), must-link and cannot-link modeling has been well studied in machine learning community (Wagstaff et al., 2001; Basu et al., 2004, 2008). Such constraints were usually generated based on the ground truth labels of data. For document clustering, word constraints constructed based on WordNet similarities have been applied (Song et al., 2013) and entity constraints based on entity types in an external KB have been used (Wang et al., a, 2016), both being considered as a kind of indirect supervision based on side information. For triplet relation clustering, relation surface similarity and entity type constraints have been explored (Wang et al., b). However the above constraints are applied to a particular form of models, co-clustering models. Compared to existing approaches, our constraints are constructed based on more recently developed KB embeddings, which is more flexible and easy to incorporate into different models.

In natural language processing community, constraints based on background knowledge are also well studied. For example, constrained conditional models (CCM) (Chang et al., 2012) provides a very flexible framework to decouple learning and inference, where in the inference step, background knowledge can be incorporated as an ILP (integer linear programming) problem. Posterior regularization (PR) (Ganchev et al., 2010) generalizes this idea so that it uses a joint learning and inference framework to incorporate the background knowledge. Both CCM and PR have many applications including the application to relation extraction (Chan and Roth, 2010; Chen et al., 2011). Compared to these existing approaches, our constraints are derived from the general-purpose KB, which is quite different from their way of manually crafting some background knowledge as declarative rules.

It is very interesting that we are similar to the PR framework. Since we use a DVAE framework as the base algorithm, there is no traditional E-step and M-step in the variational inference. Instead, only q and p probabilities parameterized by neural networks are updated. In our framework, we can add constraints to either q or p probabilities (applying to p needs modification of normalization). It is the same that we draw a biased learning process when estimating the posteriors as PR does.

6 Conclusion

In this paper, we propose a new relation discovery setting where there is no overlapped relations between the training text corpus and the KB. We propose a new learning framework of KB regularization which uses must-link and cannot-link constraints derived based on similarities in the KB embedding space. Our method improves the results over all baseline models without harming the scalability. We believe this framework is as flexible as other constraint models to be applied to many applications when we think the semantics of entities and relations provided by the KB is useful.

Corpora Generation for Grammatical Error Correction

Abstract

Grammatical Error Correction (GEC) has been recently modeled using the sequence-to-sequence framework. However, unlike sequence transduction problems such as machine translation, GEC suffers from the lack of plentiful parallel data. We describe two approaches for generating large parallel datasets for GEC using publicly available Wikipedia data. The first method extracts source-target pairs from Wikipedia edit histories with minimal filtration heuristics, while the second method introduces noise into Wikipedia sentences via round-trip translation through bridge languages. Both strategies yield similar sized parallel corpora containing around 4B tokens. We employ an iterative decoding strategy that is tailored to the loosely supervised nature of our constructed corpora. We demonstrate that neural GEC models trained using either type of corpora give similar performance. Fine-tuning these models on the Lang-8 corpus and ensembling allows us to surpass the state of the art on both the CoNLL-2014 benchmark and the JFLEG task. We provide systematic analysis that compares the two approaches to data generation and highlights the effectiveness of ensembling.

1 Introduction

Much progress in the Grammatical Error Correction (GEC) task can be credited to approaching the problem as a translation task (Brockett et al., 2006) from an ungrammatical source language to a grammatical target language. This has enabled Neural Machine Translation (NMT) sequence-to-sequence (S2S) models and techniques to be applied to the GEC task (Tao et al., 2018b; Chollampatt and Ng, 2018; Junczys-Dowmunt et al., 2018). However, the efficacy of NMT techniques is degraded for low-resource tasks (Koehn and Knowles, 2017). This poses difficulties for S2S approaches to GEC, as Lang-8, the largest publicly available parallel corpus, contains only ∼25M words (Mizumoto et al., 2011). Motivated by this data scarcity, we present two contrasting approaches to generating parallel data for GEC that make use of publicly available English language Wikipedia revision histories[1][2].

Our first strategy is to mine real-world errors. We attempt to accumulate source–target pairs from grammatical errors and their human-curated corrections gleaned from the Wikipedia revision histories. Unlike previous work (Grundkiewicz and Junczys-Dowmunt, 2014), we apply minimal filtering so as to generate a large and noisy corpus of ∼4B tokens (Table 1). As a consequence of such permissive filtering, the generated corpus contains a large number of real grammatical corrections, but also noise from a variety of sources, including edits with drastic semantic changes, imperfect corrections, ignored errors, and Wikipedia spam.

Our second strategy is to synthesize data by corrupting clean sentences. We extract target sentences from Wikipedia, and generate corre-

---

*Equal contribution. Listing order is random. Jared conducted systematic experiments to determine useful variants of the Wikipedia revisions corpus, pre-training and fine-tuning strategies, and iterative decoding. Chris implemented the ensemble and provided background knowledge and resources related to GEC. Shankar ran training and decoding experiments using round-trip translated data. Jared, Chris and Shankar wrote the paper. Noam identified Wikipedia revisions as a source of training data. Noam developed the heuristics for using the full Wikipedia revisions at scale and conducted initial experiments to train Transformer models for GEC. Noam and Niki provided guidance on training Transformer models using the *Tensor2Tensor* toolkit. Simon proposed using round-trip translations as a source for training data, and corrupting them with common errors extracted from Wikipedia revisions. Simon generated such data for this paper.

Proceedings of NAACL-HLT 2019, pages 3291–3301
Minneapolis, Minnesota, June 2 - June 7, 2019.

sponding source sentences by translating the target into another language and back. This round-trip translation introduces relatively clean errors, so the generated corpus is much less noisy than the human-derived Wikipedia corpus. However, these synthetic corruptions, unlike human errors, are limited to the domain of errors that the translation models are prone to making. Both approaches benefit from the broad scope of topics in Wikipedia.

Corpus	# sentences	# words
Lang-8	1.9M	25.0M
WikEd	12M	292 M
Wikipedia Revisions	170M	4.1B
Round-Trip Translation	176M	4.1B

Table 1: Statistics computed over extant training sets for GEC (top) and corpora generated from Wikipedia in this work (bottom).

We train the Transformer sequence-to-sequence model (Vaswani et al., 2017) on data generated from the two schemes. Fine-tuning the models on the Lang-8 corpus gives us additional improvements which allow a single model to surpass the state-of-art on both the CoNLL-2014 and the JFLEG tasks. Finally, we explore how to combine the two data sources by comparing a single model trained on all the data to an ensemble of models.

2 Data Generation from Wikipedia Revision Histories

Wikipedia provides a dump of the revision histories of all Wikipedia pages. For each Wikipedia page, the dump contains chronological snapshots of the entire content of the page before and after every submitted edit; thus two consecutive snapshots characterize a single revision to the page. Because a small number of popular pages see disproportionate traffic, some pages grow very large. As we are interested in the edits between snapshots, and not identical content that is typically in higher proportion in the revision histories for the largest pages, we discard pages larger than 64Mb. To prevent remaining large pages from skewing the dataset towards their topics with their many revisions, we downsample consecutive revisions from individual pages, selecting only $\log_{1.5}(n)$ pairs for a page with a total of n revisions. This reduces the total amount of data 20-fold. Each remaining pair of consecutive snapshots forms a source–target pair. The process for extracting examples from a page's revision history is illustrated in Figure 1.

From the XML of each page in a source–target pair, we extract and align the text, removing non-text elements. We then probabilistically cut the aligned text, skipping over non-aligned sequences. Two cuts bound an example pair, for which the source sequence is provided by the older snapshot, and the target sequence by the newer snapshot.

Following extraction of the examples, we do a small amount of corruption and filtration in order to train a model proficient at both spelling and grammar correction. We probabilistically introduce spelling errors in the source sequences at a rate of 0.003 per character, randomly selecting deletion, insertion, replacement, or transposition of adjacent characters for each introduced error.

We throw out examples exceeding a maximum length of 256 word-pieces. The majority of examples extracted by this process have identical source and target. Since this is not ideal for a GEC parallel corpus, we downsample identity examples by 99% to achieve 3.8% identical examples in the final dataset. The data generation scripts we use have been opensourced[3].

In Figure 2, we show examples of extracted source–target pairs. While some of the edits are grammatical error corrections, the vast majority are not.

3 Data Generation from Round-trip Translations

As an alternative approach to extracting the edits from Wikipedia revisions, we extract sentences from the identity examples that were discarded during edit extraction, and generate a separate parallel corpus by introducing noise into those sentences using round-trip translation via a bridge language. Therefore, the original sentence from Wikipedia is the target sentence and output of the round-trip translation is the corresponding source sentence. The round trip translations introduce noise according to both the weaknesses of the translation models and the various inherent ambiguities of translation. We create a corrupted dataset using each bridge language. We use French (Fr), German (De), Japanese (Ja) and Russian (Ru) as bridge languages because they are high-resource languages and relatively dissim-

Figure 2: Example source–target pairs from each corpus.

ilar from each other. Thus, we compute a total of four corrupted datasets. The translations are obtained using a competitive machine translation system (Wu et al., 2016).

These round trip translated sentence-pairs contained only a small fraction of identity translations compared to those that are present in real-world GEC corpora. To address this deficiency, we augment this corpus with 2.5% identity translations. Analogous to Section 2, we want the models to learn both spelling and grammar correction. Thus, we randomly corrupt single characters via insertion, deletion, and transposition, each with a probability of $0.005/3$. Round-trip translations do not contain some types of word and phrase errors (e.g., your/you're, should of/should have) and so we additionally corrupt the translated text by stochastically introducing common errors identified in Wikipedia. We first examine the Wikipedia revision histories to extract edits of up to three words whose source and target phrases are close in edit distance, and which do not contain numbers or capitalization. For each of the remaining edits (original, revised), we compute the probability that the user typed *original* when they intended to type *revised*:

$$P(\text{original}|\text{revised}) = \frac{C(\text{original}, \text{revised})}{C(\text{revised})},$$

where $C(x)$ refers to the counts of x in the corpus. We then probabilistically apply these rules to corrupt the translated text.

This process produces a parallel corpus identical in size to the Wikipedia Revision corpus, though with vastly different characteristics. Because the target sentences are Wikipedia sentences that were left unchanged for at least one Wikipedia revision, they are less likely to contain poor grammar, misspellings, or spam than the target sequences of the revisions data.

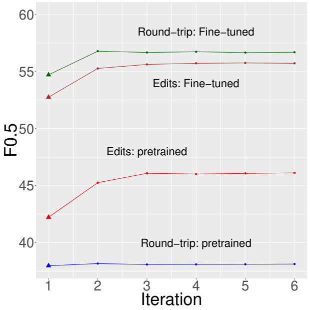

Figure 3: $F_{0.5}$ with iterative decoding on the CoNLL dev set. Triangles indicate performance with single-shot decoding.

Also, the errors introduced by round-trip translation are relatively clean, but they represent only a subset of the domain of real-world errors. In contrast, the Wikipedia data likely has good coverage of the domain of real-world grammatical errors, but is polluted by significant noise. Examples from both corpora are shown in Figure 2. Examples of round-trip translations for each bridge language are shown in Table 2.

4 Iterative Decoding

Many sentences that require grammatical correction contain multiple errors. As a result, it can be difficult to correct all errors in a single decoding pass. This is specifically a problem when using models trained on noisy parallel data such as Lang-8 where the target sentences still contain grammatical errors. Following other work on the GEC task (Dahlmeier and Ng, 2012a; Tao et al., 2018a), we employ an iterative decoding algorithm that allows the model to make multiple incremental corrections. This allows the model multiple chances to suggest individually high-confidence changes, accruing incremental improvements until it cannot find any more edits to make.

Our iterative decoding algorithm is presented in Algorithm 1. Given the source sentence S and a hypothesis H, Cost(H) refers to the negative log probability $-logP(H|S)$ using the sequence-to-sequence model. In each iteration, the algorithm performs a conventional beam search but is only allowed to output a rewrite (non-identity translation) if it has high confidence i.e., its cost is less than the cost of the identity translation times a prespecified threshold. Using iterative decoding allows a stricter threshold value than what is optimal for single-shot decoding, as a change ignored for being low confidence in one decoding iteration may be selected in the next.

Using incremental edits produces a significant improvement in performance over single-shot decoding for models trained on the Wikipedia revision data, a highly noisy corpus, while models trained on the relatively clean round-trip translation data see no improvment. All models finetuned on Lang-8 see improvement with iterative decoding (Figure 3, Table 3).

Algorithm 1: Iterative Decoding

```
Data: $I$, beam, threshold, MAXITER
Result: $\hat{T}$
for $i \in \{1, 2, ..., MAXITER\}$ do
    Nbestlist = Decode($I$, beam)
    $C_{\text{Identity}} = +\infty$
    $C_{\text{Non-Identity}} = +\infty$
    $H_{\text{Non-Identity}} = NULL$
    for $H \in Nbestlist$ do
        if $H = I$ then
            $C_{\text{Identity}} = \text{Cost}(H)$;
        else if $Cost(H) < C_{Non\text{-}Identity}$ then
            $C_{\text{Non-Identity}} = \text{Cost}(H)$
            $H_{\text{Non-Identity}} = H$
    end
        ▷ Rewrite if non-identity cost < identity cost
    if $C_{Non\text{-}Identity}/C_{Identity} < threshold$ then
        $\hat{T} = H_{\text{Non-Identity}}$        ▷ Output rewrite.
    else
        $\hat{T} = I$        ▷ Output identity.
    end
    $I = \hat{T}$        ▷ Input for next iteration.
end
```

In Table 4, we show an example of iterative decoding in action. The model continues to refine the input until it reaches a sentence that does not require any edits. We generally see fewer edits being applied as the model gets closer to the final result.

5 Model

In this work, we use the *Transformer* sequence-to-sequence model (Vaswani et al., 2017), using the *Tensor2Tensor* opensource implementation.[4] We use 6 layers for both the encoder and the decoder, 8 attention heads, embedding size $d_{\text{model}} = 1024$, a position-wise feed forward network at every layer of inner size $d_{ff} = 4096$, and Adafactor as optimizer with inverse squared root decay (Shazeer and Stern, 2018)[5]. The word tokens are split into subwords using a variant of the byte-pair encoding technique (Sennrich et al., 2016b), described in Schuster and Nakajima (2012).

We train the *Transformer* model for 5 epochs

with a batch size of approximately 64,000 word pieces. While training on the Wikipedia corpora, we set the learning rate to 0.01 for the first 10,000 steps, then decrease it proportionally to the inverse square root of the number of steps after that.

We then finetune our models on Lang-8 for 50 epochs and use a constant learning rate of 3×10^{-5}. We stop the fine-tuning before the models start to overfit on a development set drawn from Lang-8.

6 Experiments

6.1 Evaluation

We report results on the CoNLL-2014 test set (Ng et al., 2014) and the JFLEG test set (Napoles et al., 2017; Heilman et al., 2014). Our initial experiments with iterative decoding showed that increasing beam sizes beyond 4 did not yield improvements in performance. Thus, we report all results using a beam size of 4. Our ensemble models are obtained by decoding with 4 identical *Transformers* trained and finetuned separately. Ensembles of neural translation systems are typically constructed by computing the logits from each individual system and combining them using either an arithmetic average (Sutskever et al., 2014) or a geometric average (Cromieres et al., 2016). Similar to Cromieres et al. (2016), we find that a geometric average outperforms an arithmetic average. Hence, we report results using only this scheme.

Following (Grundkiewicz and Junczys-Dowmunt, 2018; Junczys-Dowmunt et al., 2018), we preprocess JFLEG development and test sets with a spell-checking component but do not apply spelling correction to CoNLL sets. For CoNLL sets, we pick the best iterative decoding threshold and number of iterations on a subset of the CoNLL-2014 training set, sampled to have the same ratio of modified to unmodified sentences as the CoNLL-2014 dev set. For JFLEG, we pick the best decoding threshold on the JFLEG dev set.We report performance of our models by measuring $F_{0.5}$ with the M^2 scorer (Dahlmeier and Ng, 2012b) on the CoNLL-2014 dev and test sets, and the GLEU+ metric (Napoles et al., 2016) on the JFLEG dev and test sets. Table 5 reports statistics computed over the development and test sets.

Test/Dev Set	# sentences	# annotators	Metric

Table 6: Performance of the models trained on variants of data extracted from Wikipedia revision histories (top panel) and then fine-tuned on Lang-8 (bottom panel), and of a model trained only on Lang-8 with the same architecture.

rate of revision downsampling, and maximum edit distance. We generate four data sets using variations of these values: *Default setting* uses the default values described in Section 2, *Max-edit-28* and *Max-edit-6* correspond to maximum edit distance of 28 and 6 wordpieces respectively, and *Dwnsample-1.35* corresponds to a revision downsampling rate of $\log_{1.35}(n)$ for a page with a total of n revisions (whereas the default setting uses a rate of $\log_{1.5}(n)$). We train a fifth model on the union of the datasets. Table 6 shows that varying the data generation parameters led to modest variation in performance, but training on the union of the diverse datasets did not yield any benefit. Fine-tuning yields large improvements for all models. As a sanity check, we also trained a model only on Lang-8 with the same architecture. All pre-trained and fine-tuned models substantially outperform this Lang-8 only model, confirming the usefulness of pre-training.

6.3 Round Trip Translations

As for the Revision data, we train a model on each of the round-trip translation datasets, and a fifth model on the union of their data, then fine-tune all models. The results are shown in Table 7. Using Japanese as the bridge language gives the best performance on CoNLL-2014, even when compared to the model trained on all round-trip data. This is likely because the error patterns generated using Japanese round-trip translations are very similar to those in CoNLL-2014 set, created from non-native speakers of English (Ng et al., 2014). Pooling all round-trip translations dilutes this similarity and lowers performance on CoNLL-2014. However, the model trained on all data performs best on the JFLEG set, which has a different distribution of errors relative to CoNLL-2014 (Napoles et al., 2017). After fine-tuning, all round-trip models perform considerably better than the Lang-8 model.

Bridge Language	CoNLL-2014			JFLEG
	Precision	Recall	$F_{0.5}$	GLEU$^+$
Round-Trip Translations				
French	33.6	21.9	30.3	50.6
German	36.4	21.2	31.8	51.3
Russian	33.5	21.1	30.0	50.5
Japanese	35.7	51.3	38.1	46.2

Russian	60.8	32.5	51.7	59.9
Japanese	60.9	38.6	54.6	61.5
All	62.1	40.0	56.0	61.6
Lang-8 only	41.2	16.4	31.7	52.8

Table 7: Performance of the models trained on the round-trip translations (top panel) and fine-tuned on Lang8 (bottom panel) and of a model trained only on Lang-8 with the same architecture.

6.4 Combining Data Sources

Having generated multiple diverse datasets, we investigate strategies for utilizing combinations of data from multiple sources. For each corpus, we train a single model on all data and compare its performance to an ensemble of the 4 individually-trained models (Table 8). The ensemble clearly outperforms the single model for both types of data. We additionally train a single model on the union of all Revisions and Round-Trip Translated datasets reported on in Tables 6 and 7, which we compare to an ensemble of the 8 models trained individually on those datasets.

When Wikipedia edits are combined with the round-trip translations, the single-model performance remains unchanged on CoNLL-2014, while the ensemble shows an improvement. This suggests that when utilizing disparate sources of data, an ensemble is preferable to combining the data.

6.5 Comparison with Other systems

We compare the performance of our best individual system, trained on all revisions, the best ensemble of 8 models trained from both revisions and roundtrip translations on the CoNLL-2014 and JFLEG datasets (Table 9). We only report performance of models that use publicly available

Model	CoNLL-2014			JFLEG

Lang-8 and CoNLL datasets. Our single system trained on all revisions outperforms all previous systems on both datasets, and our ensemble improves upon the single system result[6].

7 Error Analysis

All models trained on Wikipedia-derived data are demonstrated to benefit significantly from finetuning on Lang-8 (Tables 6 and 7). In Table 10, we compare example corrections proposed by two Wikipedia-derived models to the corrections proposed by their fine-tuned counterparts. The changes proposed by the revisions-trained model often appear to be improvements to the original sentence, but fall outside the scope of GEC. Models finetuned on Lang-8 learn to make more conservative corrections.

The finetuning on Lang-8 can be viewed as an adaptation technique that shifts the model from the Wikipedia-editing task to the GEC task. On Wikipedia, it is common to see substantial edits that make the text more concise and readable, e.g. replacing “which is RFID for short” with “(RFID)”, or removing less important clauses like “Then we can see that”. But these are not appropriate for GEC as they are editorial style fixes rather than grammatical fixes. The models trained on round-trip translation seem to be make fewer drastic changes.

Table 11 reports $F_{0.5}$ across broad error categories for models trained from revisions and round-trip translations on the CoNLL-2014 test set. The error categories were tagged using the approach in Bryant et al. (2017). Although the overall $F_{0.5}$ of the 2 ensembles are similar, there are notable differences on specific categories. The ensemble using round-trip translation performs considerably better on prepositions and pronouns while the revision ensemble is better on morphology and orthography. Thus, each system may have advantages on specific domains.

8 Related Work

Progress in GEC has accelerated rapidly since the CoNLL-2014 Shared Task (Ng et al., 2014). Rozovskaya and Roth (2016) combined a Phrase Based Machine Translation (PBMT) model trained on the Lang-8 dataset (Mizumoto et al., 2011) with error specific classifiers. Junczys-Dowmunt and Grundkiewicz (2016) combined a PBMT model with bitext features and a larger language model. The first Neural Machine Translation (NMT) model to reach the state of the art on CoNLL-2014 (Chollampatt and Ng, 2018) used an ensemble of four convolutional sequence-to-sequence models followed by rescoring. The current state of the art ($F_{0.5}$ of 56.25 on CoNLL-2014) using publicly available Lang-8 and CoNLL data was achieved by Grundkiewicz and Junczys-Dowmunt (2018) with a hybrid PBMT-NMT system. A neural-only result with an $F_{0.5}$ of 56.1 on CoNLL-2014 was reported by Junczys-Dowmunt et al. (2018) using an ensemble of neural *Transformer* models (Vaswani et al., 2017), where the decoder side of each model is pretrained as a language model. From a modeling perspective, our approach can be viewed as a direct extension of this last work. Rather than pretraining only the decoder as a language model, we pretrain on a large amount of parallel data from either Wikipedia revision histories or from round-trip translations. While pretraining on out-of-domain data has been employed previously for neural machine translation (Luong and Manning, 2015), it has not been presented in GEC thus far, perhaps due to the absence of such large datasets. Tao et al. (2018b) apply iterative decoding, where two neural models, trained in left-to-right and right-to-left directions, are applied in an interleaved manner. Similar to their study, we find that iterative decoding can improve the performance of GEC.

Table 10: Corrections from models trained on (a) Wikipedia revisions and (b) round-trip translations using Japanese as a bridge language, along with suggestions from their Lang-8 finetuned counterparts. Also shown are the corrections from the ensembles of 4 wikipedia models as well as 4 models trained on round trip translations. Example sentences are from the CoNLL-2014 dev set.

2010), (Felice et al., 2014; Xie et al., 2016; Rei et al., 2017) has investigated multiple strategies for generating artificial errors in GEC. Cahill et al. (2013) show that preposition corrections extracted from Wikipedia revisions improve the quality of a GEC model for correcting preposition errors. Back-translation (Sennrich et al., 2016a; Xie et al., 2018) addresses data sparsity by introducing noise into a clean corpus using a translation model trained in the clean to noisy direction. However, training such a reverse translation model also requires access to parallel data which is scarce for GEC. In contrast, round-trip translation attempts to introduce noise via bridge translations. Round-trip translations have been investigated for GEC. Madnani et al. Madnani et al. (2012) combine round-trip translations to generate a lattice from which the best correction is extracted using a language model. Désilets et al. (2009) use round-trip translations for correcting preposition errors. In contrast to these approaches, we employ round-trip translations for generating a large parallel training corpus for neural GEC models.

9 Discussion

Motivated by data scarcity for the GEC task, we present two contrasting approaches for generating large parallel corpora from the same publicly available data source. We believe both techniques offer promising research avenues for further development on the task.

We show that models trained exclusively on minimally filtered English Wikipedia revisions can already be valuable for the GEC task. This approach can be easily extended to the many other languages represented in Wikipedia, presenting an

Error Type	Revisions			Round-trip Translations		
	Pre-trained	Fine-tuned	Ensemble	Pre-trained	Fine-tuned	Ensemble
Adjective	16.9	29.4	36.6	14.4	27.8	37.9

Table 11: $F_{0.5}$ across error categories on the CoNLL-2014 test set.

opportunity to extend GEC into languages that may have no extant GEC corpora. While we expect pre-training on Wikipedia to give us a reasonable model, it may be crucial to fine-tune this model on small amounts of clean, in-domain corpora to achieve good performance.

When extracting examples from the Wikipedia revisions, we implemented minimal filtration in pursuit of simplicity, and to produce a sufficiently large dataset. Implementing more complex filtration in order to reduce the noise in the generated dataset will likely be a productive avenue to increase the value of this approach. The performance achieved by the reported Wikipedia revisions-trained models, both with and without finetuning, may be used as a baseline by which to evaluate smaller, cleaner datasets drawn from Wikipedia revisions.

Round-trip translation takes advantage of the advanced state of the task of Machine Translation relative to GEC by leveraging extant translation models as a source of grammatical-style data corruption. In this work, we only experiment with producing English-language GEC corpora, but this technique can be extended to any of the many languages for which translation models exist. It would be useful to assess how the translation quality influences the performance of the resulting GEC model. In our experiments with round-trip translation, we used target sentences drawn from Wikipedia to maintain a reasonable comparability between the two techniques. However, there is no constraint preventing the application of round-trip translation to diverse data sources; any source of clean text can be turned into a parallel GEC corpus. This can be used to increase diversity in the generated data, or to generate domain-specific GEC corpora (e.g. patents).

We observe that pooling two diverse data sources used to train competitively performing models on the same task can degrade performance. This suggests that within datasets useful for a specific task, there may be greater value to be discovered in finding optimal partitions of the data for training models which can then be combined using ensembles. Prior work in combining diverse data sources includes addition of special tokens (Johnson et al., 2017) and meta-learning (Finn et al., 2017). We intend to compare ensembling with these alternatives.

We have opensourced the scripts used to extract example pairs from Wikipedia, which we hope will become a resource in the further development of models for GEC as well as other NLP tasks that rely on edit histories, such as sentence re-writing (Botha et al., 2018) and text simplification (Tonelli et al., 2016).

Structural Supervision Improves Learning of Non-Local Grammatical Dependencies

Abstract

State-of-the-art LSTM language models trained on large corpora learn sequential contingencies in impressive detail and have been shown to acquire a number of non-local grammatical dependencies with some success. Here we investigate whether supervision with hierarchical structure enhances learning of a range of grammatical dependencies, a question that has previously been addressed only for subject-verb agreement. Using controlled experimental methods from psycholinguistics, we compare the performance of word-based LSTM models versus two models that represent hierarchical structure and deploy it in left-to-right processing: Recurrent Neural Network Grammars (RNNGs) (Dyer et al., 2016) and a incrementalized version of the Parsing-as-Language-Modeling configuration from Charniak et al. (2016). Models are tested on a diverse range of configurations for two classes of non-local grammatical dependencies in English—*Negative Polarity* licensing and *Filler–Gap Dependencies*. Using the same training data across models, we find that structurally-supervised models outperform the LSTM, with the RNNG demonstrating best results on both types of grammatical dependencies and even learning many of the *Island Constraints* on the filler–gap dependency. Structural supervision thus provides data efficiency advantages over purely string-based training of neural language models in acquiring human-like generalizations about non-local grammatical dependencies.

1 Introduction

Long Short-Term Memory Recurrent Neural Networks (LSTMs) (Hochreiter and Schmidhuber, 1997) have achieved state of the art language modeling performance (Jozefowicz et al., 2016) and have been shown to indirectly learn a number of non-local grammatical dependencies, such as subject-verb number agreement and filler-gap licensing (Linzen et al., 2016; Wilcox et al., 2018), although they fail to learn others, such as Negative Polarity Item and anaphoric pronoun licensing (Marvin and Linzen, 2018; Futrell et al., 2018). LSTMs, however, require large amounts of training data and remain relatively uninterpretable. One model that attempts to address both these issues is the Recurrent Neural Network Grammar (Dyer et al., 2016). RNNGs are generative models, which represent hierarchical syntactic structure and use neural control to deploy it in left-to-right processing. They can achieve state-of-the-art broad-coverage scores on language modeling and phrase structure parsing tasks, learn Noun Phrase headedness (Kuncoro et al., 2016), and outperform linear models at learning subject-verb number agreement (Kuncoro et al., 2018).

In this work, we comparatively evaluate LSTMs, RNNGs and a third model trained using syntactic supervision—similar to the Parsing-as-Language-Modeling configuration from Charniak et al. (2016)—by conducting side-by-side tests on two novel English grammatical dependencies, deploying methodology from psycholinguistics. In this paradigm, the language models are fed with hand-crafted sentences, designed to draw out behavior that belies whether they have learned the underlying syntactic dependency. For example, Linzen et al. (2016) and Kuncoro et al. (2018) assessed how well neural language models were able to learn subject-verb number agreement by feeding the prefix *The keys to the cabinet...* If the model assigns a relatively higher probability to the grammatical plural verb *are* than the ungrammatical singular *is* it can be said to have learned the agreement dependency. Here, we investigate two non-local dependencies that remain untested for RNNGs: Negative Polarity Item (NPI) licensing is the dependency between a negative licensor—

Proceedings of NAACL-HLT 2019, pages 3302–3312
Minneapolis, Minnesota, June 2 - June 7, 2019.

such as *not* or *none*—and a Negative Polarity Item such as *any* or *ever*. The filler–gap dependency is the dependency between a filler—such as *who* or *what*—and a gap, which is an empty syntactic position. Both dependencies have been shown to be learnable by LSTMs trained on large amounts of data (Wilcox et al., 2018; Marvin and Linzen, 2018). Here, we investigate whether, after controlling for size of the training data, explicit hierarchical representation results in learning advantages.

2 Methodology

2.1 Neural Language Models

Recurrent Neural Network LMs model a sentence in a purely sequential basis, without explicitly representing the latent syntactic structure. We use the LSTM architecture in Hochreiter and Schmidhuber (1997), deploying a 2-layer LSTM language model with hidden layer size 256, input embedding size 256, and dropout rate 0.3. We refer to this model as the "LSTM" model in the following sections.

Recurrent Neural Network Grammars (Dyer et al., 2016) predict joint probability of a sentence as well as its syntactic parse. RNNGs contain three sub-components, all of which are LSTMS: the *neural stack*, which keeps track of the current parse, the *output buffer*, which keeps track of previously-seen terminals and the *history of actions*. At each timestep the model can take three different actions: NT, which introduces a non-terminal symbol—such as a VP or NP—onto the stack; SHIFT, which places a terminal symbol onto the top of the stack, or REDUCE. REDUCE pops terminal symbols (words) off the stack until a non-terminal phrasal boundary is encountered; it then combines the terminals into a single representation via a bidirectional-LSTM and pushes the newly-reduced constituent back onto the stack. By reducing potentially unbounded constituents within the neural stack, the RNNG is able to create structural adjacency between co-dependent words that may be linearly distal. Following Dyer et al. (2016), we use 2-layer LSTMs with 256 hidden layer size for the stack-LSTM, action LSTM, and terminal LSTM, and dropout rate 0.3.

ActionLSTM: It is the combination of the neural stack and the REDUCE function that may give the RNNG an advantage over purely sequential models (such as LSTMS) or models that deploy syntactic supervision without explicit notions of compositionality. In order to assess the gains from explicitly modeling compositionality, we compare the previous two models against an incrementalized version of the Parsing-as-Language-Modeling configuration presented in Charniak et al. (2016). In this model, we strip an RNNG of its *neural stack* and *output buffer*, and train it to jointly predict the action sequence of a parse tree as well as the upcoming word. The action space of the model contains a set of non-terminal nodes (NT), terminal generations (GEN), as well as a (REDUCE) action, which functions only as a generic phrasal boundary marker. The model was trained using embedding size 256, dropout 0.3, and was able to achieve a parsing F1 score of 92.81 on the PTB, which is only marginally better than the performance of the original architecture on the same test set, as reported in Kuncoro et al. (2016). We will refer to this model as the "ActionLSTM" model in the following sections.

All three models are trained on the training-set portion of the English Penn Treebank standardly used in the parsing literature (PTB; sections 2-21), which consists of about **950,000 tokens** of English language news-wire text (Marcus et al., 1993). The RNNG and Action models get supervision from syntactic annotation–crucially, only constituent boundaries and major syntactic categories, with functional tags and empty categories stripped away—whereas the LSTM language model only uses the sequences of terminal words. We train the models until performance converges on the held-out PTB development-set data.

2.2 Psycholinguistic Assessment Paradigm

2.2.1 Surprisal

The **surprisal**, or negative log-conditional probability, $S(x_i)$ of a sentence's i^{th} word x_i, tells us how strongly x_i is expected in context and is also known to correlate with human processing difficulty (Smith and Levy, 2013; Hale, 2001; Levy, 2008). For sentences out of context, surprisal is:

$$S(x_i) = -\log p(x_i | x_1 \dots x_{i-1})$$

We investigate a model's knowledge of a grammatical dependency, which is the co-variance between an upstream *licensor* and a downstream *licensee*, by measuring the effect that an upstream licensor has on the surprisal of a downstream licensee. The idea is that grammatical licensors should set up an expectation for the licensee thus reducing its surprisal compared to minimal pairs in which the licensor is absent. We derive the word surprisal from the LSTM language model by directly computing the negative log value of the predicted conditional probability $p(x_i|x_1 \ldots x_{i-1})$ from the softmax layer.

Following the method in Hale et al. (2018) for estimating word surprisals from RNNG, we use word-synchronous beam search (Stern et al., 2017) to find a set of most likely incremental parses and sum their forward probabilities to approximate $P(x_1, \ldots x_i)$ and $P(x_1, \ldots x_{i-1})$ for computing the surprisal. We set the action beam size to 100 and word beam size to 10. We ensured that the correct incremental RNNG parses were present on the beam immediately before and throughout the material over which surprisal was calculated through manual spot inspection; the correct parse was almost always at the top of the beam.

2.2.2 Wh-Licensing Interaction

Unlike NPI, licensing, the filler—gap dependency is the covariance between a piece of extant material, a filler, and a piece of *absent* material, a gap. Here, we employ the methodology from Wilcox et al. (2018), which introduces the **Wh-Licensing Interaction**. To compute the wh-licensing interaction for a sentence, Wilcox et al. (2018) construct four variants, given in (1), that exhibit the four possible combinations of fillers and gaps for a specific syntactic position. The underscores are for presentational purposes only and were not included in experimental materials.

(1) a. I know that the lion devoured the gazelle at sunrise. [-FILLER -GAP]
b. *I know what the lion devoured the gazelle at sunrise. [+FILLER -GAP]
c. *I know that the lion devoured __ at sunrise. [-FILLER +GAP]
d. I know what the lion devoured __ at sunrise. [+FILLER +GAP]

If a filler sets up an expectation for a gap, then filled syntactic positions should be more surprising in the context of a filler than in a minimally-different, non-filler variants. We measure this expectation by calculating the difference of surprisal between (1-b) and (1-a). Similarly, if gaps require fillers to be licensed, transitions from transitive verbs to adjunct clauses that skip an obligatory argument should be less surprising in the context of a filler than in minimally-different, non-filler variants. We measure this expectation by computing the difference in surprisal between (1-c) and (1-d). Because the filler–gap dependency is a two-way interaction, the wh-licensing interaction consists of the difference of these two differences, which is given in (2).

(2) $(S(\text{1-b}) - S(\text{1-a})) - (S(\text{1-c}) - S(\text{1-d}))$

For basic filler—gap dependencies, we expect the presence of a filler to set up a global expectation for a gap, thus we measure the summed licensing interaction across the entire embedded clause, which we expect to be significantly above zero if the model is learning the dependency. Our experimental materials include only vocabulary items within the PTB, avoiding the need for Out of Vocabulary handling. We determine statistical significance using a mixed-effects linear regression model, using sum-coded conditions (Baayen et al., 2008). For within-model comparison we use surprisal as the dependent variable and experimental conditions as predictors; for between-model comparison, we use wh-licensing interaction as the dependent variable with model type and experimental conditions as predictors. All figures depict by-item means, with error bars representing 95% confidence intervals, computed by subtracting out the within-item means from each condition as advocated by Masson and Loftus (2003). The strength of a wh-licensing interaction can be interpreted as either its mean size in bits, or as its mean size normalized by its standard deviation across items. The latter is Cohen's d, rooted in signal-detection theory (**?**); because all our experiments involve similar number of items, it is roughly proportional to the size of wh-interaction relative to the size of the associated confidence interval.[1]

3 Negative Polarity Item Licensing

In English, Negative Polarity Items (NPIs), such as *any*, *ever* must be in the SCOPE of a negative LICENSOR such as *no*, *none*, or *not* (**?**Ladusaw, 1979). Crucially, the scope of a licensor is characterized structurally, not in purely linear terms; for present purposes, a sufficient approximation is that an NPI is in the proper scope of a licensor if it is c-commanded by it. Thus while *ever* in (3-b) and (3-d) is grammatical because it is licensed by *no* in the main-clause subject, *ever* is ungrammatical in (3-c) despite the linearly preceding *no*, be-

---

[1] All of our experiments were pre-registered online at `http://aspredicted.org/blind.php?x={xd9cw9, 3xv2du, jd384m, cy6zp6, 2hk4gf, zt73qt, f9pk9f, ab9f3h, yt6pi4}`

cause inside a subject-modifying relative clause is not a valid position for an NPI licensor; we call this a DISTRACTOR position.

(3) a. ***The** senator that supported the measure has ever found any support from her constituents.
b. **No** senator that supported the measure has ever found any support from her constituents.
c. ***The** senator that supported **no** measure has ever found any support from her constituents.
d. **No** senator that supported no measure has ever found any support from her constituents.

Learning of NPI licensing conditions by LSTM language models trained on large corpora has previously been investigated by Marvin and Linzen (2018) and Futrell et al. (2018). Futrell et al. found that the language models of both Gulordava et al. (2018) and Jozefowicz et al. (2016) (hereafter called 'Large Data LSTMs') learned a contingency between licensors and NPIs: the NPIs in examples like (3) were lower-surprisal when linearly preceded by negative licensors. However, both papers reported that these models failed to constrain the contingency along the correct structural lines: negative NPI surprisal was decreased at least as much by a preceding negative distractor as by a negative licensor.

Syntactic supervision might plausibly facilitate learning of NPI licensing conditions. We tested this following the method of Futrell et al. (2018), constructing 27 items on the design of in (3), with two variants: one included *ever* and omitting *any*, and one including *any* and omitting *ever*. Figure 1, left panel, shows the results. For the RNNG and the ActionLSTM, negative licensors and distractors alike reduced surprisal of both NPIs ($p < 0.05$ for the RNNG, $p < 0.001$ for the ActionLSTM). For the LSTM, negative licensors and distractors alike reduced surprisal of *ever* (both $p < 0.01$), but not *any*. This may seem surprising as *any* is considerably more frequent than *ever* (123 vs. 727 instances in the training data), but *any*'s non-NPI uses (e.g., *I will eat anything fried*) may complicate its learning.

From Figure 1 it is also apparent that the RNNG and ActionLSTM show signs of stronger NPI licensing effects from negation in the licensor position than in the distractor position, at least for *ever*. To quantify this, we follow Marvin and Linzen (2018) in computing item-mean classification accuracies, with classification being considered correct if the NPI is assigned higher probability in context for (3-b) than for (3-c). Results are shown in Figure 1, right panel. No

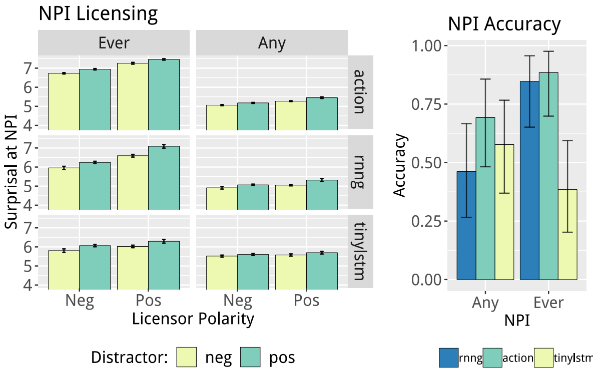

Figure 1: NPI Licensing at left: Y-axis shows surprisal at the NPI, x-axis indicates polarity of the c-commanding licensor, and color indicates distractor polarity. Licensing accuracy at right: Y-axis shows classification accuracy, x-axis indicates the NPI tested, and color indicates the model. Error bars represent 95% binomial confidence intervals.

model is significantly above chance for *any*, but for *ever* the syntactically supervised models perform much better: The RNNG reaches 85% performance, and the ActionLSTM 88%, both significantly above chance ($p < 0.001$ by binomial test for each), and are not significantly different from each other, but both better than the LSTM ($p < 0.01$ for the RNNG/LSTM; $p < 0.001$ for the ActionLSTM/LSTM by Fisher's exact test). To our knowledge this is the first demonstration of a language model learning the licensing conditions for an NPI without direct supervision.

Overall, we find that syntactic supervision facilitates the contingency of NPIs on a negative licensor in context, but is not sufficient for clean generalization of the structural conditions on NPI licensing with the training dataset used here.

4 Filler–Gap Dependencies

The dependency between a FILLER, which is a wh-word such as *who* or *what*, and a GAP, which is an empty syntactic position, is characterized by a number of properties, some of which were tested for large data LSTMs by Wilcox et al. (2018). Here we investigate the effect of syntactic supervision on filler–gap dependency learning. Syntactic annotation of the dependency itself is stripped from the training data (Figure 2), so syntactic supervision can play only an indirect facilitatory role for the models' neural learning mechanisms.

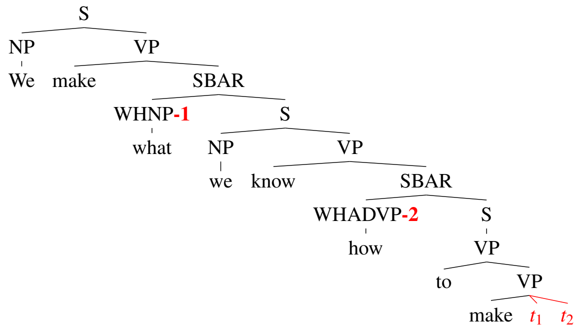

Figure 2: Example of filler–gap dependency representation in the Penn Treebank. Non-local dependency annotation indicated in bold, red font is stripped from the training data, so that the RNNG must learn about the filler-gap dependency purely through neural generalization.

Location of Gap	All Fillers	'Who'	'What'
All Positions	13907	1888	660
Subject Position	6632	1510	236
Object Position	2080	12	332
Indirect Object Position	57	0	6

Table 1: Filler—Gap Dependency Statistics for the Penn Treebank training data (used for both models).

4.1 Flexibility of Gap Position

The filler–gap dependency is flexible: a filler can license a gap in any of a number of syntactic positions, including the argument positions of subject, object, and indirect object, as illustrated in (4), as well as in other positions (e.g. the adjunct position for *how* in Figure 2).

(4) a. I know who __ introduced the accountant to the guests after lunch.
b. I know who the CEO introduced __ to the guests after lunch.
c. I know who the CEO introduced the accountant to __ after lunch.

These gap positions differ in frequency, however (Table 1): the majority (63.1%) are in some argument structure position, of which the vast majority (75.6%) are subject position (mostly subject-extracted relative clauses), 23.7% are object position, and 0.7% are indirect object position.

Using the wh-interaction measure described in Section 2.2, Wilcox et al. (2018) showed that large-data LSTMs learn filler–gap dependencies for all three argument positions, with the size of the wh-interaction generally largest for subject gaps and smallest for indirect-object gaps. Table 1 suggests that this gradation may reflect frequency of learning signal, with the dependency being learned more robustly the more frequent the extraction type. We applied the same method, adapting Wilcox et al.'s items to the smaller training dataset. The results can be seen in the upper-left panel of Figure 3.

All three models learn the filler-gap dependency for subject and object positions, and there is suggestive but inconclusive evidence for learning in the rare indirect object position. We see stronger dependency learning for more frequent gap types, as was found for large data LSTMs, and the supervised models show a much stronger wh-licensing effect than the LSTM.

4.2 Syntactic Hierarchy

As with NPIs, the filler–gap dependency is subject to a number of hierarchical, structural constraints. The most basic of these constraints is that the filler must be "above" the gap in the appropriate structural sense (to a first approximation, the filler must *c*-command the gap, though see e.g. **?** for qualifications). Hence *who* in (5-a) is a legitimate extraction from the relative clause, but (5-b) is ungrammatical as the gap is in the matrix clause, above the filler.

(5) a. The policeman who the criminal shot __ with his gun shocked the jury during the trial.
b. *The policeman who the criminal shot the politician with his gun shocked __ during the trial.

A model that properly generalizes this constraint on the filler–gap dependency should *not* show a wh-interaction for cases like (5-b): an undischarged *who* filler should not make the matrix-clause gap particularly more expected. As far as we are aware, no prior work has investigated this property of the filler–gap dependency in language models; we do so here. Because the context in (5) does not allow for an immediate *that* clause initiation for the –FILLER condition as in (1), we instantiate this condition by contrasting the +FILLER,+GAP condition of (5-b) with the variants in (6), where the *who* filler is immediately discharged as the RC verb's extracted subject:

(6) a. *The policeman who __ knows that the criminal shot the politician with his gun shocked __ during the trial. -FILLER,+GAP
b. *The policeman who the criminal shot the politician with his gun shocked the jury during the trial. +FILLER,–GAP
c. The policeman who __ knows that the criminal shot the politician with his gun shocked the jury during the trial. -FILLER,–GAP

We created 22 items following the templates of (5-a) (*Subject* condition) and (5-b) (*Matrix* condition); results are shown in the top-right panel of 3. The supervised models show a large

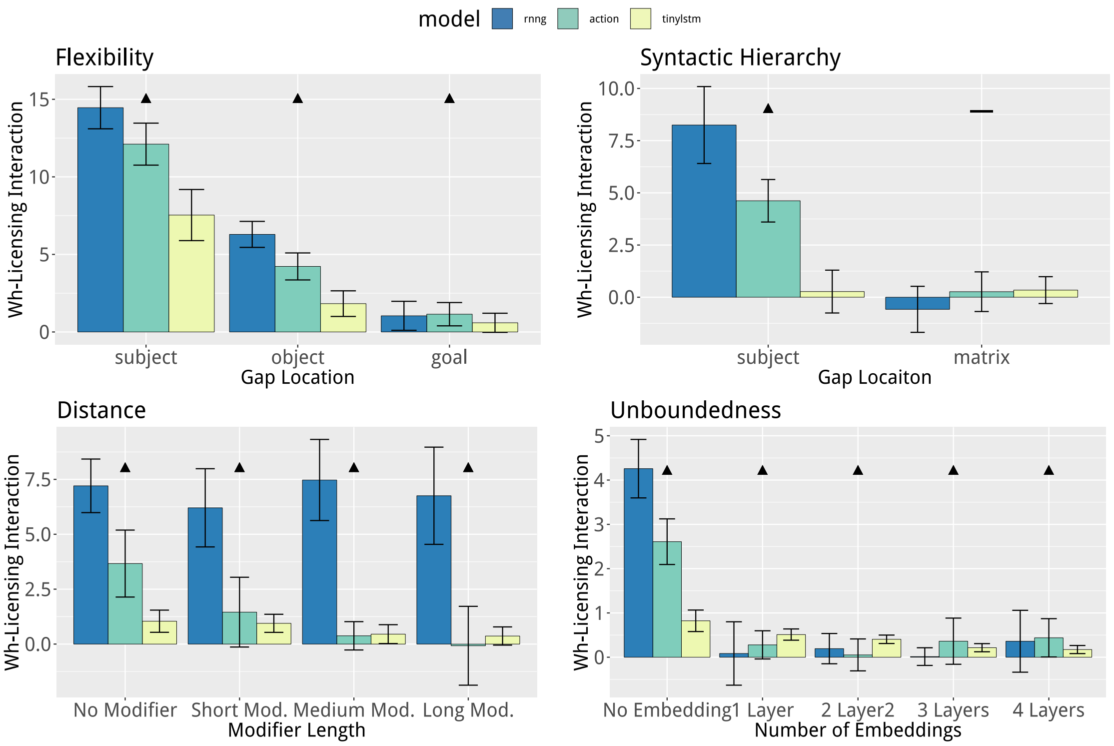

Figure 3: Model results for the basic properties of filler–gap licensing. "▲" indicates grammatical conditions in which models should display strong wh-licensing interaction, "–" indicates ungrammatical conditions in which models should display reduced wh-licensing interaction. The RNNG model significantly outperforms the LSTM model in 8/13 grammatical cases; the ActionLSTM model outperforms the LSTM model in 5/13 cases; and the RNNG outperforms the ActionLSTM model in 6/13 cases where strong licensing is expected.

wh-licensing interaction effect for a gap inside the subject-modifying relative clause—with the RNNG demonstrating more licensing interaction than the ActionLSTM—and neither model inappropriately generalizes this licensing effect to a matrix-clause gap. The LSTM shows no wh-licensing effects in either position, suggesting that syntactic supervision facilitates appropriately generalized filler-gap dependencies for subject-modifying relative clauses.[2]

4.3 Robustness to Intervening Material

For a model that learns human-like syntactic generalizations and maintains accurate phrase-like representations throughout a string, filler–gap dependencies should be robust to linearly intervening material that does not change the tree-structural relationship between the filler and the gap. Wilcox et al. (2018) found that the large-data RNNs described earlier exhibit a robust wh-interaction of this type, by introducing an optional postnominal modifier between filler and gap to sentence templates like (7), with no modification (7-a), short (3–5 word) modifiers (7-b), medium (6–8 word) modifiers (7-c), and long (8–12 word) modifiers (7-d).

(7) a. I know what your friend gave __ to Alex last weekend.
b. I know what your friend in the hat gave __ to Alex last weekend.
c. I know what your friend who you ate lunch with yesterday gave __ to Alex last weekend.
d. I know what your friend who recently took you on a walking tour of the city gave __ to Alex last weekend.

We adapted their materials for the small training dataset and tested our three models; results are shown in 3, bottom-left panel. The RNNG shows a robust licensing interaction that does not diminish with additional intervening material (all $d > 1.3$). The LSTM shows smaller wh-licensing interactions across the board; these are still substantial in the *No Modifier* and *Short Modifier* conditions ($d = 0.88, d = 0.98$, respectively), but are smaller in the *Medium Modifier* and *Long Modifier* conditions ($d = 0.45, d = 0.37$ respectively), suggesting less robustness to intervening material. The

---

[2] Results for the Larger Data LSTM models for the Hierarchy and Unboundedness experiments presented here can be found in the appendix.

ActionLSTM shows strong interactions in the *No Modifier* condition ($d = 1.02$), but weak interaction once any modifying material is introduced ($d < 0.4$ in all other conditions). This result is significant, as it indicates that RNNG is able to leverage the structural locality afforded by the neural stack to maintain robust gap expectancy.

4.4 Unboundedness

For humans, filler–gap dependencies are not only robust to linearly intervening material that does not change their tree-structural relationship, they can be STRUCTURALLY NON-LOCAL as well, propagating through intervening syntactic structures (subject to constraints examined in Section 5). For example, a filler can be extracted from multiply-nested complement clauses as in (8-b):

(8) a. I know who your aunt insulted __ at the party.
b. I know who the chauffeur said [$_S$ the hostess believed [$_S$ the butler reported [$_S$ her friend thinks your aunt insulted __ at the party.]]]

Humans show sensitivity to a single layer of sentential embedding when processing filler—gap dependencies in an offline 'complexity rating' task (Phillips et al., 2005). This may due to the relative frequency of single versus doubly-embedded filler—gap dependencies. In our training data there were 13,907 examples of filler—gap dependencies, however only 758 examples that spanned two layers of sentential embedding and 19 that spanned three layers. There were no instances of filler—gap dependencies spanning over more than three sentential embeddings, as in (8-b).

The unboundedness of filler–gap dependencies has not previously been tested for contemporary language models. To do this, we constructed 22 test items like (8), varying embedding depth within-item between zero, one, two, three, and four levels, and measured the resulting licensing interactions. The results are in Figure 3, bottom-right panel. No model's filler–gap dependency is perfectly robust to clausal embedding. The LSTM's wh-licensing interaction starts out small and diminishes with embedding depth. The RNNG and ActionLSTM show strong wh-licensing interaction in the unembedded condition but no significant wh-licensing interaction after even a single layer of embedding. Since these experimental materials are new, we also tested the large-data LSTMs on them, which exhibited much larger and more robust filler–dependency effects (Appendix B). Hence the syntactic supervision explored here is not sufficient to guarantee that learned filler–gap dependencies can be structurally unbounded.

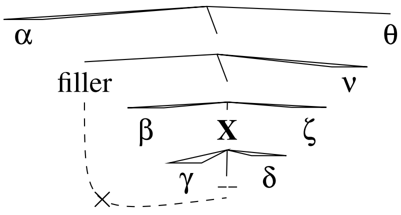

Figure 4: Anatomy of an island constraint. If node **X** is an island, then a filler outside **X** cannot associate with a gap inside **X**. For our analyses, successful learning of an island constraint implies that we should *not* see a wh-licensing interaction at the first part of the material δ immediately following the potential gap site.

5 Island Constraints

A crucial exception to the flexibility and unboundedness of filler–gap dependencies is that ISLAND CONSTRAINTS prevent association of a filler and a gap through certain types of syntactic nodes, illustrated in Figure 4 (Ross, 1967). Contemporary theories variously attribute island effects to grammatical rules, incremental processing considerations, or discourse-structural factors (Ambridge and Goldberg, 2008; Hofmeister and Sag, 2010; Sprouse and Hornstein, 2013). In our setting, a language model is sensitive to an island constraint if it *fails* to show a wh-licensing interaction between a filler and a gap that cross an island. Wilcox et al. (2018) found evidence that large-data LSTMs are sensitive to some island constraints (although see Chowdhury and Zamparelli (2018) for a contrasting view), but not to others. Here we investigate whether LSTMs would learn these from smaller training datasets, and if an RNNG's syntactic supervision provides a learning advantage for island constraints. In this section we measure the wh-licensing interaction in the material immediately following the potential gap site, which is guaranteed to implicate the model's (lack of) expectation for a gap inside the island, rather than throughout the entire embedded clause, which also implicates filler-driven expectations after the end of the island.

5.1 Adjunct Islands

Adjunct clauses block the filler–gap dependency. Wilcox et al. (2018) found evidence that large-data LSTMs are sensitive to adjunct islands, as evidenced by attenuated and often fully eliminated wh-licensing interactions for materials like (9-b)–(9-c) relative to (9-a) below. (In this and the subsequent subsections, the post-gap material used for wh-interaction computation is in **bold**.)

(9) a. The director discovered what the robbers stole __ **last night**. [Object]
b. *The director discovered what the security guard slept while the robbers stole __ **last night**. [Adj-back]
c. *The director discovered what, while the robbers stole __ **last night**, the security guard slept. [Adj-front]

We adapted these materials; results are in Figure 5, upper-left panel. The RNNG shows a strong licensing interaction in the baseline main-clause object extraction position, but no licensing interaction for a gap in an adjunct either at the back or front of the main clause. Because RNNGs failed our test for unboundedness of filler–gap dependency, however (Section 4.4), this result is inconclusive as to whether anything corresponding to an island constraint is learned. The LSTM and the ActionLSTM show no sign of filler–gap dependency attenuation from adjunct islands, in contrast to previous findings using the LSTM architecture on much larger training datasets.

5.2 Wh Islands

Embedded sentences introduced by *wh-* words are also islands; hence, (10-c) is anomalous but (10-a) and (10-b) are not.

(10)a. I know what the guide said the lion devoured __ **yesterday**. [Null Comp]
b. I know what the guide said that the lion devoured __ **yesterday**. [That Comp]
c. *I know what the guide said whether the lion devoured __ **yesterday**. [Wh- Comp]

Wilcox et al. (2018) found that the large-data LSTMs learned this island constraint: the wh-licensing interaction was eliminated or severely attenuated for the Wh-Complementizer variant but not for the other variants. Results for our three models are in Figure 5, top-right panel. These materials paint a slightly more optimistic picture than the results of Section 4.4 for the RNNG's ability to propagate a gap expectation from a filler down one level of clausal embedding. However, no models show an appreciable attenuation in the Wh- Comp condition that would suggest an island constraint-like generalization.

5.3 Complex Noun-Phrase Islands

Extractions from within clauses dominated by a lexical head noun are unacceptable; this is the Complex Noun Phrase Constraint. For example, (11-b) and (11-c) are unacceptable object extractions compared with (11-a); the same acceptability pattern holds for subject extractions.

(11)a. I know what the collector bought __ **last week**. [Argument extraction]
b. *I know what the collector bought the painting which depicted __ **last week**. [Wh- Complex NP]
c. *I know what the collector bought the painting that depicted __ **last week**. [That- Complex NP]

Wilcox et al. (2018) found that large-data LSTM behavior reflected this island constraint, with attenuated wh-licensing interactions for complex NPs like (11-b)–(11-c) and for analogous complex NPs involving subject extractions. Our results for adaptations of their materials are shown in Figure 5, bottom-left panel. All three models show attenuated wh-licensing interactions inside complex NPs in subject position, with the licensing interaction in the grammatical argument structure position greatest for the RNNG and ActionLSTM. This may be taken as an indication of Complex NP Constraint-like learning, but is inconclusive due to the models' general failure to propagate gap expectations into embedded clauses (Section 4.4).

5.4 Subject Islands

Prepositional phrases attaching to subjects are islands: this is the Subject Constraint, and accounts for the unacceptability of (12-d) compared to (12-c) (Huang, 1998).

(12)a. I know what the collector bought __ **yesterday**. [Obj Verbal-Arg]
b. I know what the collector bought a painting of __ **yesterday**. [Obj Prep-Arg]
c. I know what __ **sold** for a high price at auction. [Subj Verbal-Arg]
d. *I know what a painting of __ **sold** for a high price at auction. [Subj Prep-Arg]

Wilcox et al. (2018) found that the wh-licensing interactions of large-data LSTMs fail to distinguish between subject-modifying PPs, which cannot be extracted from, and object-modifying PPs, which can. Our results for adaptations of their materials can be seen in Figure 5, bottom right panel. The syntactically supervised models show a significant decrease between the verbal argument and prepositional argument conditions in subject position ($p < 0.001$ for RNNG; $p < 0.01$ for ActionLSTM), and no significant difference between the two conditions in object position (however, note that the licensing in object position is significantly less than the licensing in the grammatical, *Verbal Argument Subject* position, following the pattern in 4.1). LSTMs fare worse, showing a clear wh-

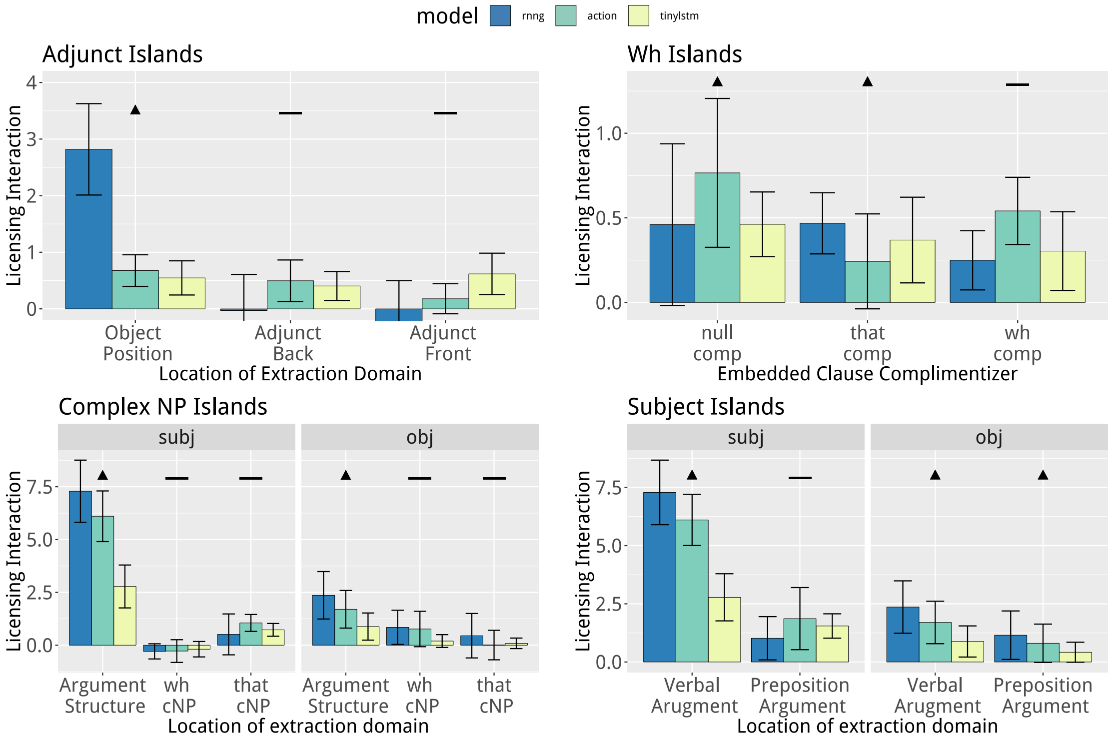

Figure 5: Model results for Syntactic Islands. "▲" indicates grammatical conditions in which models should display strong wh-licensing interaction, "–" indicates ungrammatical conditions in which models should display reduced wh-licensing interaction.

licensing interaction for subject-modifying PPs, which should be islands, and no wh-licensing interaction for object-modifying PPs.

6 Conclusion

In this paper we have argued that structural supervision provides advantages over purely string-based training of neural language models in acquiring more human-like generalizations about non-local grammatical dependencies. We have also demonstrated how the neural compositionality of the RNNG architecture can provide even further advantages, especially at maintaining expectations into structurally-local but linearly distant material. We compared RNNG, ActionLSTM and LSTM models using recently developed controlled experimental materials, and developed additional experimental materials to further test several characteristics of grammatical dependency learning for neural language models (Sections 4.2, 4.4). We found advantages for syntactic supervision in learning conditions for **Negative Polarity Item licensing** and a majority of tests involving **filler–gap dependencies**, showing particularly strong wh-licensing effects in tree-structurally-local contexts. On basic filler—gap dependency properties the RNNG significantly outperformed the LSTM in 8/13 and the ActionLSTM outperformed the LSTM on 5/13 cases where strong licensing interaction was expected. While the RNNG, and to some extent the ActionLSTM, exhibited more humanlike behavior than the LSTM for a number of **Island Constraints**, the tests were inconclusive due to the models' failure to propagate gap expectation into embedded clauses: island-like behavior may merely be sensitivity to general syntactic complexity, not the highly-specific syntactic arrangements that constitute the family of island constructions. Thus, major-category supervision does not provide enough information for the neural component to learn fully robust and human-like filler—gap dependencies from 1-million words alone. However, for some dependencies tested (i.e. NPIs) structural supervision on 1 million words provides better outcomes than even large-data LSTMs. Scaling the gains derived from structural supervision is a challenge for data-scarce NLP and is the basis for future work.

Appendix

We present results for two large data LSTM models on novel experiments described in the paper. The two models tested here are the 'BIG LSTM + CNN Inputs' from Jozefowicz et al. (2016)

(the ‘google’ model) and the highest-performing model presented in the supplementary materials of Gulordava et al. (2018) (the ‘Gulordava’ model). Both models where shown in (Wilcox et al., 2018) to represent filler—gap dependencies and some island constraints.

A Syntactic Hierarchy

We tested the two large LSTM models using our stimuli from the syntactic hierarchy experiment and measured the wh-licensing interaction across the entire embedded clause. The results of this experiment can be seen in Figure 6. Both models show significant licensing interaction in the grammatical *Subject* condition ($p < 0.001$), and a significant reduction in licensing interaction between the *Subject* and *Matrix* conditions ($p < 0.001$ in both models). Additionally, there is a significant licensing interaction in the *Matrix* condition for the Google model, but not so for the Gulordava model.

B Unboundedness

We tested the two large LSTM models from Wilcox et al. (2018) following the stimuli from our unboundedness experiment, with two variants, one that included gaps in *Object* position and one that included gaps in indirect object or *Goal* position. The results can be seen in Figure 7. For the Google model in *Object* position, we find a significant reduction of wh-licensing interaction across more than three layers of embedding ($p < 0.001$). For the Gulordava model, we find a significant reduction in wh-licensing interaction after only one layer of embedding ($p < 0.001$). In the *Goal* position: For the Google model, we find a significant reduction in licensing interaction after two layers of embedding ($p < 0.05$ for 2 layers, $p < 0.001$ for 3-4 layers). For the Gulordava model, we find no significant licensing interaction after one layer of embedding. These results indicate the larger LSTMs are able to thread gap expectation through embedded clauses.

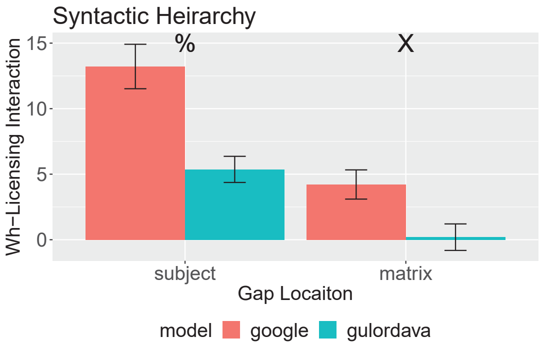

Figure 6: Syntactic Hierarchy. %s indicate conditions where we would expect a strong wh-licensing interaction, Xs where we expect low wh-licensing interaction.

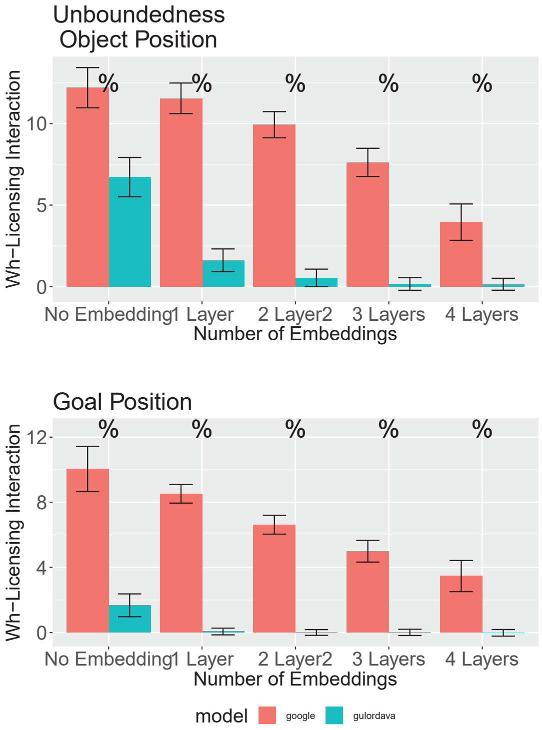

Figure 7: Unboundedness, %s indicate conditions where we expect a strong wh-licensing interaction.

Benchmarking Approximate Inference Methods for Neural Structured Prediction

Lifu Tu **Kevin Gimpel**
Toyota Technological Institute at Chicago, Chicago, IL, 60637, USA
{lifu,kgimpel}@ttic.edu

Abstract

Exact structured inference with neural network scoring functions is computationally challenging but several methods have been proposed for approximating inference. One approach is to perform gradient descent with respect to the output structure directly (Belanger and McCallum, 2016). Another approach, proposed recently, is to train a neural network (an "inference network") to perform inference (Tu and Gimpel, 2018). In this paper, we compare these two families of inference methods on three sequence labeling datasets. We choose sequence labeling because it permits us to use exact inference as a benchmark in terms of speed, accuracy, and search error. Across datasets, we demonstrate that inference networks achieve a better speed/accuracy/search error trade-off than gradient descent, while also being faster than exact inference at similar accuracy levels. We find further benefit by combining inference networks and gradient descent, using the former to provide a warm start for the latter.[1]

1 Introduction

Structured prediction models commonly involve complex inference problems for which finding exact solutions is intractable (Cooper, 1990). There are generally two ways to address this difficulty. One is to restrict the model family to those for which inference is feasible. For example, state-of-the-art methods for sequence labeling use structured energies that decompose into label-pair potentials and then use rich neural network architectures to define the potentials (Collobert et al., 2011; Lample et al., 2016; Ma and Hovy, 2016, *inter alia*). Exact dynamic programming algorithms like the Viterbi algorithm can be used for inference.

The second approach is to retain computationally-intractable scoring functions but then use approximate methods for inference. For example, some researchers relax the structured output space from a discrete space to a continuous one and then use gradient descent to maximize the score function with respect to the output (Belanger and McCallum, 2016). Another approach is to train a neural network (an "inference network") to output a structure in the relaxed space that has high score under the structured scoring function (Tu and Gimpel, 2018). This idea was proposed as an alternative to gradient descent in the context of structured prediction energy networks (Belanger and McCallum, 2016).

In this paper, we empirically compare exact inference, gradient descent, and inference networks for three sequence labeling tasks. We train conditional random fields (CRFs) for sequence labeling with neural networks used to define the potentials. We choose a scoring function that permits exact inference via Viterbi so that we can benchmark the approximate methods in terms of search error in addition to speed and accuracy. We consider three families of neural network architectures to serve as inference networks: convolutional neural networks (CNNs), recurrent neural networks (RNNs), and sequence-to-sequence models with attention (seq2seq; Sutskever et al., 2014; Bahdanau et al., 2015). We also use multi-task learning while training inference networks, combining the structured scoring function with a local cross entropy loss.

Our empirical findings can be summarized as follows. Gradient descent works reasonably well for tasks with small label sets and primarily local structure, like part-of-speech tagging. However, gradient descent struggles on tasks with long-distance dependencies, even with small label set sizes. For tasks with large label set sizes, inference networks and Viterbi perform comparably,

---

Proceedings of NAACL-HLT 2019, pages 3313–3324
Minneapolis, Minnesota, June 2 - June 7, 2019.

with Viterbi taking much longer. In this regime, it is difficult for gradient descent to find a good solution, even with many iterations.

In comparing inference network architectures, (1) CNNs are the best choice for tasks with primarily local structure, like part-of-speech tagging; (2) RNNs can handle longer-distance dependencies while still offering high decoding speeds; and (3) seq2seq networks consistently work better than RNNs, but are also the most computationally expensive.

We also compare search error between gradient descent and inference networks and measure correlations with input likelihood. We find that inference networks achieve lower search error on instances with higher likelihood (under a pretrained language model), while for gradient descent the correlation between search error and likelihood is closer to zero. This shows the impact of the use of dataset-based learning of inference networks, i.e., they are more effective at amortizing inference for more common inputs.

Finally, we experiment with two refinements of inference networks. The first fine-tunes the inference network parameters for a single test example to minimize the energy of its output. The second uses an inference network to provide a warm start for gradient descent. Both lead to reductions in search error and higher accuracies for certain tasks, with the warm start method leading to a better speed/accuracy trade-off.

2 Sequence Models

For sequence labeling tasks, given an input sequence $\boldsymbol{x} = \langle x_1, x_2, ..., x_{|\boldsymbol{x}|}\rangle$, we wish to output a sequence $\boldsymbol{y} = \langle \mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_{|\boldsymbol{x}|}\rangle \in \mathcal{Y}(\boldsymbol{x})$. Here $\mathcal{Y}(\boldsymbol{x})$ is the structured output space for $\boldsymbol{x}$. Each label $\mathbf{y}_t$ is represented as an L-dimensional one-hot vector where L is the number of labels.

Conditional random fields (CRFs; Lafferty et al., 2001) form one popular class of methods for structured prediction, especially for sequence labeling. We define our structured energy function to be similar to those often used in CRFs for sequence labeling:

$$E_\Theta(\boldsymbol{x}, \boldsymbol{y}) = \\ -\left(\sum_t \sum_{i=1}^{L} y_{t,i}\left(\mathbf{u}_i^\top f(\boldsymbol{x}, t)\right) + \sum_t \mathbf{y}_{t-1}^\top \mathbf{W} \mathbf{y}_t\right)$$

where $y_{t,i}$ is the ith entry of the vector $\mathbf{y}_t$. In the standard discrete-label setting, each $\mathbf{y}_t$ is a one-hot vector, but this energy is generalized to be able to use both discrete labels and continuous relaxations of the label space, which we will introduce below. Also, we use $f(\boldsymbol{x}, t) \in \mathbb{R}^d$ to denote the "input feature vector" for position t, $\mathbf{u}_i \in \mathbb{R}^d$ is a label-specific parameter vector used for modeling the local scoring function, and $\mathbf{W} \in \mathbb{R}^{L \times L}$ is a parameter matrix learned to model label transitions. For the feature vectors we use a bidirectional long short-term memory (BLSTM; Hochreiter and Schmidhuber, 1997), so this forms a BLSTM-CRF (Lample et al., 2016; Ma and Hovy, 2016).

For training, we use the standard conditional log-likelihood objective for CRFs, using the forward and backward dynamic programming algorithms to compute gradients. For a given input $\boldsymbol{x}$ at test time, prediction is done by choosing the output with the lowest energy:

$$\underset{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})}{\operatorname{argmin}}\, E_\Theta(\boldsymbol{x}, \boldsymbol{y})$$

The Viterbi algorithm can be used to solve this problem exactly for the energy defined above.

2.1 Modeling Improvements: BLSTM-CRF+

For our experimental comparison, we consider two CRF variants. The first is the basic model described above, which we refer to as BLSTM-CRF. Below we describe three additional techniques that we add to the basic model. We will refer to the CRF with these three techniques as BLSTM-CRF+. Using these two models permits us to assess the impact of model complexity and performance level on the inference method comparison.

Word Embedding Fine-Tuning. We used pretrained, fixed word embeddings when using the BLSTM-CRF model, but for the more complex BLSTM-CRF+ model, we fine-tune the pretrained word embeddings during training.

Character-Based Embeddings. Character-based word embeddings provide consistent improvements in sequence labeling (Lample et al., 2016; Ma and Hovy, 2016). In addition to pretrained word embeddings, we produce a character-based embedding for each word using a character convolutional network like that of Ma and Hovy (2016). The filter size is 3 characters and the character embedding dimensionality is 30. We use max pooling over the character sequence in the word and the resulting embedding is concatenated with the word embedding before being passed to the BLSTM.

Dropout. We also add dropout during training (Hinton et al., 2012). Dropout is applied before the character embeddings are fed into the CNNs, at the final word embedding layer before the input to the BLSTM, and after the BLSTM. The dropout rate is 0.5 for all experiments.

3 Gradient Descent for Inference

To use gradient descent (GD) for structured inference, researchers typically relax the output space from a discrete, combinatorial space to a continuous one and then use gradient descent to solve the following optimization problem:

$$\operatorname*{argmin}_{\boldsymbol{y} \in \mathcal{Y}_R(\boldsymbol{x})} E_\Theta(\boldsymbol{x}, \boldsymbol{y})$$

where $\mathcal{Y}_R$ is the relaxed continuous output space. For sequence labeling, $\mathcal{Y}_R(\boldsymbol{x})$ consists of length-$|\boldsymbol{x}|$ sequences of probability distributions over output labels. To obtain a discrete labeling for evaluation, the most probable label at each position is returned.

There are multiple settings in which gradient descent has been used for structured inference, e.g., image generation (Johnson et al., 2016), structured prediction energy networks (Belanger and McCallum, 2016), and machine translation (Hoang et al., 2017). Gradient descent has the advantage of simplicity. Standard autodifferentiation toolkits can be used to compute gradients of the energy with respect to the output once the output space has been relaxed. However, one challenge is maintaining constraints on the variables being optimized. Therefore, we actually perform gradient descent in an even more relaxed output space $\mathcal{Y}_{R'}(\boldsymbol{x})$ which consists of length-$|\boldsymbol{x}|$ sequences of vectors, where each vector $\mathbf{y}_t \in \mathbb{R}^L$. When computing the energy, we use a softmax transformation on each $\mathbf{y}_t$, solving the following optimization problem with gradient descent:

$$\operatorname*{argmin}_{\boldsymbol{y} \in \mathcal{Y}_{R'}(\boldsymbol{x})} E_\Theta(\boldsymbol{x}, \mathrm{softmax}(\boldsymbol{y})) \tag{1}$$

where the softmax operation above is applied independently to each vector $\mathbf{y}_t$ in the output structure $\boldsymbol{y}$.

4 Inference Networks

Tu and Gimpel (2018) define an **inference network** ("infnet") $\mathbf{A}_\Psi : \mathcal{X} \to \mathcal{Y}_R$ and train it with the goal that

$$\mathbf{A}_\Psi(\boldsymbol{x}) \approx \operatorname*{argmin}_{\boldsymbol{y} \in \mathcal{Y}_R(\boldsymbol{x})} E_\Theta(\boldsymbol{x}, \boldsymbol{y})$$

where $\mathcal{Y}_R$ is the relaxed continuous output space as defined in Section 3. For sequence labeling, for example, an inference network $\mathbf{A}_\Psi$ takes a sequence $\boldsymbol{x}$ as input and outputs a distribution over labels for each position in $\boldsymbol{x}$. Below we will consider three families of neural network architectures for $\mathbf{A}_\Psi$.

For training the inference network parameters Ψ, Tu and Gimpel (2018) explored stabilization and regularization terms and found that a local cross entropy loss consistently worked well for sequence labeling. We use this local cross entropy loss in this paper, so we perform learning by solving the following:

$$\operatorname*{argmin}_{\Psi} \sum_{\langle \boldsymbol{x}, \boldsymbol{y} \rangle} E_\Theta(\boldsymbol{x}, \mathbf{A}_\Psi(\boldsymbol{x})) + \lambda \ell_{\text{token}}(\boldsymbol{y}, \mathbf{A}_\Psi(\boldsymbol{x}))$$

where the sum is over $\langle \boldsymbol{x}, \boldsymbol{y} \rangle$ pairs in the training set. The token-level loss is defined:

$$\ell_{\text{token}}(\boldsymbol{y}, \mathbf{A}(\boldsymbol{x})) = \sum_{t=1}^{|\boldsymbol{y}|} \mathrm{CE}(\mathbf{y}_t, \mathbf{A}(\boldsymbol{x})_t) \tag{2}$$

where $\mathbf{y}_t$ is the L-dimensional one-hot label vector at position t in $\boldsymbol{y}$, $\mathbf{A}(\boldsymbol{x})_t$ is the inference network's output distribution at position t, and CE stands for cross entropy. We will give more details on how ℓ_{token} is defined for different inference network families below. It is also the loss used in our non-structured baseline models.

4.1 Inference Network Architectures

We now describe options for inference network architectures for sequence labeling. For each, we optionally include the modeling improvements described in Section 2.1. When doing so, we append "+" to the setting's name to indicate this (e.g., infnet+).

4.1.1 Convolutional Neural Networks

CNNs are frequently used in NLP to extract features based on symbol subsequences, whether words or characters (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014;

Kim et al., 2016; Zhang et al., 2015). CNNs use filters that are applied to symbol sequences and are typically followed by some sort of pooling operation. We apply filters over a fixed-size window centered on the word being labeled and do not use pooling. The feature maps $f_n(\boldsymbol{x}, t)$ for $(2n+1)$-gram filters are defined:

$$f_n(\boldsymbol{x}, t) = g(\mathbf{W}_n[\mathbf{v}_{x_{t-n}}; ...; \mathbf{v}_{x_{t+n}}] + \mathbf{b}_n)$$

where g is a nonlinearity, $\mathbf{v}_{x_t}$ is the embedding of word x_t, and $\mathbf{W}_n$ and $\mathbf{b}_n$ are filter parameters. We consider two CNN configurations: one uses $n = 0$ and $n = 1$ and the other uses $n = 0$ and $n = 2$. For each, we concatenate the two feature maps and use them as input to the softmax layer over outputs. In each case, we use H filters for each feature map.

4.1.2 Recurrent Neural Networks

For sequence labeling, it is common to use a BLSTM that runs over the input sequence and produces a softmax distribution over labels at each position in the sequence. We use this "BLSTM tagger" as our RNN inference network architecture. The parameter H refers to the size of the hidden vectors in the forward and backward LSTMs, so the full dimensionality passed to the softmax layer is $2H$.

4.1.3 Sequence-to-Sequence Models

Sequence-to-sequence (seq2seq; Sutskever et al. 2014) models have been successfully used for many sequential modeling tasks. It is common to augment models with an attention mechanism that focuses on particular positions of the input sequence while generating the output sequence (Bahdanau et al., 2015). Since sequence labeling tasks have equal input and output sequence lengths and a strong connection between corresponding entries in the sequences, Goyal et al. (2018) used fixed attention that deterministically attends to the ith input when decoding the ith output, and hence does not learn any attention parameters. It is shown as follows:

$$P(\mathbf{y}_t \mid \mathbf{y}_{<t}, \boldsymbol{x}) = \text{softmax}(\mathbf{W}_s[\mathbf{h}_t, \mathbf{s}_t])$$

where $\mathbf{s}_t$ is the hidden vector at position t from a BLSTM run over $\boldsymbol{x}$, $\mathbf{h}_t$ is the decoder hidden vector at position t, and $\mathbf{W}_s$ is a parameter matrix. The concatenation of the two hidden vectors is used to produce the distribution over labels.

When using this inference network, we redefine the local loss to the standard training criterion for seq2seq models, namely the sum of the log losses for each output conditioned on the previous outputs in the sequence. We always use the previous predicted label as input (as used in "scheduled sampling," Bengio et al., 2015) during training because it works better for our tasks. In our experiments, the forward and backward encoder LSTMs use hidden dimension H, as does the LSTM decoder. Thus the model becomes similar to the BLSTM tagger except with conditioning on previous labeling decisions in a left-to-right manner.

We also experimented with the use of beam search for both the seq2seq baseline and inference networks and did not find much difference in the results. Also, as alternatives to the deterministic position-based attention described above, we experimented with learned local attention (Luong et al., 2015) and global attention, but they did not work better on our tasks.

4.2 Methods to Improve Inference Networks

To further improve the performance of an inference network for a particular test instance $\boldsymbol{x}$, we propose two novel approaches that leverage the strengths of inference networks to provide effective starting points and then use instance-level fine-tuning in two different ways.

4.2.1 Instance-Tailored Inference Networks

For each test example $\boldsymbol{x}$, we initialize an instance-specific inference network $\mathbf{A}_\Psi(\boldsymbol{x})$ using the trained inference network parameters, then run gradient descent on the following loss:

$$\underset{\Psi}{\operatorname{argmin}}\, E_\Theta(\boldsymbol{x}, \mathbf{A}_\Psi(\boldsymbol{x})) \tag{3}$$

This procedure fine-tunes the inference network parameters for a single test example to minimize the energy of its output. For each test example, the process is repeated, with a new instance-specific inference network being initialized from the trained inference network parameters.

4.2.2 Warm-Starting Gradient Descent with Inference Networks

Given a test example $\boldsymbol{x}$, we initialize $\boldsymbol{y} \in \mathcal{Y}_{R'}(\boldsymbol{x})$ using the inference network and then use gradient descent by solving Eq. 1 described in Section 3 to update $\boldsymbol{y}$. However, the inference network output is in $\mathcal{Y}_R(\boldsymbol{x})$ while gradient descent works with the more relaxed space $\mathcal{Y}_{R'}(\boldsymbol{x})$. So we simply use the logits from the inference network, which are the score vectors before the softmax operations.

5 Experimental Setup

We perform experiments on three tasks: Twitter part-of-speech tagging (POS), named entity recognition (NER), and CCG supersense tagging (CCG).

5.1 Datasets

POS. We use the annotated data from Gimpel et al. (2011) and Owoputi et al. (2013) which contains 25 POS tags. For training, we combine the 1000-tweet OCT27TRAIN set and the 327-tweet OCT27DEV set. For validation, we use the 500-tweet OCT27TEST set and for testing we use the 547-tweet DAILY547 test set. We use the 100-dimensional skip-gram embeddings from Tu et al. (2017) which were trained on a dataset of 56 million English tweets using `word2vec` (Mikolov et al., 2013). The evaluation metric is tagging accuracy.

NER. We use the CoNLL 2003 English data (Tjong Kim Sang and De Meulder, 2003). There are four entity types: PER, LOC, ORG, and MISC. There is a strong local dependency between neighboring labels because this is a labeled segmentation task. We use the BIOES tagging scheme, so there are 17 labels. We use 100-dimensional pretrained GloVe (Pennington et al., 2014) embeddings. The task is evaluated with micro-averaged F1 score using the `conlleval` script.

CCG. We use the standard splits from CCGbank (Hockenmaier and Steedman, 2002). We only keep sentences with length less than 50 in the original training data when training the CRF. The training data contains 1,284 unique labels, but because the label distribution has a long tail, we use only the 400 most frequent labels, replacing the others by a special tag $*$. The percentages of $*$ in train/development/test are 0.25/0.23/0.23%. When the gold standard tag is $*$, the prediction is always evaluated as incorrect. We use the same GloVe embeddings as in NER. Because of the compositional nature of supertags, this task has more non-local dependencies. The task is evaluated with per-token accuracy.

5.2 Training and Tuning

For the optimization problems mentioned below, we use stochastic gradient descent with momentum as the optimizer. Full details of hyperparameter tuning are in the appendix.

Local Baselines. We consider local (non-structured) baselines that use the same architectures as the inference networks but train using only the local loss ℓ_{token}.

Structured Baselines. We train the BLSTM-CRF and BLSTM-CRF+ models with the standard conditional log-likelihood objective. We tune hyperparameters on the development sets.

Gradient Descent for Inference. We use gradient descent for structured inference by solving Eq. 1. We randomly initialize $\boldsymbol{y} \in \mathcal{Y}_{R'}(\boldsymbol{x})$ and, for N iterations, we compute the gradient of the energy with respect to $\boldsymbol{y}$, then update $\boldsymbol{y}$ using gradient descent with momentum, which we found to generally work better than constant step size. We tune N and the learning rate via instance-specific oracle tuning, i.e., we choose them separately for each input to maximize performance (accuracy or F1 score) on that input. Even with this oracle tuning, we find that gradient descent struggles to compete with the other methods.

Inference Networks. To train the inference networks, we first train the BLSTM-CRF or BLSTM-CRF+ model with the standard conditional log-likelihood objective. The hidden sizes H are tuned in that step. We then fix the energy function and train the inference network $\mathbf{A}_{\Psi}$ using the combined loss from Section 4.

For instance-tailored inference networks and when using inference networks as a warm start for gradient descent, we tune the number of epochs N and the learning rate on the development set, and report the performance on the test set, using the same values of N and the learning rate for all test examples.

6 BLSTM-CRF Results

This first section of results uses the simpler BLSTM-CRF modeling configuration. In Section 7 below we present results with the stronger BLSTM-CRF+ configuration and also apply the same modeling improvements to the baselines and inference networks.

	Twitter POS Tagging			NER			CCG Supertagging		
	CNN	BLSTM	seq2seq	CNN	BLSTM	seq2seq	CNN	BLSTM	seq2seq
local baseline	89.6	88.0	88.9	79.9	85.0	85.3	90.6	92.2	92.7
infnet	**89.9**	89.5	89.7	82.2	85.4	86.1	91.3	92.8	**92.9**
gradient descent	89.1			84.4			89.0		
Viterbi	89.2			**87.2**			92.4		

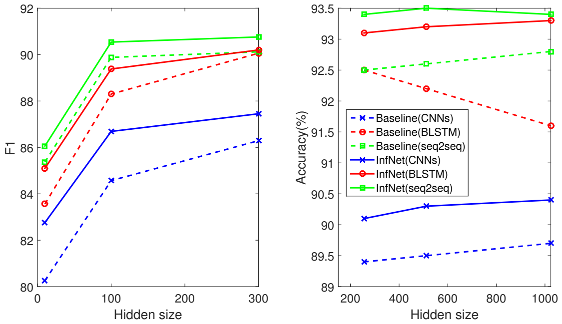
Table 1: Test results for all tasks. Inference networks, gradient descent, and Viterbi are all optimizing the BLSTM-CRF energy. Best result per task is in bold.

Table 1 shows test results for all tasks and architectures. The inference networks use the same architectures as the corresponding local baselines, but their parameters are trained with both the local loss and the BLSTM-CRF energy, leading to consistent improvements. CNN inference networks work well for POS, but struggle on NER and CCG compared to other architectures. BLSTMs work well, but are outperformed slightly by seq2seq models across all three tasks. Using the Viterbi algorithm for exact inference yields the best performance for NER but is not best for the other two tasks.

It may be surprising that an inference network trained to mimic Viterbi would outperform Viterbi in terms of accuracy, which we find for the CNN for POS tagging and the seq2seq inference network for CCG. We suspect this occurs for two reasons. One is due to the addition of the local loss in the inference network objective; the inference networks may be benefiting from this multi-task training. Edunov et al. (2018) similarly found benefit from a combination of token-level and sequence-level losses. The other potential reason is beneficial inductive bias with the inference network architecture. For POS tagging, the CNN architecture is clearly well-suited to this task given the strong performance of the local CNN baseline. Nonetheless, the CNN inference network is able to improve upon both the CNN baseline and Viterbi.

Hidden Sizes. For the test results in Table 1, we did limited tuning of H for the inference networks based on the development sets. Figure 1 shows the impact of H on performance. Across H values, the inference networks outperform the baselines. For NER and CCG, seq2seq outperforms the BLSTM which in turn outperforms the CNN.

Tasks and Window Sizes. Table 2 shows that CNNs with smaller windows are better for POS, while larger windows are better for NER and CCG. This suggests that POS has more local dependencies among labels than NER and CCG.



(a) NER (b) CCG Supertagging

Figure 1: Development results for inference networks with different architectures and hidden sizes (H).

		{1,3}-gram	{1,5}-gram
POS	local baseline	89.2	88.7
	infnet	**89.6**	89.0
NER	local baseline	84.6	85.4
	infnet	86.7	**86.8**
CCG	local baseline	89.5	90.4
	infnet	90.3	**91.4**

Table 2: Development results for CNNs with two filter sets ($H = 100$).

6.1 Speed Comparison

Asymptotically, Viterbi takes $\mathcal{O}(nL^2)$ time, where n is the sequence length. The BLSTM and our deterministic-attention seq2seq models have time complexity $\mathcal{O}(nL)$. CNNs also have complexity $\mathcal{O}(nL)$ but are more easily parallelizable. Table 3 shows test-time inference speeds for inference networks, gradient descent, and Viterbi for the BLSTM-CRF model. We use GPUs and a minibatch size of 10 for all methods. CNNs are 1-2 orders of magnitude faster than the others. BLSTMs work almost as well as seq2seq models and are 2-4 times faster in our experiments. Viterbi is actually faster than seq2seq when L is small, but for CCG, which has $L = 400$, it is 4-5 times slower. Gradient descent is slower than the others because it generally needs many iterations (20-50) for competitive performance.

	CNN	BLSTM	seq2seq	Viterbi	GD
POS	12500	1250	357	500	20
NER	10000	1000	294	360	23
CCG	6666	1923	1000	232	16

Table 3: Speed comparison of inference networks across tasks and architectures (examples/sec).

6.2 Search Error

We can view inference networks as approximate search algorithms and assess characteristics that affect search error. To do so, we train two LSTM language models (one on word sequences and one on gold label sequences) on the Twitter POS data. We also compute the difference in the BLSTM-CRF energies between the inference network output $\boldsymbol{y}_{inf}$ and the Viterbi output $\boldsymbol{y}_{vit}$ as the search error: $E_{\Theta}(\boldsymbol{x}, \boldsymbol{y}_{inf}) - E_{\Theta}(\boldsymbol{x}, \boldsymbol{y}_{vit})$. We compute the same search error for gradient descent.

For the BLSTM inference network, Spearman's ρ between the word sequence perplexity and search error is 0.282; for the label sequence perplexity, it is 0.195. For gradient descent inference, Spearman's ρ between the word sequence perplexity and search error is 0.122; for the label sequence perplexity, it is 0.064. These positive correlations mean that for frequent sequences, inference networks and gradient descent exhibit less search error. We also note that the correlations are higher for the inference network than for gradient descent, showing the impact of amortization during learning of the inference network parameters. That is, since we are learning to do inference from a dataset, we would expect search error to be smaller for more frequent sequences, and we do indeed see this correlation.

7 BLSTM-CRF+ Results

We now compare inference methods when using the improved modeling techniques described in Section 2.1 (i.e., the setting we called BLSTM-CRF+). We use these improved techniques for all models, including the CRF, the local baselines, gradient descent, and the inference networks. When training inference networks, both the inference network architectures and the structured energies use the techniques from Section 2.1. So, when referring to inference networks in this section, we use the name infnet+.

The results are shown in Table 4. With a more powerful local architecture, structured prediction is less helpful overall, but inference networks still improve over the local baselines on 2 of 3 tasks.

	POS	NER	CCG
local baseline	91.3	90.5	94.1
infnet+	91.3	90.8	94.2
gradient descent	90.8	89.8	90.4
Viterbi	90.9	91.6	94.3

Table 4: Test results with BLSTM-CRF+. For local baseline and inference network architectures, we use CNN for POS, seq2seq for NER, and BLSTM for CCG.

	F1
local baseline (BLSTM)	90.3
infnet+ (1-layer BLSTM)	90.7
infnet+ (2-layer BLSTM)	91.1
Viterbi	91.6

Table 5: NER test results (for BLSTM-CRF+) with more layers in the BLSTM inference network.

POS. As in the BLSTM-CRF setting, the local CNN baseline and the CNN inference network outperform Viterbi. This is likely because the CRFs use BLSTMs as feature networks, but our results show that CNN baselines are consistently better than BLSTM baselines on this task. As in the BLSTM-CRF setting, gradient descent works quite well on this task, comparable to Viterbi, though it is still much slower.

NER. We see slightly higher BLSTM-CRF+ results than several previous state-of-the-art results (cf. 90.94; Lample et al., 2016 and 91.37; Ma and Hovy, 2016). The stronger BLSTM-CRF+ configuration also helps the inference networks, improving performance from 90.5 to 90.8 for the seq2seq architecture over the local baseline. Though gradient descent reached high accuracies for POS tagging, it does not perform well on NER, possibly due to the greater amount of non-local information in the task.

While we see strong performance with infnet+, it still lags behind Viterbi in F1. We consider additional experiments in which we increase the number of layers in the inference networks. We use a 2-layer BLSTM as the inference network and also use weight annealing of the local loss hyperparameter λ, setting it to $\lambda = e^{-0.01t}$ where t is the epoch number. Without this annealing, the 2-layer inference network was difficult to train. The weight annealing was helpful for encouraging the inference network to focus more on the non-local information in the energy function rather than the token-level loss. As shown in Table 5, these changes yield an improvement of 0.4 in F1.

		Twitter POS Tagging		NER		CCG Supertagging	
	N	Acc. (↑)	Energy (↓)	F1 (↑)	Energy (↓)	Acc. (↑)	Energy (↓)

	5	91.2	-163.12	91.4	-231.45	94.4	-482.64
	10	91.2	-163.15	91.5	-231.46	94.4	-482.78

Table 6: Test set results of approximate inference methods for three tasks, showing performance metrics (accuracy and F1) as well as average energy of the output of each method. The inference network architectures in the above experiments are: CNN for POS, seq2seq for NER, and BLSTM for CCG. N is the number of epochs for GD inference or instance-tailored fine-tuning.

CCG. Our BLSTM-CRF+ reaches an accuracy of 94.3%, which is comparable to several recent results (93.53, Xu et al., 2016; 94.3, Lewis et al., 2016; and 94.50, Vaswani et al., 2016). The local baseline, the BLSTM inference network, and Viterbi are all extremely close in accuracy. Gradient descent struggles here, likely due to the large number of candidate output labels.

7.1 Speed, Accuracy, and Search Error

Table 6 compares inference methods in terms of both accuracy and energies reached during inference. For each number N of gradient descent iterations in the table, we tune the learning rate per-sentence and report the average accuracy/F1 with that fixed number of iterations. We also report the average energy reached. For inference networks, we report energies both for the output directly and when we discretize the output (i.e., choose the most probable label at each position).

Gradient Descent Across Tasks. The number of gradient descent iterations required for competitive performance varies by task. For POS, 20 iterations are sufficient to reach accuracy and energy close to Viterbi. For NER, roughly 40 iterations are needed for gradient descent to reach its highest F1 score, and for its energy to become very close to that of the Viterbi outputs. However, its F1 score is much lower than Viterbi. For CCG, gradient descent requires far more iterations, presumably due to the larger number of labels in the task. Even with 1000 iterations, the accuracy is 4% lower than Viterbi and the inference networks. Unlike POS and NER, the inference network reaches much lower energies than gradient descent on CCG, suggesting that the inference network may not suffer from the same challenges of searching high-dimensional label spaces as those faced by gradient descent.

Inference Networks Across Tasks. For POS, the inference network does not have lower energy than gradient descent with ≥ 20 iterations, but it does have higher accuracy. This may be due in part to our use of multi-task learning for inference networks. The discretization of the inference network outputs increases the energy on average for this task, whereas it decreases the energy for the other two tasks. For NER, the inference network reaches a similar energy as gradient descent, especially when discretizing the output, but is considerably better in F1. The CCG tasks shows the largest difference between gradient descent and the inference network, as the latter is much better in both accuracy and energy.

Instance Tailoring and Warm Starting. Across tasks, instance tailoring and warm starting lead to lower energies than infnet+. The improvements in energy are sometimes joined by improvements in accuracy, notably for NER where the gains range from 0.4 to 0.7 in F1.

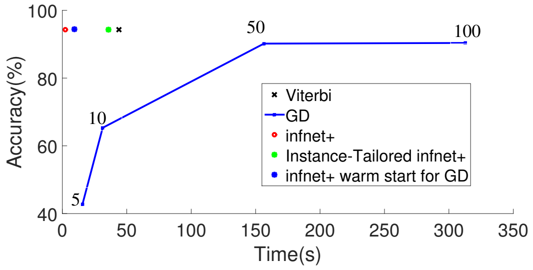

Figure 2: CCG test results for inference methods (GD = gradient descent). The x-axis is the total inference time for the test set. The numbers on the GD curve are the number of gradient descent iterations.

Warm starting gradient descent yields the lowest energies (other than Viterbi), showing promise for the use of gradient descent as a local search method starting from inference network output.

Wall Clock Time Comparison. Figure 2 shows the speed/accuracy trade-off for the inference methods, using wall clock time for test set inference as the speed metric. On this task, Viterbi is time-consuming because of the larger label set size. The inference network has comparable accuracy to Viterbi but is much faster. Gradient descent needs much more time to get close to the others but plateaus before actually reaching similar accuracy. Instance-tailoring and warm starting reside between infnet+ and Viterbi, with warm starting being significantly faster because it does not require updating inference network parameters.

8 Related Work

The most closely related prior work is that of Tu and Gimpel (2018), who experimented with RNN inference networks for sequence labeling. We compared three architectural families, showed the relationship between optimal architectures and downstream tasks, compared inference networks to gradient descent, and proposed novel variations.

We focused in this paper on sequence labeling, in which CRFs with neural network potentials have emerged as a state-of-the-art approach (Lample et al., 2016; Ma and Hovy, 2016; Strubell et al., 2017; Yang et al., 2018). Our results suggest that inference networks can provide a feasible way to speed up test-time inference over Viterbi without much loss in performance. The benefits of inference networks may be coming in part from multi-task training; Edunov et al. (2018) similarly found benefit from combining token-level and sequence-level losses.

We focused on structured prediction in this paper, but inference networks are useful in other settings as well. For example, it is common to use a particular type of inference network to approximate posterior inference in neural approaches to latent-variable probabilistic modeling, such as variational autoencoders (Kingma and Welling, 2013) and, more closely related to this paper, variational sequential labelers (Chen et al., 2018). In such settings, Kim et al. (2018) have found benefit with instance-specific updating of inference network parameters, which is related to our instance-level fine-tuning. There are also connections between structured inference networks and amortized structured inference (Srikumar et al., 2012) as well as methods for neural knowledge distillation and model compression (Hinton et al., 2015; Ba and Caruana, 2014; Kim and Rush, 2016).

Gradient descent is used for inference in several settings, e.g., structured prediction energy networks (Belanger and McCallum, 2016), image generation applications (Mordvintsev et al., 2015; Gatys et al., 2015), finding adversarial examples (Goodfellow et al., 2015), learning paragraph embeddings (Le and Mikolov, 2014), and machine translation (Hoang et al., 2017). Gradient descent has started to be replaced by inference networks in some of these settings, such as image transformation (Johnson et al., 2016; Li and Wand, 2016). Our results provide more evidence that gradient descent can be replaced by inference networks or improved through combination with them.

9 Conclusion

We compared several methods for approximate inference in neural structured prediction, finding that inference networks achieve a better speed/accuracy/search error trade-off than gradient descent. We also proposed instance-level inference network fine-tuning and using inference networks to initialize gradient descent, finding further reductions in search error and improvements in performance metrics for certain tasks.

Acknowledgments

We would like to thank Ke Li for suggesting experiments that combine inference networks and gradient descent, the anonymous reviewers for their feedback, and NVIDIA for donating GPUs used in this research.

A Appendix

Local Baselines. We consider local (non-structured) baselines that use the same architectures as the inference networks but train using only the local loss ℓ_{token}. We tune the learning rate ($\{5, 1, 0.5, 0.1, 0.05, 0.01, 0.005, 0.001, 0.0005\}$). We train on the training set, use the development sets for tuning and early stopping, and report results on the test sets.

Structured Baselines. We train the BLSTM-CRF and BLSTM-CRF+ models with the standard conditional log-likelihood objective. We tune hyperparameters on the development sets. The tuned BLSTM hidden size H for BLSTM-CRF is 100 for POS/NER and 512 for CCG; for BLSTM-CRF+ the tuned hidden size is 100 for POS, 200 for NER, and 400 for CCG.

Gradient Descent for Inference. For the number of epochs N, we consider values in the set $\{5, 10, 20, 30, 40, 50, 100, 500, 1000\}$. For each N, we tune the learning rate over the set $\{1\text{e}^4, 5\text{e}^3, 1\text{e}^3, 500, 100, 50, 10, 5, 1\}$). These learning rates may appear extremely large when we are accustomed to choosing rates for empirical risk minimization, but we generally found that the most effective learning rates for structured inference are orders of magnitude larger than those effective for learning. To provide as strong performance as possible for the gradient descent method, we tune N and the learning rate via oracle tuning, i.e., we choose them separately for each input to maximize performance (accuracy or F1 score) on that input.

Inference Networks. To train the inference networks, we first train the BLSTM-CRF or BLSTM-CRF+ model with the standard conditional log-likelihood objective. The hidden sizes H are tuned in that step. We then fix the energy function and train the inference network $\mathbf{A}_\Psi$ using the combined loss from Section 4. We tune the learning rate over the set $\{5, 1, 0.5, 0.1, 0.05, 0.01, 0.005, 0.001, 0.0005\}$ for the inference network and the local loss weight λ over the set $\{0.2, 0.5, 1, 2, 5\}$. We use early stopping on the development sets and report the results on the test sets using the trained inference networks.

Evaluating and Enhancing the Robustness of Dialogue Systems: A Case Study on a Negotiation Agent

Abstract

Recent research has demonstrated that goal-oriented dialogue agents trained on large datasets can achieve striking performance when interacting with human users. In real world applications, however, it is important to ensure that the agent performs smoothly interacting with not only regular users but also those malicious ones who would attack the system through interactions in order to achieve goals for their own advantage. In this paper, we develop algorithms to evaluate the robustness of a dialogue agent by carefully designed attacks using adversarial agents. Those attacks are performed in both black-box and white-box settings. Furthermore, we demonstrate that adversarial training using our attacks can significantly improve the robustness of a goal-oriented dialogue system. On a case-study of the negotiation agent developed by (Lewis et al., 2017), our attacks reduced the average advantage of rewards between the attacker and the trained RL-based agent from 2.68 to -5.76 on a scale from -10 to 10 for randomized goals. Moreover, with the proposed adversarial training, we are able to improve the robustness of negotiation agents by 1.5 points on average against all our attacks.

1 Introduction

Crafting an intelligent agent to communicate in the dialogue system using natural languages has been a long-standing problem in AI. It requires designing an agent to understand, plan and generate natural language to achieve different goals such as question-answering, cooperation, negotiation etc (Vinyals and Le, 2015; Li et al., 2017; Serban et al., 2016; Dhingra et al., 2016; Serban et al., 2016). Inspired by recent successes in deep neural networks, (Lewis et al., 2017) has recently developed an end-to-end learning framework to train a recurrent neural network (RNN)-based negotiation agent in goal-oriented dialogue systems. This NN-based technique has been identified as one of the state-of-the-arts and has been applied to several other tasks (Bahdanau et al., 2014; Luong et al., 2015; Rush et al., 2015; Chan et al., 2016).

Although NN-based dialogue agents have shown convincing performance on several tasks, it is not clear whether they also work well when facing malicious users or agents. To answer this question, we study how to evaluate the robustness of a goal-oriented dialogue system. For simplicity, we consider a goal-oriented agent A that aims to maximize some score, and define the "robustness" of A as the worst-case performance under any feasible agent A'. We also call A' an **adversarial agent** that tries to "attack" A since it aims to minimize A's score. The problem of evaluating the robustness of A can then be solved by designing an adversarial agent to attack A. For instance, considering a negotiation agent that can decide when to make a deal, we say the agent is not robust if an adversarial agent can fool the target agent to make a deal with significant lower scores. Ideally, before deploying an agent into real systems, we need to ensure it performs smoothly under strong adversarial attacks.

The concept of adversarial agent is related to recent studies on adversarial examples for image classifiers—it has been shown that a carefully designed small perturbation can easily make neural networks mis-classify (Goodfellow et al., 2014; Szegedy et al., 2013; Moosavi Dezfooli et al., 2016; Carlini and Wagner, 2017; Cheng et al., 2019), and several recent works has extended these attacks to natural language processing models such as sentiment analysis (Gao et al., 2018; Yang et al., 2018) and machine translation (Ebrahimi et al., 2018; Cheng et al., 2018). However, all of the previous work consider attacking a static model, where except input im-

age/sentence there is no interaction between the attacker and the target model. Instead, we investigate a much more challenging problem, where there can be many turns of interactions between adversarial and target agents. This leads to several difficulties including 1) How to lead the target agent to a bad state and 2) how to force the target agent to make a wrong decision. Therefore, previous methods for attacking static models cannot be directly applied.

In this paper, we tackle the aforementioned challenges by proposing several novel ways to design an adversarial agent to evaluate the robustness of goal-oriented dialogue systems. We highlight our major contributions as follows:

- We propose a framework to generate adversarial agents in both black-box and white-box settings. To the best of our knowledge, this is the first work on crafting adversarial agents instead of adversarial examples in an interactive dialogue system.

- We conduct a series of studies on the negotiation agent proposed in (Lewis et al., 2017). We demonstrate that the proposed strategies can successfully attack existing negotiation agents to significantly reduce their average score. For instance, our attacks can reduce the average advantage of the RL-based negotiation agent from 2.68 to -5.76 on random problems with the total value of 10.

- We also show that through the proposed iterative adversarial training procedure, we could significantly improve the robustness of a goal-oriented agent against various attacks.

2 Related work

2.1 Goal-oriented dialogue agent

Goal-oriented dialogue systems aim at building a conversation model that is capable of accomplishing tasks through the interactions with human using natural language (Li et al., 2017; Eric and Manning, 2017; Wen et al., 2016; Wei et al., 2018; Bordes et al., 2016). Traditional approaches to learn a goal-oriented intelligent agent relies heavily on dialogue states annotated in the training data (Wen et al., 2016; Henderson et al., 2014). The use of state annotations allows a cleaner separation of the reasoning and natural language aspects of dialogues. However, it is very expensive to annotate every state in a large amount of training data. (Bordes et al., 2016) explores end-to-end goal orientated dialogue with a supervised model. And (He et al., 2017) uses task-specific rules to combine the task input and dialogue history into a more structured state representation. Recently, reinforcement learning has been widely used in dialogue systems to increase the agent versatility (Mordatch and Abbeel, 2017) and improve the agent's performance in goal-oriented tasks such as cooperative bot-bot dialogues (Das et al., 2017) and negotiation tasks (Lewis et al., 2017).

2.2 Adversarial examples in NLP applications

Algorithms have been proposed to craft adversarial sentences in NLP applications. (Papernot et al., 2016) uses Fast Gradient Sign method to generate adversarial example on RNN/LSTM based model. (Li et al., 2016) learns the importance of words by deleting them in sentiment analysis task and then use reinforcement learning to locate such words. (Samanta and Mehta, 2017) and (Liang et al., 2017) generate adversarial sequences by inserting or replacing existing words with typos and synonyms. (Gao et al., 2018) aims to attack sentiment classification models in a black-box setting. It develops some scoring functions to find the most important words to modify. (Jia and Liang, 2017) aims to fool the SQuAD reading comprehension system by adding crafted sentences. (Yang et al., 2018) proposes a greedy algorithm to swap the word/character and uses a Gumbel softmax function to reduce the computation. (Ebrahimi et al., 2018) aims to generate adversarial examples on character CNN model in machine translation problem by using Jacobian matrix to determine which word/character should be replaced or deleted. (Zhao et al., 2017) generated natural adversarial example using Generative Adversarial Networks (GANs). (Cheng et al., 2018) proposed a framework to conduct non-overlapping and targeted keyword attack on seq2seq model.

All the above-mentioned work focus on the static setting, i.e., the input does not depend on the model's output. However, in our work, one agent's input depends on the other agent's output, which makes the input undecidable in the beginning. Therefore, an adversarial sentence or example is not enough to conduct attack in dialogue systems. Instead, for the first time, we propose novel ways to construct a adversarial agent, which can bait the target agent to step to a wrong state and make a bad decision.

2.3 Defense against adversarial examples

Many defense algorithms have been proposed recently to enhance the robustness of classification models. Among them, adversarial training (Madry et al., 2018; Goodfellow et al., 2014) has become one of the most successful methods, which uses both clean and adversarial examples to train a robust model. (Wong and Kolter, 2018) proposed another kind of adversarial training to improve the verification lower bound of neural networks; (Liu and Hsieh, 2019) combines the idea of generative adversarial network (GAN) and adversarial training to further boost the robustness on test images. Another promising way to enhance robustness is by adding randomness to the model. (Liu et al., 2018) shows adding randomness to both input and intermediate layers of neural networks can improve robustness; (Liu et al., 2019; Ye and Zhu, 2018) show that combining Bayesian neural network (with randomized weights) and adversarial training can achieve state-of-the-art adversarial error under attacks. However, all the existing defense methods only work for static models (usually for classification tasks). In this paper, we propose an adversarial training algorithm for an agent using RL with an "adversarial agent". This is to our knowledge the first algorithm for improving the robustness of an agent.

3 Competitive Negotiation Dialogues

We use the negotiation agent developed in (Lewis et al., 2017) as the running example in this paper. Note that our algorithm can be generalized to other goal-oriented dialogue systems by designing a different scoring function according to the task.

In a competitive negotiation dialogue setting, two agents are negotiating with each other over a set of items. We adopt the same setting as (Lewis et al., 2017), in which case items can be categorized into either a ball, a hat or a book. Each agent is given the goal of the conversation (denoted by g), which contains the initial values and the quantities of each of the three items. Agents then negotiate to maximize the total value of their possessed items. Agents are allowed to negotiate up to a maximum of 10 turns. Scores will be granted to agents based on the total value of the items if they reach an agreement. If they choose not to agree, 0 score will be granted to both agents. A competitive negotiation dialogue example played by human and agent could be found in Table 1.

Input		
Human	3x**book** value 2 3x**hat** value 1 1x**ball** value 1	
Agent	3x**book** value 1 3x**hat** value 2 1x**ball** value 1	
Human	I'd like the books and the hats.	
Agent	I will take the books and hats.	
Human	I need the books and at least one other object.	
Agent	Ok, you can have one book and one ball	
Human	If I can have all books, I can leave you the rest.	
Agent	Deal	
Human	$\langle selection \rangle$	
Output		**Reward**
Human	3x**hat** 1x**ball**	7/10
Agent	3x**book**	6/10

Table 1: Competitive negotiation dialogue generated between agent and human.

We assess the robustness of a trained end-to-end negotiation agent used in (Lewis et al., 2017). In the negotiation chatbot setting, agents first chat using natural language and then make a selection based on what they have chatted with. We refer to the first phase as **negotiation phase** and the second phase as **decision phase**.

In the negotiation phase, conversation response at time t, x_t is generated word by word based on chat history $x_{0..t-1}$ and the goal of the conversation g. The conversation model is controlled by a speaking module θ and tokens are randomly sampled from probability distribution p_θ. This process continues recursively until an end-of-sentence token $\langle EOS \rangle$ or selection token $\langle selection \rangle$ token is generated. When $\langle EOS \rangle$ is encountered, the turn terminates and the conversation is handled to another agent. When $\langle selection \rangle$ is encountered, the negotiation phase terminates and the negotiation will reach the decision phase.

$$x_t \sim p_\theta(x_t | x_{0...t-1}, g) \tag{1}$$

In the decision phase, both agents will output a decision o based on a decision module probability distribution p'_θ. Agents' decisions will be based on conversation history $x_{0...T}$ up to the current time step T and the goal of the conversation g. Here O is a set of all legitimate selections, which is defined to be a space of where each selection must be greater or equal than 0 and the sum of selections for the same item must be equal to its original quantity. Since we only have a few items, it is possible to enumerate all the possibilities to get the set O.

$$o^* = \arg\max_{o \in O} \prod_i p'_\theta(o_i | x_{0...T}, g) \qquad (2)$$

Agents will then collect rewards (i.e. scores) from the environment (which will be 0 if they output conflicted decisions, e.g. the total number of items are different from the initial amount). It is important to keep the agent producing sentences that are correct both grammatically and semantically and keeping them competitive at the same time. Therefore, a common strategy is to train agents using supervised learning to learn natural language and to use reinforcement learning to optimize models' performance using on goal-oriented learning. We measure two statistics **score** and **agreement**. **score** is the average score for each agent (0-10). **agreement** is the percentage of dialogues where both agents agreed on the same decision. To measure the extent of success of our adversarial agent, we use **advantage** which is easy to compute directly from adversarial agent score minus target agent score, i.e. $S_{adv} - S_{ori}$.

4 Proposed Black-box Attack Algorithms

We first build our adversarial agent in black-box setting. Black-box setting in goal-oriented dialogue system is defined where the target agent is unknown to the attacker, but it is possible to make queries to obtain the final decision made by the target agent. To be noted, our aim is to test the robustness of the target agent. Therefore, in the decision phase we let adversarial agent chooses the complementary of target agent's choice, so those two agents will always reach agreement. The adversarial agent thus only has the speaking module and there is no decision network needed. In this section we proposed two adversarial agents in the black-box setting.

4.1 Reinforcement learning attack

Inspired by the procedure of goal-based reinforcement learning, we modified the reward function of our adversarial agent with the advantage instead of the score he got:

$$r^{adv} = S_{adv} - S_{ori} \qquad (3)$$

where S_{adv} and S_{ori} are adversarial agent score and target agent score respectively. After a complete dialogue has been generated, we update adversarial agent's parameters based on the outcome of the negotiation.

To learn the adversarial agent's speaking network by reinforcement learning, we denote the subset of tokens generated by the adversarial agent as X^{adv}. In the completed dialogue, γ is the discount factor that rewards actions at the end of the dialogue more strongly, and μ is a running average of completed dialogue rewards so far. We define the future reward R for an action $x_t \in X^{adv}$ as follows:

$$R(x_t) = \sum_{x_t \in X^{adv}} \gamma^{T-t}(r^{adv} - \mu). \qquad (4)$$

Then by a standard policy gradient algorithm, we could train our adversarial agent. Note that this attack doesn't require the knowledge on the target agent's structure/weights, and the experimental results demonstrate significant attack performance over regular agents.

4.2 Transfer attack

Transfer attack is a popular idea for attacking black-box models (Papernot et al., 2017). In dialogue systems, we can also consider the following transfer process: a sentence that leads to low r^{adv} in one dialogue might also lead to similar results in another dialogue. To implement this idea, we first collect a list of last sentences spoken by the adversarial agent from dialogues with high reward, denoted by L. In the conversations, we let our adversarial agent and the target agent negotiate n turns using the regular speaking module, and then plug in one sentence in L at the $(n + 1)$-th turn. Our experimental results show that this transfer attack does not work well in practice.

5 Proposed White-box Attack Algorithms

In the white-box setting, we assume that the attacker can access every part of the target agent, including the weights of both speaking and decision models, and the decision output in every dialogue. Similar to the black-box attacks, we let the adversarial agent choose the complementary of target agent's choices to ensure 100% agreement. By exploiting the knowledge of the target agent's model, white-box attacks can achieve much higher advantage than black-box attacks.

5.1 Force target agent to select at a fixed turn

To begin with, we consider a simplified strategy where we first let our adversarial agent and the target agent negotiate n turns using regular speaking module. For the $(n+1)$-th turn, we propose the following two ways to modify the output of regular speaking module to maximize the rewards of adversarial agent.

5.1.1 Reactive attack

The first strategy is that the adversarial agent produces a sentence that forces the target agent to say $\langle selection \rangle$. The conversation will then enter the decision phase. At the same time, the sentence produced by the adversarial agent should guide the target agent to make a bad selection that would be in favor of the adversarial agent. We call this method **reactive attack**.

We formulate this strategy as an optimization problem. Let $\hat{\mathbf{x}} = x_{t_n \ldots T-1}$ be the output sentence generated by adversarial agent in the speaking model after n -th turn. Specifically, we define $x_{0 \ldots T-1}$ as all the tokens in the dialogue history before $\langle selection \rangle$. $Z_r(x_{0 \ldots T-1})$ indicates the logit layer outputs for predicting x_T based on chat history $x_{0 \ldots T-1}$ in the speaking model. $Z_o(x_{0 \ldots T})$ indicates the logit layer outputs on conversation history $x_{0 \ldots T}$ in the decision model. Because we have a constraint to force the target agent to say the end-of-dialog token $\langle selection \rangle$, we could format this constraint as

$$[Z_r(x_{0 \ldots T-1})]_{k_{sel}} - \max_{i \neq k_{sel}} [Z_r(x_{0 \ldots T-1})]_i \geq 0 \quad (5)$$

where k_{sel} is the corresponding index of end-of-dialog token $\langle selection \rangle$.

At the same time, the score of output o should be in favor of our adversarial agent. Assume the original decision output is o',

$$L(\hat{\mathbf{x}}) = \max\{[Z_o(x_{0 \ldots T})]_{o'} - \max_{o \in \bar{O}} [Z_o(x_{0 \ldots T})]_o, -\kappa\} \quad (6)$$

where $\bar{O}$ is the set of outputs that score of adversarial agent is greater than target agent i.e. $\bar{O} = \{o \in \bar{O} | S_{adv}(o) > S_{ori}(o)\}$, and $\kappa \geq 0$ denotes the confidence margin parameter. Note that $\hat{\mathbf{x}}$ is a sub-sequence in $x_{0 \ldots T}$, so the right hand side of (6) is a function of $\hat{\mathbf{x}}$.

Combining these two equations together, we can get our final objective function:

$$\min_{\hat{\mathbf{x}}} \quad L(\hat{\mathbf{x}}) \quad (7)$$
$$\text{s.t. } [Z_r(x_{0 \ldots T-1})]_{k_{sel}} - \max_{i \neq k_{sel}} [Z_r(x_{0 \ldots T-1})]_i \geq 0$$

Eq (7) is a discrete optimization problem since $\hat{x}$ is the sentence produced by adversarial agent.

In this paper, we use a modified version of the greedy algorithm to optimize (7). Although the original algorithm proposed in (Yang et al., 2018) only considered the unconstrained discrete problem, we show that the following slightly modified version performs well for solving (7). At each iteration, we try to replace each word in $\hat{x}$ by the special token $\langle PAD \rangle$. A word that achieves minimal loss after swapping with $\langle PAD \rangle$ is then selected as the word to be replaced. Then we try to replace the selected word with each word in the vocabulary. For all the trials that satisfy the constraint, we choose the one with minimal loss and conduct the actual change. We run this procedure iteratively to minimize (7). In the experiments, we only replace two words in $\hat{x}$ to ensure the fluency and correctness of the adversarial sentences.

5.1.2 Preemptive attack

The other attack strategy is to produce a sentence to guide the target agent to lower its demand in the reply instead of making target agent say end-of-dialog token. And after the reply from target agent, the adversarial agent speaks the end-of-dialogue token to enter the decision phase. Similar to the reactive attack, adversarial agent's score should be greater than target agent's score in the decision phase. Clearly, this strategy is more challenging than the previous one because there is an intermediate sentence spoken by the target agent before end-of-dialogue. We call this preemptive attack.

Let $\hat{\mathbf{x}} = x_{t_n \ldots t_{n_T}}$ be the output sentence generated by adversarial agent in the speaking model after turn n, where t_n is the first word and t_{n_T} is the last word of the sentence. Similarly, we could formally turn the intuition into optimization problem as follows:

$$L(\hat{\mathbf{x}}) = \max\{[Z_o(x_{0 \ldots T})]_{o'} - \max_{o \in \bar{O}} [Z_o(x_{0 \ldots T})]_o, -\kappa\} \quad (8)$$

Since we do not need to force target agent to say end-of-dialogue, the problem becomes an unconstrained discrete optimization problem. We then

Algorithm 1 Arbitrary turn attack algorithm

```
**Input:** Target agent B, Input goal $g$
**Output:** Dialogue $x_{0...T}$, Agent score $S_{adv}$ and $S_{ori}$
while $\langle selection \rangle$ is not generated do
  Set the loss $L(\cdot)$ to be (7)
  Optimize the Loss $L(\cdot)$
  if $L(\cdot) < 0$ then
    Add the output into the dialogue
  else
    Set the loss $L(\cdot)$ in to be (8)
    Optimize the Loss $L(\cdot)$
    if $L(\cdot) < 0$ then
      Add the output into the dialogue
    else
      if Transfer Attack then
        Randomly add a sentence in $L$ (malicious sentences) into the dialogue.
      else
        Add the sentence generated by regular speaking model into the dialogue (delayed attack).
      end if
    end if
  end if
end while
Generate $o$ using dialogue $x_{0...T}$
Calculate $S_{adv}$ and $S_{ori}$
**Return:** $x_{0...T}$,$S_{adv}$,$S_{ori}$
```

directly apply the unconstrained version of greedy algorithm (Yang et al., 2018) to solve it.

5.2 Force target agent to select at arbitrary turn

While we could let our adversarial agent and the target agent negotiate n turns, it is still unknown which n should be chosen to get the best performance. In other words, we aim to not only know what to say but also when to say to fool the target agent.

We propose two strategies to force target agent to make bad decisions at arbitrary turn. The details are presented in Algorithm 1. When it is the turn for adversarial agent to speak, we first try to apply reactive and preemptive attacks. If both attacks couldn't make the loss $L(\cdot)$ less than 0, there are two strategies: 1) just output the sentence generated by the regular speaking module (delayed attack), and 2) conduct transfer attack. The comparisons can be found in the experiments.

6 Adversarial Training

Adversarial training is a popular method to improve the robustness of machine learning models (Miyato et al., 2016; Madry et al., 2018). In this section, we use the agents designed in the previous sections to improve the robustness of the target agent.

In standard adversarial training for neural network models (Goodfellow et al., 2014; Jia and Liang, 2017), adversarial examples (images or sentences) generated by an attack are added to the training procedure to refine the model. Since our setting is interactive and there is no fixed data used in selfplay, we should conduct training with *adversarial agents* instead of adversarial examples. Moreover, as pointed out by (Jia and Liang, 2017), training on the examples generated by a single attack will lead to over-fitting to a particular attack, so we should do adversarial training iteratively.

Taking the black-box RL agent as an example, we consider the following min-max formulation:

$$\min_{\theta^{ori}}\{\max_{\theta^{adv}} S_{adv} - S_{ori}\}, \tag{9}$$

where θ^{ori} is the weights for the target agent and θ^{adv} is the weights for the adversarial black-box agent. We solve (9) by the following alternating minimization procedure. At each iteration, we first update the target agent (θ^{ori}) using the standard policy gradient algorithm, and then use our RL algorithm in Section 4.1 to update adversarial agent to counter the target model. We iteratively conduct these updates until convergence. The experiments show that the adversarial training procedure can improve the robustness not only under RL attack but also under other white-box attacks.

7 Experimental Results

We perform extensive experiments on evaluating the robustness of the negotiation agents developed in (Lewis et al., 2017). Furthermore, we show that the robustness of negotiation agents can be significantly improved using the proposed adversarial training procedure. Our codes are publicly available at `https://github.com/cmhcbb/Robustness-of-Dialogue-systems`.

7.1 Experimental Setup

We use the code released by the authors (Lewis et al., 2017) and follow their instructions to get the target end-to-end negotiation agents. More specifically, we first train the model on 5808 dialogues, based on 2236 unique scenarios in supervised way to imitate the actions of human users. We call this model supervised model (SV agent). Then we use reinforcement learning to conduct goal-oriented training in order to maximize the agent' reward. The second model is called the reinforcement learning model (RL agent). As a result, when doing selfplay between RL agent and SV agent, we could get RL agent with 5.86 perplexity, 89.57% agreement and 7.23 average score, while SV agent achieves 5.47 perplexity and 4.55 average score. These numbers are similar to the numbers reported in (Lewis et al., 2017).

To evaluate the robustness of these agents, we conduct all the proposed attacks on both supervised model (SV agent) and reinforcement learning model (RL agent). The successfulness of an attack is measured by average score advantage and positive advantage rate (PAR). Average score advantage is defined by averaged adversarial agent's score minus average target agent's score. The value is in the region of $[-10, 10]$ since the total values are controlled to be 10 for both sides, and a larger advantage indicates a more successful attack. Also, we define positive advantage rate (PAR) as the ratio of dialogues that the adversarial agent gets a higher score than the target agent. We will see that most attacks developed in this paper will improve both average score advantage and PAR. Note that this is the first work on attacking a goal-oriented dialogue agent so there is no previous method that could be included in the comparisons.

7.2 Results on Black-box Attacks

As introduced in Section 4, we have two black-box attacks: reinforcement learning attack (RL attack) and Transfer attack.

RL Attack. In the reinforcement learning attack, we use a learning rate of 0.1, clip gradients above 1.0, and set the discount factor $\gamma = 0.95$ in (4). We train the adversarial agent for 4 epochs on all scenarios. From Table 2, we observe that with 100% agreement rate, our adversarial agent could gain 2.32 score advantage against the RL agent and 4.25 advantage against the SV agent. Also, our agent achieves a relatively high positive advantage rate at 84.45% and 69.35% respectively. We show some adversarial dialogues played by adversarial agent and target agent in Table 3. It shows that RL agent is able to identify the weak point of target agent by saying ”take book you get rest”, which could easily let the agent accept the deal and make a bad selection that is inconsistent with the context of dialogue.

Transfer attack. In transfer attack, we first let our adversarial agent speak the sentence generated by the speaking model with target agent for 3 turns. If the end-of-dialog token has never been mentioned, in the 4th turn, the adversarial agent speaks the sentence generated by our RL agent. The detailed results are shown in Table 2. We observe that the transfer attack is not successful—only -0.13 and -1.189 score advantage are achieved. We found that transferring sentences between dialogues is not successful because the item values and conversation histories are quite different between dialogues.

7.3 Results on White-box Attacks

We conduct the white-box attacks introduced in Section 5.

Force target agent to select at a fixed turn. There are two types of algorithms (reactive attack and preemptive attack) introduced in Section 5.1. The detailed results are shown in Table 2. We observe that the reactive attack could achieve better results than black-box method with 5.40 score advantage against SV agent and 4.98 score advantage against RL agent. On the other hand, preemptive attack is not that successful—it gets 2.81 advantage against SV agent and 0.77 score advantage against RL agent. Furthermore, we have included some adversarial dialogues played by white-box adversarial agent and target agent in Table 4. From these examples, we could see that white-box adversarial agent could generate the adversarial sentences, slightly unnatural however still readable, that could fool the target agent to make terrible decisions.

Force target agent to select at arbitrary turn. To determine when should we begin the attack, we design combinations of reactive attack, preemptive attack and transfer attack or delayed attack in Section 5.2. Here, we conduct experiments to validate the effectiveness of these two attack combinations. From Table 2, the combinations achieve better results than all the previous attacks. The best result is achieved by the combination of reactive attack, preemptive attack and delayed attack

	vs SV agent			vs RL agent		
Model	**PAR%**	**Score(advantage)**	**Agreement%**	**PAR%**	**Score(advantage)**	**Agreement%**
RL model(w/o attack)	75.79	7.23 vs 4.55 (2.68)	89.57	44.70	5.05 vs 5.00 (0.05)	76.36
Transfer attack	44.43	6.41 vs 6.54 (-0.13)	100	36.10	5.65 vs 6.84 (-1.19)	100
RL attack	84.45	8.28 vs 4.03 (4.25)	100	69.35	7.11 vs 4.79 (2.32)	100
Reactive attack	87.00	8.83 vs 3.43 (5.40)	100	90.23	8.72 vs 3.77 (4.95)	100
Preemptive attack	71.86	7.76 vs 4.95 (2.81)	100	69.23	6.78 vs 6.01 (0.77)	100
RA+PA+DA	84.33	8.79 vs 2.96 (5.83)	100	86.93	8.73 vs 2.95 (5.78)	100
RA+PA+TA	83.12	8.67 vs 3.05 (5.62)	100	89.74	8.62 vs 2.92 (5.70)	100

Table 2: Negotiation task evaluation with different adversarial agent on 2000 randomly generated scenarios, against the supervised model and reinforcement learning model. The maximum socre is 10. When agents failed to agree, all agents get 0 score. PAR stands for positive advantage rate. RA+PA+DA stands for the combination of reactive attack, preemptive attacka and delayed attack. RA+PA+TA stands for the combination of reactive attack, preemptive attacka and transfer attack.

(RA+PA+DA), which gets 5.83 advantage against SV agent and 5.78 score advantage against RL agent, with very high positive advantage rates at 84.33% and 86.93% respectively. We have included some adversarial dialogues played by this adversarial agent and the target agent in Table 5. We observe that with the delayed attack, the adversarial agent can decide **when to attack**, thus achieves much better performance than attacking at a fixed turn.

7.4 Adversarial Training

Using the algorithm proposed in Section 6, we conduct adversarial training using the black-box RL attack model. The results are shown in Table 6. First, we observe that the adversarial trained model achieves much better performance against black-box RL attack; the advantage of RL attack drops from 2.32 to -1.8. Moreover, the model achieves consistently better performance against other white-box attacks. For instance, the advantage of the strongest RA+PA+DA attack is reduced from 5.78 to 3.98.

	vs advtrain model		
Model	**PAR%**	**Score(advantage)**	**Agreement%**
RL model(w/o attack)	48.67	6.51 vs 6.64 (-0.13)	91.75
Transfer attack	23.05	4.93 vs 7.59 (-2.66)	100
RL attack	62.61	5.71 vs 7.51 (-1.80)	100
Reactive attack	80.76	8.83 vs 4.31 (4.52)	100
Preemptive attack	34.39	5.64 vs 7.41 (-1.77)	100
RA+PA+DA	73.96	8.05 vs 4.07 (3.98)	100
RA+PA+TA	73.45	8.06 vs 4.13 (3.93)	100

Table 6: Negotiation task evaluation with different adversarial agent on 2000 randomly generated scenarios, against adversarial trained model.

7.5 Analysis and Discussions

RL agents are more robust than SV agents. From Table 2, we could see that all the attack methods perform better when facing SV agents than RL agents. It is because that SV agents only learn to mimic human's action and are trained only on human data. Therefore, it is reasonable that RL agents are more robust than SV agents.

The importance of arbitrary turns. In reactive attack and preemptive attack, we begin our attack at the n-th turn and we set $n = 2$ in the experiments. Here we show the results with different n in Table 7. We observe that the performance of white-box attacks are quite consistent with different choices of n. This probably indicates that there the best n varies for different cases. Therefore, if we could change the n from case to case adaptively, which is done by delayed attack, we could see a performance boost.

n	**PAR%**	**Score(advantage)**	**Agreement%**
1	94.02	8.84 vs 3.32 (5.52)	100
2	90.23	8.72 vs 3.77 (4.95)	100
3	92.02	8.81 vs 3.62 (5.19)	100
4	90.35	8.71 vs 3.87 (4.84)	100

Table 7: Negotiation task evaluation with different choices of n against RL model.

Adversarial training helps to improve the robustness. We then try to investigate the robustness of the adversarial trained model. We found that in the original model, it is easy for an attacker to find a sentence to quickly end the dialogue. However, after adversarial training, it becomes much harder to find such sentences. Moreover, although we only conduct adversarial training on black-box RL model, the adversarial trained model still achieves better performance against other white-box attacks. This indicates that the adversarial trained model could probably detect the slight unnaturalness of those sentences and thus have a better reading comprehension ability.

8 Conclusion

In this paper, we develop adversarial agents to evaluate the robustness of a goal-oriented dialogue system. Our experimental results show that the current NN-based models are not robust against our adversarial agents. Furthermore, by iterative adversarial training using our black-box RL agent, we can significantly improve the robustness of the dialogue system.

Abstract

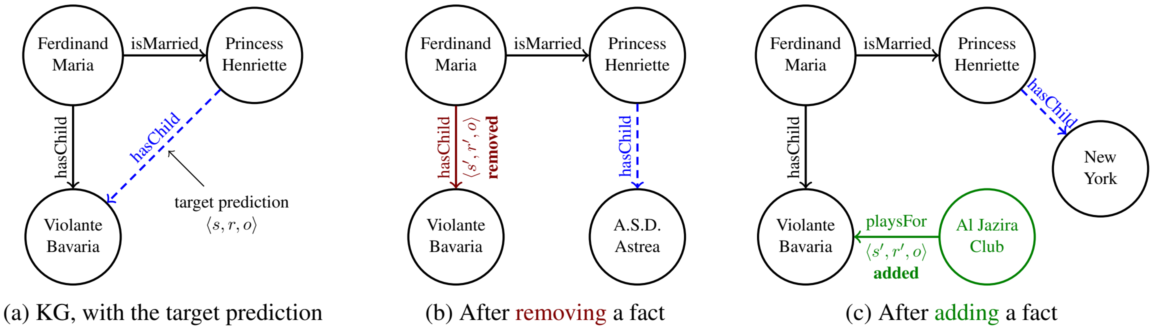
Representing entities and relations in an embedding space is a well-studied approach for machine learning on relational data. Existing approaches, however, primarily focus on improving accuracy and overlook other aspects such as robustness and interpretability. In this paper, we propose adversarial modifications for link prediction models: identifying the fact to add into or remove from the knowledge graph that changes the prediction for a target fact after the model is retrained. Using these single modifications of the graph, we identify the most influential fact for a predicted link and evaluate the sensitivity of the model to the addition of fake facts. We introduce an efficient approach to estimate the effect of such modifications by approximating the change in the embeddings when the knowledge graph changes. To avoid the combinatorial search over all possible facts, we train a network to *decode* embeddings to their corresponding graph components, allowing the use of gradient-based optimization to identify the adversarial modification. We use these techniques to evaluate the robustness of link prediction models (by measuring sensitivity to additional facts), study interpretability through the facts most responsible for predictions (by identifying the most influential neighbors), and detect incorrect facts in the knowledge base.

1 Introduction

Knowledge graphs (KG) play a critical role in many real-world applications such as search, structured data management, recommendations, and question answering. Since KGs often suffer from incompleteness and noise in their facts (links), a number of recent techniques have proposed models that *embed* each entity and relation into a vector space, and use these embeddings to predict facts. These dense representation models for link prediction include tensor factorization [Nickel et al., 2011, Socher et al., 2013, Yang et al., 2015], algebraic operations [Bordes et al., 2011, 2013b, Dasgupta et al., 2018], multiple embeddings [Wang et al., 2014, Lin et al., 2015, Ji et al., 2015, Zhang et al., 2018], and complex neural models [Dettmers et al., 2018, Nguyen et al., 2018]. However, there are only a few studies [Kadlec et al., 2017, Sharma et al., 2018] that investigate the quality of the different KG models. There is a need to go beyond just the accuracy on link prediction, and instead focus on whether these representations are robust and stable, and what facts they make use of for their predictions.

In this paper, our goal is to design approaches that minimally change the graph structure such that the prediction of a target fact changes the most after *the embeddings are relearned*, which we collectively call *Completion Robustness and Interpretability via Adversarial Graph Edits* (CRIAGE). First, we consider perturbations that remove a neighboring link for the target fact, thus identifying the *most influential* related fact, providing an explanation for the model's prediction. As an example, consider the excerpt from a KG in Figure 1a with two observed facts, and a target *predicted fact* that Princes Henriette is the parent of Violante Bavaria. Our proposed graph perturbation, shown in Figure 1b, identifies the existing fact that Ferdinal Maria is the father of Violante Bavaria as the one when removed and model retrained, will change the prediction of Princes Henriette's child. We also study attacks that add a new, fake fact into the KG to evaluate the robustness and sensitivity of link prediction models to small additions to the graph. An example attack for the original graph in Figure 1a, is depicted in Figure 1c. Such perturbations to the the training data are from a family of adversarial modifications that have been applied to other machine learning tasks, known as *poisoning* [Biggio et al., 2012, Corona et al., 2013, Biggio

Proceedings of NAACL-HLT 2019, pages 3336–3347
Minneapolis, Minnesota, June 2 - June 7, 2019.



(a) KG, with the target prediction (b) After removing a fact (c) After adding a fact

Figure 1: **Completion Robustness and Interpretability via Adversarial Graph Edits (CRIAGE):** Change in the graph structure that changes the prediction of the *retrained* model, where (a) is the original sub-graph of the KG, (b) removes a neighboring link of the target, resulting in a change in the prediction, and (c) shows the effect of adding an attack triple on the target. These modifications were identified by our proposed approach.

et al., 2014, Zügner et al., 2018].

Since the setting is quite different from traditional adversarial attacks, search for link prediction adversaries brings up unique challenges. To find these minimal changes for a target link, we need to identify the fact that, when added into or removed from the graph, will have the biggest impact on the predicted score of the target fact. Unfortunately, computing this change in the score is expensive since it involves retraining the model to recompute the embeddings. We propose an efficient estimate of this score change by approximating the change in the embeddings using Taylor expansion. The other challenge in identifying adversarial modifications for link prediction, especially when considering addition of fake facts, is the combinatorial search space over possible facts, which is intractable to enumerate. We introduce an *inverter* of the original embedding model, to *decode* the embeddings to their corresponding graph components, making the search of facts tractable by performing efficient gradient-based continuous optimization.

We evaluate our proposed methods through following experiments. First, on relatively small KGs, we show that our approximations are accurate compared to the true change in the score. Second, we show that our additive attacks can effectively reduce the performance of state of the art models [Yang et al., 2015, Dettmers et al., 2018] up to 27.3% and 50.7% in Hits@1 for two large KGs: WN18 and YAGO3-10. We also explore the utility of adversarial modifications in explaining the model predictions by presenting rule-like descriptions of the most influential neighbors. Finally, we use adversaries to detect errors in the KG, obtaining up to 55% accuracy in detecting errors.

2 Background and Notation

In this section, we briefly introduce some notations, and existing relational embedding approaches that model knowledge graph completion using dense vectors. In KGs, facts are represented using triples of subject, relation, and object, $\langle s, r, o\rangle$, where $s, o \in \xi$, the set of entities, and $r \in \mathcal{R}$, the set of relations. To model the KG, a scoring function $\psi : \xi \times \mathcal{R} \times \xi \rightarrow \mathbb{R}$ is learned to evaluate whether any given fact is true. In this work, we focus on *multiplicative* models of link prediction[1], specifically DistMult [Yang et al., 2015] because of its simplicity and popularity, and ConvE [Dettmers et al., 2018] because of its high accuracy. We can represent the scoring function of such methods as $\psi(s, r, o) = \mathbf{f}(\mathbf{e}_s, \mathbf{e}_r) \cdot \mathbf{e}_o$, where $\mathbf{e}_s, \mathbf{e}_r, \mathbf{e}_o \in \mathbb{R}^d$ are embeddings of the subject, relation, and object respectively. In DistMult, $\mathbf{f}(\mathbf{e}_s, \mathbf{e}_r) = \mathbf{e}_s \odot \mathbf{e}_r$, where $\odot$ is element-wise multiplication operator. Similarly, in ConvE, $\mathbf{f}(\mathbf{e}_s, \mathbf{e}_r)$ is computed by a convolution on the concatenation of $\mathbf{e}_s$ and $\mathbf{e}_r$.

We use the same setup as Dettmers et al. [2018] for training, i.e., incorporate binary cross-entropy loss over the triple scores. In particular, for subject-relation pairs (s, r) in the training data G, we use binary $y_o^{s,r}$ to represent negative and positive facts. Using the model's probability of truth as $\sigma(\psi(s, r, o))$ for $\langle s, r, o\rangle$, the loss is defined as:

$$\mathcal{L}(G) = \sum_{(s,r)} \sum_{o} y_o^{s,r} \log(\sigma(\psi(s, r, o))) + (1 - y_o^{s,r}) \log(1 - \sigma(\psi(s, r, o))). \quad (1)$$

Gradient descent is used to learn the embeddings $\mathbf{e}_s, \mathbf{e}_r, \mathbf{e}_o$, and the parameters of $\mathbf{f}$, if any.

---

[1] As opposed to *additive* models, such as TransE [Bordes et al., 2013a], as categorized in Sharma et al. [2018].

3 Completion Robustness and Interpretability via Adversarial Graph Edits (CRIAGE)

For adversarial modifications on KGs, we first define the space of possible modifications. For a target triple $\langle s, r, o\rangle$, we constrain the possible triples that we can remove (or inject) to be in the form of $\langle s', r', o\rangle$ i.e s' and r' may be different from the target, but the object is not. We analyze other forms of modifications such as $\langle s, r', o'\rangle$ and $\langle s, r', o\rangle$ in appendices A.1 and A.2, and leave empirical evaluation of these modifications for future work.

3.1 Removing a fact (CRIAGE-Remove)

For explaining a target prediction, we are interested in identifying the observed fact that has the most influence (according to the model) on the prediction. We define *influence* of an observed fact on the prediction as the change in the prediction score if the observed fact was not present when the embeddings were learned. Previous work have used this concept of influence similarly for several different tasks [Kononenko et al., 2010, Koh and Liang, 2017]. Formally, for the target triple $\langle s, r, o\rangle$ and observed graph G, we want to identify a neighboring triple $\langle s', r', o\rangle \in G$ such that the score $\psi(s, r, o)$ when trained on G and the score $\overline{\psi}(s, r, o)$ when trained on $G-\{\langle s', r', o\rangle\}$ are maximally different, i.e.

$$\underset{(s',r')\in\text{Nei}(o)}{\operatorname{argmax}} \quad \Delta_{(s',r')}(s, r, o) \tag{2}$$

where $\Delta_{(s',r')}(s, r, o) = \psi(s, r, o)-\overline{\psi}(s, r, o)$, and $\text{Nei}(o) = \{(s', r')|\langle s', r', o\rangle \in G\}$.

3.2 Adding a new fact (CRIAGE-Add)

We are also interested in investigating the robustness of models, i.e., how sensitive are the predictions to small additions to the knowledge graph. Specifically, for a target prediction $\langle s, r, o\rangle$, we are interested in identifying a single fake fact $\langle s', r', o\rangle$ that, when added to the knowledge graph G, changes the prediction score $\psi(s, r, o)$ the most. Using $\overline{\psi}(s, r, o)$ as the score after training on $G \cup \{\langle s', r', o\rangle\}$, we define the adversary as:

$$\underset{(s',r')}{\operatorname{argmax}} \, \Delta_{(s',r')}(s, r, o) \tag{3}$$

where $\Delta_{(s',r')}(s, r, o) = \psi(s, r, o) - \overline{\psi}(s, r, o)$. The search here is over any possible $s' \in \xi$, which is often in the millions for most real-world KGs, and $r' \in \mathcal{R}$. We also identify adversaries that *increase* the prediction score for specific false triple, i.e., for a target fake fact $\langle s, r, o\rangle$, the adversary is $\operatorname{argmax}_{(s',r')} -\Delta_{(s',r')}(s, r, o)$, where $\Delta_{(s',r')}(s, r, o)$ is defined as before.

3.3 Challenges

There are a number of crucial challenges when conducting such adversarial attack on KGs. First, evaluating the effect of changing the KG on the score of the target fact ($\overline{\psi}(s, r, o)$) is expensive since we need to update the embeddings by retraining the model on the new graph; a very time-consuming process that is at least linear in the size of G. Second, since there are many candidate facts that can be added to the knowledge graph, identifying the most promising adversary through search-based methods is also expensive. Specifically, the search size for unobserved facts is $|\xi| \times |\mathcal{R}|$, which, for example in YAGO3-10 KG, can be as many as $4.5M$ possible facts for a single target prediction.

4 Efficiently Identifying the Modification

In this section, we propose algorithms to address mentioned challenges by (1) approximating the effect of changing the graph on a target prediction, and (2) using continuous optimization for the discrete search over potential modifications.

4.1 First-order Approximation of Influence

We first study the addition of a fact to the graph, and then extend it to cover removal as well. To capture the effect of an adversarial modification on the score of a target triple, we need to study the effect of the change on the vector representations of the target triple. We use $\mathbf{e}_s$, $\mathbf{e}_r$, and $\mathbf{e}_o$ to denote the embeddings of s, r, o at the solution of $\operatorname{argmin} \mathcal{L}(G)$, and when considering the adversarial triple $\langle s', r', o\rangle$, we use $\overline{\mathbf{e}_s}$, $\overline{\mathbf{e}_r}$, and $\overline{\mathbf{e}_o}$ for the new embeddings of s, r, o, respectively. Thus $\overline{\mathbf{e}_s}, \overline{\mathbf{e}_r}, \overline{\mathbf{e}_o}$ is a solution to $\operatorname{argmin} \mathcal{L}(G \cup \{\langle s', r', o\rangle\})$, which can also be written as $\operatorname{argmin} \mathcal{L}(G) + \mathcal{L}(\langle s', r', o\rangle)$. Similarly, $\mathbf{f}(\mathbf{e}_s, \mathbf{e}_r)$ changes to $\mathbf{f}(\overline{\mathbf{e}_s}, \overline{\mathbf{e}_r})$ after retraining.

Since we only consider adversaries in the form of $\langle s', r', o\rangle$, we only consider the effect of the attack on $\mathbf{e}_o$ and neglect its effect on $\mathbf{e}_s$ and $\mathbf{e}_r$. This assumption is reasonable since the adversary is connected with o and directly affects its embedding when added, but it will only have a secondary, negligible effect on $\mathbf{e}_s$ and $\mathbf{e}_r$, in comparison to its effect on $\mathbf{e}_o$. Further, calculating the effect of the attack on $\mathbf{e}_s$ and $\mathbf{e}_r$ requires a third order derivative of the loss, which is not practical ($O(n^3)$ in the number of parameters). In other words, we assume that $\overline{\mathbf{e}_s} \simeq \mathbf{e}_s$ and $\overline{\mathbf{e}_r} \simeq \mathbf{e}_r$. As a result, to calculate the effect of the attack, $\overline{\psi}(s,r,o) - \psi(s,r,o)$, we need to compute $\overline{\mathbf{e}_o} - \mathbf{e}_o$, followed by:

$$\overline{\psi}(s,r,o) - \psi(s,r,o) = \mathbf{z}_{s,r}(\overline{\mathbf{e}_o} - \mathbf{e}_o) \tag{4}$$

where $\mathbf{z}_{s,r} = \mathbf{f}(\mathbf{e}_s, \mathbf{e}_r)$. We now derive an efficient computation for $\overline{\mathbf{e}_o} - \mathbf{e}_o$. First, the derivative of the loss $\mathcal{L}(\overline{G}) = \mathcal{L}(G) + \mathcal{L}(\langle s', r', o\rangle)$ over $\mathbf{e}_o$ is:

$$\nabla_{e_o}\mathcal{L}(\overline{G}) = \nabla_{e_o}\mathcal{L}(G) - (1-\varphi)\mathbf{z}_{s',r'} \tag{5}$$

where $\mathbf{z}_{s',r'} = \mathbf{f}(\mathbf{e}'_s, \mathbf{e}'_r)$, and $\varphi = \sigma(\psi(s', r', o))$. At convergence, after retraining, we expect $\nabla_{e_o}\mathcal{L}(\overline{G}) = 0$. We perform first order Taylor approximation of $\nabla_{e_o}\mathcal{L}(\overline{G})$ to get:

$$\begin{aligned} 0 \simeq & -(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'} + \\ & (H_o + \varphi(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'}\mathbf{z}_{s',r'})(\overline{\mathbf{e}_o} - \mathbf{e}_o) \end{aligned} \tag{6}$$

where H_o is the $d \times d$ Hessian matrix for o, i.e., second order derivative of the loss w.r.t. $\mathbf{e}_o$, computed sparsely. Solving for $\overline{\mathbf{e}_o} - \mathbf{e}_o$ gives us, $\overline{\mathbf{e}_o} - \mathbf{e}_o =$:

$$(1-\varphi)(H_o + \varphi(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'}\mathbf{z}_{s',r'})^{-1}\mathbf{z}^{\mathsf{T}}_{s',r'}.$$

In practice, H_o is positive definite, making $H_o + \varphi(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'}\mathbf{z}_{s',r'}$ positive definite as well, and invertible. Then, we compute the score change as:

$$\begin{aligned} &\overline{\psi}(s,r,o) - \psi(s,r,o) = \mathbf{z}_{s,r}(\overline{\mathbf{e}_o} - \mathbf{e}_o) \qquad (7) \\ &= \mathbf{z}_{s,r}((1-\varphi)(H_o + \varphi(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'}\mathbf{z}_{s',r'})^{-1}\mathbf{z}^{\mathsf{T}}_{s',r'}). \end{aligned}$$

Calculating this expression is efficient since H_o is a $d \times d$ matrix (d is the embedding dimension), and $\mathbf{z}_{s,r}, \mathbf{z}_{s',r'} \in \mathbb{R}^d$. Similarly, we estimate the score change of $\langle s, r, o\rangle$ after *removing* $\langle s', r', o\rangle$ as:

$$-\mathbf{z}_{s,r}((1-\varphi)(H_o + \varphi(1-\varphi)\mathbf{z}^{\mathsf{T}}_{s',r'}\mathbf{z}_{s',r'})^{-1}\mathbf{z}^{\mathsf{T}}_{s',r'}).$$

4.2 Continuous Optimization for Search

Using the approximations provided in the previous section, Eq. (7) and (4.1), we can use brute force enumeration to find the adversary $\langle s', r', o\rangle$. This approach is feasible when removing an observed triple since the search space of such modifications is usually small; it is the number of observed facts that share the object with the target. On the other hand, finding the most influential unobserved fact to add requires search over a much larger space of all possible unobserved facts (that share the object). Instead, we identify the most influential unobserved fact $\langle s', r', o\rangle$ by using a gradient-based algorithm on vector $\mathbf{z}_{s',r'}$ in the embedding space (reminder, $\mathbf{z}_{s',r'} = \mathbf{f}(\mathbf{e}'_s, \mathbf{e}'_r)$), solving the following continuous optimization problem in $\mathbb{R}^d$:

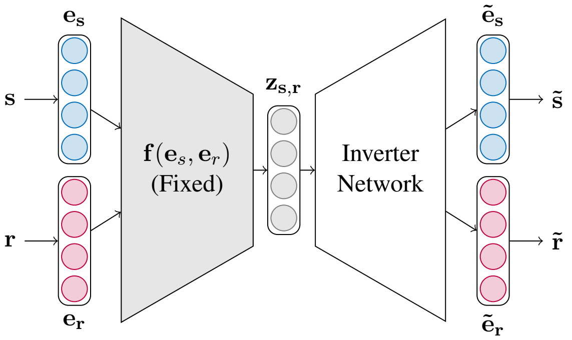


Figure 2: **Inverter Network** The architecture of our inverter function that translate $\mathbf{z}_{s,r}$ to its respective $(\tilde{s}, \tilde{r})$. The encoder component is fixed to be the encoder network of DistMult and ConvE respectively.

$$\underset{\mathbf{z}_{s',r'}}{\operatorname{argmax}}\, \Delta_{(s',r')}(s,r,o). \tag{8}$$

After identifying the optimal $\mathbf{z}_{s',r'}$, we still need to generate the pair (s', r'). We design a network, shown in Figure 2, that maps the vector $\mathbf{z}_{s',r'}$ to the entity-relation space, i.e., translating it into (s', r'). In particular, we train an auto-encoder where the encoder is fixed to receive the s and r as one-hot inputs, and calculates $\mathbf{z}_{s,r}$ in the same way as the DistMult and ConvE encoders respectively (using trained embeddings). The decoder is trained to take $\mathbf{z}_{s,r}$ as input and produce s and r, essentially inverting $\mathbf{f}$ and the embedding layers. As our decoder, for DistMult, we pass $\mathbf{z}_{s,r}$ through a linear layer and then use two other linear layers for the subject and the relation separately, providing one-hot vectors as $\tilde{s}$ and $\tilde{r}$. For ConvE, we pass $\mathbf{z}_{s,r}$ through a deconvolutional layer, and then use the same architecture as the DistMult decoder. Although we could use maximum inner-product search [Shrivastava and Li, 2014] for DistMult instead of our defined inverter function, we are looking for a general approach that works across multiple models.

We evaluate the performance of our inverter networks (one for each model/dataset) on correctly recovering the pairs of subject and relation from the test set of our benchmarks, given the $\mathbf{z}_{s,r}$. The accuracy of recovered pairs (and of each argument)

	WordNet		YAGO	
	DistMult	ConvE	DistMult	ConvE
Recover s	93.4	96.1	97.2	98.1
Recover r	91.3	95.3	99.0	99.6
Recover $\{s, r\}$	89.5	94.2	96.4	98.0

Table 1: **Inverter Functions Accuracy**, we calculate the accuracy of our inverter networks in correctly recovering the pairs of subject and relation from the test set of our benchmarks.

	# Rels	#Entities	# Train	#Test
Nations	56	14	1592	200
Kinship	26	104	4,006	155
WN18	18	40,943	141,442	5000
YAGO3-10	37	123,170	1,079,040	5000

Table 2: **Data Statistics** of the benchmarks.

is given in Table 1. As shown, our networks achieve a very high accuracy, demonstrating their ability to invert vectors $\mathbf{z}_{s,r}$ to $\{s, r\}$ pairs.

5 Experiment Setup

Datasets To evaluate our method, we conduct several experiments on four widely used KGs. To validate the accuracy of the approximations, we use smaller sized Kinship and Nations KGs for which we can make comparisons against more expensive but less approximate approaches. For the remaining experiments, we use YAGO3-10 and WN18 KGs, which are closer to real-world KGs in their size and characteristics (see Table 2).

Models We implement all methods using the same loss and optimization for training, i.e., AdaGrad and the binary cross-entropy loss. We use validation data to tune the hyperparameters and use a grid search to find the best hyperparameters, such as regularization parameter, and learning rate of the gradient-based method. To capture the effect of our method on link prediction task, we study the change in commonly-used metrics for evaluation in this task: mean reciprocal rank (MRR) and Hits@K. Further, we use the same hyperparameters as in Dettmers et al. [2018] for training link prediction models for these knowledge graphs.

Influence Function We also compare our method with influence function (IF) [Koh and Liang, 2017]. The influence function approximates the effect of upweighting a training sample on the loss for a specific test point. We use IF to approximate the change in the loss after removing a triple as:

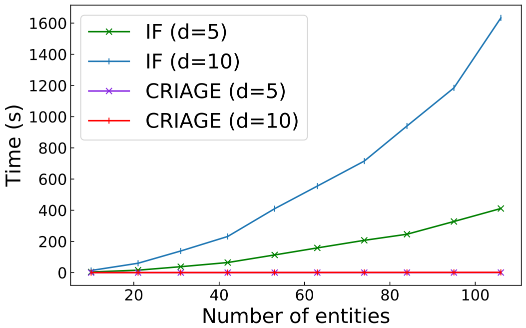

Figure 3: **Influence function vs CRIAGE**. We plot the average time (over 10 facts) of influence function (IF) and CRIAGE to identify an adversary as the number of entities in the Kinship KG is varied (by randomly sampling subgraphs of the KG). Even with small graphs and dimensionality, IF quickly becomes impractical.

$$\mathcal{I}_{\text{up,loss}}(\langle s', r', o\rangle, \langle s, r, o\rangle) = \\ -\nabla_\theta \mathcal{L}(\langle s, r, o\rangle, \hat{\theta})^\intercal H_{\hat{\theta}}^{-1} \nabla_\theta \mathcal{L}(\langle s', r', o\rangle, \hat{\theta}) \quad (9)$$

where $\langle s', r', o\rangle$ and $\langle s, r, o\rangle$ are training and test samples respectively, $\hat{\theta}$ represents the optimum parameters and $\mathcal{L}(\langle s, r, o\rangle, \hat{\theta})$ represents the loss function for the test sample $\langle s, r, o\rangle$. Influence function does not scale well, so we only compare our method with IF on the smaller size KGs.

6 Experiments

We evaluate CRIAGE by (6.1) comparing CRIAGE estimate with the actual effect of the attacks, (6.2) studying the effect of adversarial attacks on evaluation metrics, (6.3) exploring its application to the interpretability of KG representations, and (6.4) detecting incorrect triples.

6.1 Influence Function vs CRIAGE

To evaluate the quality of our approximations and compare with influence function (IF), we conduct leave one out experiments. In this setup, we take all the neighbors of a random target triple as candidate modifications, remove them one at a time, retrain the model each time, and compute the *exact* change in the score of the target triple. We can use the magnitude of this change in score to rank the candidate triples, and compare this *exact* ranking with ranking as predicted by: CRIAGE-Remove, influence function with and without Hessian matrix, and the original model score (with the intuition that facts that the model is most confident of will have

Methods	Nations				Kinship			
	Adding		Removing		Adding		Removing	
	ρ	τ	ρ	τ	ρ	τ	ρ	τ
Ranking Based on Score	0.03	0.02	-0.01	-0.01	-0.09	-0.06	0.01	0.01
Influence Function without Hessian	0.15	0.12	0.12	0.1	0.77	0.71	0.77	0.71
CRIAGE (Brute Force)	0.95	0.84	0.94	0.85	0.99	0.97	0.99	0.95
Influence Function	0.99	0.95	0.99	0.96	0.99	0.98	0.99	0.98

Table 3: **Ranking modifications by their impact on the target**. We compare the *true* ranking of candidate triples with a number of approximations using ranking correlation coefficients. We compare our method with influence function (IF) with and without Hessian, and ranking the candidates based on their score, on two KGs ($d = 10$, averaged over 10 random targets). For the sake of brevity, we represent the Spearman's ρ and Kendall's τ rank correlation coefficients simply as ρ and τ.

the largest impact when removed). Similarly, we evaluate CRIAGE-Add by considering 200 random triples that share the object entity with the target sample as candidates, and rank them as above.

The average results of Spearman's ρ and Kendall's τ rank correlation coefficients over 10 random target samples is provided in Table 3. CRIAGE performs comparably to the influence function, confirming that our approximation is accurate. Influence function is slightly more accurate because they use the complete Hessian matrix over all the parameters, while we only approximate the change by calculating the Hessian over $\mathbf{e}_o$. The effect of this difference on scalability is dramatic, constraining IF to very small graphs and small embedding dimensionality ($d \leq 10$) before we run out of memory. In Figure 3, we show the time to compute a single adversary by IF compared to CRIAGE, as we steadily grow the number of entities (randomly chosen subgraphs), averaged over 10 random triples. As it shows, CRIAGE is mostly unaffected by the number of entities while IF increases quadratically. Considering that real-world KGs have tens of thousands of times more entities, making IF unfeasible for them.

6.2 Robustness of Link Prediction Models

Now we evaluate the effectiveness of CRIAGE to successfully *attack* link prediction by adding false facts. The goal here is to identify the attacks for triples in the test data, and measuring their effect on MRR and Hits@ metrics (ranking evaluations) after conducting the attack and retraining the model.

Since this is the first work on adversarial attacks for link prediction, we introduce several baselines to compare against our method. For finding the adversarial fact to add for the target triple $\langle s, r, o\rangle$, we consider two baselines: 1) choosing a random fake fact $\langle s', r', o\rangle$ (**Random Attack**); 2) finding (s', r') by first calculating $\mathbf{f}(\mathbf{e}_s, \mathbf{e}_r)$ and then feeding $-\mathbf{f}(\mathbf{e}_s, \mathbf{e}_r)$ to the decoder of the inverter function (**Opposite Attack**). In addition to CRIAGE-Add, we introduce two other alternatives of our method: (1) **CRIAGE-FT**, that uses CRIAGE to *increase* the score of fake fact over a test triple, i.e., we find the fake fact the model ranks second after the test triple, and identify the adversary for them, and (2) **CRIAGE-Best** that selects between CRIAGE-Add and CRIAGE-FT attacks based on which has a higher estimated change in score.

All-Test The result of the attack on all test facts as targets is provided in the Table 4. CRIAGE-Add outperforms the baselines, demonstrating its ability to effectively attack the KG representations. It seems DistMult is more robust against random attacks, while ConvE is more robust against designed attacks. CRIAGE-FT is more effective than CRIAGE-Add since changing the score of a fake fact is easier than of actual facts; there is no existing evidence to support fake facts. We also see that YAGO3-10 models are more robust than those for WN18. Looking at sample attacks (provided in Appendix A.4), CRIAGE mostly tries to change the *type* of the target object by associating it with a subject and a relation for a different entity type.

Uncertain-Test To better understand the effect of attacks, we consider a subset of test triples that 1) the model predicts correctly, 2) difference between their scores and the negative sample with the highest score is minimum. This "Uncertain-Test" subset contains 100 triples from each of the original

	Models	**YAGO3-10**				**WN18**			
		All-Test		**Uncertain-Test**		**All-Test**		**Uncertain-Test**

Table 4: **Robustness of Representation Models**, the effect of adversarial attack on link prediction task. We consider two scenario for the target triples, 1) choosing the whole test dataset as the targets (All-Test) and 2) choosing a subset of test data that models are uncertain about them (Uncertain-Test).

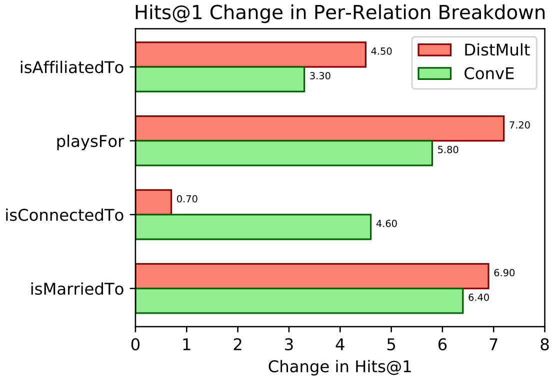

Figure 4: Per-Relation Breakdown showing the effect of CRIAGE-Add on different relations in YAGO3-10.

test sets, and we provide results of attacks on this data in Table 4. The attacks are much more effective in this scenario, causing a considerable drop in the metrics. Further, in addition to CRIAGE significantly outperforming other baselines, they indicate that ConvE's confidence is much more robust.

Relation Breakdown We perform additional analysis on the YAGO3-10 dataset to gain a deeper understanding of the performance of our model. As shown in Figure 4, both DistMult and ConvE provide a more robust representation for isAffiliatedTo and isConnectedTo relations, demonstrating the confidence of models in identifying them. Moreover, the CRIAGE affects DistMult more in playsFor and isMarriedTo relations while affecting ConvE more in isConnectedTo relations.

Table 5: **Extracted Rules** for identifying the most influential link. We extract the patterns that appear more than 90% times in the neighborhood of the target triple. The output of CRIAGE-Remove is presented in red.

6.3 Interpretability of Models

To be able to understand and interpret why a link is predicted using the opaque, dense embeddings, we need to find out which part of the graph was most influential on the prediction. To provide such explanations for each predictions, we identify the most influential fact using CRIAGE-Remove. Instead of focusing on individual predictions, we aggregate the explanations over the whole dataset for each relation using a simple rule extraction technique: we

Methods	$\langle s', r', o\rangle$ **Noise**		$\langle s', r, o\rangle$ **Noise**	
	Hits@1	Hits@2	Hits@1	Hits@2
Random	19.7	39.4	19.7	39.4
Lowest	16	37	26	47
CRIAGE	42	62	55	76

Table 6: **Error Detection Accuracy** in the neighborhood of 100 chosen samples. We choose the neighbor with the least value of $\Delta_{(s',r')}(s, r, o)$ as the incorrect fact. This experiment assumes we know each target fact has exactly one error.

find simple patterns on subgraphs that surround the target triple and the removed fact from CRIAGE-Remove, and appear more than 90% of the time. We only focus on extracting length-2 horn rules, i.e., $R_1(a, c) \wedge R_2(c, b) \Rightarrow R(a, b)$, where $R(a, b)$ is the target and $R_2(c, b)$ is the removed fact.

Table 5 shows extracted YAGO3-10 rules that are common to both models, and ones that are not. The rules show several interesting inferences, such that hasChild is often inferred via married parents, and isLocatedIn via transitivity. There are several differences in how the models reason as well; DistMult often uses the hasCapital as an intermediate step for isLocatedIn, while ConvE *incorrectly* uses isNeighbor. We also compare against rules extracted by Yang et al. [2015] for YAGO3-10 that utilizes the structure of DistMult: they require domain knowledge on types and cannot be applied to ConvE. Interestingly, the extracted rules contain all the rules provided by CRIAGE, demonstrating that CRIAGE can be used to accurately interpret models, including ones that are not interpretable, such as ConvE. These are preliminary steps toward interpretability of link prediction models, and we leave more analysis of interpretability to future work.

6.4 Finding Errors in Knowledge Graphs

Here, we demonstrate another potential use of adversarial modifications: finding erroneous triples in the knowledge graph. Intuitively, if there is an error in the graph, the triple is likely to be inconsistent with its neighborhood, and thus the model should put least trust on this triple. In other words, the error triple should have the least influence on the model's prediction of the training data. Formally, to find the incorrect triple $\langle s', r', o\rangle$ in the neighborhood of the train triple $\langle s, r, o\rangle$, we need to find the triple $\langle s', r', o\rangle$ that results in the *least* change $\Delta_{(s',r')}(s, r, o)$ when removed from the graph.

To evaluate this application, we inject random triples into the graph, and measure the ability of CRIAGE to detect the errors using our optimization. We consider two types of incorrect triples: 1) incorrect triples in the form of $\langle s', r, o\rangle$ where s' is chosen randomly from all of the entities, and 2) incorrect triples in the form of $\langle s', r', o\rangle$ where s' and r' are chosen randomly. We choose 100 random triples from the observed graph, and for each of them, add an incorrect triple (in each of the two scenarios) to its neighborhood. Then, after retraining DistMult on this noisy training data, we identify error triples through a search over the neighbors of the 100 facts. The result of choosing the neighbor with the least influence on the target is provided in the Table 6. When compared with baselines that randomly choose one of the neighbors, or assume that the fact with the lowest score is incorrect, we see that CRIAGE outperforms both of these with a considerable gap, obtaining an accuracy of 42% and 55% in detecting errors.

7 Related Work

Learning relational knowledge representations has been a focus of active research in the past few years, but to the best of our knowledge, this is the first work on conducting adversarial modifications on the link prediction task.

Knowledge graph embedding There is a rich literature on representing knowledge graphs in vector spaces that differ in their scoring functions [Wang et al., 2017, Goyal and Ferrara, 2018, Fooshee et al., 2018]. Although CRIAGE is primarily applicable to multiplicative scoring functions [Nickel et al., 2011, Socher et al., 2013, Yang et al., 2015, Trouillon et al., 2016], these ideas apply to additive scoring functions [Bordes et al., 2013a, Wang et al., 2014, Lin et al., 2015, Nguyen et al., 2016] as well, as we show in Appendix A.3.

Furthermore, there is a growing body of literature that incorporates an extra types of evidence for more informed embeddings such as numerical values [Garcia-Duran and Niepert, 2017], images [Oñoro-Rubio et al., 2017], text [Toutanova et al., 2015, 2016, Tu et al., 2017], and their combinations [Pezeshkpour et al., 2018]. Using CRIAGE, we can gain a deeper understanding of these methods, especially those that build their embeddings wit hmultiplicative scoring functions.

Interpretability and Adversarial Modification There has been a significant recent interest in conducting an adversarial attacks on different machine learning models [Biggio et al., 2014, Papernot et al., 2016, Dong et al., 2017, Zhao et al., 2018a,b, Brunet et al., 2018] to attain the interpretability, and further, evaluate the robustness of those models. Koh and Liang [2017] uses influence function to provide an approach to understanding black-box models by studying the changes in the loss occurring as a result of changes in the training data. In addition to incorporating their established method on KGs, we derive a novel approach that differs from their procedure in two ways: (1) instead of changes in the loss, we consider the changes in the scoring function, which is more appropriate for KG representations, and (2) in addition to searching for an attack, we introduce a gradient-based method that is much faster, especially for "adding an attack triple" (the size of search space make the influence function method infeasible). Previous work has also considered adversaries for KGs, but as part of training to improve their representation of the graph [Minervini et al., 2017, Cai and Wang, 2018].

Adversarial Attack on KG Although this is the first work on adversarial attacks for link prediction, there are two approaches [Dai et al., 2018, Zügner et al., 2018] that consider the task of adversarial attack on graphs. There are a few fundamental differences from our work: (1) they build their method on top of a path-based representations while we focus on embeddings, (2) they consider node classification as the target of their attacks while we attack link prediction, and (3) they conduct the attack on small graphs due to restricted scalability, while the complexity of our method does not depend on the size of the graph, but only the neighborhood, allowing us to attack real-world graphs.

8 Conclusions

Motivated by the need to analyze the robustness and interpretability of link prediction models, we present a novel approach for conducting adversarial modifications to knowledge graphs. We introduce CRIAGE, completion robustness and interpretability via adversarial graph edits: identifying the fact to add into or remove from the KG that changes the prediction for a target fact. CRIAGE uses (1) an estimate of the score change for any target triple after adding or removing another fact, and (2) a gradient-based algorithm for identifying the most influential modification. We show that CRIAGE can effectively reduce ranking metrics on link prediction models upon applying the attack triples. Further, we incorporate the CRIAGE to study the interpretability of KG representations by summarizing the most influential facts for each relation. Finally, using CRIAGE, we introduce a novel automated error detection method for knowledge graphs. We have release the open-source implementation of our models at: `https://pouyapez.github.io/criage`.

A Appendix

We approximate the change on the score of the target triple upon applying attacks other than the $\langle s', r', o\rangle$ ones. Since each relation appears many times in the training triples, we can assume that applying a single attack will not considerably affect the relations embeddings. As a result, we just need to study the attacks in the form of $\langle s, r', o\rangle$ and $\langle s, r', o'\rangle$. Defining the scoring function as $\psi(s, r, o) = \mathbf{f}(\mathbf{e}_s, \mathbf{e}_r) \cdot \mathbf{e}_o = \mathbf{z}_{s,r} \cdot \mathbf{e}_o$, we further assume that $\psi(s, r, o) = \mathbf{e}_s \cdot \mathbf{g}(\mathbf{e}_r, \mathbf{e}_o) = \mathbf{e}_s \cdot \mathbf{x}_{r,o}$.

A.1 Modifications of the Form $\langle s, r', o'\rangle$

Using similar argument as the attacks in the form of $\langle s', r', o\rangle$, we can calculate the effect of the attack, $\overline{\psi}(s, r, o) - \psi(s, r, o)$ as:

$$\overline{\psi}(s, r, o) - \psi(s, r, o) = (\overline{\mathbf{e}_s} - \mathbf{e}_s)\mathbf{x}_{s,r} \tag{10}$$

where $\mathbf{x}_{s,r} = \mathbf{g}(\mathbf{e}_r, \mathbf{e}_o)$.

We now derive an efficient computation for $(\overline{\mathbf{e}_s} - \mathbf{e}_s)$. First, the derivative of the loss $\mathcal{L}(\overline{G}) = \mathcal{L}(G) + \mathcal{L}(\langle s, r', o'\rangle)$ over $\mathbf{e}_s$ is:

$$\nabla_{e_s}\mathcal{L}(\overline{G}) = \nabla_{e_s}\mathcal{L}(G) - (1 - \varphi)\mathbf{x}_{r',o'} \tag{11}$$

where $\mathbf{x}_{r',o'} = \mathbf{g}(\mathbf{e}'_r, \mathbf{e}'_o)$, and $\varphi = \sigma(\psi(s, r', o'))$. At convergence, after retraining, we expect $\nabla_{e_s}\mathcal{L}(\overline{G}) = 0$. We perform first order Taylor approximation of $\nabla_{e_s}\mathcal{L}(\overline{G})$ to get:

$$\begin{aligned} 0 \simeq & -(1 - \varphi)\mathbf{x}^{\mathsf{T}}_{r',o'} + \\ & (H_s + \varphi(1 - \varphi)\mathbf{x}^{\mathsf{T}}_{r',o'}\mathbf{x}_{r',o'})(\overline{\mathbf{e}_s} - \mathbf{e}_s) \end{aligned} \tag{12}$$

where H_s is the $d \times d$ Hessian matrix for s, i.e. second order derivative of the loss w.r.t. $\mathbf{e}_s$, computed sparsely. Solving for $\overline{\mathbf{e}_s} - \mathbf{e}_s$ gives us:

$$\begin{aligned} & \overline{\mathbf{e}_s} - \mathbf{e}_s = \\ & (1 - \varphi)(H_s + \varphi(1 - \varphi)\mathbf{x}^{\mathsf{T}}_{r',o'}\mathbf{x}_{r',o'})^{-1}\mathbf{x}^{\mathsf{T}}_{r',o'} \end{aligned}$$

In practice, H_s is positive definite, making $H_s + \varphi(1 - \varphi)\mathbf{x}^{\mathsf{T}}_{r',o'}\mathbf{x}_{r',o'}$ positive definite as well, and invertible. Then, we compute the score change as:

$$\begin{aligned} & \overline{\psi}(s, r, o) - \psi(s, r, o) = \mathbf{x}_{r,o}(\overline{\mathbf{e}_s} - \mathbf{e}_s) = \\ & ((1 - \varphi)(H_s + \varphi(1 - \varphi)\mathbf{x}^{\mathsf{T}}_{r',o'}\mathbf{x}_{r',o'})^{-1}\mathbf{x}^{\mathsf{T}}_{r',o'})\mathbf{x}_{r,o}. \end{aligned} \tag{13}$$

A.2 Modifications of the Form $\langle s, r', o\rangle$

In this section we approximate the effect of attack in the form of $\langle s, r', o\rangle$. In contrast to $\langle s', r', o\rangle$ attacks, for this scenario we need to consider the change in the $\mathbf{e}_s$, upon applying the attack, in approximation of the change in the score as well. Using previous results, we can approximate the $\overline{\mathbf{e}_o} - \mathbf{e}_o$ as:

$$\begin{aligned} & \overline{\mathbf{e}_o} - \mathbf{e}_o = \\ & \qquad (1 - \varphi)(H_o + \varphi(1 - \varphi)\mathbf{z}^{\mathsf{T}}_{s,r'}\mathbf{z}_{s,r'})^{-1}\mathbf{z}^{\mathsf{T}}_{s,r'} \end{aligned} \tag{14}$$

	Target Triple	CRIAGE-Add
DistMult	Brisbane Airport, isConnectedTo, Boulia Airport	Osman Ozköylü, isPoliticianOf, Boulia Airport
	Jalna District, isLocatedIn, India	United States, hasWonPrize, India
	Quincy Promes, wasBornIn, Amsterdam	Gmina Krzeszyce, hasGender, Amsterdam
	Princess Henriette, hasChild, Violante Bavaria	Al Jazira Club, playsFor, Violante Bavaria
ConvE	Brisbane Airport, isConnectedTo, Boulia Airport	Victoria Wood, wasBornIn, Boulia Airport
	National Union(Israel), isLocatedIn, Jerusalem	Sejad Halilović, isAffiliatedTo, Jerusalem
	Robert Louis, influences, David Leavitt	David Louhoungou, hasGender, David Leavitt
	Princess Henriette, hasChild, Violante Bavaria	Jonava, isAffiliatedTo, Violante Bavaria

Table 7: Top adversarial triples for target samples.

and similarly, we can approximate $\overline{\mathbf{e}_s} - \mathbf{e}_s$ as:

$$\overline{\mathbf{e}_s} - \mathbf{e}_s = (1-\varphi)(H_s + \varphi(1-\varphi)\mathbf{x}_{r',o}^\intercal \mathbf{x}_{r',o})^{-1}\mathbf{x}_{r',o}^\intercal \tag{15}$$

where H_s is the Hessian matrix over $\mathbf{e}_s$. Then using these approximations:

$$\mathbf{z}_{s,r}(\overline{\mathbf{e}_o} - \mathbf{e}_o) = \mathbf{z}_{s,r}((1-\varphi)(H_o + \varphi(1-\varphi)\mathbf{z}_{s,r'}^\intercal \mathbf{z}_{s,r'})^{-1}\mathbf{z}_{s,r'}^\intercal)$$

and:

$$(\overline{\mathbf{e}_s} - \mathbf{e}_s)\mathbf{x}_{r,\bar{o}} = ((1-\varphi)(H_s + \varphi(1-\varphi)\mathbf{x}_{r',o}^\intercal \mathbf{x}_{r',o})^{-1}\mathbf{x}_{r',o}^\intercal)\mathbf{x}_{r,\bar{o}}$$

and then calculate the change in the score as:

$$\begin{aligned}&\overline{\psi}(s,r,o) - \psi(s,r,o) = \\ &\mathbf{z}_{s,r}.(\overline{\mathbf{e}_o} - \mathbf{e}_o) + (\overline{\mathbf{e}_s} - \mathbf{e}_s).\mathbf{x}_{r,\bar{o}} = \\ &\mathbf{z}_{s,r}((1-\varphi)(H_o + \varphi(1-\varphi)\mathbf{z}_{s,r'}^\intercal \mathbf{z}_{s,r'})^{-1}\mathbf{z}_{s,r'}^\intercal) + \\ &((1-\varphi)(H_s + \varphi(1-\varphi)\mathbf{x}_{r',o}^\intercal \mathbf{x}_{r',o})^{-1}\mathbf{x}_{r',o}^\intercal)\mathbf{x}_{r,\bar{o}}\end{aligned} \tag{16}$$

A.3 First-order Approximation of the Change For TransE

In here we derive the approximation of the change in the score upon applying an adversarial modification for TransE [Bordes et al., 2013a]. Using similar assumptions and parameters as before, to calculate the effect of the attack, $\overline{\psi}(s,r,o)$ (where $\psi(s,r,o) = |\mathbf{e}_s + \mathbf{e}_r - \mathbf{e}_o|$), we need to compute $\overline{\mathbf{e}_o}$. To do so, we need to derive an efficient computation for $\overline{\mathbf{e}_o}$. First, the derivative of the loss $\mathcal{L}(\overline{G}) = \mathcal{L}(G) + \mathcal{L}(\langle s', r', o\rangle)$ over $\mathbf{e}_o$ is:

$$\nabla_{e_o}\mathcal{L}(\overline{G}) = \nabla_{e_o}\mathcal{L}(G) + (1-\varphi)\frac{\mathbf{z}_{s',r'} - \mathbf{e}_o}{\psi(s',r',o)} \tag{17}$$

where $\mathbf{z}_{s',r'} = \mathbf{e}'_s + \mathbf{e}'_r$, and $\varphi = \sigma(\psi(s',r',o))$. At convergence, after retraining, we expect $\nabla_{e_o}\mathcal{L}(\overline{G}) = 0$. We perform first order Taylor approximation of $\nabla_{e_o}\mathcal{L}(\overline{G})$ to get:

$$0 \simeq (1-\varphi)\frac{(\mathbf{z}_{s',r'} - \mathbf{e}_o)^\intercal}{\psi(s',r',o)} + (H_o - H_{s',r',o})(\overline{\mathbf{e}_o} - \mathbf{e}_o) \tag{18}$$

$$H_{s',r',o} = (1-\varphi)\varphi\frac{(\mathbf{z}_{s',r'} - \mathbf{e}_o)^\intercal(\mathbf{z}_{s',r'} - \mathbf{e}_o)}{\psi(s',r',o)^2} + \frac{1-\varphi}{\psi(s',r',o)} - (1-\varphi)\frac{(\mathbf{z}_{s',r'} - \mathbf{e}_o)^\intercal(\mathbf{z}_{s',r'} - \mathbf{e}_o)}{\psi(s',r',o)^3} \tag{19}$$

where H_o is the $d \times d$ Hessian matrix for o, i.e., second order derivative of the loss w.r.t. $\mathbf{e}_o$, computed sparsely. Solving for $\overline{\mathbf{e}_o}$ gives us:

$$\overline{\mathbf{e}_o} = -(1-\varphi)(H_o - H_{s',r',o})^{-1}\frac{(\mathbf{z}_{s',r'} - \mathbf{e}_o)^\intercal}{\psi(s',r',o)} + \mathbf{e}_o \tag{20}$$

Then, we compute the score change as:

$$\begin{aligned}\overline{\psi}(s,r,o) &= |\mathbf{e}_s + \mathbf{e}_r - \overline{\mathbf{e}_o}| \\ &= |\mathbf{e}_s + \mathbf{e}_r + (1-\varphi)(H_o - H_{s',r',o})^{-1} \\ &\frac{(\mathbf{z}_{s',r'} - \mathbf{e}_o)^\intercal}{\psi(s',r',o)} - \mathbf{e}_o|\end{aligned} \tag{21}$$

Calculating this expression is efficient since H_o is a $d \times d$ matrix.

A.4 Sample Adversarial Attacks

In this section, we provide the output of the CRIAGE-Add for some target triples. Sample adversarial attacks are provided in Table 7. As it shows, CRIAGE-Add attacks mostly try to change the *type* of the target triple's object by associating it with a subject and a relation that require a different entity types.

Instructions for NAACL-HLT 2019 Proceedings

Anonymous NAACL submission

Abstract

This document contains the instructions for preparing a camera-ready manuscript for the proceedings of NAACL-HLT 2019. The document itself conforms to its own specifications, and is therefore an example of what your manuscript should look like. These instructions should be used for both papers submitted for review and for final versions of accepted papers. Authors are asked to conform to all the directions reported in this document.

1 Credits

This document has been adapted from the instructions for earlier ACL and NAACL proceedings, including those for ACL 2018 by Shay Cohen, Kevin Gimpel, and Wei Lu, NAACL 2018 by Margaret Michell and Stephanie Lukin, 2017/2018 (NA)ACL bibtex suggestions from Jason Eisner, ACL 2017 by Dan Gildea and Min-Yen Kan, NAACL 2017 by Margaret Mitchell, ACL 2012 by Maggie Li and Michael White, those from ACL 2010 by Jing-Shing Chang and Philipp Koehn, those for ACL 2008 by JohannaD. Moore, Simone Teufel, James Allan, and Sadaoki Furui, those for ACL 2005 by Hwee Tou Ng and Kemal Oflazer, those for ACL 2002 by Eugene Charniak and Dekang Lin, and earlier ACL and EACL formats. Those versions were written by several people, including John Chen, Henry S. Thompson and Donald Walker. Additional elements were taken from the formatting instructions of the *International Joint Conference on Artificial Intelligence* and the *Conference on Computer Vision and Pattern Recognition*.

2 Introduction

The following instructions are directed to authors of papers submitted to NAACL-HLT 2019 or accepted for publication in its proceedings. All authors are required to adhere to these specifications. Authors are required to provide a Portable Document Format (PDF) version of their papers. **The proceedings are designed for printing on A4 paper.**

3 General Instructions

Manuscripts must be in two-column format. Exceptions to the two-column format include the title, authors' names and complete addresses, which must be centered at the top of the first page, and any full-width figures or tables (see the guidelines in Subsection 3.6). **Type single-spaced.** Start all pages directly under the top margin. See the guidelines later regarding formatting the first page. The manuscript should be printed single-sided and its length should not exceed the maximum page limit described in Section 5. Pages are numbered for initial submission. However, **do not number the pages in the camera-ready version**.

By uncommenting `\aclfinalcopy` at the top of this document, it will compile to produce an example of the camera-ready formatting; by leaving it commented out, the document will be anonymized for initial submission. When you first create your submission on softconf, please fill in your submitted paper ID where `***` appears in the `\def\aclpaperid{***}` definition at the top.

The review process is double-blind, so do not include any author information (names, addresses) when submitting a paper for review. However, you should maintain space for names and addresses so that they will fit in the final (accepted) version. The NAACL-HLT 2019 LaTeX style will create a titlebox space of 2.5in for you when `\aclfinalcopy` is commented out.

The author list for submissions should include all (and only) individuals who made substantial contributions to the work presented. Each author

Proceedings of NAACL-HLT 2019, pages 3348–3354
Minneapolis, Minnesota, June 2 - June 7, 2019.

listed on a submission to NAACL-HLT 2019 will be notified of submissions, revisions and the final decision. No authors may be added to or removed from submissions to NAACL-HLT 2019 after the submission deadline.

3.1 The Ruler

The NAACL-HLT 2019 style defines a printed ruler which should be presented in the version submitted for review. The ruler is provided in order that reviewers may comment on particular lines in the paper without circumlocution. If you are preparing a document without the provided style files, please arrange for an equivalent ruler to appear on the final output pages. The presence or absence of the ruler should not change the appearance of any other content on the page. The camera ready copy should not contain a ruler. (LaTeX users may uncomment the `\aclfinalcopy` command in the document preamble.)

Reviewers: note that the ruler measurements do not align well with lines in the paper – this turns out to be very difficult to do well when the paper contains many figures and equations, and, when done, looks ugly. In most cases one would expect that the approximate location will be adequate, although you can also use fractional references (*e.g.*, the first paragraph on this page ends at mark 108.5).

3.2 Electronically-available resources

NAACL-HLT provides this description in LaTeX2e (`naaclhlt2019.tex`) and PDF format (`naaclhlt2019.pdf`), along with the LaTeX2e style file used to format it (`naaclhlt2019.sty`) and an ACL bibliography style (`acl_natbib.bst`) and example bibliography (`naaclhlt2019.bib`). These files are all available at `http://naacl2019.org/downloads/naaclhlt2019-latex.zip`. We strongly recommend the use of these style files, which have been appropriately tailored for the NAACL-HLT 2019 proceedings.

3.3 Format of Electronic Manuscript

For the production of the electronic manuscript you must use Adobe's Portable Document Format (PDF). PDF files are usually produced from LaTeX using the *pdflatex* command. If your version of LaTeX produces Postscript files, you can convert these into PDF using *ps2pdf* or *dvipdf*. On Windows, you can also use Adobe Distiller to generate PDF.

Please make sure that your PDF file includes all the necessary fonts (especially tree diagrams, symbols, and fonts with Asian characters). When you print or create the PDF file, there is usually an option in your printer setup to include none, all or just non-standard fonts. Please make sure that you select the option of including ALL the fonts. **Before sending it, test your PDF by printing it from a computer different from the one where it was created.** Moreover, some word processors may generate very large PDF files, where each page is rendered as an image. Such images may reproduce poorly. In this case, try alternative ways to obtain the PDF. One way on some systems is to install a driver for a postscript printer, send your document to the printer specifying "Output to a file", then convert the file to PDF.

It is of utmost importance to specify the **A4 format** (21 cm x 29.7 cm) when formatting the paper. When working with `dvips`, for instance, one should specify `-t a4`. Or using the command `\special{papersize=210mm,297mm}` in the latex preamble (directly below the `\usepackage` commands). Then using `dvipdf` and/or `pdflatex` which would make it easier for some.

Print-outs of the PDF file on A4 paper should be identical to the hardcopy version. If you cannot meet the above requirements about the production of your electronic submission, please contact the publication chairs as soon as possible.

3.4 Layout

Format manuscripts two columns to a page, in the manner these instructions are formatted. The exact dimensions for a page on A4 paper are:

- Left and right margins: 2.5 cm
- Top margin: 2.5 cm
- Bottom margin: 2.5 cm
- Column width: 7.7 cm
- Column height: 24.7 cm
- Gap between columns: 0.6 cm

Papers should not be submitted on any other paper size. If you cannot meet the above requirements about the production of your electronic submission, please contact the publication chairs above as soon as possible.

Type of Text	Font Size	Style
paper title	15 pt	bold
author names	12 pt	bold
author affiliation	12 pt	
the word “Abstract”	12 pt	bold
section titles	12 pt	bold
document text	11 pt	
captions	10 pt	
abstract text	10 pt	
bibliography	10 pt	
footnotes	9 pt	

Table 1: Font guide.

3.5 Fonts

For reasons of uniformity, Adobe’s **Times Roman** font should be used. In LaTeX2e this is accomplished by putting

```
\usepackage{times}
\usepackage{latexsym}
```

in the preamble. If Times Roman is unavailable, use **Computer Modern Roman** (LaTeX2e’s default). Note that the latter is about 10% less dense than Adobe’s Times Roman font.

3.6 The First Page

Center the title, author’s name(s) and affiliation(s) across both columns. Do not use footnotes for affiliations. Do not include the paper ID number assigned during the submission process. Use the two-column format only when you begin the abstract.

Title: Place the title centered at the top of the first page, in a 15-point bold font. (For a complete guide to font sizes and styles, see Table 1) Long titles should be typed on two lines without a blank line intervening. Approximately, put the title at 2.5 cm from the top of the page, followed by a blank line, then the author’s names(s), and the affiliation on the following line. Do not use only initials for given names (middle initials are allowed). Do not format surnames in all capitals (*e.g.*, use “Mitchell” not “MITCHELL”). Do not format title and section headings in all capitals as well except for proper names (such as “BLEU”) that are conventionally in all capitals. The affiliation should contain the author’s complete address, and if possible, an electronic mail address. Start the body of the first page 7.5 cm from the top of the page.

Command	Output	Command	Output
`{\"a}`	ä	`{\c c}`	ç
`{\^e}`	ê	`{\u g}`	ğ
``{\`i}``	ì	`{\l}`	ł
`{\.I}`	İ	`{\~n}`	ñ
`{\o}`	ø	`{\H o}`	ő
`{\'u}`	ú	`{\v r}`	ř
`{\aa}`	å	`{\ss}`	ß

Table 2: Example commands for accented characters, to be used in, *e.g.*, BibTeX names.

The title, author names and addresses should be completely identical to those entered to the electronical paper submission website in order to maintain the consistency of author information among all publications of the conference. If they are different, the publication chairs may resolve the difference without consulting with you; so it is in your own interest to double-check that the information is consistent.

Abstract: Type the abstract at the beginning of the first column. The width of the abstract text should be smaller than the width of the columns for the text in the body of the paper by about 0.6 cm on each side. Center the word **Abstract** in a 12 point bold font above the body of the abstract. The abstract should be a concise summary of the general thesis and conclusions of the paper. It should be no longer than 200 words. The abstract text should be in 10 point font.

Text: Begin typing the main body of the text immediately after the abstract, observing the two-column format as shown in the present document. Do not include page numbers.

Indent: Indent when starting a new paragraph, about 0.4 cm. Use 11 points for text and subsection headings, 12 points for section headings and 15 points for the title.

3.7 Sections

Headings: Type and label section and subsection headings in the style shown on the present document. Use numbered sections (Arabic numerals) in order to facilitate cross references. Number subsections with the section number and the subsection number separated by a dot, in Arabic numerals. Do not number subsubsections.

Citations: Citations within the text appear in parentheses as (Gusfield, 1997) or, if the author’s name appears in the text itself, as Gusfield (1997). Using the provided LaTeX style, the former is accomplished using `\cite` and the latter with `\shortcite` or `\newcite`. Collapse multi-

output	natbib	previous ACL style files
(Gusfield, 1997)	`\citep`	`\cite`
Gusfield (1997)	`\citet`	`\newcite`
(1997)	`\citeyearpar`	`\shortcite`

Table 3: Citation commands supported by the style file. The citation style is based on the natbib package and supports all natbib citation commands. It also supports commands defined in previous ACL style files for compatibility.

ple citations as in (Gusfield, 1997; Aho and Ullman, 1972); this is accomplished with the provided style using commas within the `\cite` command, *e.g.*, `\cite{Gusfield:97,Aho:72}`. Append lowercase letters to the year in cases of ambiguities. Treat double authors as in (Aho and Ullman, 1972), but write as in (Chandra et al., 1981) when more than two authors are involved. Collapse multiple citations as in (Gusfield, 1997; Aho and Ullman, 1972). Also refrain from using full citations as sentence constituents.

We suggest that instead of

> "(Gusfield, 1997) showed that ..."

you use

> "Gusfield (1997) showed that ..."

If you are using the provided LaTeX and BibTeX style files, you can use the command `\citet` (cite in text) to get "author (year)" citations.

If the BibTeX file contains DOI fields, the paper title in the references section will appear as a hyperlink to the DOI, using the hyperref LaTeX package. To disable the hyperref package, load the style file with the `nohyperref` option:

```
\usepackage[nohyperref]{naaclhlt2019}
```

Digital Object Identifiers: As part of our work to make ACL materials more widely used and cited outside of our discipline, ACL has registered as a CrossRef member, as a registrant of Digital Object Identifiers (DOIs), the standard for registering permanent URNs for referencing scholarly materials. As of 2017, we are requiring all camera-ready references to contain the appropriate DOIs (or as a second resort, the hyperlinked ACL Anthology Identifier) to all cited works. Thus, please ensure that you use BibTeX records that contain DOI or URLs for any of the ACL materials that you reference. Appropriate records should be found for most materials in the current ACL Anthology at `http://aclanthology.info/`.

As examples, we cite (Goodman et al., 2016) to show you how papers with a DOI will appear in the bibliography. We cite (Harper, 2014) to show how papers without a DOI but with an ACL Anthology Identifier will appear in the bibliography.

As reviewing will be double-blind, the submitted version of the papers should not include the authors' names and affiliations. Furthermore, self-references that reveal the author's identity, *e.g.*,

> "We previously showed (Gusfield, 1997) ..."

should be avoided. Instead, use citations such as

> "Gusfield (1997) previously showed ... "

Any preliminary non-archival versions of submitted papers should be listed in the submission form but not in the review version of the paper. NAACL-HLT 2019 reviewers are generally aware that authors may present preliminary versions of their work in other venues, but will not be provided the list of previous presentations from the submission form.

Please do not use anonymous citations and do not include when submitting your papers. Papers that do not conform to these requirements may be rejected without review.

References: Gather the full set of references together under the heading **References**; place the section before any Appendices. Arrange the references alphabetically by first author, rather than by order of occurrence in the text. By using a .bib file, as in this template, this will be automatically handled for you. See the `\bibliography` commands near the end for more.

Provide as complete a citation as possible, using a consistent format, such as the one for *Computational Linguistics* or the one in the *Publication Manual of the American Psychological Association* (American Psychological Association, 1983). Use of full names for authors rather than initials is preferred. A list of abbreviations for common computer science journals can be found in the ACM *Computing Reviews* (for Computing Machinery, 1983).

The LaTeX and BibTeX style files provided roughly fit the American Psychological Association format, allowing regular citations, short citations and multiple citations as described above.

- Example citing an arxiv paper: (Rasooli and Tetreault, 2015).
- Example article in journal citation: (Ando and Zhang, 2005).
- Example article in proceedings, with location: (Borschinger and Johnson, 2011).
- Example article in proceedings, without location: (Andrew and Gao, 2007).

See corresponding .bib file for further details.

Submissions should accurately reference prior and related work, including code and data. If a piece of prior work appeared in multiple venues, the version that appeared in a refereed, archival venue should be referenced. If multiple versions of a piece of prior work exist, the one used by the authors should be referenced. Authors should not rely on automated citation indices to provide accurate references for prior and related work.

Appendices: Appendices, if any, directly follow the text and the references (but see above). Letter them in sequence and provide an informative title: **Appendix A. Title of Appendix**.

3.8 Footnotes

Footnotes: Put footnotes at the bottom of the page and use 9 point font. They may be numbered or referred to by asterisks or other symbols.[1] Footnotes should be separated from the text by a line.[2]

3.9 Graphics

Illustrations: Place figures, tables, and photographs in the paper near where they are first discussed, rather than at the end, if possible. Wide illustrations may run across both columns. Color illustrations are discouraged, unless you have verified that they will be understandable when printed in black ink.

Captions: Provide a caption for every illustration; number each one sequentially in the form: "Figure 1. Caption of the Figure." "Table 1. Caption of the Table." Type the captions of the figures and tables below the body, using 10 point text. Captions should be placed below illustrations. Captions that are one line are centered (see Table 1). Captions longer than one line are left-aligned (see Table 2). Do not overwrite the default caption sizes. The naaclhlt2019.sty file is compatible with the caption and subcaption packages; do not add optional arguments.

3.10 Accessibility

In an effort to accommodate people who are color-blind (as well as those printing to paper), grayscale readability for all accepted papers will be encouraged. Color is not forbidden, but authors should ensure that tables and figures do not rely solely on color to convey critical distinctions. A simple criterion: All curves and points in your figures should be clearly distinguishable without color.

4 Translation of non-English Terms

It is also advised to supplement non-English characters and terms with appropriate transliterations and/or translations since not all readers understand all such characters and terms. Inline transliteration or translation can be represented in the order of: original-form transliteration "translation".

5 Length of Submission

The NAACL-HLT 2019 main conference accepts submissions of long papers and short papers. Long papers may consist of up to eight (8) pages of content plus unlimited pages for references. Upon acceptance, final versions of long papers will be given one additional page – up to nine (9) pages of content plus unlimited pages for references – so that reviewers' comments can be taken into account. Short papers may consist of up to four (4) pages of content, plus unlimited pages for references. Upon acceptance, short papers will be given five (5) pages in the proceedings and unlimited pages for references. For both long and short papers, all illustrations and tables that are part of the main text must be accommodated within these page limits, observing the formatting instructions given in the present document. Papers that do not conform to the specified length and formatting requirements are subject to be rejected without review.

NAACL-HLT 2019 does encourage the submission of additional material that is relevant to the reviewers but not an integral part of the paper. There are two such types of material: appendices,

---

[1] This is how a footnote should appear.

[2] Note the line separating the footnotes from the text.

which can be read, and non-readable supplementary materials, often data or code. Do not include this additional material in the same document as your main paper. Additional material must be submitted as one or more separate files, and must adhere to the same anonymity guidelines as the main paper. The paper must be self-contained: it is optional for reviewers to look at the supplementary material. Papers should not refer, for further detail, to documents, code or data resources that are not available to the reviewers. Refer to Appendix A and Appendix B for further information.

Workshop chairs may have different rules for allowed length and whether supplemental material is welcome. As always, the respective call for papers is the authoritative source.

Acknowledgments

The acknowledgments should go immediately before the references. Do not number the acknowledgments section. Do not include this section when submitting your paper for review.

Preparing References:

Include your own bib file like this: `\bibliographystyle{acl_natbib}` `\bibliography{naaclhlt2019}`

where `naaclhlt2019` corresponds to a naaclhlt2019.bib file.

A Appendices

Appendices are material that can be read, and include lemmas, formulas, proofs, and tables that are not critical to the reading and understanding of the paper. Appendices should be **uploaded as supplementary material** when submitting the paper for review. Upon acceptance, the appendices come after the references, as shown here. Use `\appendix` before any appendix section to switch the section numbering over to letters.

B Supplemental Material

Submissions may include non-readable supplementary material used in the work and described in the paper. Any accompanying software and/or data should include licenses and documentation of research review as appropriate. Supplementary material may report preprocessing decisions, model parameters, and other details necessary for the replication of the experiments reported in the paper. Seemingly small preprocessing decisions can sometimes make a large difference in performance, so it is crucial to record such decisions to precisely characterize state-of-the-art methods.

Nonetheless, supplementary material should be supplementary (rather than central) to the paper. **Submissions that misuse the supplementary material may be rejected without review.** Supplementary material may include explanations or details of proofs or derivations that do not fit into the paper, lists of features or feature templates, sample inputs and outputs for a system, pseudo-code or source code, and data. (Source code and data should be separate uploads, rather than part of the paper).

The paper should not rely on the supplementary material: while the paper may refer to and cite the supplementary material and the supplementary material will be available to the reviewers, they will not be asked to review the supplementary material.

Transferable Neural Projection Representations

Abstract

Neural word representations are at the core of many state-of-the-art natural language processing models. A widely used approach is to pretrain, store and look up word or character embedding matrices. While useful, such representations occupy huge memory making it hard to deploy on-device and often do not generalize to unknown words due to vocabulary pruning.

In this paper, we propose a skip-gram based architecture coupled with Locality-Sensitive Hashing (LSH) projections to learn efficient dynamically computable representations. Our model does not need to store lookup tables as representations are computed on-the-fly and require low memory footprint. The representations can be trained in an unsupervised fashion and can be easily transferred to other NLP tasks. For qualitative evaluation, we analyze the nearest neighbors of the word representations and discover semantically similar words even with misspellings. For quantitative evaluation, we plug our transferable projections into a simple LSTM and run it on multiple NLP tasks and show how our transferable projections achieve better performance compared to prior work.

1 Introduction

Pre-trained word representations are at the core of many neural language understanding models. Among the most popular and widely used word embeddings are word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and ELMO (Peters et al., 2018). The biggest challenge with word embedding is that they require lookup and a large memory footprint, as we have to store one entry (d-dim vector) per word and it blows up.

In parallel, the tremendous success of deep learning models and the explosion of mobile, IoT devices coupled together with the growing user privacy concerns have led to the need for deploying deep learning models on-device for inference. This has led to new research in compressing large and complex deep learning models for low power on-device deployment. Recently, (Ravi and Kozareva, 2018) developed an on-device neural text classification model. They proposed to reduce the memory footprint of large neural networks by replacing the input word embeddings with projection based representations. (Ravi and Kozareva, 2018) used n-gram features to generate binary LSH (Charikar, 2002) randomized projections on the fly surpassing the need to store word emebdding tables and reducing the memory size. The projection models reduce the memory occupied by the model from $O(|V|)$ to $O(n_{\mathbb{P}})$, where $|V|$ refers to the vocabulary size and $n_{\mathbb{P}}$ refers to number of projection operations (Ravi, 2017). Two key advantages of the projection based representations over word embeddings are: (1) they are fixed and have low memory size; (2) they can handle out of vocabulary words. However, the projections in (Ravi and Kozareva, 2018) are static and currently do not leverage pre-training on large unsupervised corpora, which is an important property to make the projections transferable to new tasks.

In this paper, we propose to combine the best of both worlds by learning transferable neural projection representations over randomized LSH projections. We do this by introducing new neural architecture inspired by the skip gram model of (Mikolov et al., 2013) and combined with a deep MLP plugged on top of LSH projections. In order to make this model train better, we introduce new regularizing loss function, which minimizes the cosine similarities of the words within a mini-batch. The loss function is critical for generalization.

In summary, our model (1) requires a fixed and low memory footprint, (2) can handle out of vo-

Minneapolis, Minnesota, June 2 - June 7, 2019.

cabulary words and misspellings, (3) captures semantic and syntactic properties of words; (4) can be easily plugged to other NLP models and (5) can support training with data augmentation by perturbing characters of input words. To validate the performance of our approach, we conduct a qualitative analysis of the nearest neighbours in the learned representation spaces and a quantitative evaluation via similarity, language modeling and NLP tasks.

2 Neural Projection Model

We propose a novel model (NP-SG) to learn compact neural representations that combines the benefit of representation learning approaches like skip-gram model with efficient LSH projections that can be computed on-the-fly.

2.1 Vanilla Skip-Gram Model

In the skip-gram model (Mikolov et al., 2013), we learn continuous distributed representations for words in a large fixed vocabulary, $\mathbb{V}$ to predict the context words surrounding them in documents. We maintain an embedding look up table, $v(w) \in \mathbb{R}^d$ for every word, $w \in \mathbb{V}$.

For each word, w_t in the training corpus of size T, the set of context words $\mathbb{C}_t = \{w_{t-W_t}, \ldots, w_{t-1}, w_{t+1}, \ldots, w_{t+W_t}\}$ includes W_t words to the left and right of w_t respectively. W_t is the window size randomly sampled from the set $\{1, 2, \ldots, N\}$, where N is the maximum window size. Given a pair of words, $\{w_c, w_t\}$, the probability of w_c being within the context window of w_t is given by equation 1.

$$\begin{aligned} \mathrm{P}(w_c|w_t) &= \sigma(v'(w_c)^\intercal v(w_t)) \\ &= \frac{1}{1+\exp(-v'(w_c)^\intercal v(w_t))} \end{aligned} \tag{1}$$

where v, v' are input and context embedding look up tables.

2.2 Neural Projection Skip-Gram (NP-SG)

In the neural projection approach, we replace the input embedding look up table, $v(w)$ in equation 1 with a deep n-layer MLP over the binary projection, $\mathbb{P}(w)$ as shown equation 2.

$$v_{\mathbb{P}}(w) = \mathbb{N}(f_n(\mathbb{P}(w))) \tag{2}$$

where $v_{\mathbb{P}}(w) \in \mathbb{R}^d$, f_n is a n-layer deep neural network encoder with $ReLU$ non-linear activations after each layer except for the last layer as shown in Figure 1. $\mathbb{N}$ refers to a normalization applied to the final layer of f_n. We experimented with Batch-normalization, L2-normalization and layer normalization; batch-normalization works the best.

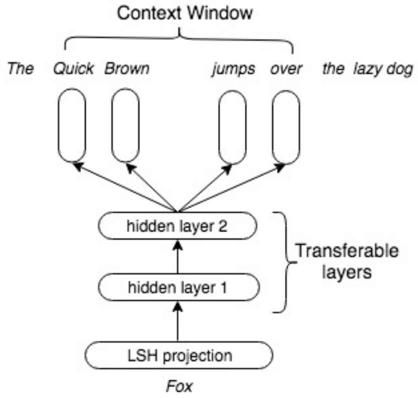

Figure 1: Neural Projection Skip-gram (NP-SG) model

The binary projection $\mathbb{P}(w)$ is computed using locality-sensitive projection operations (Ravi, 2017) which can be performed on-the-fly (i.e., without any embedding look up) to yield a fixed, low-memory footprint binary vector. Unlike (Ravi and Kozareva, 2018) which uses *static* projections to encode the entire input text and learn a classifier, NP-SG creates a *trainable* deep projection representation for words using LSH projections over character-level features combined with contextual information learned via the skip-gram architecture.

2.3 Training NP-SG Model

We follow a similar approach as Mikolov et al. (2013) and others for training our neural projection skip-gram model (NP-SG). We define the training objective to maximize the probability of predicting the context words given the current word. Formally, the model tries to learn the word embeddings by maximizing the objective, $J(\theta)$ known as negative sampling (NEG), given by equation 3.

$$J(\theta) = \sum_{t=1}^{T} \sum_{w_c \in \mathbb{C}_t} J_{w_t, w_c}(\theta) \tag{3}$$

$$\begin{aligned} J_{w_t,w_c}(\theta) &= \log(\mathrm{P}(w_c|w_t)) \\ &+ \sum_{i=1, w_i \sim \mathrm{P}_n(w)}^{k} \log(1 - \mathrm{P}(w_i|w_t)) \end{aligned} \tag{4}$$

where k is the number of randomly sampled words from the training corpus according to the noise distribution, $\mathrm{P}_n(w) \propto U(w)^{3/4}$, where $U(w)$ is the unigram distribution of the training corpus.

Model improvements: Training an NP-SG model as is, though efficient, may not lead to highly discriminative representations. During training, we noticed that the word representations, $v_{\mathbb{P}}(w)$ were getting projected in a narrow sub-space where the cosine similarities of all the words in the dataset were too close to 1.0. This made the convergence slower and led to poor generalization.

2.4 Discriminative NP-SG Models

To encourage the word representations to be more spaced out in terms of the cosine similarities, we introduce an additional explicit regularizing L2-loss function. With the assumption that the words in each mini-batch are randomly sampled, we add a L2-loss over the cosine similarities between all the words within a mini-batch, as shown in equation 6.

$$Loss = J(\theta) + \mathrm{L}_2^{cs}(\mathbf{w}_{mb}) \tag{5}$$

$$\mathrm{L}_2^{cs}(\mathbf{w}_{mb}) = \lambda \cdot \| \{\mathrm{CS}(w_i, w_j) \,|\, i, j \in [0, mb)\} \|_2^2 \tag{6}$$

where $\mathrm{CS}(w_i, w_j)$ refers to the cosine similarity between w_i and w_j, mb refers to the mini-batch size and $\mathbf{w}_{mb}$ refers to the words in the mini-batch. We enforce this using a simple outerproduct trick. We extract the cosine-similarities between all the words within a mini-batch in a single shot by computing the outer-product of the L_2 row normalized word representations corresponding to each mini-batch $\hat{v}_{\mathbb{P}}(\mathbf{w}_{mb})$, as shown in equation 7.

$$\mathrm{L}_2^{cs}(\mathbf{w}_{mb}) = \frac{\lambda}{2} \cdot \| \,\mathrm{Flatten}(\hat{v}_{\mathbb{P}}(\mathbf{w}_{mb}) \cdot \hat{v}_{\mathbb{P}}(\mathbf{w}_{mb})^{\intercal}) \,\|_2^2 \tag{7}$$

2.5 Improved NP-SG Training

Since the NP-SG model does not have a fixed vocabulary size, we can be flexible and leverage a lot more information during training compared to standard skip-gram models which require vocabulary pruning for feasibility.

To improve training for NP-SG model, we augment the dataset with inputs words after applying character level perturbations to them. The perturbations are such a way that they are commonly occurring misspellings in documents. We mainly experiment with three types of pertub operation APIs (Gao et al., 2018).

- *insert(word, n)* : We randomly choose *n* chars from the character vocabulary and insert them randomly into the input *word*. We ignore the locations of first and last character in the word for the *insert* operation. Example transformation: $sample \rightarrow samnple$.
- *swap(word, n)* : We randomly swap the location of two characters in the word *n* times. As with the *insert* operation, we ignore the first and last character in the word for the *swap* operation. Example transformation: $sample \rightarrow sapmle$.
- *duplicate(word, n)* : We randomly duplicate a character in the word by *n* times. Example transformation: $sample \rightarrow saample$.

We would like to note that the perturbation operations listed above are not exhaustive and we plan to experiment with more operations in the future.

3 Training Setup

3.1 Dataset

We train our skipgram models on the wikipedia data XML dump, ***enwik9***[1]. We extract the normalized English text from the XML dump using the Matt Mahoneys pre-processing perl script[2]. We fix the vocabulary to the top $100k$ frequently occurring words. We sub-sample words in the training corpus, dropping them with probability, $\mathrm{P}(w) = 1 - \sqrt{t/freq(w)}$, where $freq(w)$ is the frequency of occurrence of w in the corpus and we set the threshold, t to 10^{-5}. We perturb the input words with a probability of 0.4 using a randomly chosen perturbation described in Section 2.5.

3.2 Implementation Details

We fix the number of random projections to 80 and the projection dimension to 14. We use a 2-layer MLP (sizes: $[2048, 100]$) regularized with dropout (with probability of 0.65) and weight decay (regularization parameter of 0.0005) to transform the binary random projections to continuous word representation. For the vanilla skipgram model, we fix the embedding size to 100. For both models, we use 25 negative samples for the NEG loss. We learn the parameters using the Adam optimizer (Kingma and Ba, 2014) with a default learning rate of 0.001, clipping the gradients which have a norm larger than 5.0. We initialize the weights of the MLP using Xavier initialization, and output embeddings

uniformly random in the range $[-1.0, 1.0]$. We use a batch size of 1024 in all our experiments. We found that $\lambda = 0.01$ for the outerproduct loss to be working better after experimenting with other values. Training time for our model was around 0.85 times that of the skipgram model. Both the models were trained for 10 epochs.

4 Experiments

We show both qualitative and quantitative evaluation on multiple tasks for the NP-SG model.

4.1 Qualitative Evaluation and Results

Table 2 shows the nearest neighbors produced by NP-SG for select words. Independent of whether it is an original or misspelled word, our NP-SG model accurately retrieves relevant and semantically similar words.

Word	*Nearest neighbours*
king	reign, throne, kings, knights, vii, regent
kingg	vii, younger, peerage, iv, tiberius, frederick
woman	man, young, girl, child, girls, women
wwoamn	man, herself, men, couple, herself, alive
city	town, village, borough, township, county
ciity	town, village, borough, county, unorganized
time	few, times, once, entire, prominence, since
tinme	times, once, takes, taken, another, only
zero	two, three, seven, one, eight, four
zzero	two, three, five, six, seven, four

Table 2: Sampled nearest neighbors for NP-SG.

4.2 Quantitative Evaluation and Results

We evaluate our NP-SG model on similarity, language modeling and text classification tasks. Similarity tests the ability to capture words, while language modeling and classification warrant the ability to transfer the neural projections.

4.2.1 Similarity Task

We evaluate our NP-SG word representations on 4 different widely used benchmark datasets for measuring similarities.

Dataset: *MTurk-287* (Radinsky et al., 2011) has 287 pairs of words and was constructed by crowdsourcing the human similarity ratings using Amazon Mechanical Turk. *WS353* (Finkelstein et al., 2001) has 353 pairs of similar English words rated by humans and is further split into *WS353-SIM*. *WS353-REL* (Agirre et al., 2009) captures different types of similarities and relatedness. *RW-STANFORD* (Luong et al., 2013) has 2034 rare word pairs sampled from different frequency bins. **Evaluation:** For all the datasets, we compute the Spearmans rank correlation coefficient between the rankings computed by skip-gram models (baseline SG and NP-SG) and the human rankings. We use cosine similarity metric to measure word similarity. **Results:** Table 1 shows that NP-SG, with significantly smaller number of parameters comes close to the skip-gram model (SG) and even outperforms it with 2.5x-10x compression. NP-SG gets better representations even with misspellings which cannot be handled by vanilla SG.

It is interesting to note that the vanilla skip-gram model does well on *WS353-SIM* compared to *WS353-REL*. This behavior is reversed in our NP-SG model, which indicates that it captures meronym-holonym relationships better than the vanilla skip-gram model. Although NP-SG handles out of vocabulary words in the form of misspellings, it needs further improvement for rare word similarity task. We plan to improve it by including context word n-gram features in the LSH projection function, allowing NP-SG to also leverage information from the context words in the case of rare words and provide word sense disambiguation.

4.2.2 Language Modeling

We applied NP-SG to language modeling task on the Penn Treebank (PTB)(Taylor et al., 2003) dataset. We consider a single layer LSTM with hidden size of 2048 for the language model task. With the input embedding size of 200, we observed a perplexity of ≈ 120 on the test set after training for 5 epochs. We replace the input embeddings in the LSTM with transferable encoder layer of the NP-SG model. We train the LSTMs with and without pretrained initializations. Since we observed convergence issues with the single layer NP-SG representation, we considered 2-layer MLP with layer sizes (1024, 256) for the NP-SG representations. We found that while the model without pretrained NP-SG layer got stuck at a perplexity of around 300, the pretrained version converged to a perplexity of 140, comparable to the embedding based network. We leave the analysis of the impact of the deeper NP-SG layers to the future work.

4.2.3 Text Classification

For the text classification evaluations, we used two different tasks and datasets. For the dialog act classification task, we used the MRDA dataset from the ICSI Meeting Recorder Dialog Act Corpus (Adam et al., 2003). MRDA is a multiparty dialog annotated with 5 dialog act tags. For the question classification task, we used the TREC dataset (Lin and Katz, 2006). The task is given a question to predict the most relevant category.

We trained a single layer LSTM (hidden size: 256) with and without the pretrained NP-SG layers. Overall, we observed accuracy improvements of $+5.7\%$ and $+3.75\%$ compared to baseline models without pretrained NP-SG initializations on TREC and MRDA respectively.

5 Conclusion

In this paper, we introduced a new neural architecture (NP-SG), which learns transferable word representations that can be efficiently and dynamically computed on device without any embedding look up. We proposed an unsupervised method to train the new architecture and learn more discriminative word representations. We compared the new model with a skip-gram approach and showed qualitative and quantitative comparisons on multiple language tasks. The evaluations show that our NP-SG model learns better representations even with misspellings and reaches competitive results with skip-gram on similarity tasks, even outperforming with 2.5x-10x fewer parameters.

Abstract

Semantic role labeling (SRL) is a task to recognize all the predicate-argument pairs of a sentence, which has been in a performance improvement bottleneck after a series of latest works were presented. This paper proposes a novel syntax-agnostic SRL model enhanced by the proposed associated memory network (AMN), which makes use of inter-sentence attention of label-known associated sentences as a kind of memory to further enhance dependency-based SRL. In detail, we use sentences and their labels from train dataset as an associated memory cue to help label the target sentence. Furthermore, we compare several associated sentences selecting strategies and label merging methods in AMN to find and utilize the label of associated sentences while attending them. By leveraging the attentive memory from known training data, Our full model reaches state-of-the-art on CoNLL-2009 benchmark datasets for syntax-agnostic setting, showing a new effective research line of SRL enhancement other than exploiting external resources such as well pre-trained language models.

1 Introduction

Semantic role labeling (SRL) is a task to recognize all the predicate-argument pairs of a given sentence and its predicates. It is a shallow semantic parsing task, which has been widely used in a series of natural language processing (NLP) tasks, such as information extraction (Liu et al., 2016) and question answering (Abujabal et al., 2017).

Generally, SRL is decomposed into four classification subtasks in pipeline systems, consisting of predicate identification, predicate disambiguation, argument identification, and argument classification. In recent years, great attention (Zhou and Xu, 2015; Marcheggiani et al., 2017; He et al., 2017, 2018a,b) has been turned to deep learning method, especially Long Short-term Memory (LSTM) network for learning with automatically extracted features. (Zhou and Xu, 2015) proposed the first end-to-end recurrent neural network (RNN) to solve the SRL task. (Marcheggiani et al., 2017) studied several predicate-specified embedding and decoding methods. (He et al., 2017) delivered a full study on the influence of RNN training and decoding strategies. Whether to use the syntactic information for SRL is also studied actively (He et al., 2017, 2018b).

Since the recent work of (Marcheggiani et al., 2017), which surprisingly shows syntax-agnostic dependency SRL for the first time can be rival of syntax-aware models, SRL has been more and more formulized into standard sequence labeling task on a basis of keeping syntax unavailable. A series of work on SRL received further performance improvement following this line through further refining neural model design (He et al., 2018a). Different from all previous work, we propose to introduce an associated memory network which builds memory from known data through the inter-sentence attention to enhance syntax-agnostic model even further.

Inspired by the observation that people always refer to other similar problems and their solutions when dealing with a problem they have never seen, like query in their memory, we want to utilize similar known samples which include the associated sentences and their annotated labels to help model label target sentence. To reach such a goal, we adopt a memory network component, and use inter-sentence attention to fully exploit the information in memory.

---

Proceedings of NAACL-HLT 2019, pages 3361–3371
Minneapolis, Minnesota, June 2 - June 7, 2019.

Based on Memory Network (Weston et al., 2014; Sukhbaatar et al., 2015), (Miller et al., 2016) proposed Key-Value Memory Network (KV-MemNN) to solve Question Answering problem and gain large progress. Our proposed method is similar to KV-MemNN, but with a different definition of key-value and different information distilling process. Thus, we propose a carefully designed inter-sentence attention mechanism to handle it.

Recently, there are also some attempts to make use of attention mechanism in SRL task. (Tan et al., 2018; Strubell et al., 2018) focus on self-attention, which only uses the information of the input sentence as the source of attention. (Cai et al., 2018) makes use of biaffine attention (Dozat and Manning, 2017) for decoding in SRL, which was the current state-of-the-art (SOTA) in CoNLL-2009 benchmark as this work was embarking. Different from all previous work, we utilize inter-sentence attention to help model leverage associated information from other known sentences in the memory.

To our best knowledge, this is the first time to use memory network in the SRL task. Our evaluation on CoNLL-2009 benchmarks shows that our model outperforms or reaches other syntax-agnostic models on English, and achieves competitive results on Chinese, which indicates that memory network learning from known data is indeed helpful to SRL task.

There are several SRL annotation conventions, such as PropBank (Bonial et al., 2012) and FrameNet (Baker et al., 1998). This paper focuses on the former convention. Under PropBank convention, there are two role representation forms, which are span-based SRL, such as CoNLL 2005 and CoNLL 2012 shared tasks, and dependency-based SRL, such as CoNLL 2009 shared task. The former uses span to represent argument, while the latter uses the headword of the span to represent the argument. As the latter has been more actively studied due to dependency style SRL for convenient machine learning, we will focus on dependency SRL only in this work.

Given a sentence **S**, the goal of dependency SRL task is to find all the predicate-argument pairs (p, a). The following shows an example sentence with semantic role labels marked in subscripts.

She$_{A0}$ has **lost**$_{v}$ **it**$_{A1}$ **just**$_{ARGM-MNR}$ as quickly.

Here, *v* means the predicate, *A0* means the agent, *A1* means the patient and *ARGM-MNR* means how an action *v* is performed.

In the rest of this paper, we will describe our model in Section 2. Then, the experiment set-up and results are given in Section 3. Related works about SRL and attention mechanism will be given in Section 4. Conclusions and future work are drawn in Section 5.

2 Model

An SRL system usually consists of four pipeline modules: predicate identification and disambiguation, argument identification and classification. Following most of previous work, we focus on the last two steps in standard SRL task: argument identification and classification. The predicate identification subtask is not needed in CoNLL-2009 shared task[1], and we follow previous work (He et al., 2018b) to handle the predicate disambiguation subtask. This work will only focus on the argument labeling subtask through sequence labeling formalization. We first describe our base model in Section 2.1. Then we introduce the proposed associated memory network including the inter-sentence attention design and label merging strategies in Section 2.2. The full model architecture is shown in Figure 1.

2.1 Base Model

Word Embedding

We use the concatenation of the following embeddings as the representation for every word. (1) Random-initialized word embedding $x_i^{re} \in \mathbb{R}^{d_{re}}$ (2) GloVe (Pennington et al., 2014) word embedding $x_i^{pe} \in \mathbb{R}^{d_{pe}}$ pre-trained on 6B tokens (3) Random-initialized part-of-speech (POS) tag embedding $x_i^{pos} \in \mathbb{R}^{d_{pos}}$ (4) Random-initialized lemma embedding $x_i^{le} \in \mathbb{R}^{d_{le}}$ (5) Contextualized word embedding derived by applying fully connected layer on ELMo embedding $x_i^{ce} \in \mathbb{R}^{d_{ce}}$ (Peters et al., 2018), and (6) Random-initialized predicate specified flag embedding $x_i^{pred} \in \mathbb{R}^{d_{pred}}$. The final representation of each word is:

$$x_i = x_i^{re} \circ x_i^{pe} \circ x_i^{pos} \circ x_i^{le} \circ x_i^{ce} \circ x_i^{pred}$$

where $\circ$ stands for concatenation operator.

---

[1] In CoNLL-2009 task, the predicates information is already identified when testing.

BiLSTM Encoder

LSTM network is known to handle the dependency over long sentence well, and can effectively model the context information when encoding. Therefore, we leverage a stacked BiLSTM network $LSTM_e$ to be our encoder. It takes word embedding sequence $\mathbf{x} = [x_i]_{i=1}^{n_\mathbf{S}}$ of sentence $\mathbf{S} = [w_i]_{i=1}^{n_\mathbf{S}}$ as input ($n_\mathbf{S}$ is the length of sentence), and outputs two different hidden states $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ for word w_i by processing the sequence in forward and backward directions. The final contextual representation of word w_i is the concatenation of two hidden states $h_i = \overrightarrow{h_i} \circ \overleftarrow{h_i}$.

Then, we use a final softmax layer after the BiLSTM encoding to predict the label of each word.

2.2 Associated Memory Network

Using the base model as backbone, we introduce an associated memory network (AMN) component for further performance improvement. The proposed AMN memorizes known associated sentences and their labels, then the useful clue in the memory will be delivered to the SRL module through an inter-sentence mechanism. AMN processing includes three steps, associated sentence selection, inter-sentence attention and label merging.

Associated Sentence Selection

We aim to utilize the associated sentences and their labels to help our model label the target sentences. For the sake of fairness, we only use the sentences in train dataset as our source. However, it is impossible to attend all the sentences in train dataset because of the extremely high computational and memory cost. Therefore, we propose a filter to select the most useful sentences from the given dataset (train dataset in this paper) when given the label-unknown sentence **S**.

The filter algorithm is straightforward. First, We compute the distance of every two sentences. Then, we sort all the sentences in train dataset according to their distances with the target sentence **S**, and select top m sentences $\{\mathbf{A}_j\}_{j=1}^{m}$ with the minimum distances and their label sequences $\{\mathbf{L}_j\}_{j=1}^{m}$ as our associated attention. m is the memory size.

As for the computation of distance between two sentences, we formally consider three types of distances, which are *edit distance (ED)*, *word moving distance (WMD)* and *smooth inverse frequency distance (SD)*, plus *random distance (RD)* as baseline. These distances are defined as follows,

- *edit distance* This method uses the edit distance of the POS tag sequences of two sentences as the distance value.
- *word moving distance* Following (Kusner et al., 2015), this method takes word moving distance of two sentences[2].
- *smooth inverse frequency distance* Following (Arora et al., 2017), we use Euclidean distance between the SIF embedding of two sentences as the distance value.
- *random distance* This method returns a random value for distance computation thus lead to selecting sentences randomly in the train dataset.

Inter-sentence Attention

This part aims to attain the inter-sentence attention matrix, which can be also regarded as the core memory part of the AMN. The input sentence **S** and associated sentences $\{\mathbf{A}_j\}_{j=1}^{m}$ first go through a stacked BiSLTM network $LSTM_a$ to encode the sentence-level information to each word representation[3]:

$$\mathbf{S}' = LSTM_a(\mathbf{S})$$

$$\mathbf{A}'_j = LSTM_a(\mathbf{A}_j) \;\; j \in \{1, 2, ..., m\}$$

where $\mathbf{S}' = [x'_i]_{i=1}^{n_\mathbf{S}}$ and $\mathbf{A}'_j = [x'_{j,k}]_{k=1}^{n_j}$ are the lists of new word representations, with each word representation is a vector $x' \in \mathbb{R}^{d_a}$, where d_a is the size of hidden state in $LSTM_a$.

Then, for each associated sentence $\mathbf{A}'_j$, we multiply it with the input sentence representation $\mathbf{S}'$ to get the raw attention matrix M_j^{raw}.

$$M_j^{raw} = \mathbf{S}'\mathbf{A}_j'^T$$

Every element $M_j^{raw}(i,k) = x'_i \cdot x'^T_{j,k}$ can be regarded as an indicator of similarity between the i^{th} word in input sentence $\mathbf{S}'$ and the k^{th} word in associated sentence $\mathbf{A}'_j$.

Finally, we perform softmax operation on every row in M_j^{raw} to normalize the value so that it can

---

[2] In this paper, we use relaxed word moving distance (rwmd) for efficiency

[3] Here we abuse the symbol $\mathbf{S}$ and $\mathbf{A}_j$ for meaning both the word sequence $[w_i]$ and the embedded sequence $[x_i]$

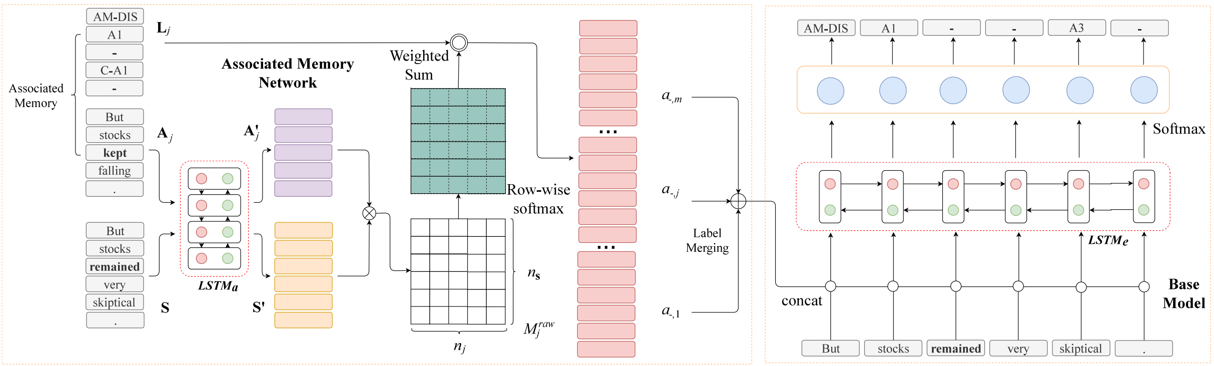

Figure 1: Semantic role labeling with associated memory network, where S is the input sentence with its length n_{S}. A_j is the j^{th} associated sentence of S with its label sequence L_j and its length n_j. S' and A'_j are the result of $LSTM_1$ with S and A_j as input respectively. d_{ae} is the dimension of argument embedding. M_j^{raw} is the raw attention matrix of A_j and S. $a_{-,j} = [a_{1,j}, a_{2,j}, ..., a_{n_{\mathrm{S}},j}]$ is the associated-sentence-specified attention embedding.

be considered as probability from input sentence $\mathbf{S}$ to associated sentence $\mathbf{A}_j$.

$$\alpha_{i,j} = f([M_j^{raw}(i,1)..., M_j^{raw}(i,n_j)])$$

$$M_j = [\alpha_{1,j}, \alpha_{2,j}, ..., \alpha_{n_{\mathbf{S}},j}]$$

where $f(\cdot)$ stands for softmax function. $\alpha_{i,j}$ can be regarded as probability vector indicating the similarity between the i^{th} word in sentence $\mathbf{S}$ and every word in the associated sentence $\mathbf{A}'_j$.

Label Merging

In order to utilize the labels $\{\mathbf{L}_j\}_{j=1}^m$ of the associated sentences during decoding, a label merging needs to be done.

We use randomly initialized argument embedding $x^{ae} \in \mathbb{R}^{d_{ae}}$ to embed each argument label. Therefore, the label sequence $\mathbf{L}_j$ of associated sentence $\mathbf{A}_j$ can be written as $\mathbf{L}_j = [x_{j,k}^{ae}]_{k=1}^{n_j}$.We treat the probability vector $\alpha_{i,j}$ as weight to sum all the elements in L_j to get the associated-sentence-specified argument embedding $a_{i,j}$, which represents the attention embedding of word $w_i \in \mathbf{S}$ calculated from the j^{th} associated sentence $\mathbf{A}_j$ and label $\mathbf{L}_j$.

$$a_{i,j} = \alpha_{i,j} \cdot \mathbf{L}_j^T = \sum_{k=1}^{n_j} \alpha_{i,j}(k) x_{j,k}^{ae}$$

Because the associated sentences are different, the overall contributions of these argument embeddings should be different. We let the model itself learn how to make use of these argument embeddings. Following attention combination mechanism from (Libovickỳ and Helcl, 2017), we consider four ways to merge the label information.

1) Concatenation All the associated argument embedding are concatenated as the final attention embeddings.

$$a_i = a_{i,1} \circ a_{i,2} \circ ... \circ a_{i,m}$$

2) Average The average value of all the associated argument embeddings is used as the final attention embedding.

$$a_i = \frac{1}{m} \sum_{j=1}^m a_{i,j}$$

3) Weighted Average The weighted average of all the associated argument embedding is used as the final attention embedding. We calculate the mean value of every raw similarity matrix M_j^{raw} to indicate the similarity between input sentence $\mathbf{S}$ and associated sentence $\mathbf{A}_j$, and we use the softmax function to normalize them to get a probability vector β indicating the similarity of input sentence $\mathbf{S}$ towards all the associated sentences $\{\mathbf{A}_j\}_{j=1}^m$.

$$\beta = f([g(M_1^{raw}), ..., g(M_m^{raw})])$$

where $f(\cdot)$ stands for softmax function and $g(\cdot)$ represents the mean function. Then, we use the probability vector β as weight to sum all the associated-sentence-specified attention embedding $a_{i,j}$ to get the final attention embedding a_i of the i^{th} word w_i in input sentence $\mathbf{S}$.

$$a_i = \sum_{j=1}^m \beta(j) a_{i,j}$$

4) Flat This method does not use $a_{i,j}$ information. First, we concatenate all the raw similarity matrix M_j^{raw} along the row.

$$M^{raw} = [M_1^{raw}, M_2^{raw}, ..., M_m^{raw}]$$

Then, we perform softmax operation on every row in M^{raw} to normalize the value so that it can be considered as probability from input sentence $\mathbf{S}$ to all associated sentences $\mathbf{A}_j$.

$$\gamma_i = f([M_{i,1}^{raw}, M_{i,2}^{raw} ..., M_{i,n_{all}}^{raw}])$$

Name	**Meaning**	**Value**
d_{re}	random word embedding	100
d_{pe}	pre-trained word embedding	100
d_{pos}	POS embedding	32
d_{le}	lemma embedding	100
d_{ce}	contextualized embedding	128
d_{pred}	flag embedding	16
d_{ae}	argument embedding	128
m	memory size	4
k_e	#$LSTM_e$ layers	2
k_a	#$LSTM_a$ layers	3
d_e	$LSTM_e$ hidden state	512
d_a	$LSTM_a$ hidden state	512
r_d	dropout rate	0.1
l_r	learning rate	0.001

Table 1: Hyper-parameter settings (signal #x means number of x).

where $f(\cdot)$ stands for softmax operation. $n_{all} = \sum_{j=1}^{m} n_j$ is the total length of all m associated sentences.

We also concatenate the associated label information, and use γ_i as weight to sum the concatenated label sequence as final attention embedding.

$$\mathbf{L} = [\mathbf{L}_1, \mathbf{L}_2, ..., \mathbf{L}_j], \quad a_i = \gamma_i \cdot \mathbf{L}^T$$

After we have the final attention embedding a_i, we concatenate it with word embedding x_i as the input of the BiLSTM encoder $LSTM_e$.

3 Experiments

We conduct experiments on CoNLL-2009 (Hajič et al., 2009) English and Chinese dataset. We use the standard training, development and test data split provided by CoNLL-2009 shared task. The word lemma, word POS are the predicted ones given in CoNLL-2009 dataset. Adam optimizer (Kingma and Ba, 2014) is used for training to minimize the categorical cross entropy loss. All the hyper-parameters we use are listed in Table 1. All parameters are learned during training, and are randomly initialized except the pre-trained GloVe (Pennington et al., 2014) word embeddings.

For English, We independently determine the best distance calculating method and the best merging method one after another. First, we select a distance according to the results on development set and then we determine the merging method with the selected distance method. At last we explore the impact of memory size. For Chinese, we obtain the result with similar parameters as for the best model in English. The English and Chinese GloVe word embeddings are both trained on Wikipedia. The pretrained English ELMo model is from (Peters et al., 2018), and the Chinese one is from (Che et al., 2018), which is hosted at (Fares et al., 2017). The model is trained for maximum 20 epochs for the nearly best model based on development set results. We re-run our model using different initialized parameters for 4 times and report the average performance[4].

of 95.01% and 95.58% on development and test sets. We compare our full model (using *edit distance* and *average method*) with the reported state-of-the-art models on both English and Chinese dataset. The results are in Tables 2, 3 and 4.

For English in-domain test, our model outperforms the syntax-agnostic model in (He et al., 2018b), whose architecture is quite similar to our base model. Our model achieves 89.6% in F_1 score, which is the same with current SOTA syntax-agnostic model (Cai et al., 2018). Besides, our result is competitive with existing syntax-aware and better than ensemble models.

The advantage is more salient on English out-of-domain test set. The F_1 score of our model is 79.7%, which is 0.7% higher than the current SOTA syntax-agnostic model (Cai et al., 2018). The result is also competitive with the best syntax-aware model (Li et al., 2018). The comparisons show that the proposed model has a greater generalization ability.

For Chinese, starting with the similar parameters as for the best model in English, we find that attending 5 associated sentences shows a better result on Chinese. Our model achieves 83.8% F_1 score, outperforming (He et al., 2018b) with an improvement of 2.0% in F_1 score. Our result is also competitive with that of (Cai et al., 2018).

Note that our method is not conflict with the one in (Cai et al., 2018), which leverages biaffine attention (Dozat and Manning, 2017) for decoding. However, due to experiment cycle, we are not able to combine these two methods together. We will leave the combination as future work.

In the following part, we conduct several ablation studies on our model. All the experiments are re-run 2-4 times and the average values are reported on CoNLL-2009 English development set.

None	88.7	86.9	87.8

Table 6: Ablations about label merging method on CoNLL-2009 English development set.

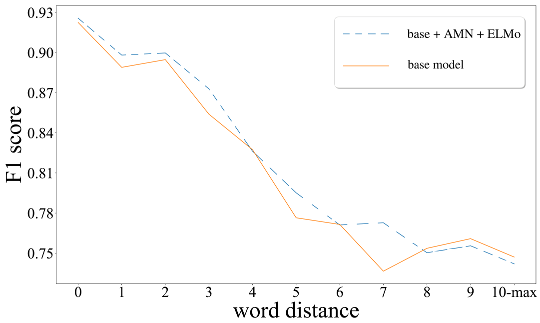

Figure 2: The comparison of our full model and base model with distance increases.

3.2 Ablation on Distance Method

Table 5 shows the performance of different distance calculating methods. All models use *average method* for label merging, and the memory size m is set to 4. It can be observed from Table 5 that edit distance performs best among all the distance calculating methods, with 88.3% F_1 score. All the distance calculating methods have surpassed the base model, showing that the proposed AMN is effective. Note that even the random distance model performs better than the base model, with an improvement of 0.3% in F_1 score, which shows that the proposed AMN can effectively extract useful information from even poorly related sentences. Besides, associated sentence selection methods based on word embeddings like WMD and SD have similar performance with random distance (RD), which shows simple word embedding may not be good enough signal indicator to measure semantic structure similarity in SRL task. On the contrary, we may also try to explain why even the random distance selection may work to some extent. As sentences always have core arguments label such as A0, A1 and A2, associated sentences even from random selection may also have such labels, which makes them helpful to enhance SRL over these labels. This may explain why our model with randomly selected associated sentences can distinguish core arguments better.

3.3 Ablation on Label Merging Method

Table 6 shows the performance of different label merging methods. All models use *edit distance* with 4 associated sentences. The result shows that *Average* label merging strategy gives the best performance, achieving 88.3% in F_1 score with an improvement of 0.5% compared to the baseline model.

Note that our weighted average model does not outperform the average model, which is a surprise to us. We speculate that the current weight calculation method needs to be more improved to fit the concerned task.

3.4 ELMo vs. AMN

Table 7 compares the performance contribution from ELMo and AMN. Our model can achieve better performance only using informative clue from training set in terms of AMN design, rather than focusing on external resource like ELMo. However, even though our baseline SRL has been enhanced by ELMo, it can still receive extra performance improvement from the propose AMN. Note that our enhancement from the proposed AMN keeps effective when ELMo is included (a 0.5% enhancement on baseline over the 0.3% enhancement on ELMo baseline)

3.5 Ablation on Memory Size

We show the effect of different memory size in Figure 3. Note that more associated sentences means more cost on time and space. We test memory size m from 2 to 6 (which reaches the limit under experiment setting in 11G GPU). We also fit the measured points with a linear function (the blue line in Figure 3). The performance of our model has a general trend of increasing when the memory size becomes larger, which shows the potential of the proposed AMN.

System (syntax-aware)	P	R	F_1
(He et al., 2018b)	86.8	85.8	86.3
(He et al., 2018b) + ELMo	87.7	87.0	87.3
(Li et al., 2018)	87.7	86.7	87.2
(Li et al., 2018) + ELMo	**89.2**	**87.6**	**88.4**
Ours (syntax-agnostic)	P	R	F_1
Base	86.9	85.0	86.0
Base + AMN	86.9	85.6	86.3
Base + ELMo	88.7	86.9	87.8
Ours + AMN + ELMo	**89.0**	**87.5**	**88.3**

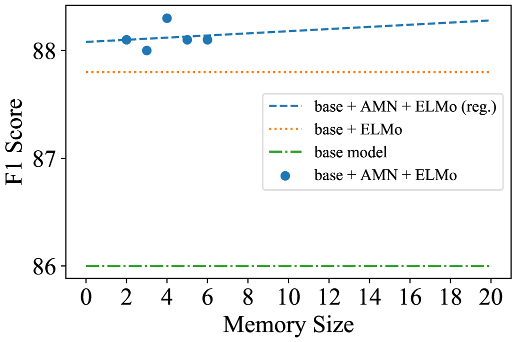

Figure 3: Model performance on English development set with different memory sizes, in which *base+AMN+ELMo* (*reg.*) indicates the general trend of our base model enhanced by the AMN when the memory size is enlarged.

3.6 Analysis on Confusion Matrix

To further understand the advance of the proposed method, we conduct an error type break down analysis. Figures 4 and 5 show the confusion matrices of labeling errors in the baseline model and our model on development set, respectively. We only show the main and most informative type of arguments. Every number in these figures stands for the times of occurrence. Comparing these two confusion matrixes shows that the proposed model makes fewer mistakes between core arguments such as $A0$, $A1$, and $A2$. AMN indeed helps when labeling them. It is also noted that, as in (He et al., 2017; Tan et al., 2018), the model still easily confuses ARG2 with AM-DIR, AM-LOC and AM-MNR.

Figure 5: Confusion matrix for labeling errors in proposed model.

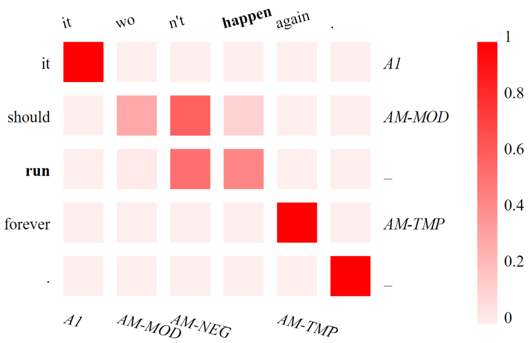

Figure 6: Visualization of similar matrix M. The input sentence is at the left of the matrix, with its golden argument label at the right. The associated sentence is at the top of the matrix, with its golden argument label at the bottom. Their predicate is bolded.

3.7 Analysis of Performance on Distance

We compare the performance concerning with the distance of argument and predicate on our best model and base model in Figure 2, from which we can observe that our model performs better nearly at any distance.

3.8 Case Study on AMN

To explore how the AMN works in the model, we visualize the similarity matrix M of some sentences from development set in Figure 6. The input sentence is

it$_{A1}$ **should**$_{AM-MOD}$ **run**$_{v}$ **forever**$_{AM-TMP}$.

And the associated sentence is

it$_{A1}$ **wo**$_{AM-MOD}$ **n't**$_{AM-NEG}$ **happen**$_{v}$ **again**$_{AM-TMP}$.

The current predicates are **run**, **happen** respectively. The visualization shows that inter-sentence attention can find and align the word in the similar context correctly, which shows that the proposed AMN is reasonable and effective.

4 Related Works

Early attempts (Pradhan et al., 2005; Zhao et al., 2009a,b, 2013; Roth and Woodsend, 2014) to the SRL task were mainly linear classifiers. The main focus was how to find proper feature templates that can best describe the sentences. (Pradhan et al., 2005) utilized a SVM classifier with rich syntactic features. (Toutanova et al., 2008) took the structural constraint into consideration by using a global reranker. (Zhao et al., 2009c) adopted a maximum entropy model with large scale feature template selection. (Roth and Woodsend, 2014) explored the distributional word representations as new feature to gain more powerful models.

Recently, a great attention has been paid on neural networks. (Zhou and Xu, 2015) proposed an end-to-end model using stacked BiLSTM network combined with CRF decoder without any syntactic input. (Marcheggiani et al., 2017) explored the predicate-specified encoding and decoding and also provided a syntax-agnostic LSTM model. (He et al., 2017) followed (Zhou and Xu, 2015) and analyzed all popular methods for initialization and regularization in LSTM network.

By considering that our approach also bor-rows power from the memory, the proposed inter-sentence attention in our AMN shares features with memory networks, which was proposed in (Weston et al., 2014) with motivation that memory may reduce the long-term forgetting issues. (Sukhbaatar et al., 2015) and (Miller et al., 2016) later further improved this work. However, we use quite different mechanisms to store the memory, and the effectiveness of our model needs a carefully designed attention mechanism to handle the sequence-level information distilling.

Attention mechanism was first used by (Bahdanau et al., 2014) in machine translation. Recently, (Tan et al., 2018) and (Strubell et al., 2018) proposed to use self-attention mechanism in SRL task. (Cai et al., 2018) leveraged the biaffine attention (Dozat and Manning, 2017) for better decoding performance. Different from all the existing work, we instead introduce an inter-sentence attention to further enhance the current state-of-the-art SRL.

5 Conclusions and Future Work

This paper presents a new alternative improvement on strong SRL baselines. We leverage memory network which seeks power from known data, the associated sentences, and thus is called associated memory network (AMN). The performance of our model on CoNLL-2009 benchmarks shows that the proposed AMN is effective on SRL task.

As to our best knowledge, this is the first attempt to use memory network in SRL task. There is still a large space to explore along this research line. For example, our weighted average method may need more carefully improved. Our model can be built over the biaffine attention which has been verified effective in (Cai et al., 2018)[5], and the encoder in our model can be improved with more advanced forms such as Transformer (Vaswani et al., 2017). At last, as this work is done on a basis of quite limited computational resources, only one piece of nVidia 1080Ti (11G graphic memory), much plentiful available computational resource will greatly enable us to explore more big model setting (i.e., larger memory size m) for more hopefully better performance improvement.

Abstract

Sequence tagging models for constituent parsing are faster, but less accurate than other types of parsers. In this work, we address the following weaknesses of such constituent parsers: (a) high error rates around closing brackets of long constituents, (b) large label sets, leading to sparsity, and (c) error propagation arising from greedy decoding. To effectively close brackets, we train a model that learns to switch between tagging schemes. To reduce sparsity, we decompose the label set and use multi-task learning to jointly learn to predict sublabels. Finally, we mitigate issues from greedy decoding through auxiliary losses and sentence-level fine-tuning with policy gradient. Combining these techniques, we clearly surpass the performance of sequence tagging constituent parsers on the English and Chinese Penn Treebanks, and reduce their parsing time even further. On the SPMRL datasets, we observe even greater improvements across the board, including a new state of the art on Basque, Hebrew, Polish and Swedish.[1]

1 Introduction

Constituent parsing is a core task in natural language processing (NLP), with a wide set of applications. Most competitive parsers are slow, however, to the extent that it is prohibitive of downstream applications in large-scale environments (Kummerfeld et al., 2012). Previous efforts to obtain speed-ups have focused on creating more efficient versions of traditional shift-reduce (Sagae and Lavie, 2006; Zhang and Clark, 2009) or chart-based parsers (Collins, 1997; Charniak, 2000). Zhu et al. (2013), for example, presented a fast shift-reduce parser with transitions learned by a SVM classifier. Similarly, Hall et al. (2014) introduced a fast GPU implementation for Petrov and Klein (2007), and Shen et al. (2018) significantly improved the speed of the Stern et al. (2017) greedy top-down algorithm, by learning to predict a list of syntactic distances that determine the order in which the sentence should be split.

In an alternative line of work, some authors have proposed new parsing paradigms that aim to both reduce the complexity of existing parsers and improve their speed. Vinyals et al. (2015) proposed a machine translation-inspired sequence-to-sequence approach to constituent parsing, where the input is the raw sentence, and the 'translation' is a parenthesized version of its tree. Gómez-Rodríguez and Vilares (2018) reduced constituent parsing to sequence tagging, where only n tagging actions need to be made, and obtained one of the fastest parsers to date. However, the performance is well below the state of the art (Dyer et al., 2016; Stern et al., 2017; Kitaev and Klein, 2018a).

Contribution We first explore different factors that prevent sequence tagging constituent parsers from obtaining better results. These include: high error rates when long constituents need to be closed, label sparsity, and error propagation arising from greedy inference. We then present the technical contributions of the work. To effectively close brackets of long constituents, we combine the relative-scale tagging scheme used by Gómez-Rodríguez and Vilares (2018) with a secondary top-down absolute-scale scheme. This makes it possible to train a model that learns how to switch between two encodings, depending on which one is more suitable at each time step. To reduce label sparsity, we recast the constituent-parsing-as-sequence-tagging problem as multi-task learning (MTL) (Caruana, 1997), to decompose a large label

---

[1] After this paper was submitted, Kitaev and Klein (2018b) have improved our results using their previous self-attentive constituent parser (Kitaev and Klein, 2018a) and BERT representations (Devlin et al., 2018) as input to their system. We will acknowledge these results in the Experiments section.

Proceedings of NAACL-HLT 2019, pages 3372–3383
Minneapolis, Minnesota, June 2 - June 7, 2019.

space and also obtain speed ups. Finally, we mitigate error propagation using two strategies that come at no cost to inference efficiency: auxiliary tasks and policy gradient fine-tuning.

2 Preliminaries

We briefly introduce preliminaries that we will build upon in the rest of this paper: encoding functions for constituent trees, sequence tagging, multi-task learning, and reinforcement learning.

Notation We use w=$[w_0, w_1, ..., w_n]$ to refer to a raw input sentence and bold style lower-cased and math style upper-cased characters to refer to vectors and matrices, respectively (e.g. $\mathbf{x}$ and $\mathbf{W}$).

2.1 Constituent Parsing as Sequence Tagging

Gómez-Rodríguez and Vilares (2018) define a linearization function of the form $\Phi_{|w|} : T_{|w|} \rightarrow L^{(|w|-1)}$ to map a phrase structure tree with $|w|$ words to a sequence of labels of length $|w| - 1$.[2] For each word w_t, the function generates a label $l_t \in L$ of the form l_t=(n_t, c_t, u_t), where:

- n_t encodes the number of ancestors in common between between w_t and w_{t+1}. To reduce the number of possible values, n_t is encoded as the relative variation in the number of common ancestors with respect to n_{t-1}.
- c_t encodes the lowest common ancestor between w_t and w_{t+1}.
- u_t contains the unary branch for w_t, if any.

Figure 1 explains the encoding with an example.

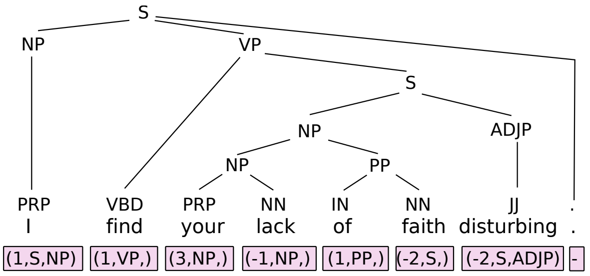

Figure 1: A constituent tree linearized as by Gómez-Rodríguez and Vilares (2018).

2.2 Sequence Tagging

Sequence tagging is a structured prediction task that generates an output label for every input token. Long short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997) are a popular architecture for such tasks, often giving state-of-the-art performance (Reimers and Gurevych, 2017; Yang and Zhang, 2018).

Tagging with LSTMs In LSTMs, the prediction for the ith element is conditioned on the output of the previous steps. Let LSTM$_\theta(\mathbf{x}_{1:n})$ be a parametrized function of the network, where the input is a sequence of vectors $\mathbf{x}_{1:n}$, its output is a sequence of hidden vectors $\mathbf{h}_{1:n}$. To obtain better contextualized hidden vectors, it is possible to instead use bidirectional LSTMS (Schuster and Paliwal, 1997). First, a LSTM$^l_\theta$ processes the tokens from left-to-right and then an independent LSTM$^r_\theta$ processes them from right-to-left. The ith final hidden vector is represented as the concatenation of both outputs, i.e. BILSTM$_\theta(\mathbf{x}, i)$ = LSTM$^l_\theta(\mathbf{x}_{[1:i]}) \circ$ LSTM$^r_\theta(\mathbf{x}_{[|\mathbf{x}|:i]})$. BILSTMs can be stacked in order to obtain richer representations. To decode the final hidden vectors into discrete labels, a standard approach is to use a feed-forward network together with a softmax transformation, i.e. $P(y|\mathbf{h}_i) = softmax(W \cdot \mathbf{h}_i + \mathbf{b})$. We will use the BILSTM-based model by Yang and Zhang (2018), for direct comparison against Gómez-Rodríguez and Vilares (2018), who use the same model. As input, we will use word embeddings, PoS-tag embeddings and a second word embedding learned by a character-based LSTM layer. The model is optimized minimizing the categorical cross-entropy loss, i.e. $\mathcal{L} = -\sum log(P(y|\mathbf{h}_i))$. The architecture is shown in Figure 2.

2.3 Multi-task Learning

Multi-task learning is used to solve multiple tasks using a single model architecture, with task-specific classifier functions from the outer-most representations (Caruana, 1997; Collobert and Weston, 2008). The benefits are intuitive: sharing a common representation for different tasks acts as a generalization mechanism and allows to address them in a parallel fashion. The *hard-sharing* strategy is the most basic MTL architecture, where the internal representation is fully shared across all tasks. The approach has proven robust for a number of NLP tasks (Bingel and Søgaard, 2017) and comes with certain guarantees if a common, op-

---

[2] They (1) generate a dummy label for the last word and (2) pad sentences with a beginning- and end-of-sentence tokens.

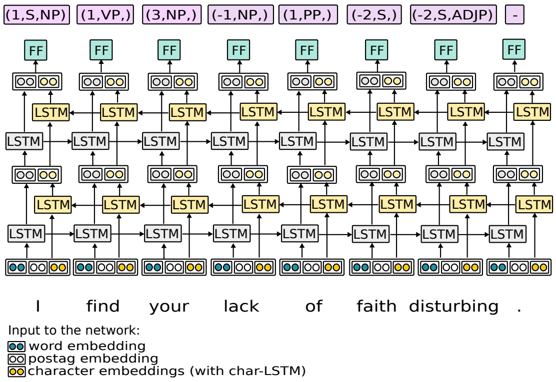

Figure 2: The baseline architecture used in this work. The input to the network is a concatenation of word embeddings, PoS-tag embeddings and a second word embedding learned by a character-based LSTM layer.

timal representation exists (Baxter, 2000). Dong et al. (2015) use it for their multilingual machine translation system, where the encoder is a shared gated recurrent neural network (Cho et al., 2014) and the decoder is language-specific. Plank et al. (2016) also use a hard-sharing setup to improve the performance of BILSTM-based PoS taggers. To do so, they rely on *auxiliary tasks*, i.e, tasks that are not of interest themselves, but that are co-learned in a MTL setup with the goal of improving the network's performance on the main task(s). We will introduce auxiliary tasks for sequence tagging constituent parsing later on in this work. A MTL architecture can also rely on *partial sharing* when the different tasks do not fully share the internal representations (Duong et al., 2015; Rei, 2017; Ruder et al., 2019) and recent work has also shown that hierarchical sharing (e.g. low-level task outputs used as input for higher-level ones) could be beneficial (Søgaard and Goldberg, 2016; Sanh et al., 2018).

2.4 Policy Gradient Fine-tuning

Policy gradient (PG) methods are a class of reinforcement learning algorithms that directly learn a parametrized policy, by which an agent selects actions based on the gradient of a scalar performance measure with respect to the policy. Compared to other reinforcement learning methods, PG is well-suited to NLP problems due to its appealing convergence properties and effectiveness in high-dimensional spaces (Sutton and Barto, 2018).

Previous work on constituent parsing has employed PG methods to mitigate the effect of exposure bias, finding that they function as a model-agnostic substitute for dynamic oracles (Fried and Klein, 2018). Similarly, Le and Fokkens (2017) apply PG methods to Chen and Manning (2014)'s transition-based dependency parser to reduce error propagation. In this work, we also employ PG to fine-tune models trained using supervised learning. However, our setting (sequence tagging) has a considerably larger action space than a transition parser. To deal with that, we will adopt a number of variance reduction and regularization techniques to make reinforcement learning stable.

3 Methods

We describe the methods introduced in this work, motivated by current limitations of existing sequence tagging models, which are first reviewed. The source code can be found as a part of `https://github.com/aghie/tree2labels`.

3.1 Motivation and Analysis

For brevity, we limit this analysis to the English Penn Treebank (PTB) (Marcus et al., 1993). We reproduced the best setup by Gómez-Rodríguez and Vilares (2018), which we are using as baseline, and run the model on the development set. We below show insights for the elements of the output tuple (n_t, c_t, u_t), where n_t is the number of levels in common between w_t and w_{t+1}, c_t is the non-terminal symbol shared at that level, and u_t is a leaf unary chain located at w_t.

High error rate on closing brackets We first focus on predicting relative tree levels (n_t). See Figure 3 for F-scores over n_t labels. The sparsity on negative n_ts is larger than for the positive ones, and we see that consequently, the performance is also significantly worse for negative n_t values, and performance worsens with higher negative values. This indicates that the current model cannot effectively identify the end of long constituents. This is a known source of error for shift-reduce or chart-based parsers, but in the case of sequence tagging parsers, the problem seems particularly serious.

Sparsity The label space is large and sparse: the output labels are simply the possible values in the tuple (n_t, c_t, u_t). An analysis over the PTB training set shows a total of 1423 labels, with 58% of them occurring 5 or less times. These infrequent cases might be difficult to predict, even if some of the elements of the tuple are common.

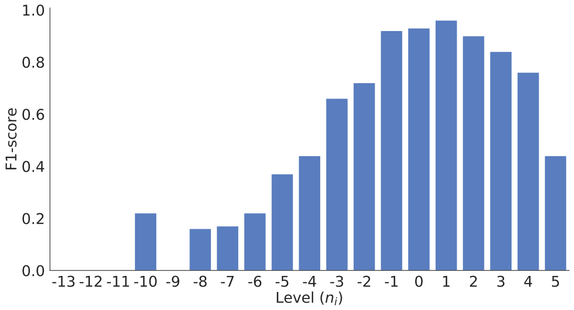

Figure 3: F-score for n_t labels on the PTB dev set using Gómez-Rodríguez and Vilares (2018).

Greedy decoding Greedy decoding is prone to issues such as error propagation. This is a known source of error in transition-based dependency parsing (Qi and Manning, 2017); in contrast with graph-based parsing, in which parsing is reduced to global optimization over edge-factored scores (McDonald et al., 2005).

In the case of BILSTM-based sequence tagging parsers, for a given word w_t, the output label as encoded by Gómez-Rodríguez and Vilares (2018) only reflects a relation between w_t and w_{t+1}. We hypothesize that even if the hidden vector representations are globally contextualized over the whole sequence, the intrinsic locality of the output label also turns into error propagation and consequently causes a drop in the performance. These hypotheses will be tested in §4. In particular, we will evaluate the impact of the different methods intended to perform structured inference (§3.4).

3.2 Dynamic Encodings

Gómez-Rodríguez and Vilares (2018) encode the number of common ancestors n_t, from the output tuple (n_t, c_t, u_t), as the variation with respect to n_{t-1}. We propose instead to encode certain elements of a sentence using a secondary linearization function. The aim is to generate a model that can dynamically switch between different tagging schemes at each time step t to select the one that represents the relation between w_t and w_{t+1} in the most effective way.

On the one hand, the relative-scale encoding is effective to predict the beginning and the end of short constituents, i.e. when a short constituent must be predicted ($|n_t| \leq 2$). On the other hand, with a relative encoding scheme, the F-score was low for words where the corresponding n_t has a large negative value (as showed in Figure 3). This matches a case where a long constituent must be closed: w_t is located at a deep level in the tree and will only (probably) share a few ancestors with w_{t+1}. These configurations are encoded in a more sparse way by a relative scheme, as the n_t value shows a large variability and it depends on the depth of the tree in the current time step. We can obtain a compressed representation of these cases by using a *top-down absolute scale* instead, as any pair of words that share the same m top levels will be equally encoded. The absolute scale becomes however sparse when predicting deep levels. Figure 4 illustrates the strengths and weaknesses of both encodings with an example, and how a dynamically encoded tree helps reduce variability on n_t values.

In our particular implementation, we will be using the following setup:

- $\Phi_{|w|} : T_{|w|} \rightarrow L^{|w|-1}$, the relative-scale encoding function, is used by default.
- $\Omega_{|w|} : T_{|w|} \rightarrow L'^{|w|-1}$ is the secondary linearization function that maps words to labels according to a top-down absolute scale. Ω is used iff: (1) $\Omega(w_{[t:t+1]}) = (n'_t, c'_t, u'_t)$ with $n'_t \leq 3$, i.e. w_t and w_{t+1} share at most the three top levels, and (2) $\Phi(w_{[t:t+1]}) = (n_t, c_t, u_t)$ with $n_t \leq -2$, i.e. w_t is at least located two levels deeper in the tree than w_{t+1}.[3]

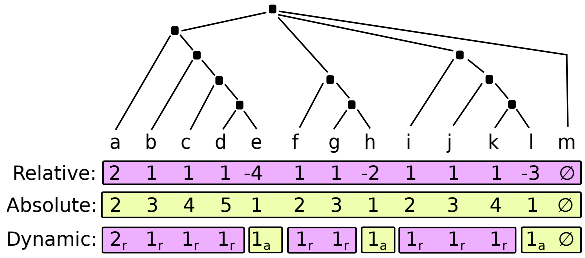

Figure 4: A synthetic constituent tree where n_t is encoded using a relative scheme, a top-down absolute scale, and an ideal dynamic combination. The relative scheme is appropriate to open and close short constituents, but becomes sparse when encoding the large ones, e.g. n_t for the tokens 'e', 'h' and 'l'. The opposite problem is observed for the top-down absolute scheme (e.g. tokens from 'a' to 'd'). The dynamic linearization combines the best of both encodings (we use the subscript 'r' to denote the labels coming from the relative encoding, and 'a' from the absolute one).

---

[3] The values were selected based on the preliminary experiments of Figure 3.

3.3 Decomposition of the label space

We showed that labels of the form $(n_t, c_t, u_t) \in L$ are sparse. An intuitive approach is to decompose the label space into three smaller sub-spaces, such that $n_i \in N$, $c_i \in C$ and $u_i \in U$. This reduces the output space from potentially $|N| \times |C| \times |U|$ labels to just $|N| + |C| + |U|$. We propose to learn this decomposed label space through a multi-task learning setup, where each of the subspaces is considered a different task, namely task$_N$, task$_C$ and task$_U$. The final loss is now computed as $\mathcal{L} = \mathcal{L}_n + \mathcal{L}_c + \mathcal{L}_u$.

We relied on a hard-sharing architecture, as it has been proved to reduce the risk of overfitting the shared parameters (Baxter, 1997). A natural issue that arises is that the prediction of labels from different label sub-spaces could be interdependent to a certain extent, and therefore a hierarchical sharing architecture could also be appropriate. To test this, in preliminary experiments we considered variants of hierarchical sharing architectures. We fed the output of the task$_U$ as input to task$_N$ and/or task$_C$. Similarly, we tested whether it was beneficial to feed the output of task$_N$ into task$_C$, and viceversa. However, all these results did not improve those of the hard-sharing model. In this context, in addition to a generalization mechanism, the shared representation could be also acting as way to keep the model aware of the potential interdependencies that might exist between subtasks.

3.4 Mitigating Effects of Greedy Decoding

We propose two ways to mitigate error propagation arising from greedy decoding in constituent parsing as sequence tagging: auxiliary tasks and policy gradient fine-tuning. Note that we want to optimize bracketing F-score *and* speed. For this reason we do *not* explore approaches that come at a speed cost in testing time, such as beam-search or using conditional random fields (Lafferty et al., 2001) on top of our LSTM.

Auxiliary tasks Auxiliary tasks force the model to take into account patterns in the input space that can be useful to solve the main task(s), but that remain ignored due to a number of factors, such as the distribution of the output label space (Rei, 2017). In a similar fashion, we use auxiliary tasks as a way to force the parser to pay attention to aspects beyond those needed for greedy decoding. We propose and evaluate two separate strategies:

1. Predict partial labels n_{t+k} that are k steps from the current time step t. This way we can jointly optimize at each time step a prediction for the pairs $(w_t, w_{t+1}), \ldots, (w_{t+k}, w_{t+k+1})$. In particular, we will experiment both with previous and upcoming n_k's, setting $|k|$=1.

2. Predict the syntactic distances presented by Shen et al. (2018), which reflect the order a sentence must be split to obtain its constituent tree using a top-down parsing algorithm (Stern et al., 2017). The algorithm was initially defined for binary trees, but its adaptation to *n*-ary trees is immediate: leaf nodes have a split priority of zero and the ancestors' priority is computed as the maximum priority of their children plus one. In this work, we use this algorithm in a sequence tagging setup: the label assigned to each token corresponds to the syntactic distance of the lowest common ancestor with the next token. This is illustrated in Figure 5.

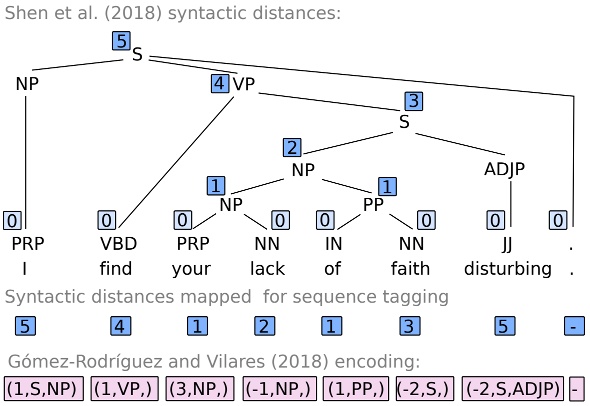

Figure 5: A constituent with syntactic distances attached to each non-terminal symbol, according to Shen et al. (2018). Distances can be used for sequence tagging, providing additional information to our base encoding (Gómez-Rodríguez and Vilares, 2018)

The proposed auxiliary tasks provide different types of contextual information. On the one hand, the encoding of the n_ts by Gómez-Rodríguez and Vilares (2018) only needs to know about w_t and w_{t+1} paths to generate the label for the time step t. On the other hand, to compute the syntactic distance of a given non-terminal symbol, we need to compute the syntactic distances of its subtree, providing a more global, but also sparser context. For training, the loss coming from the auxiliary task(s) is weighted by β=0.1, i.e, the final loss is computed as $\mathcal{L} = \mathcal{L}_n + \mathcal{L}_c + \mathcal{L}_u + \beta \sum_a \mathcal{L}_a$.

Policy gradient fine-tuning Policy gradient training methods allow us to fine-tune our models with a tree-level objective, optimizing directly for bracketing F-score. We start off with a converged supervised model as our initial policy. The sequence labeling model can be seen as a functional approximation of the policy π parametrized by θ, which at timestep t selects a label l_t=(n_t, c_t, u_t)[4] given the current state of the model's parameters, s_t. The agent's reward, R_{tree}, is then derived from the bracketing F-score. This can be seen as a variant of the REINFORCE algorithm (Williams, 1992) where the policy is updated by gradient ascent in the direction of:

$$\Delta_\theta log\pi(l_t|s_t;\theta)R_{tree} \quad (1)$$

Baseline and Variance Reduction We use as baseline a copy of a pre-trained model where the parameters are frozen. The reward used to scale the policy gradient can then be seen as an estimate of the advantage of an action l_t in state s_t over the baseline model. This is equivalent to $R_{tree}-B_{tree}$, where R_{tree} is the bracketing F-score of a sequence sampled from the current policy and B_{tree} is the the tree-level F-score of the sequence greedily predicted by the baseline. To further reduce the variance, we standardize the gradient estimate Δ_θ using its running mean and standard deviation for all candidates seen in training so far. In initial experiments without these augmentations, we observed that fine-tuning with vanilla PG often led to a deterioration in performance. To encourage exploration away from the converged supervised model's policy, we add the entropy of the policy to the objective function (Williams and Peng, 1991). Moreover, following Lillicrap et al. (2015), we optionally add noise sampled from a noise process N to the policy. The gradient of our full fine-tuning objective function takes the following form:

$$\begin{aligned}\Delta_\theta(log\pi(l_t|s_t;\theta) + N)(R_{tree} - B_{tree})\\ + \beta\Delta_\theta H(\pi(s_t;\theta) + N) \quad (2)\end{aligned}$$

where H is the entropy and β controls the strength of the entropy regularization term.

4 Experiments

We now review the impact of the proposed techniques on a wide variety of settings.

Datasets We use the English Penn Treebank (PTB) (Marcus et al., 1993) and the Chinese Penn Treebank (CTB) (Xue et al., 2005). For these, we use the same predicted PoS tags as Dyer et al. (2016). We also provide detailed results on the SPMRL treebanks (Seddah et al., 2014),[5] a set of datasets for constituent parsing on morphologically rich languages. For these, we use the predicted PoS tags provided together with the corpora. To the best of our knowledge, we provide the first evaluation on the SPMRL datasets for sequence tagging constituent parsers.

Metrics We report bracketing F-scores, using the EVALB and the EVAL-SPMRL scripts. We measure the speed in terms of sentences per second.

Setup We use NCRFpp (Yang and Zhang, 2018), for direct comparison against Gómez-Rodríguez and Vilares (2018). We adopt bracketing F-score instead of label accuracy for model selection and report this performance as our second baseline. After 100 epochs, we select the model that fared best on the development set. We use GloVe embeddings (Pennington et al., 2014) for our English models and `zzgiga` embeddings (Liu and Zhang, 2017) for the Chinese models, for a more homogeneous comparison against other parsers (Dyer et al., 2016; Liu and Zhang, 2017; Fernández-González and Gómez-Rodríguez, 2018). ELMo (Peters et al., 2018) or BERT (Devlin et al., 2018) could be used to improve the precision, but in this paper we focus on keeping a good speed-accuracy tradeoff. For SPMRL, no pretrained embeddings are used, following Kitaev and Klein (2018a). As a side note, if we wanted to improve the performance on these languages we could rely on the CoNLL 2018 shared task pretrained word embeddings (Zeman et al., 2018) or even the multilingual BERT model[6]. Our models are run on a single CPU[7] (and optionally on a consumer-grade GPU for further comparison) using a batch size of 128 for testing. Additional hyperparameters can be found in Appendix A.

4.1 Results

Table 1 contrasts the performance of our models against the baseline on the PTB development set.

Model	F-score	(+/-)	Sents/s
Gómez and Vilares (2018)	89.70	-	109
Our baseline	89.77	(+0.07)	111
+ DE	90.22	(+0.52)	111
+ MTL	90.38	(+0.68)	130
aux(n_{t+1})	90.41	(+0.71)	130
aux(n_{t-1})	90.57	(+0.87)	130
aux(distances)	90.55	(+0.85)	130
+ PG	**90.70**	(+1.00)	130

Table 1: Results on the PTB dev set, compared against Gómez-Rodríguez and Vilares (2018). DE refers to dynamic encoding and MTL to a model that additionally casts the problem as multi-task learning. Each auxiliary task is added separately to the baseline with DE and MTL. Policy gradient fine-tunes the model that includes the best auxiliary task.

To show that the model which employs dynamic encoding is better (+0.52) than the baseline when it comes to closing brackets from long constituents, we compare their F-scores in Figure 6. When we recast the constituent-parsing-as-sequence-tagging problem as multi-task learning, we obtain both a higher bracketing F-score (+0.68) and speed (1.17x faster). Fusing strategies to mitigate issues from greedy decoding also leads to better models (up to +0.87 when adding an auxiliary task[8] and up to +1.00 if we also fine-tune with PG). Note that including auxiliary tasks and PG come at a time cost in training, but not in testing, which makes them suitable for fast parsing.

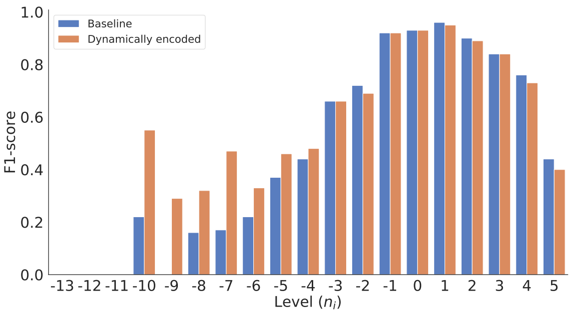

Figure 6: F-score for n_ts on the PTB dev set, obtained by the Gómez-Rodríguez and Vilares (2018) baseline (in blue, first bar for each n_t, already shown in Figure 3) and our model with dynamically encoded trees (in orange, second bar).

Table 2 replicates the experiments on the CTB and the SPMRL dev sets. The dynamic encoding improves the performance of the baseline on large treebanks, e.g. German, French or Korean, but causes some drops in the smaller ones, e.g. Swedish or Hebrew. Overall, casting the problem as multitask learning and the strategies used to mitigate error propagation lead to improvements.

For the experiments on the test sets we select the models that summarize our contributions: the models with dynamic encoding and the multi-task setup, the models including the best auxiliary task, and the models fine-tuned with policy gradient.

Tables 3, 4 and 5 compare our parsers against the state of the art on the PTB, CTB and SPMRL test sets. Gómez-Rodríguez and Vilares (2018) also run experiments without character embeddings, to improve speed without suffering from a big drop in performance. For further comparison, we also include them as additional results (shadowed). In a related line, Smith et al. (2018) show that for dependency parsing two out of three embeddings (word, postag and characters) can suffice.

4.2 Discussion

The results across the board show that the dynamic encoding has a positive effect on 6 out of 10 treebanks. Casting the constituent-parsing-as-sequence-labeling problem as MTL surpasses the baseline for all tested treebanks (and it leads to better parsing speeds too). Finally, by mitigating issues from greedy decoding we further improve the performance of all models that include dynamic encodings and multi-task learning.

On the PTB, our models are both faster and more accurate than existing sequence tagging or sequence-to-sequence models, which already were among the fastest parsers (Gómez-Rodríguez and Vilares, 2018; Vinyals et al., 2015). We also outperform other approaches that were not surpassed by the original sequence tagging models in terms of F-score (Zhu et al., 2013; Fernández-González and Martins, 2015). On the CTB our techniques also have a positive effect. The baseline parses 70 sents/s on the CTB, while the full model processes up to 120. The speed up is expected to be larger than the one obtained for the PTB because the size of the label set for the baseline is bigger, and it is reduced in a greater proportion when the constituent-parsing-as-sequence-labeling problem is cast as MTL.

On the SPMRL corpora, we provide the first evaluation of sequence labeling constituent parsers, to verify if these perform well on mor-

---

[8] We observed that adding more than one auxiliary task did not translate into a clear improvement. We therefore chose the auxiliary task that performed the best in the development set.

phologically rich languages. We then evaluated whether the proposed techniques can generalize on heterogeneous settings. The tendency observed for the original tagging models by Gómez-Rodríguez and Vilares (2018) is similar to the one for the PTB and CTB: they improve other fast parsers, e.g. Coavoux and Crabbé (2016), in 5 out of 8 treebanks and Fernández-González and Martins (2015) in 7 out of 8, but their performance is below more powerful models. When incorporating the techniques presented in this work, we outperform the original sequence tagging models on all datasets. We outperform the current best model for Basque, Hebrew and Polish (Kitaev and Klein, 2018a) and for Swedish (Björkelund et al., 2014), which corresponds to the four smallest treebanks among the SPMRL datasets. This indicates that even if sequence tagging models are conceptually simple and fast, they can be very suitable when little training data is available. This is also of special interest in terms of research for low-resource languages. Again, casting the problem as MTL reduces the parsing time for all tested treebanks, as reflected in Table 6. Finally, for treebanks such as French, designing methods to handle multi-word expressions could lead to better results, getting closer to other parsers (Coavoux and Crabbé, 2017).

5 Conclusion

We have explored faster and more precise sequence tagging models for constituent parsing. We proposed a multitask-learning architecture that employs dynamic encodings, auxiliary tasks, and policy gradient fine-tuning. We performed experiments on the English and Chinese Penn Treebanks, and also on the SPMRL datasets. Our models improve current sequence tagging parsers on all treebanks, both in terms of performance and speed. We also report state-of-the-art results for the Basque, Hebrew, Polish, and Swedish datasets. The methods presented in this work are specifically designed for constituent parsing. However, it seems natural to apply some of these to other NLP tagging tasks, e.g. using multi-task learning to predict sub-level morphological information for morphologically-rich part-of-speech tagging.

Abstract

Named entity recognition (NER) is a common task in Natural Language Processing (NLP), but it remains more challenging in Chinese because of its lack of natural delimiters. Therefore, Chinese Word Segmentation (CWS) is usually necessary as the first step for Chinese NER. However, models based on word-level embeddings and lexicon features often suffer from segmentation errors and out-of-vocabulary (OOV) problems. In this paper, we investigate a **C**onvolutional **A**ttention **N**etwork (**CAN**) for Chinese NER, which consists of a character-based convolutional neural network (CNN) with local-attention layer and a gated recurrent unit (GRU) with global self-attention layer to capture the information from adjacent characters and sentence contexts. Moreover, differently from other approaches, CAN-NER does not depend on any external resources like lexicons and employing small-size char embeddings makes CAN-NER more practical for real systems scenarios. Extensive experimental results show that our approach outperforms state-of-the-art methods without word embedding and external lexicon resources on different domains datasets.

1 Introduction

Named Entity Recognition (NER) aims at identifying text spans which are associated with a specific semantic entity type such as person (PER), organization (ORG), location (LOC), and geopolitical entity (GPE). NER has received constant research attention as it is the first step in a wide range of downstream Natural Language Processing (NLP) tasks, e.g., entity linking (Gupta et al., 2017), relation extraction (Miwa and Bansal, 2016), event extraction (Chen et al., 2015), and coreference resolution (Fragkou, 2017). The standard approach in existing state-of-the-art models for English NER treats the problem as a word-by-word sequence labeling task and makes full use of the Recurrent Neural Network (RNN) and Conditional Random Field (CRF) to capture context information at the word level (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Liu et al., 2018). These models for English NER predict a tag for each word assuming that words can be separated clearly by explicit word separators, e.g., blank spaces. As the Chinese language has no natural delimiters, it would be intuitive to apply Chinese Word Segmentation (CWS) first to get word boundaries and then use a word-level sequence labeling model similar to the English NER models. However, word boundaries can be ambiguous in Chinese, which leads to the possibility that entity boundaries do not match word boundaries. For example, the term “西藏自治区 (Tibet Autonomous Region)” is a GPE-type entity in NER, but it could be segmented as a single word or as two words “西藏 (Tibet)” and “自治区 (autonomous region)” separately, depending on different granularity of segmentation tools. Most of the time, however, it is hard to determine the correct granularity for word segmentation. Also, as shown in Figure 1, different segmentation can lead to different sentence meanings in Chinese, which could even result in different named entities. Obviously, if entity boundaries are

Sentence:
南京市长江大桥

Segmentation 1:
南京市 | 长江大桥
Nanjing City, Yangtze River Bridge
Location, Location

Segmentation 2:
南京 | 市长 | 江大桥
Nanjing, Mayor, Jiang Daqiao
Location, Title, Person

Minneapolis, Minnesota, June 2 - June 7, 2019.

mistakenly detected in segmentation, it will negatively affect entity tagging in word-based NER models. Furthermore, most recent neural network-based Chinese NER models rely heavily on word-level embeddings and external lexicon sets (Huang et al., 2017; Zhang and Yang, 2018). The quality of such models strongly relies on the different word embedding representations and lexicon features. Moreover, word-based models tend to suffer from OOV issues as Chinese words can be very diverse and named entities are an important source of OOV words. Other potential limitations are as follows: (1) Dependency on word embeddings increases model size and makes the fine-tuning process more costly during training (while negatively affecting latency in testing/decoding); (2) It is hard to learn word representation correctly without enough labeled utterances for named entities are usually rarer proper nouns. (3) Large lexicons are very costly for real NER systems as they greatly increase memory usage and latency in feature extraction (matching), which makes models inefficient; (4) It is very costly to remove noise from large lexicons and any update to pre-trained word embeddings or lexicons requires model retraining. Meanwhile, character-level embedding by itself can only carry limited information due to losing word and word-sequence information. For instance, the character “拍” in words “球拍” (bat) and “拍卖” (auction) has very different meanings. How to better integrate segmentation-related information and exploit local context information is the key feature in a character-based model. Zhang and Yang (2018) leverage lexicons to add all the embeddings of candidate word segmentation to their last character embeddings as soft features, and construct a convolutional neural network (CNN) to encode characters as word-level information. Cao et al. (2018) propose a multi-task architecture to learn NER tagging and Chinese word segmentation together, with each part using a character-based Bi-LSTM. In this paper, we propose a convolutional attention layer to capture the implicit relations within adjacent characters, in which the position features from word segmentation are soft hints for character combinations. With the segmentation vector softly concatenating into character embedding, the convolutional attention layer is able to group implicitly meaning-related characters and help bypass the impact of segmentation errors. A BiGRU structure with a global self-attention layer on the whole sentence is utilized to capture sentence-level dependencies. Extensive experimental results show that our approach outperforms state-of-the-art methods without relying on external resources (e.g. word embedding, external lexicon) across different corpora. The main contributions of this paper can be summarized as follows:

- We first combine CNNs with the local-attention mechanism to enhance the ability of the model to capture implicitly local context relations among character sequences. Compared with experimental results against a baseline with a regular CNN layer, our Convolutional Attention layer leads to substantial performance improvements.

- We introduce a character-based Chinese NER model that consists of combined CNN with local attention and BiGRU with global self-attention layers. Our model achieves state-of-the-art F1-scores without using any external resources like word embeddings and lexicon resources, which make it very practical for real-world NER systems.

2 Methodology

We utilize BiGRU-CRF as our basic model structure. Our model considers multi-level context features in three layers: i) convolutional attention layer, ii) GRU layer, and iii) global attention layer. The whole architecture of our proposed model is illustrated in Figure 2.

2.1 Formulation

In the Chinese NER task, we denote an input sentence as $\mathbf{X}_i = \{x_{i,1}, x_{i,2}, x_{i,3}, ..., x_{i,\tau}\}$, where $x_{i,\tau} \in \mathbb{R}^{d_e}$ represents the τ-th character in sentence $\mathbf{X}_i$ and d_e is the dimension of the input embeddings. Correspondingly, we denote the sentence label sequence as $\mathbf{Y}_i = \{y_{i,1}, y_{i,2}, y_{i,3}, ..., y_{i,\tau}\}$, where $y_{i,\tau} \in \mathcal{Y}$ belongs to the set of all possible labels. The objective is learning a function $f_\theta : \mathbf{X} \mapsto \mathbf{Y}$ to obtain the entity types including the ‘O’ type for all the characters in the input text. In the following text, we take one instance as the example and therefore omit subindex i in the formula.

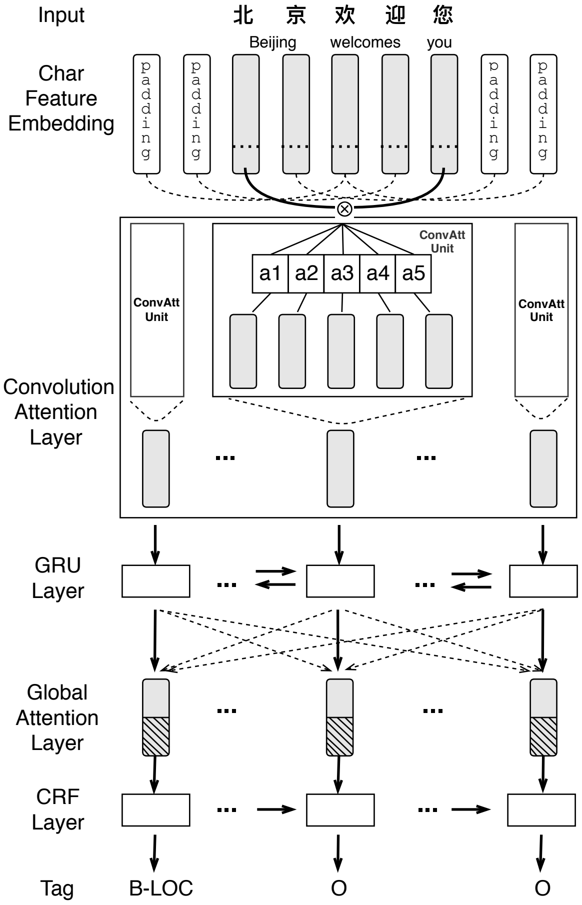

Figure 2: Overall model architecture. A convolutional attention layer is constructed to encode both character- and word-level information. The BiGRU-CRF layer is extended by a global self-attention layer to capture long sequential sentence-level relations.

2.2 Convolutional Attention Layer

The convolutional attention layer aims to encode the sequence of input characters and implicitly group meaning-related characters in the local context. The input representation for each character is constructed as $x = [x_{ch}; x_{seg}]$, where $x_{ch} \in \mathbb{R}^{d_{ch}}$ and $x_{seg} \in \mathbb{R}^{d_{seg}}$ are character embedding and segmentation mask, respectively. The segmentation information is encoded by BMES scheme (Wang and Xu, 2017).

For every window in the CNN, whose window size is k, we first concatenate a position embedding to each character embedding, helping to keep sequential relations in the local window context. The dimension of the position embedding equals to the window size k with the initial values of 1 at the position where the character lies in the window and 0 at other positions. So, the dimension of the concatenated embedding is $d_e = d_{ch} + d_{pos} + d_{seg}$. We then apply local attention inside the window to capture the relations between the center character and each context token, followed by a CNN with sum-pooling layer. We set the hidden dimension as d_h. For the j-th character, the local attention takes all the concatenated embeddings $x_{j-\frac{k-1}{2}}, ...x_j, ..., x_{j+\frac{k-1}{2}}$ in the window as its input and outputs k hidden vectors $h_{j-\frac{k-1}{2}}, ..., h_j, ..., h_{j+\frac{k-1}{2}}$. The hidden vectors are calculated as follows:

$$h_m = \alpha_m x_m, \tag{1}$$

where $m \in \{j - \frac{k-1}{2}, ..., j + \frac{k-1}{2}\}$ and α_m is the attention weight, which is calculated as:

$$\alpha_m = \frac{\exp s(x_j, x_m)}{\sum_{n \in \{j-\frac{k-1}{2}, ..., j+\frac{k-1}{2}\}} \exp s(x_j, x_n)}. \tag{2}$$

The score function s is defined as follows:

$$s(x_j, x_k) = v^\top \tanh(W_1 x_j + W_2 x_k), \tag{3}$$

where $v \in \mathbb{R}^{d_h}$ and $W_1, W_2 \in \mathbb{R}^{d_h, d_e}$.

The CNN layer contains d_h kernels on a context window of k tokens as:

$$h_j^c = \sum_k [W^c * h_{j-\frac{k-1}{2}:j+\frac{k-1}{2}} + b^c], \tag{4}$$

where $W^c \in \mathbb{R}^{k \times d_h \times d_e}$ and $b^c \in \mathbb{R}^{k \times d_h}$. The $*$ operation denotes element-wise product and $h_{j-\frac{k-1}{2}:j+\frac{k-1}{2}}$ means a concatenation of the hidden states $h_{j-\frac{k-1}{2}}, ..., h_{j+\frac{k-1}{2}}$, both of which are calculated at the first dimension. Finally sum-pooling is also conducted on the first dimension.

2.3 BiGRU-CRF with Global Attention

After extracting the local context features by the convolutional attention layer, we feed them into a BiGRU-CRF based model to predict final label for each character. This layer models the sequential sentence information and it is calculated as follows:

$$h_j^r = \text{BiGRU}(h_{j-1}^r, h_j^c; W^r, U^r), \tag{5}$$

where h_j^c is the output of the convolutional attention layer, h_{j-1}^r is the previous hidden state for the BiGRU layer, and $W^r, U^r \in \mathbb{R}^{d_h \times d_h}$ are its parameters.

A global self-attention layer is utilized to better handle sentence-level information, as:

$$h_j^g = \sum_{s=1}^{n} \alpha_{j,s}^g h_s^r \tag{6}$$

where $j = 1, ..., \tau$ denotes all characters in a sentence instance and $\alpha^g_{j,s}$ is calculated as:

$$\alpha^g_{j,s} = \frac{\exp s(h^r_j, h^r_s)}{\sum_{n \in \{1,...,\tau\}} \exp s(h^r_j, h^r_n)}. \tag{7}$$

The score function s is similar to Equation 3 with different parameters $v^g \in \mathbb{R}^{d_h}$ and $W^g_1, W^g_2 \in \mathbb{R}^{d_h, d_h}$ instead.

Finally, a standard CRF layer is used at the top of the concatenation of the output of the BiGRU and global attention layers, which is denoted as $H_\tau = [h^r_\tau; h^g_\tau]$. Given the predicted tag sequence $\mathbf{Y} = \{y_1, y_2, y_3, ..., y_\tau\}$, the probability of the ground-truth label sequence is computed by:

$$P(\mathbf{Y}|\mathbf{X}) = \frac{exp(\sum_i(\mathbf{W}^{y_i}_{\text{CRF}} H_i + b^{(y_{i-1},y_i)}_{\text{CRF}}))}{\sum_{y'} exp(\sum_i(\mathbf{W}^{y'_i}_{\text{CRF}} H_i + b^{(y'_{i-1},y'_i)}_{\text{CRF}}))}, \tag{8}$$

where y' denotes an arbitrary label sequence, $\mathbf{W}^{y_i}_{\text{CRF}}$ and $b^{(y_{i-1},y_i)}_{\text{CRF}}$ are trainable parameters. In decoding, we use the Viterbi algorithm to get the predicted tag sequence.

2.4 Training

For training, we exploit log-likelihood objective as the loss function. Given a set of training examples $\{(\mathbf{X}_i, \mathbf{Y}_i)\}|^K_{i=1}$, the loss function L can be defined as follows:

$$L = \sum_{i=1}^{K} logP(\mathbf{Y}_i|\mathbf{X}_i) \tag{9}$$

In the training phase, at each iteration, we first shuffle all the training instances, and then feed them to the model with batch updates. We use the AdaDelta (Zeiler, 2012) algorithm to optimize the final objective with all the parameters as described in Section 3.1.

Dataset	Type	Train	Test	Dev

3 Experiments

To demonstrate the effectiveness of our proposed model, we have run multiple experiments on Chinese NER datasets covering different domains. This section describes the details of each dataset, settings, and results in our experiments. Standard precision (P), recall (R) and F1-score (F1) are used as evaluation metrics.

3.1 Experimental Settings

Data We use four datasets in our experiments. For the news domain, we experiment on OntoNotes 4 (Weischedel et al., 2011) and MSRA NER dataset from SIGHAN Bakeoff 2006 (Levow, 2006). For the social media domain, we adopt the same annotated Weibo corpus as Peng and Dredze (2015) which is extracted from Sina Weibo[1]. For more variety in test domains, we also use a Chinese Resume dataset (Zhang and Yang, 2018) collected from Sina Finance[2].

The Weibo dataset is annotated with four entity types: PER (Person), ORG (Organization), LOC (Location), and GPE (Geo-Political Entity); and it includes both named and nominal mentions. This corpus is already divided into training, development, and test sets. The Chinese Resume dataset is annotated with eight types of named entities: CONT (Country), EDU (Educational Institution), LOC, PER, ORG, PRO (Profession), RACE (Ethnicity/Background), and TITLE (Job Title). OntoNotes 4 is annotated with four named entity categories: PER, ORG, LOC, and GPE. We follow the same data split method of Che et al. (2013) over OntoNotes 4. Lastly, the MSRA 2006 dataset contains three annotated named entities: ORG, PER and LOC. A development subset is

Models	NE	NM	Overall
Peng and Dredze (2015)	51.96	61.05	56.05
Peng and Dredze (2016)*	55.28	62.97	58.99
He and Sun (2017a)	50.60	59.32	54.82

CAN-NER Model	**55.38**	**62.98**	**59.31**

Table 2: Weibo NER results

---

[1] http://www.weibo.com/

[2] http://finance.sina.com.cn/stock/index.html

not available for the MSRA dataset. The detailed statistics of each datasets are shown in Table 1.

Gold segmentation is unavailable for Weibo, Chinese Resume, and MSRA test sections. We follow Zhang and Yang (2018) to automatically segment these by using the model described in Yang et al. (2017). We treat NER as a sequential labeling problem and adopt the BIOES tagging style since it has been shown to produce better results than straight BIO (Yang et al., 2018b).

Hyper-parameter settings For hyper-parameter configuration, we adjust them according to the performance on the described development sets for Chinese NER. We set the character embedding size, hidden sizes of CNN and BiGRU to 300 dims. After comparing experimental results with different CNN window sizes, we set the window size as 5. Adadelta is used for optimization, with an initial learning rate of 0.005. The character embeddings used in our experiments are from Li et al. (2018), which is trained by Skip-Gram with Negative Sampling (SGNS) on Baidu Encyclopedia.

3.2 Experimental Results

In this section, we describe the experimental results of our proposed model and previous state-of-the-art methods on four datasets: Weibo, Chinese Resume, OntoNotes 4, and MSRA. We propose two baselines for comparison, and show the CAN-NER model results. In the experiment results table, we use Baseline to represent a pure BiGRU + CRF model; and Baseline + CNN to indicate the base model with a CNN layer.

3.2.1 Weibo Dataset

Here we compare our proposed model with the latest models on the Weibo dataset.[3] Table 2 shows the F1-scores for named entities (NE), nominal entities (NM, excluding named entities), and both (Overall). We observe that our proposed model achieves state-of-the-art performance.

Existing state-of-the-art systems include Peng and Dredze (2016), He and Sun (2017b), Cao et al. (2018) and Zhang and Yang (2018), which leverage rich external data like cross-domain data, semi-supervised data, and lexicons, or joint-train NER and Chinese Word Segmentation (CWS).[4] In the first block of Table 2, we report the performance of the latest models. Peng and Dredze (2015) propose a model that jointly trains embeddings with NER and it achieves a F1-score of 56.05% on overall performance. The model (Peng and Dredze, 2016) that jointly trains NER and CWS reaches a F1-score of 58.99%. He and Sun (2017b) propose a unified model to exploit cross-domain and semi-supervised data, which improves the F1-score from 54.82% to 58.23% compared with the model proposed by He and Sun (2017a). Cao et al. (2018) use an adversarial transfer learning framework to incorporate task-shared word boundary information from CWS and achieves a F1-score of 58.70%. Zhang and Yang (2018) leverage a lattice structure to integrate lexicon information into their model and achieve a F1-score of 58.79%.

In the second block of Table 2, we give the results of our baselines and proposed models. While the BiGRU + CRF baseline only achieves a F1-score of 53.80%, adding a normal CNN layer as featurizer improves the score to 55.91%. Replacing the CNN with our convolutional attention layer greatly improves the F1-score to 59.31%, which outperforms other models. The improvement demonstrates the effectiveness of our proposed model.

Models	P	R	F1
Zhang and Yang (2018)^{1†}	94.53	94.29	94.41
Zhang and Yang (2018)^{2‡}	94.07	94.42	94.24
Zhang and Yang (2018)^{3}	94.81	94.11	94.46
Baseline	93.71	93.74	93.73
Baseline + CNN	94.36	**94.85**	94.60
CAN-NER Model	**95.05**	94.82	**94.94**

Table 3: Results on Chinese Resume Dataset. For models proposed by Zhang and Yang (2018), 1 represents the char-based LSTM model, 2 indicates the word-based LSTM model and 3 is the Lattice model.

3.2.2 Chinese Resume Dataset

The Chinese Resume test results are shown in Table 3. Zhang and Yang (2018) released the Chinese Resume dataset and they achieve a F1-score of 94.46%. It can be seen that our proposed baseline (CNN + BiGRU + CRF) outperforms Zhang and Yang (2018) with F1-score of 94.60%.

---

[3] In Table 2,3, 4 and 5, we use $*$ to denote a model with external labeled data for semi-supervised learning. † denotes that the model use external lexicon data. Zhang and Yang (2018) with ‡ is the char-based model in the paper.

[4] The results of Peng and Dredze (2015, 2016) are taken from Peng and Dredze (2017)

Models	P	R	F1
Yang et al. (2016)	65.59	71.84	68.57
Yang et al. (2016)*	72.98	**80.15**	**76.40**
Che et al. (2013)*	**77.71**	72.51	75.02
Wang et al. (2013)*	76.43	72.32	74.32
Zhang and Yang (2018)†	76.35	71.56	73.88
Zhang and Yang (2018)‡	74.36	69.43	71.81
Baseline	70.67	71.64	71.15
Baseline + CNN	72.69	71.51	72.10
CAN-NER Model	75.05	72.29	73.64

Table 4: Results on OntoNotes

Adding our convolutional attention leads a further improvement and achieves state-of-the-art F1-score of 94.94%, which further demonstrates the effectiveness of our proposed model.

3.2.3 OntoNotes Dataset

Table 4 shows comparisons on the OntoNotes 4 dataset. The first block in the table lists the performance of previous methods for Chinese NER. Yang et al. (2016) propose a model combining neural and discrete feature, e.g., POS tagging features, CWS features and orthographic features, improving the F1-score from 68.57% to 76.40%. Leveraging bilingual data, Che et al. (2013) and Wang et al. (2013) achieves F1-scores of 74.32% and 73.88% respectively. Zhang and Yang (2018)‡ is a recent model that uses a character-based model with bichar and softword.

The second block of Table 4 shows the results of our baselines and proposed model. Consistently with observations on the Weibo and Resume datasets, our Convolutional Attention layer leads to a substantial increment on F1-score. Our proposed model achieves a competitive F1-score of 73.64% among character-based model without using external data (e.g., Zhang and Yang (2018)‡).

3.2.4 MSRA Dataset

Table 5 shows experiment results on the MSRA 2006 dataset. Chen et al. (2006), Zhang et al. (2006), and Zhou et al. (2013) leverage rich handcrafted features and Lu et al. (2016) exploit multi-prototype embedding features. Dong et al. (2016) introduce radical features into LSTM-CRF. Cao et al. (2018) make use of Adversarial Transfer Learning and global self-attention to improve model performance. Yang et al. (2018a) propose a character-based CNN-BiLSTM-CRF model to incorporate stroke embeddings and generate n-gram features. Zhang and Yang (2018) introduce a lattice structure to incorporate lexicon information into the neural network, which actually includes word embedding information. Although this model achieves state-of-the-art F1-score at 93.18%, it leverages external lexicon data and thus the result is dependent on the quality of the lexicon. At the bottom section of the table, we can see that Baseline + CNN already outperforms most previous methods. Compared with Zhang and Yang (2018), our char-based method achieves a competitive F1-score of 92.97% without any additional lexicon data and word embedding information. Moreover, CAN-NER model achieves state-of-the-art result among the character-based models.

Models	P	R	F1
Chen et al. (2006)	91.22	81.71	86.20
Zhang et al. (2006)*	92.20	90.18	91.18

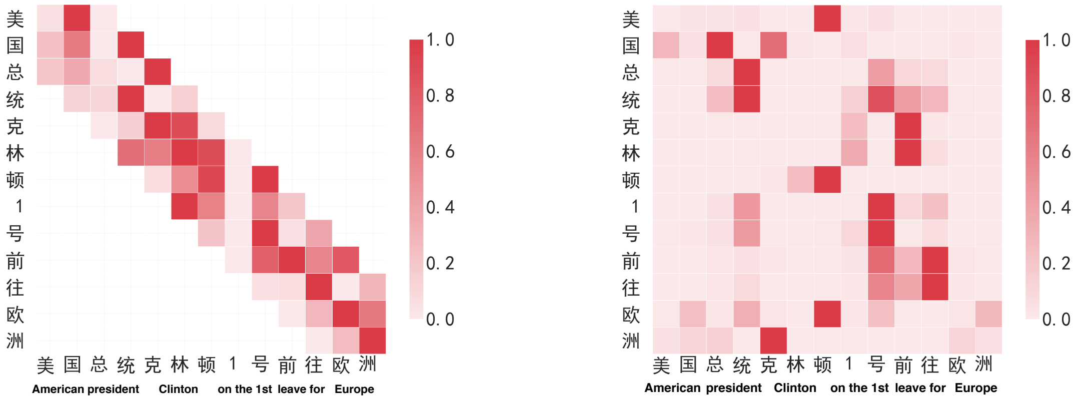
3.3 Discussion

This section discusses the model effectiveness and the experimental results.

3.3.1 Effectiveness of Convolutional Attention and Global Self-Attention

As shown in Tables 2, 3, and 5, our proposed model's performance demonstrates the effectiveness of the Convolutional Attention Network. To better evaluate the effect of the Attention Mechanism, we visualize the normalized attention weights α_m^l for each window from Eq. 2, as in Figure 3a. Each row of the matrix represents location attention weights in each window. For example, the third row indicates that the relationship between center character "总" and contexts "美 国 总 统 克". We can see from the Figure 3a that the word-level features can be extracted through the local attention. In the context, the center character "美" tends to have a stronger connection with



(a) Local attention.

(b) Global self-attention.

Figure 3: Attention visualization. The left-side image shows the normalized Convolutional Attention weights in each window in a sentence. The right-side indicates the global self-attention weights for the whole sentence. In both pictures, the x-axis represents context, while the y-axis represents the input query in the attention mechanism.

its related character “国”, which means they have a higher probability of forming the Chinese word “美国 (American)”. Also for characters “克”, “林”, and “顿”, they tend to have a strong connection because “克林顿” means “Clinton”. Characters “欧” and “洲” also have strong connections, as seen in Figure 3a, because “欧洲” represents “Europe” in Chinese. Therefore, both experiment results and visualization verifies that the Convolutional Attention is effective in obtaining phrase-level information between adjacent characters.

In Figure 3b, we visualize the global self-attention matrix. From the picture, we can find that global self-attention can capture the sentence context information from the long-distance relationship of words to overcome the limitation of Recurrent Neural Networks. For the word “克林顿 (Clinton)”, the global self-attention learns the dependencies with “前往 (leave for)” and “1号 (on the 1st)”. Distinguished by the red color, “克林顿 (Clinton)” has a stronger connection with “前往 (leave for)” than with “1号 (on the 1st)”, which matches the expectation that the predicate in a sentence provides more information to the subject than adverbs of time.

3.3.2 Results Analysis

Our proposed model outperforms previous work on th eWeibo and Chinese Resume datasets and reaches competitive results on both MSRA and OntoNotes 4 datasets without using any external resources. The experiments results demonstrate the effectiveness of our proposed model, especially among char-based models. The performance improvement after adding Convolutional Attention Layer and Global Attention Layer verifies that our model can capture the relationship between character and its local context, as well as the relationship between word and global context. However, although we can obtain comparable or better results to other models that utilize no external resources, we find that our model performance on the OntoNotes 4 dataset still has room for improvement (2.76% F1-score gap to the best model that leverages additional data). This may be explained by specific discrete features and external resources (e.g., other labeled data or lexicons) having a more positive influence on this specific dataset, while CAN-NER cannot learn enough information from only the training set. However, we were not able to identify the precise contributors to the gap based on the available corresponding resources.

4 Related Work

4.1 Neural Network Models

Neural networks, such as LSTM and CNN, have been shown to outperform conventional machine learning methods without requiring handcrafted features. Collobert et al. (2011) describe a CNN-CRF model that reaches competitive results compared to the best statistical models at the time. More recently, the LSTM-CRF architecture has become a quasi-standard on NER tasks. Huang et al. (2015) employed BiLSTM to extract word-level context information and Lample et al. (2016) further introduced a hierarchy structure by incorporating BiLSTM-based character embeddings. Multiple recent works integrating word-level information and character-level information have been found to achieve improved performance (dos Santos et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016; Lample et al., 2016; Chen et al., 2019). Moreover, external knowledge has also been exploited for NER, as has character-level knowledge, both pre-trained (Peters et al., 2017) and co-trained (Liu et al., 2018). More recently, large-scale pre-trained language representations with deep language models have been proposed to help improve the performance of downstream NLP tasks. E.g., ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018).

4.2 Attention Mechanism

Also, Attention Mechanisms have shown very good performance on a variety of tasks including machine translation, machine comprehension, and related NLP tasks (Vaswani et al., 2017; Seo et al., 2016; Tan et al., 2018a). In language understanding, Shen et al. (2018) exploit self-attention to learn long range dependencies. Rei et al. (2016) proposed a model employing an attention mechanism to combine the character-based representation with the word embedding instead of simply concatenating them. This method allows the model to dynamically decide which source of information to use for each word, and therefore outperforming the concatenation method used in previous work. More recently, Tan et al. (2018b) and Cao et al. (2018) employ self-attention to directly capture the global dependencies of the inputs for NER tasks and demonstrate the effectiveness of self-attention in Chinese NER.

4.3 Chinese NER

Multiple previous efforts have tried to address the Chinese language challenge of not having explicit word boundaries. Traditional models depended on hand-crafted features and CRFs-based models (He and Wang, 2008; Mao et al., 2008) and character-based LSTM-CRF models have been applied to Chinese NER to utilize both character- and radical-level representations (Dong et al., 2016). Peng and Dredze (2015) applied character positional embeddings and proposed a jointly trained model for embeddings and NER. To better integrate word boundary information into Chinese NER model, Peng and Dredze (2016) co-trained NER and word segmentation to improve performance in both tasks. He and Sun (2017b) unified cross-domain learning and semi-supervised learning to obtain information from out-of-domain corpora and in-domain unannotated text. Instead of performing word segmentation first, Recently, Zhang and Yang (2018) proposed constructing a word-character lattice by matching words in texts with a lexicon to avoid segmentation errors. Cao et al. (2018) use an adversarial network to jointly train Chinese NER task and Chinese Word Segmentation tasks to extract task-shared word boundary information. Also, Yang et al. (2018c) leverage character-level BiLSTM to extract higher-level features from crowd-annotations.

5 Conclusion

In this paper, we propose CAN-NER, a Convolutional Attention Network model to improve Chinese NER performance and preclude word embedding and additional lexicon dependencies; thus making the model more efficient and robust. In our model, we implement local-attention CNN and Bi-GRU with the global self-attention structure to capture word-level features and context information with char-level features. Extensive experiments show that our model outperforms the state-of-art systems on the different domain datasets.

Decomposed Local Models for Coordinate Structure Parsing

Hiroki Teranishi[1] **Hiroyuki Shindo**[1] **Yuji Matsumoto**[1,2]
[1]Nara Institute of Science and Technology

Abstract

We propose a simple and accurate model for coordination boundary identification. Our model decomposes the task into three subtasks during training; finding a coordinator, identifying inside boundaries of a pair of conjuncts, and selecting outside boundaries of it. For inference, we make use of probabilities of coordinators and conjuncts in the CKY parsing to find the optimal combination of coordinate structures. Experimental results demonstrate that our model achieves state-of-the-art results, ensuring that the global structure of coordinations is consistent.

1 Introduction

Coordination is a frequently occurring structure that consists of conjuncts joined by a coordinator word. Since conjunct spans are one of the major ambiguities, identifying them is difficult, even for humans. For instance, in the sentence "*Toshiba's line of portables, for example, features the T-1000, which is in the same weight class* <u>*but*</u> *is much slower* <u>*and*</u> *has less memory,* <u>*and*</u> *the T-1600, which also uses a 286 microprocessor,* <u>*but*</u> *which weighs almost twice as much* <u>*and*</u> *is three times the size*," we cannot find correct conjuncts for each coordinator at a glance. The presence of coordination makes a sentence more ambiguous and longer, resulting in errors in syntactic parsing.

To identify the conjuncts of a given coordinator, previous studies have explored two properties of coordinate structures: (1) similarity – conjuncts tend to be similar; (2) replaceability – conjuncts can be replaced. Ficler and Goldberg (2016b) combine the syntactic parser and neural networks to compute the similarity and replaceability features of conjuncts. Teranishi et al. (2017) also exploit the two properties without deploying any syntactic parser, and achieve state-of-the-art results. Although both approaches outperform the similarity-based approaches (Shimbo and Hara, 2007; Hara et al., 2009), they cannot handle more than two conjuncts in a coordination, and multiple coordinations in a sentence at one time. Hence, their systems may produce coordinations that conflict with each other. In contrast, Hara et al. (2009) define production rules for coordination in order to output consistent coordinate structures.

Here, we propose a new framework for coordination boundary identification. We generalize a scoring function that takes a pair of spans with a coordinator and returns a higher score when the two spans appear to be coordinated. Using this function in the CKY parsing with production rules for coordination, our system produces globally consistent coordinations in a given sentence. To obtain such a function, we decompose the task into three independent subtasks – finding a coordinator, identifying the inner boundaries of a pair of conjuncts and delineating its outer boundaries. We use three different neural networks for the tasks, and the networks are trained on the basis of their local decisions. Our method is inspired by recent successes with locally-trained models for structured inference problems such as constituency parsing (Teng and Zhang, 2018) and dependency parsing (Dozat and Manning, 2017) without globally-optimized training. Experimental results reveal that our model outperforms existing systems and our strong baseline, an extension of Teranishi et al. (2017), and ensures that the global structure of the coordinations is consistent.

In summary, our contributions include the following:

- We propose a simple framework that trains a generalized scoring function of a pair of conjuncts and uses it for inference.
- We decompose the task and use three local models that interoperate for the CKY parsing.

Proceedings of NAACL-HLT 2019, pages 3394–3403
Minneapolis, Minnesota, June 2 - June 7, 2019.

- We establish a system that can accommodate more than two conjuncts in a sentence.
- Our system outperforms existing ones, particularly because it produces globally consistent coordinate structures.

2 Coordination Boundary Identification

2.1 Coordinate Structure

A *coordinate structure* or *coordination* is a syntactic structure in which two or more elements, known as *conjuncts*, are linked by *coordinator*(s). In addition to coordinating words, such as "and," "or," or "but," some punctuation marks function secondarily to connect two conjuncts. We refer to those punctuation marks as *sub-coordinator*s. Sub-coordinators cannot independently conjoin phrases to form a coordinate structure. The presence of a coordination is usually signaled by the appearance of a coordinator; however, coordinating words do not always lead to coordinations. For instance, "but" is not a coordinator when it functions as a preposition. In this paper, we refer to a word that can be a coordinator or sub-coordinator as a *coordinator key*.

2.2 Task Definition and Difficulties

The task of coordination boundary identification is to find conjunct spans of a given coordinating word. If a coordinating word does not act as a coordinator, a system must return NONE; denoting the absence of a coordinate structure. The difficulties in this task arise when there are multiple coordinate structures in a sentence or more than two conjuncts in a single coordinate structure. If there is more than one coordinate structure in a sentence, each coordinate structure must be isolated from the others or integrated into the other(s). In other words, coordinate structures cannot be partially overlapped. When there are more than two conjuncts in a coordinate structure, it has to be ascertained whether the punctuation marks are sub-coordinators that bring one more conjunct, and if so, which coordinate structure they belong to. Thus, we must identify how many conjuncts a coordinate structure contains and the location of those conjuncts in the coordinate structure — whether it is nested in or isolated from other coordinate structures.

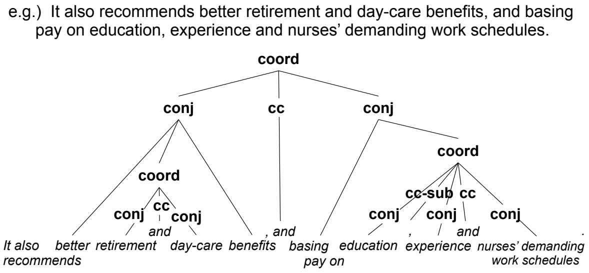

Figure 1: An example of a coordinate tree.

2.3 Coordinate Structures as a Tree

Invoking Shimbo and Hara (2007), we use a tree to represent the coordinate structures in a sentence. We call this tree a **coordinate tree**. Figure 1 shows an example of a coordinate tree. Tree structures are particularly suitable because the ranges of coordinate structures are always consistent, and conjuncts are shown as nodes without being limited by the frequency of their occurrence. Our system produces a coordinate tree using the CKY algorithm and then retrieves well-formed coordinate structures from the tree. In this work, we focus on how to learn the scoring function that assigns higher scores to probable pairs of conjuncts for the CKY parsing.

3 Proposed Method

Our proposed model consists of three parts: a coordinator classifier and the inner and outer-boundary scoring models. Figure 2 is the overview of our framework. The coordinator classifier is a binary classifier that ascertains whether a word functions as a coordinator or not. The inner-boundary scoring model computes the score for a pair of conjuncts on the basis of their boundaries that are in proximity to a coordinator. This means that the model produces a score based on the end of the left conjunct and the beginning of the right conjunct. Similarly, the outer-boundary scoring model assigns a score to a pair of the beginning of the left conjunct and the end of the right conjunct. Using the inner and outer-boundary scoring models, our model calculates all possible combinations of the four boundaries, and then produces their probabilities. Given the local probabilities, we run the CKY algorithm to find the globally optimal coordinate structures in the sentence. In this section, we formulate our model based on the details of the neural networks' architecture; afterward, we describe the parsing method.

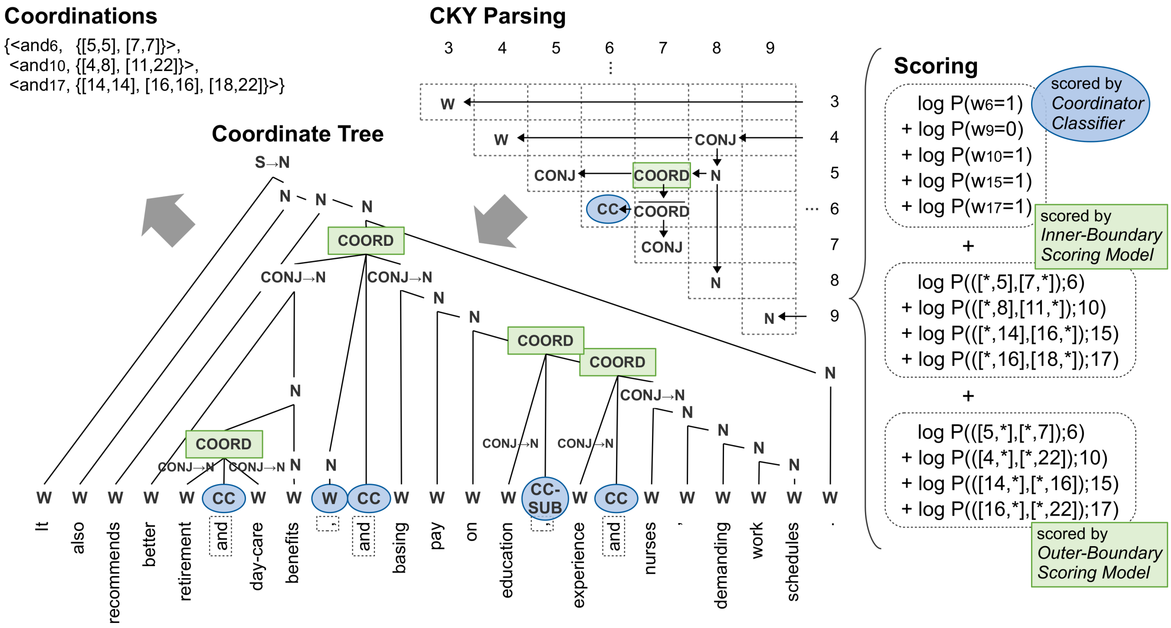

Figure 2: Overview of the proposed framework for coordination boundary identification. The scores of circular nodes are assigned by the coordinator classifier, and the scores of rectangular nodes are assigned by the inner and outer-boundary scoring models.

3.1 Model

Given a sentence that consists of N words $w_{1:N} = w_1, \ldots, w_N$ with the corresponding part-of-speech (POS) tags $p_{1:N} = p_1, \ldots, p_N$, our model outputs a set of coordinate structures $\{\langle c, \{[b_1, e_1], \ldots, [b_n, e_n]\}\rangle\}(n \geq 2)$ where c is a coordinator and $[b_k, e_k]$ is the k-th conjunct spanning from the b_k-th word to the e_k-th word. Although we cannot know the number of coordinate structures and conjuncts in each coordinate structure, we can use coordinator keys as clues to find pairs of conjuncts. Our model tries to find pairs of conjuncts, rather than coordinate structures, in a sentence.

$$\begin{aligned} X &= \{w_{1:N}, p_{1:N}, C\} \\ C &= \{t | w_t \in \mathbb{S}_{cc} \cup \mathbb{S}_{\textit{sub-cc}}\} \\ Y &= \{\langle y_t^{ckey}, y_t^{pair}\rangle | t \in C\} \end{aligned} \tag{1}$$

where y_t^{ckey} is a label that indicates whether w_t is the actual coordinator ($y_t^{ckey} = 1$) or not ($y_t^{ckey} = 0$), and y_t^{pair} is a pair of conjunct spans. $y_t^{pair} = \varnothing$ when $y_t^{ckey} = 0$. When $t = 1$ or $t = N$, $y_t^{ckey} = 0$ because it does not form a coordinate structure within the sentence. In this paper, we define $\mathbb{S}_{cc}$ and $\mathbb{S}_{\textit{sub-cc}}$ as {"and", "or", "but", "nor", "and/or"} and {",", ";", ":"}, respectively. We use two different models to identify inner and outer boundaries of y_t^{pair}, because enumerating all possible inner and outer boundaries of y_t^{pair} requires time complexity $\mathcal{O}(N^2) + \mathcal{O}(N^2) = \mathcal{O}(N^2)$, whereas enumerating all possible y_t^{pair} requires time complexity $\mathcal{O}(N^4)$[1].

Coordinator Classifier

The coordinator classifier is a binary classifier that predicts the label of a coordinator key.

$$P(y_t^{ckey} | w_t, \theta) = \mathrm{softmax}(f_{ckey}(w_t)) \tag{2}$$

The training loss of the binary classification is computed by the following equation:

$$\ell_\theta^{ckey}(X, Y) = - \sum_{\langle y_t^{ckey}, y_t^{pair}\rangle \in Y} \log P(y_t^{ckey} | w_t, \theta) \tag{3}$$

Inner-Boundary Scoring Model

The inner-boundary scoring model assigns a score to a pair of conjunct spans on the basis of inner boundaries. We use b^l, e^l, b^r, e^r to denote the beginning of a left conjunct, the end of the left conjunct, the beginning of a right conjunct, and the end of the right conjunct, respectively. The score

---

[1] For division of four boundaries, "two beginnings and two ends" or "left span and right span" can be chosen instead. In preliminary experiments, "left span and right span" models perform poorly, and "two beginnings and two ends" models perform well, but worse than "inner and outer-boundary" models.

of the inner-boundary pair (e^l, b^r) for a coordinator key w_t is calculated as follows:

$$\textsc{Score}_{\theta}^{inner}(e^l, b^r, w_t) = f_{inner}(e^l, b^r, w_t) \tag{4}$$

The probabilities of the inner boundaries are normalized distributions over all possible inner boundary pairs:

$$\begin{aligned} I_{w_t} = \{&(1, t+1), (1, t+2), \ldots, (1, N), \\ &(2, t+1), \ldots, (t-1, N)\} \end{aligned} \tag{5}$$

$$\begin{aligned} &P(y_t^{pair} = ([*, e^l], [b^r, *]) | w_t, \theta) = \\ &\frac{\exp\left(\textsc{Score}_{\theta}^{inner}(e^l, b^r, w_t)\right)}{\sum\limits_{(e'^l, b'^r) \in I_{w_t}} \exp\left(\textsc{Score}_{\theta}^{inner}(e'^l, b'^r, w_t)\right)} \end{aligned} \tag{6}$$

$$\begin{aligned} &\ell_{\theta}^{inner}(X, Y) = \\ &\quad - \sum_{\langle y_t^{ckey}, y_t^{pair} \rangle \in Y} y_t^{ckey} \log P(y_t^{pair} | w_t, \theta) \end{aligned} \tag{7}$$

The term $y_t^{ckey} \log P(y_t^{pair} | w_t, \theta)$ means the cross-entropy loss is activated only for positive coordinator keys ($y_t^{ckey} = 1$) and is disabled otherwise ($y_t^{ckey} = 0$).

Outer-Boundary Scoring Model

Similarly to the inner-boundary scoring model, we define the probability $P(y_t^{pair} = ([b^l, *], [*, e^r]) | w_t, \theta)$ based on the set of all the outer-boundary pairs O_{w_t}; the loss is defined as ℓ_{θ}^{outer} using the scoring function $\textsc{Score}_{\theta}^{outer}(b^l, e^r, w_t) = f_{outer}(b^l, e^r, w_t)$. Note that I_{w_t} and O_{w_t} are identical because their possible pairs are the same. Based on the inner pair probability $P(y_t^{pair} = ([*, e^l], [b^r, *]) | w_t, \theta)$ and the outer pair probability $P(y_t^{pair} = ([b^l, *], [*, e^r]) | w_t, \theta)$, the most probable pair is produced by:

$$\begin{aligned} y_t^{pair} = &\mathop{\arg\max}_{(\hat{e}^l, \hat{b}^r)} P(([*, \hat{e}^l], [\hat{b}^r, *]) | w_t, \theta) \\ &\cup \mathop{\arg\max}_{(\hat{b}^l, \hat{e}^r)} P(([\hat{b}^l, *], [*, \hat{e}^r]) | w_t, \theta) \end{aligned} \tag{8}$$

3.2 CKY Parsing

Our three models predict coordinators including sub-coordinators, and the inner and outer boundaries of their coordinating conjuncts. Such local predictions may cause conflicts between different coordinate structures. Furthermore, two conjuncts linked by a sub-coordinator must be embedded in another coordinate structure formed by a coordinator. To overcome these limitations, we use the CKY algorithm to find the optimal coordinations in a sentence. In particular, we define the CFG rules to produce a coordinate tree, as used in Hara et al. (2009). Our CFG rules, distinct from those of Hara et al. (2009) [2], are shown in Table 1. Based on these rules, we can map a coordinate tree to the one-to-one corresponding syntactic tree, covering 99.5% coordinations in the Penn Treebank [3].

Non-terminals			
COORD	Coordination		
CONJ	Conjunct		
CC	Coordinating conjunction		
CC-SUB	Sub-coordinator		
W	Word		
N	Non-coordination		
S	Sentence		
Rules for coordinations			
(1)	COORD	→	CONJ N? CC N? CONJ
(2)	COORD	→	CONJ CC-SUB COORD
(3)	CONJ	→	COORD
(4)	CONJ	→	N
Rules for non-coordinations			
(5)	S	→	COORD
(6)	S	→	N
(7)	N	→	COORD N
(8)	N	→	W COORD
(9)	N	→	W N
(10)	N	→	W
Rules for pre-terminals			
(11)	CC	→	(and|or|but|nor|and/or)
(12)	CC-SUB	→	(,|;|:)
(13)	W	→	*

Table 1: Production rules for coordinate trees. (. . . | . . .) matches one of the elements and "*" matches any word. "?" indicates zero or one occurrence of the preceding element.

3.2.1 Scoring

We give scores only to coordination nodes denoted as COORD, and pre-terminals. When scoring pre-terminals, we assign $\log P(w_k = 1)$ to CC and CC-SUB, and $\log(P(w_k = 0))$ to W if $w_k \in \mathbb{S}_{cc} \cup \mathbb{S}_{sub\text{-}cc}$, otherwise 0. When scoring the CO-

---

[2] Our rules can produce coordinate structures that contain arbitrary length phrase(s) around coordinators, while conjuncts always appear next to coordinators in their rules.

[3] Most of the non-derivable coordinations are in the form like "A and B and C" where a coordinating word is regarded as a sub-coordinator. Even so, this expression can be parsed as a nested coordinate structure by the rules.

ORD, we take the left conjunct and the right conjunct which are linked by the CC. Thus, in the rule (2), the conjunct pair linked by a CC-SUB is the incoming CONJ and the leftmost CONJ in the child COORD. Using a coordinator and its pair of conjuncts, we assign $\log P(([i,j],[l,m])) = \log P(([*,j],[l,*])) + \log P(([i,*],[*,m]))$ to the COORD. The best scoring coordinate tree can be found efficiently using dynamic programming with time complexity $\mathcal{O}(N^3)$.

3.3 Neural Network Models

We use neural networks as instantiations of f_{ckey}, f_{inner}, and f_{outer} that we have introduced in this section.

Encoder

To get sentence-level representations for a sequence of words and POS tags, we use bidirectional long short-term memories (BiLSTMs) (Hochreiter and Schmidhuber, 1997).

$$\mathbf{h}_{1:N} = \mathrm{BiLSTMs}(f_{input}(w_{1:N}, p_{1:N})) \qquad (9)$$

The dimensionality of each resulting vector $\mathbf{h}_t$ is $2d^{hidden}$. For the BiLSTMs inputs, we use f_{input} to map words and POS tags onto their representations. We can use different word representations including a pretrained word model, ELMo (Peters et al., 2018), BERT (Devlin et al., 2018) or character-level LSTMs/convolutional neural networks (CharCNNs). We demonstrate the differences between the different choices in Section 4. The entire network consisting of f_{input} and BiLSTMs is referred to as the encoder; it is shared by the three neural networks in the higher layer.

Coordinator Classifier

We use a linear transformation of the sentence-level representation of a coordinator key for f_{ckey}.

$$f_{ckey}(w_t) = \mathbf{W}^{ckey}\mathbf{h}_t + \mathbf{b}^{ckey} \qquad (10)$$

where $\mathbf{W}^{ckey} \in \mathbb{R}^{2\times 2d^{hidden}}$ and $\mathbf{b}^{ckey} \in \mathbb{R}^2$ are the model parameters of the classifier.

Inner-Boundary Scoring Model

From the sentence-level representations produced by the encoder, the inner-boundary scoring model concatenates two representations of inner boundaries, and then feeds the produced vector into a multilayered perceptron (MLP).

$$\begin{aligned} & f_{inner}(e^l, b^r, w_t) = \\ & \quad \mathbf{w}_2^{in}\,\mathrm{ReLU}(\mathbf{W}_1^{in}[\mathbf{h}_{e^l}; \mathbf{h}_{b^r}] + \mathbf{b}_1^{in}) + \mathrm{b}_2^{in} \end{aligned} \qquad (11)$$

where $\mathbf{W}_1^{in} \in \mathbb{R}^{d^{in}\times 4d^{hidden}}$, $\mathbf{b}_1^{in} \in \mathbb{R}^{d^{in}}$, $\mathbf{w}_2^{in} \in \mathbb{R}^{d^{in}}$ and $\mathrm{b}_2^{in} \in \mathbb{R}^1$ are the parameters of the inner-boundary scoring model.

Outer-Boundary Scoring Model

Using sentence-level representations, the outer-boundary scoring model takes two vectors that are calculated by subtracting the adjacent vectors to the coordinator from the boundary vectors. These subtraction operations are intended to capture the semantic distance and relatedness between two spans (Teranishi et al., 2017). The model then passes the vector to a MLP.

$$\begin{aligned} & f_{feature}(b^l, e^r, w_t, \mathbf{h}_{1:N}) = \\ & \quad [\mathbf{h}_{b^l} - \mathbf{h}_{t+1}; \mathbf{h}_{e^r} - \mathbf{h}_{t-1}] \end{aligned} \qquad (12)$$

$$\begin{aligned} & f_{outer}(b^l, e^r, w_t) = \\ & \quad \mathbf{w}_2^{out}\,\mathrm{ReLU}(\mathbf{W}_1^{out}\,\mathbf{r}) + \mathbf{b}_1^{out}) + \mathrm{b}_2^{out} \\ & \quad \mathbf{r} = f_{feature}(b^l, e^r, w_t, \mathbf{h}_{1:N}) \end{aligned} \qquad (13)$$

where $\mathbf{W}_1^{out} \in \mathbb{R}^{d^{out}\times 4d^{hidden}}$, $\mathbf{b}_1^{out} \in \mathbb{R}^{d^{out}}$, $\mathbf{w}_2^{out} \in \mathbb{R}^{d^{out}}$ and $\mathrm{b}_2^{out} \in \mathbb{R}^1$ are the parameters of the outer-boundary scoring model.

3.4 Learning

To train the set of parameter θ of our neural networks, we minimize the following loss function:

$$\begin{aligned} L(\theta) = \sum_{(X,\hat{Y})\in D} \Big(& \ell_\theta^{ckey}(X,\hat{Y}) \\ & + \ell_\theta^{inner}(X,\hat{Y}) \\ & + \ell_\theta^{outer}(X,\hat{Y}) \Big) \end{aligned} \qquad (14)$$

where D is a set of pairs of a sentence and its correct coordinate structures in a training dataset. Thus, our submodels are trained jointly.

Why local training?

Instead of learning the scoring functions on the basis of local decisions, we can directly train our models combined with the CKY parsing using a structured max-margin objective between the scores of the best predicted and gold trees. In preliminary experiments, however, such a global training requires careful hyperparameter tuning and is hard to optimize stably, resulting in slightly better performance than the method of Teranishi et al. (2017).

4 Experiments

4.1 Settings

4.1.1 Datasets

We use the coordination-annotated Penn Treebank (Ficler and Goldberg, 2016a) (PTB) and Genia Treebank beta (Kim et al., 2003) (GENIA). Unlike the evaluation by Teranishi et al. (2017) and Ficler and Goldberg (2016b), we strip the PTB of all quotation marks (“) and (”) to normalize irregular coordinations such as ⟨... *“Daybreak,” “Daywatch,” “Newsday,” and “Newsnight,”* ... ⟩. We follow the standard train/development/test split on the PTB. For the GENIA, we do not apply the preprocessing described above. We evaluate the model through a five-fold cross-validation, as in Hara et al. (2009).

4.1.2 Model

We use pretrained word vectors, POS tags, and character vectors produced by the CharCNN (Ma and Hovy, 2016), regarded as the *default*. We also investigate the performance of the model, using three different word representations for the encoder: (1) pretrained word embeddings; GloVe (Pennington et al., 2014) for the PTB, BioASQ (Tsatsaronis et al., 2012) for the GENIA, (2) contextualized sentence embeddings; ELMo, (3) randomly initialized word vectors. For the PTB, POS tags are obtained using the Stanford POS Tagger (Toutanova et al., 2003) with 10-way jackknifing. For the GENIA, we use the gold POS tags, as in Hara et al. (2009). To optimize the model parameters, we use Adam (Kingma and Ba, 2015). Other hyperparameters are described in Appendix A.

4.1.3 Baseline Model

We adopt our implementation of Teranishi et al. (2017) as the baseline. The original model of Teranishi et al. (2017) predicts the beginning and the end of a coordinate structure, and then splits it into conjuncts by commas. Their model decides the boundary of a coordinate structure individually, which may cause conflicts with that of other coordinate structure(s). Thus, we extend their model to find the best combination of coordinate structures, greedily choosing most probable boundaries without conflicts[4]. For the baseline model, we use the same encoder as that of our default model. Hereinafter, we refer to this baseline model as *Teranishi+17:+ext*.

4.1.4 Evaluation

We evaluate the systems on the basis of the ability to predict conjunct spans with the precision, recall, and F1 measures on the PTB. To compare the performance of our model with Teranishi et al. (2017), we adjudge the predicted conjuncts correct based on the following metrics.

- **whole**: matches at the beginning of the first conjunct and the end of the last conjunct.
- **outer**: matches in the first conjunct and the last conjunct.
- **inner**: matches in the two conjuncts adjacent to the coordinator.
- **exact**: matches in all the conjuncts.

In addition, we pay particular attention to the evaluation of NP coordination.

For the GENIA, we measure the recall values of coordinate structures by the aforementioned metrics; previous studies, on the other hand, evaluated their systems based only on the whole metric. Also, we evaluate the performance of our model based on syntactic categories.

4.2 Results

Tables 2 and 3 show the experimental results on the PTB and GENIA datasets. On the PTB, our model outperforms the baseline and existing methods for all metrics. We cannot compare its performance with that of existing methods because of its use of the preprocessing for quotation marks; nevertheless, our model achieves significant improvements. Our model is more accurate than the baseline because ours learns both the inner and outer boundaries of conjunct pairs including those of sub-coordinators, while the baseline learns only the coordination boundaries. On the GENIA, our model also outperforms the baseline on the exact metric. While our model has some limitations when it comes to predicting the beginning and the end of coordinations, it performs better on the inner metric. In contrast, Teranishi+17:+ext achieves the best results on the whole metric, whereas it performs poorly on the other metrics. This performance reflects the differences between the algorithms of the two systems. Our model builds a coordinate tree in a bottom-up manner and predicts inner conjuncts accurately. On the other hand, the baseline model predicts the entire span of a coordinate structure and splits them into conjuncts in a top-down fashion. That is why the base-

---

[4] We did not add the constraint to situate a nested coordination in the parent conjunct.

line model cannot predict coordinated clauses labeled as "S," that are likely to be longer and to contain non-coordinating commas. The shortcoming of our model is that our bottom-up parsing may cause errors due to wrong decisions in the early stage of the parsing; this is observed as poor performance in the whole metric.

4.3 Analysis

Complete match in a sentence

We investigate the ability of our system to predict all the coordinate structures in a sentence precisely. We categorize sentences into the following four groups[5].

All: All sentences that have any coordinate structure.

- **Simple**: Sentences that have only one coordinate structure consisting of two conjuncts.
- **Complex**: Sentences that are categorized as Consecutive and/or Multiple.
