Observed from the training process of NMT models, performance on the validation set does not improve monotonically. When the performance of the training model on the validation set declines, we could always select the best checkpoint so far as the teacher, because it has the best generalization performance. Specially, when the best checkpoint is generated at the current time step, we only update the teacher model but perform no distillation. Figure 1 gives an illustration of this process.

The online distillation process is summarized in Algorithm 1. We use t to denote the training step and θ_t to denote the parameters at time step t. We denote T_k as the time step the k-th time when the model is evaluated on validation and ΔT as the validation interval, for which $T_{k+1} = T_k + \Delta T$. Let $\hat{T}_k$ ($\hat{T}_k \leq T_k$) be the time step when the best checkpoint is obtained up to T_k, and $\theta_{\mathcal{T}}$ as the teacher's parameters to lead the following training process. If the current checkpoint is the best checkpoint so far, i.e. $\hat{T}_k = T_k$, we update the teacher to be this new checkpoint $\theta_{\mathcal{T}} = \theta_{\hat{T}_k}$ (in Line 16 and 20). The loss for the training process at time step t ($T_k < t < T_{k+1}$) is defined as follows:

$$\mathcal{L}_t(\theta) = \begin{cases} \mathcal{L}(\theta) & \hat{T}_k = T_k \\ \mathcal{L}(\theta) + \mathcal{L}_{\text{W-KD}}(\theta) & \text{otherwise,} \end{cases} \tag{8}$$

where $\mathcal{L}(\theta)$ and $\mathcal{L}(\theta)_{\text{W-KD}}$ is defined in Equation 4 and 7, respectively (in Line 5-8).

3.3 Integrated with Mean Teacher

Knowledge distillation usually works better when teacher models have better performance. As Tarvainen and Valpola (2017) proposed in their work, averaging model parameters over training steps tends to produce a more accurate model that using final parameters directly. They called this method as *Mean Teacher*.

Following Tarvainen and Valpola (2017), besides updating parameters, we maintain the exponential moving average (EMA) of the model parameters as:

$$\theta'_t = \alpha\theta'_{t-1} + (1-\alpha)\theta_t, \tag{9}$$

where t is the update step, θ is the parameters of the training model and θ' the parameters of EMA. α is the decay weight which is close to 1.0, and typically in multiple-nines range, i.e., 0.999, 0.9999. By doing so, at each timestep t, parameters of NMT model θ_t has their corresponding EMA parameters θ'_t.

Whenever we update teacher model $\theta_{\mathcal{T}}$ with the current best checkpoint, we can use its EMA parameters instead (in Line 17-18). It can further improve the generalization ability of the teacher model, and bring a better performance of knowledge distillation. We will show in §4.2 that using meaning teacher indeed achieves better performance.

Algorithm 1: Online Distillation from Checkpoints

```
1  Input: validation interval $\Delta T$; validation count $k$; EMA decay weight $\alpha$; initial model parameters $\theta_0$
2  Initialization: $k = 0$; $t = 0$; $T_0 = -1, \hat{T}_0 = -1$; $\theta_{\mathcal{T}} = \emptyset$; $\theta'_0 = \theta_0$; $\mathcal{L}_0(\theta) = \mathcal{L}(\theta)$

23     $k = k + 1$;
```

4 Experiments

4.1 Setups

To evaluate the effectiveness of our method, we conduct experiments on four machine translation tasks: NIST Chinese-English, WMT17 Chinese-English, IWSLT15 English-Vietnamese, and WMT17 English-Turkish. We conduct experiments based on an open source implementation of Transformer (Vaswani et al., 2017) model in NJUNMT-pytorch[1]. For all the translation experiments, we use SacreBLEU [2] to report reproducible BLEU scores.

We also present an experiment on machine reading comprehension, showing our method could also be applied to other tasks.

Datasets For NIST Chinese-English translation task, training data consists of 1.34M LDC sentence pairs[3], with 40.8M Chinese words and 45.8M English words, respectively. We use NIST2003 dataset set as the validation set and NIST 2004,

Table 1: Case-insensitive BLEU scores of Chinese-English translation on NIST datasets. "Average"means average scores on NIST04, 05 and 06.

2005, 2006 as test sets. We filter out sentence pairs whose source or target side contain more than 50 words. We use BPE (Sennrich et al., 2016b) with 30K merge operations on both sides.

For WMT17 Chinese-English translation task, we use the pre-processed version released by WMT[4]. We only use CWMT part of WMT Corpus. We use newsdev2017 as the validation set and newstest2017 s the test set. We learn a BPE model with 32K merge operations and keep all the BPE tokens in the vocabulary. We limit the maximal sentence length as 100 after BPE segmentation.

For IWSLT15 English-Vietnamese translation task, we directly use the pre-processed data used in Luong and Manning (2015) [5], which has 133K sentence pairs, with 2.70M English words and 3.31M Vietnamese words. We use the released validation and test set, which has 1553 and 1268 sentences respectively. Following the settings in Huang et al. (2017), the Vietnamese and English vocabulary size are 7,709 and 17,191, respectively.

For WMT17 English-Turkish translation task, We use the pre-processed data released by WMT17[6]. It has 207K sentence pairs, with 5.21M English words and 4.63 Turkish words. We use newstest2016 as our validation set and newstest2017 as the test set. We use joint BPE segmentation (Sennrich et al., 2017) to process the whole training data. The merge operations are 16K.

Implementation Details Without specific statement, we follow the *transformer_base_v1* hyperparameters settings [7], with 6 layers in both encoder and decoder, 512 hidden units and 8 attention heads in multi-head attention mechanism and 2048 hidden units in feed-forward layers. Parameters are optimized using Adam(Kingma and Ba, 2014). The initial learning rate is set as 0.1 and scheduled according to the method proposed in Vaswani et al. (2017), with warm-up steps as 4000.

We periodically evaluate the training model on the validation set by doing translation and compute the BLEU scores. We stop training when 50 subsequent of BLEU scores on validation set do not get improvement. We use beam search with beam size as 5.

4.2 Evaluation on Chinese-English Translation Tasks

We first evaluate the capability of our method for improving performance when there are plenty of training data. We conduct experiments on both NIST and WMT17 Chinese-English Translation tasks.

Results on NIST Dataset We compare our method with several ways to utilize checkpoints[8]:

- **last-k-smoothing**: After training the baseline model, we average the parameters of the last k checkpoints as the final model.
- **best-k-smoothing**: Average the parameters of the best k checkpoints, instead of the last k,

[5] https://github.com/tefan-it/nmt-en-vi

[6] http://data.statmt.org/wmt17/translation-task/preprocessed/tr-en/

[7] https://github.com/tensorflow/tensor2tensor/blob/v1.3.0/tensor2tensor/models/transformer.py

[8] We set $k = 5$ in this experiments.

as the final model. In this case, checkpoints may have better performance but higher variance which could be harmful to parameters averaging.

- **best-k-ensemble**: Do ensemble inference (average the output probabilities) with the best k checkpoints (Chen et al., 2017).

As shown in Table 1, our baseline is comparable to the other two recent published results (Zhang et al. (2018b), Yang et al. (2018)). In consistent with Chen et al. (2017), using checkpoints for smoothing or ensemble does improve the baseline system. Using EMA parameters also improve the baseline system as well, which is in consist with (Tarvainen and Valpola, 2017).

Compared to the baseline, our approach ODC brings translation improvement across different test sets and achieves 42.48 BLEU scores on average(+1.09 BLEU v.s. baseline). This result confirms that using best checkpoint as teacher indeed helps improving the performance of the translation model.

Besides, ODC is comparable to the best results among smoothing and ensemble on baseline's checkpoints (achieved by best-k-ensemble). Considering that best-k-ensemble needs to decode with k models, while ODC decodes only one, our model enjoys a better efficiency. Furthermore, we can achieve further improvement by combining these methods on checkpoints generated by ODC.

Results also show that ODC-EMA (§3.3) could achieve additional improvement from ODC itself (43.13 v.s. 42.48 BLEU), demonstrating that using EMA of the best checkpoint instead can bring better knowledge distillation performance, as it generates a better teacher model.

Results on WMT17 Dataset We present the results on WMT17 Chinese-English translation task in Table 2. We report the results of the baseline, ODC and a recent result published by Zhang et al. (2018c). To make a fair comparison, we follow the experiment setting in Zhang et al. (2018c). The experiment results show similar trends with those on the NIST datasets. Applying ODC leads to the result of 24.22 BLEU, which is 0.85 BLEU higher compared with baseline.

SYSTEM	newsdev2017	newstest2017
Zhang et al. (2018c)	-	23.01
baseline	21.96	23.37
ODC	**22.24**	**24.22**

Table 2: Case-sensitive BLEU scores on WMT17 Chinese-English Translation

4.3 Evaluation on Low-resource Scenario

We also apply our method to two low resource translation tasks, i.e., IWSLT2015 English-Vietnamese (EN2VI) and WMT17 English-Turkish (EN2TR). Due to the limited amount of training data, models are more likely to suffer from over-fitting. Therefore, we use a higher dropout rate of 0.2 and weight decay, another common technique against over-fitting, with decay weight set as 10^{-3} as the default setting. We implement weight decay as AdamW (Loshchilov and Hutter, 2017) does.

Besides, we further experiment with grid search on the validation set for optimal hyper-parameters of dropout rate and weight decay, which may lead to better results. We adopt a simple heuristic, which first searches an optimal dropout rate, and then further searches weight decay coefficients based on this dropout. We experiment with dropout as 0.2, 0.3, 0.4, and weight decay as 10^{-1}, 10^{-2} and 10^{-3}.

SYSTEMS	EN2VI	EN2TR
Zhang et al. (2018a)	-	12.11
tensor2tensor	28.43	-
baseline	28.56	12.20
baseline w/ grid-search	29.01	12.51
ODC	**29.47**	**12.92**
ODC w/ grid-search	**29.59**	**13.18**

Table 3: Case-sensitive BLEU scores on two low resource translation tasks.

As in Table 3, our baseline is comparable to two recent published results, respectively: EN2TR from Zhang et al. (2018c) and EN2VI from official release tensor2tensor problem[9]. Grid hyper-parameter search does improve the baseline system. ODC leads to better results compared to the baseline, as well as the baseline with grid parameter search. ODC can achieve further improvement after searching for optimal hyper-parameters of dropout and weight decay.

---

4.4 Evaluation on Machine Reading Comprehension

Although our main research is focused for the task of machine translation, the idea of ODC could be applied to other tasks as well. We experiments on the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016), a machine reading comprehension task.

SQuAD contains 107,785 human-generated reading comprehension questions, with 536 Wikipedia articles. Each question is associated with a paragraph extracted from an article, and the corresponding answer is a span from this article. A machine reading comprehension model is designed to predict the start and end positions in the article of the answer.

The state-of-the-art machine reading comprehension system also employs a deep neural network structure, which is similar to NMT. We apply our ODC method on **BiDAF++** (Choi et al., 2018), a multi-layer SQuAD model that augments BiDAF (Seo et al., 2016) with self-attention and contextualized embeddings. We evaluate the model after each epoch and implement the knowledge distillation by teaching the student with the output distribution of answer start and end positions predicted by the best checkpoint.

For the results, ODC improves a base BiDAF++ from 76.83 to 77.40, in EM scores, showing that our method can be applied to a broader range of tasks.

5 Analysis

We conduct further analysis to probe into the reasons for the advantages of ODC. We first show that our method can significantly alleviate the overfitting issue in data-limited condition. After that, we show that parameters gained from our method tend to be wider minimums, which represents better generalization.

5.1 Effectiveness on reducing over-fitting

Taking IWSLT15 English-Vietnamese as a test-bed, we analyze whether our method could help handle the over-fitting issue. We first plot the curve of the loss on the validation set at each training step for the different models (in Figure 2, the top curve with rounds). It is easy to see that the loss curve of the baseline increases as the training goes after 50K steps, indicating a severe over-fitting. With better dropout rate and weight decay, the over-fitting is less severe; while with ODC the loss curve shows a more steady trend of decrease, and is almost always under the other two's.

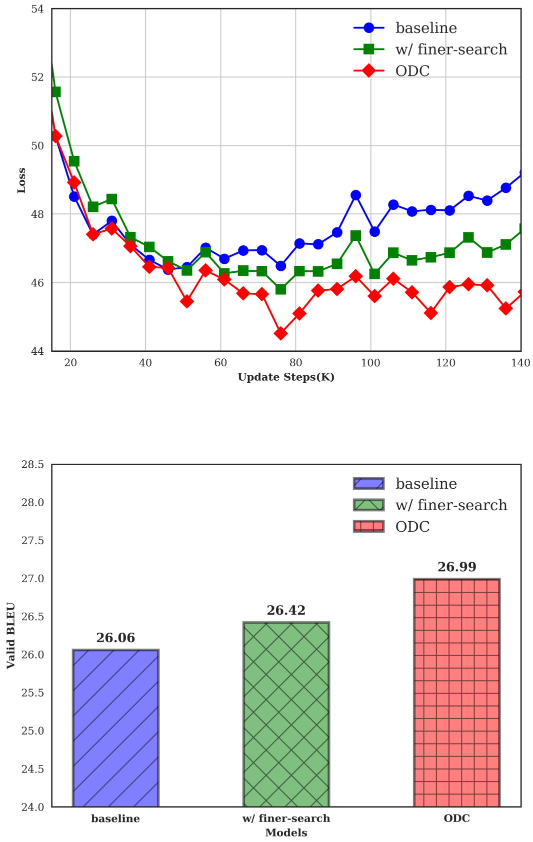

Figure 2: Loss curves (top) and final BLEU scores (bottom) on the validation set of baseline, baseline with grid-search and ODC, respectively.

The final BLEU score on the validation set (Figure 2, bottom) shows corresponding result. The grid search of hyper-parameters improves the BLEU from 26.06 to 26.42 in BLEU, while ODC achieves 26.99.

Both results indicate that our method is more effective at handling the over-fitting problem. We hold that minimizing the cross-entropy between the teacher model and the student model serves as regularization to the training of the student model, which avoids the model getting into over-fitting.

5.2 ODC Brings Wider Minimum

In the training process in Chinese-English tasks, we do not observe obvious over-fitting issue as shown in low resource translation tasks. In this section, we analyze how ODC helps the model generalization. Keskar et al. (2016) proposed that the width

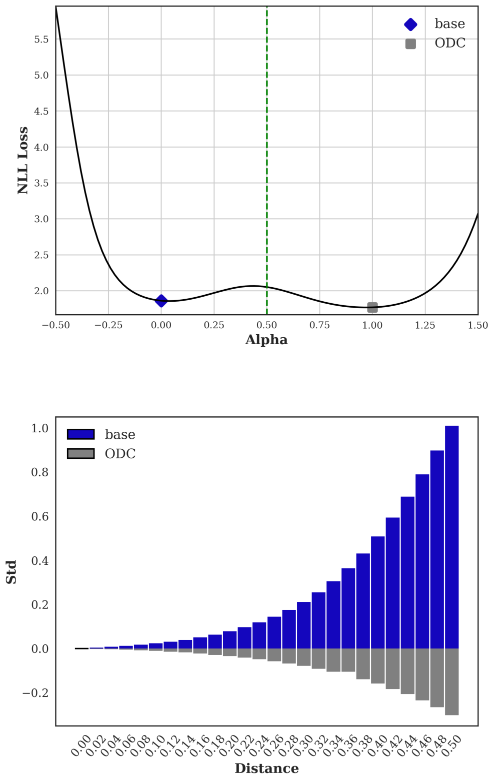

Figure 3: The upper plot shows the validation losses curve along the line segment decided by parameters of baseline and ODC. The bottom plot shows the standard deviations within the neighborhood of baseline and ODC at different distances.

of the minimum in a loss surface is related to its generalization ability. Therefore, we compare the generalization capability between baseline system and our ODC method by exploring around the parameters.

We make use of the visualization technique employed in (Goodfellow and Vinyals, 2014) and analyze the results on the NIST data set. Let θ_{base} and θ_{ODC} denote the final parameters obtained from baseline and ODC. Consider the line:

$$\theta(\alpha) = \alpha \cdot \theta_{\text{ODC}} + (1.0 - \alpha) \cdot \theta_{\text{base}}, \qquad (10)$$

which connects θ_{base} ($\alpha = 0.0$) and θ_{ODC} ($\alpha = 1.0$). We plot the value of Equation 4 as a function of α (normalized by count of words per sentence) with $\theta = \theta(\alpha)$. We draw α from -1.0 to 2.0 at an interval of 0.02. In this way, the width of θ_{base} and θ_{ODC} can be represented as the steepness of the curve nearby. To further quantitatively represent the steepness, we compute the standard deviation of values on this curve within different distances to the two parameters, respectively. We plot them in Figure 3.

From Figure 3 we can see that the loss curve behaves steeper around the parameters of baseline than of ODC. Besides, the standard deviations of losses around the baseline model are consistently higher than ODC within all the distances. It is evident that the parameters of ODC act as a wider minimum c and explains why ODC can lead to a more generalized model.

6 Related Works

6.1 Regularization in NMT

Regularization has broad applications in training NMT models to improve performance and avoid over-fitting. There are some common regularization techniques, such as L^2 normalization and dropout (Srivastava et al., 2014). These methods are simple and easy to implement but need carefully tuning on the validation set. These methods are also orthogonal to our method.

There are also some works to exploit regularization techniques in fine tuning of NMT model. Barone et al. (2017a) proposed a tuneout method which randomly replaces columns of weight matrices of out-of-domain parameter matrices. Khayrallah et al. (2018) shared similar training object with us, as they computed the KL divergence between out-of-domain and in-domain model. Both of their works request a pre-trained teacher model, while we are work on a more general training problem which does not require such kind of model.

6.2 Online Knowledge Distillation

While traditional knowledge distillation requires a static, pre-trained teacher model, online knowledge distillation tends to overcome this problem by selecting or generating a teacher dynamically from scratch.

To the best of our knowledge, Zhang et al. (2017) is the first trial to replace the offline teacher model. They trained peer models to teach each other simultaneously. Compared to their work, our method uses the best checkpoint as the teacher, which avoids introducing extra parameters. Furlanello et al. (2018) tends to update teacher model during the training procedure iteratively, but their method needs to train the teacher model until convergence in each iteration. Instead, our method only needs one phase of training, whose overhead is relatively small.

Lan et al. (2018) using an ensemble of several branches of the model as teacher for computer vision tasks, which only needs one-phase training as well. However, their method relies heavily on the multi-branch structures of the tasks, which are not widely applicable in neural machine translation.

7 Conclusion

In this paper, we propose an online knowledge distillation method with the teacher model generated from checkpoints during the training procedure. Experiments on four machine translation tasks and a machine reading task show that our method outperforms strong baseline systems. Further analysis shows that our method can effectively alleviate the over-fitting issue, and tend to find a wider minimum.

Value-based Search in Execution Space for Mapping Instructions to Programs

Dor Muhlgay[1] **Jonathan Herzig**[1] **Jonathan Berant**[1,2]

[1]School of Computer Science, Tel-Aviv University

Abstract

Training models to map natural language instructions to programs, given target world supervision only, requires searching for good programs at training time. Search is commonly done using beam search in the space of partial programs or program trees, but as the length of the instructions grows finding a good program becomes difficult. In this work, we propose a search algorithm that uses the target world state, known at training time, to train a *critic* network that predicts the expected reward of every search state. We then score search states on the beam by interpolating their expected reward with the likelihood of programs represented by the search state. Moreover, we search not in the space of programs but in a more compressed state of program executions, augmented with recent entities and actions. On the SCONE dataset, we show that our algorithm dramatically improves performance on all three domains compared to standard beam search and other baselines.

1 Introduction

Training models that can understand natural language instructions and execute them in a real-world environment is of paramount importance for communicating with virtual assistants and robots, and therefore has attracted considerable attention (Branavan et al., 2009; Vogel and Jurafsky, 2010; Chen and Mooney, 2011). A prominent approach is to cast the problem as semantic parsing, where instructions are mapped to a high-level programming language (Artzi and Zettlemoyer, 2013; Long et al., 2016; Guu et al., 2017). Because annotating programs at scale is impractical, it is desirable to train a model from instructions, an initial world state, and a target world state only, letting the program itself be a latent variable.

Learning from such weak supervision results in a difficult search problem at training time. The model must search for a program that when executed leads to the correct target state. Early work employed lexicons and grammars to constrain the search space (Clarke et al., 2010; Liang et al., 2011; Krishnamurthy and Mitchell, 2012; Berant et al., 2013; Artzi and Zettlemoyer, 2013), but recent success of sequence-to-sequence models (Sutskever et al., 2014) shifted most of the burden to learning. Search is often performed simply using beam search, where program tokens are emitted from left-to-right, or program trees are generated top-down (Krishnamurthy et al., 2017; Yin and Neubig, 2017; Cheng et al., 2017; Rabinovich et al., 2017) or bottom-up (Liang et al., 2017; Guu et al., 2017; Goldman et al., 2018). Nevertheless, when instructions are long and complex and reward is sparse, the model may never find enough correct programs, and training will fail.

In this paper, we propose a novel search algorithm for mapping a sequence of natural language instructions to a program, which extends the standard beam-search in two ways. First, we capitalize on the target world state being available at training time and train a *critic* network that given the language instructions, current world state, and target world state estimates the expected future reward for each search state. In contrast to traditional beam search where states representing partial programs are scored based on their likelihood only, we also consider expected future reward, leading to a more targeted search at training time. Second, rather than search in the space of programs, we search in a more compressed execution space, where each state is defined by a partial program's execution result.

We evaluated our method on the SCONE dataset, which includes three different domains where long sequences of 5 instructions are mapped to programs. We show that while standard beam

Proceedings of NAACL-HLT 2019, pages 1942–1954
Minneapolis, Minnesota, June 2 - June 7, 2019.

search gets stuck in local optima and is unable to discover good programs for many examples, our model is able to bootstrap, improving final performance by 20 points on average. We also perform extensive analysis and show that both value-based search as well as searching in execution space contribute to the final performance. Our code and data are available at `http://gitlab.com/tau-nlp/vbsix-lang2program`.

2 Background

Mapping instructions to programs invariably involves a *context*, such as a database or a robotic environment, in which the program (or logical form) is executed. The goal is to train a model given a training set $\{(x_{(j)} = (c_{(j)}, \mathbf{u}_{(j)}), y_{(j)})\}_{j=1}^{N}$, where c is the context, $\mathbf{u}$ is a sequence of natural language instructions, and y is the target state of the environment after following the instructions, which we refer to as *denotation*. The model is trained to map the instructions $\mathbf{u}$ to a program $\mathbf{z}$ such that executing $\mathbf{z}$ in the context c results in the denotation y, which we denote by $[\![\mathbf{z}]\!]_c = y$. Thus, the program $\mathbf{z}$ is a latent variable we must search for at both training and test time. When the sequence of instructions is long, search becomes hard, particularly in the early stages of training.

Recent work tackled the training problem using variants of reinforcement learning (RL) (Suhr and Artzi, 2018; Liang et al., 2018) or maximum marginal likelihood (MML) (Guu et al., 2017; Goldman et al., 2018). We now briefly describe MML training, which we base our training procedure on, and outperformed RL in past work under comparable conditions (Guu et al., 2017).

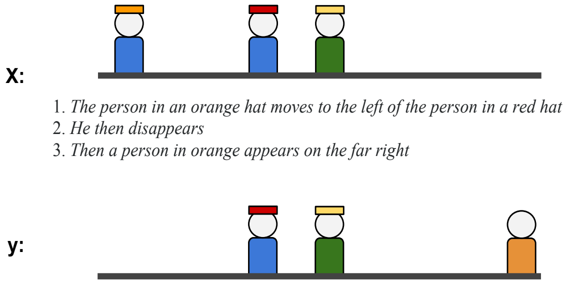
We denote by $\pi_\theta(\cdot)$ a model, parameterized by θ, that generates the program $\mathbf{z}$ token by token from left to right. The model π_θ receives the context c, instructions $\mathbf{u}$ and previously predicted tokens $z_{1\ldots t-1}$, and returns a distribution over the next program token z_t. The probability of a program prefix is defined to be: $p_\theta(z_{1\ldots t} \mid \mathbf{u}, c) = \prod_{i=1}^{t} \pi_\theta(z_i \mid \mathbf{u}, c, z_{1\ldots i-1})$. The model is trained to maximize the MML objective:

$$J_{MML} = \log \prod_{(c,\mathbf{u},y)} p_\theta(y \mid c, \mathbf{u}) = \sum_{(c,\mathbf{u},y)} \log(\sum_{\mathbf{z}} p_\theta(\mathbf{z} \mid \mathbf{u}, c) \cdot R(\mathbf{z})),$$

where $R(\mathbf{z}) = 1$ if $[\![\mathbf{z}]\!]_c = y$, and 0 otherwise (For brevity, we omit c and y from $R(\cdot)$). Typically, the MML objective is optimized with stochastic gradient ascent, where the gradient for an example $(c, \mathbf{u}, y)$ is:

$$\nabla_\theta J_{MML} = \sum_{z} q(z) \cdot R(z) \nabla_\theta \log p_\theta(z|c, \mathbf{u})$$

$$q(z) := \frac{R(z) \cdot p_\theta(z|c, \mathbf{u})}{\sum_{\tilde{z}} R(\tilde{z}) \cdot p_\theta(\tilde{z}|c, \mathbf{u})}.$$



1. *The person in an orange hat moves to the left of the person in a red hat*
2. *He then disappears*
3. *Then a person in orange appears on the far right*

Figure 1: Example from the SCENE domain in SCONE (3 utterances), where people with different hats and shirts are located in different positions. The example contains (from top to bottom): an initial world (the people's properties, from left to right: a blue shirt with an orange hat, a blue shirt with a red hat, and a green shirt with a yellow hat), a sequence of natural language instructions, and a target world (the people's properties, from left to right: blue shirt with a red hat, green shirt with a yellow hat, and an orange shirt).

The search problem arises because it is impossible to enumerate the set of all programs, and thus the sum over programs is approximated by a small set of high probability programs, which have high weights $q(\cdot)$ that dominate the gradient. Search is commonly done with *beam-search*, an iterative algorithm that builds an approximation of the highest probability programs according to the model. At each time step t, the algorithm constructs a beam B_t of at most K program prefixes of length t. Given a beam B_{t-1}, B_t is constructed by selecting the K most likely *continuations* of prefixes in B_{t-1} , according to $p_\theta(z_{1..t}|\cdot)$. The algorithm runs L iterations, and returns all complete programs discovered.

In this paper, our focus is the search problem that arises at training time when training from denotations, i.e., finding programs that execute to the right denotation. Thus, we would like to focus on scenarios where programs are long, and standard beam search fails. We next describe the SCONE dataset, which provides such an opportunity.

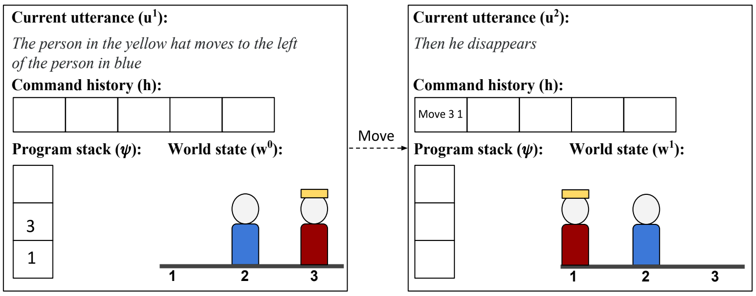


Figure 2: An illustration of a state transition in SCONE. π_θ predicted the action token MOVE. Before the transition (left), the command history is empty and the program stack contains the arguments 3 and 1, which were computed in previous steps. Note that the state does not include the partial program that computed those arguments. After transition (right), the executor popped the arguments from the program stack and applied the action MOVE 3 1: the man in position 3 (a person with a yellow hat and a red shirt) moved to position 1 (to the left of the person with the blue shirt), and the action is added to the execution history with its arguments. Since this action terminated the command, π_θ advanced to the next utterance.

The SCONE dataset Long et al. (2016) presented the SCONE dataset, where a sequence of instructions needs to be mapped to a program consisting of a sequence of executable commands. The dataset has three domains, where each domain includes several objects (such as *people* or *beakers*), each with different properties (such as *shirt color* or *chemical color*). SCONE provides a good environment for stress-testing search algorithms because a long sequence of instructions needs to be mapped to a program. Figure 1 shows an example from the SCENE domain.

Formally, the context in SCONE is a *world* specified by a list of positions, where each position may contain an object with certain properties. A formal language is defined to interact with the world. The formal language contains *constants* (e.g., numbers and colors), *functions* that allow to query the world and refer to objects and intermediate computations, and *actions*, which are functions that modify the world state. Each command is composed of a single action and several arguments constructed recursively from constants and functions. E.g., the command MOVE(HASHAT(YELLOW), LEFTOF(HASSHIRT(BLUE))), contains the action MOVE, which moves a person to a specified position. The person is computed by HASHAT(YELLOW), which queries the world for the position of the person with a yellow hat, and the target position is computed by LEFTOF(HASSHIRT(BLUE)). We refer to Guu et al. (2017) for a full description of the language.

Our goal is to train a model that given an initial world w^0 and a sequence of natural language *utterances* $\mathbf{u} = (u^1, \ldots, u^M)$, will map each utterance u^i to a command z^i such that applying the program $\mathbf{z} = (z^1, \ldots, z^M)$ on w^0 will result in the target world, i.e., $[\![\mathbf{z}]\!]_{w^0} = w^M = y$.

3 Markov Decision Process Formulation

To present our algorithm, we first formulate the problem as a Markov Decision Process (MDP), which is a tuple $(\mathcal{S}, \mathcal{A}, R, \delta)$. To define the state set $\mathcal{S}$, we assume all program prefixes are executable, which can be easily done as we show below. The *execution result* of a prefix $\tilde{z}$ in the context c, denoted by $[\![\tilde{z}]\!]_c^{ex}$, contains its denotation and additional information stored in the executor. Let $\mathcal{Z}_{\text{pre}}$ be the set of all valid programs prefixes. The set of states is defined to be $\mathcal{S} = \{(x, [\![\tilde{z}]\!]_c^{ex}) \mid \tilde{z} \in \mathcal{Z}_{\text{pre}}\}$, i.e., the input paired with all possible execution results.

The action set $\mathcal{A}$ includes all possible program tokens [1], and the transition function $\delta : \mathcal{S} \times \mathcal{A} \rightarrow \mathcal{S}$ is computed by the executor. Last, the reward $R(s, a) = 1$ iff the action a ends the program and leads to a state $\delta(s, a)$ where the denotation is equal to the target y. The model $\pi_\theta(\cdot)$ is a parameterized policy that provides a distribution over the program vocabulary at each time step.

SCONE as an MDP We define the partial execution result $[\![\tilde{z}]\!]_c^{ex}$ in SCONE, as described by Guu et al. (2017). We assume that SCONE's formal language is written in postfix notations, e.g., the instruction MOVE(HASHAT(YELLOW), LEFTOF(HASSHIRT(BLUE))) is written as YELLOW HASHAT BLUE HASSHIRT LEFTOF MOVE.

---

[1] Decoding is constrained to valid program tokens only.

With this notation, a partial program can be executed left-to-right by maintaining a *program stack*, ψ. The executor pushes constants (YELLOW) to ψ, and applies functions (HASHAT) by popping their arguments from ψ and pushing back the computed result. Actions (MOVE) are applied by popping arguments from ψ and performing the action in the current world.

To handle references to previously executed commands, SCONE's formal language includes functions that provide access to actions and arguments in previous commands. To this end, the executor maintains an *execution history*, $\mathbf{h}^i = (e^1, \ldots, e^i)$, a list of executed actions and their arguments. Thus, the execution result of a program prefix is $[\![\tilde{z}]\!]^{ex}_{w^0} = (w^{i-1}, \psi, \mathbf{h}^{i-1})$.

We adopt the model from Guu et al. (2017) (architecture details in appendix A): The policy π_θ observes ψ and u^i, the current utterance being parsed, and predicts a token. When the model predicts an action token that terminates a command, the model moves to the next utterance (until all utterances have been processed). The model uses functions to query the world w^{i-1} and history $\mathbf{h}^{i-1}$. Thus, each MDP state in SCONE is a pair $s = (u^i, [\![\tilde{z}]\!]^{ex}_{w^0})$. Figure 2 illustrates a state transition in the SCENE domain. Importantly, the state does not store the full program's prefix, and many different prefixes may lead to the same state. Next, we describe a search algorithm for this MDP.

4 Searching in Execution Space

Model improvement relies on generating correct programs given a possibly weak model. Standard beam-search explores the space of all program token sequences up to some fixed length. We propose two technical contributions to improve search: (a) We simplify the search problem by searching for correct executions rather than correct programs; (b) We use the target denotation at training time to better estimate partial program scores in the search space. We describe those next.

4.1 Reducing program search to execution search

Program space can be formalized as a directed tree $T = (\mathcal{V}_T, \mathcal{E}_T)$, where vertices $\mathcal{V}_T$ are program prefixes, and labeled edges $\mathcal{E}_T$ represent prefixes' continuations: an edge $e = (\tilde{z}, \tilde{z}')$ labeled with the token a, represents a continuation of the prefix $\tilde{z}$ with the token a, which yields the prefix $\tilde{z}'$. The root of the graph represents the empty sequence. Similarly, *Execution space* is a directed graph $G = (\mathcal{V}_G, \mathcal{E}_G)$ induced from the MDP described in Section 3. Vertices $\mathcal{V}_G$ represent MDP states, which express execution results, and labeled edges $\mathcal{E}_G$ represent transitions. An edge (s_1, s_2) labeled by token a means that $\delta(s_1, a) = s_2$. Since multiple programs have the same execution result, execution space is a compressed representation of program space. Figure 3 shows a few commands in both program and execution space. Execution space is smaller, and so searching in it is easier.

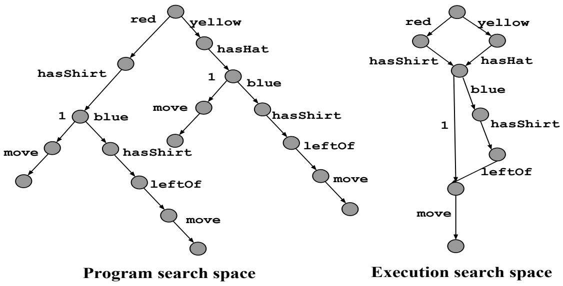

Figure 3: A set of commands represented in program space (left) and execution space (right). The commands relate to the first world in Figure 2. Since multiple prefixes have the same execution result (e.g., YELLOW HASHAT and RED HASSHIRT), the execution space is smaller.

Each path in execution space represents a different program prefix, and the path's final state represents its execution result. Program search can therefore be reduced to execution search: given an example $(c, \mathbf{u}, y)$ and a model π_θ, we can use π_θ to explore in execution space, discover *correct terminal states*, i.e. states corresponding to correct full programs, and extract paths leading to those states. As the number of paths may be exponential in the size of the graph, we can use beam-search to extract the most probable correct programs (according to the model) in the discovered graph.

Our approach is similar to the DPD algorithm (Pasupat and Liang, 2016), where CKY-style search is performed in denotation space, followed by search in a pruned space of programs. However, DPD was used without learning, and the search was not guided by a trained model, which is a major part of our algorithm.

4.2 Value-based Beam Search in Execution Space

We propose **V**alue-based **B**eam **S**earch **i**n e**X**ecution space (VBSIX), a variant of beam

Algorithm 1 Program Search with VBSIX

```
 1: function ProgramSearch($c, \mathbf{u}, y, \pi_\theta, V_\phi$)
 2:     $G, \mathcal{T} \leftarrow$ VBSIX($c, \mathbf{u}, y, \pi_\theta, V_\phi$)
 3:     $\mathcal{Z} \leftarrow$ Find paths in $G$ that lead to states in $\mathcal{T}$ with beam search
 4:     Return $\mathcal{Z}$
 5: function VBSIX($c, \mathbf{u}, y, \pi_\theta, V_\phi$)
 6:     $\mathcal{T} \leftarrow \emptyset, P \leftarrow \{\}$                 ▷ init terminal states and DP chart
 7:     $s_0$ := The empty program parsing state
 8:     $B_0 \leftarrow \{s_0\}, G = (\{s_0\}, \emptyset)$                ▷ Init beam and graph
 9:     $P_0[s_0] \leftarrow 1$                               ▷ The probability of $s_0$ is 1
10:     for $t \in [1 \dots L]$ do
11:         $B_t \leftarrow \emptyset$
12:         for $s \in B_{t-1}, a \in \mathcal{A}$ do
13:             $s' \leftarrow \delta(s, a)$
14:             Add edge $(s, s')$ to $G$ labeled with $a$
15:             if $s'$ is correct terminal then
16:                 $\mathcal{T} \leftarrow \mathcal{T} \cup \{s'\}$
17:             else
18:                 $P_t[s'] \leftarrow P_t[s'] + P_{t-1}[s] \cdot \pi_\theta(a|s)$
19:                 $B_t \leftarrow B_t \cup \{s'\}$
20:         Sort $B_t$ by AC-Scorer($\cdot$)
21:         $B_t \leftarrow$ Keep the top-$K$ states in $B_t$
22:     Return $G, \mathcal{T}$
23: function AC-Scorer($s, P_t, V_\phi, y$)
24:     Return $P_t[s] + V_\phi(s, y)$
```

search modified for searching in execution space, that scores search states with a value-based network. VBSIX is formally defined in Algorithm 1, which we will refer to throughout this section.

Standard beam search is a breadth-first traversal of the program space tree, where a fixed number of vertices are kept in the beam at every level of the tree. The selection of vertices is done by scoring their corresponding prefixes according to $p_\theta(z_{1 \dots t} \mid \mathbf{u}, c)$. VBSIX applies the same traversal in execution space (lines 10-21). However, since each vertex in the execution space represents an execution result and not a particular prefix, we need to modify the scoring function.

Let s be a vertex discovered in iteration t of the search. We propose two scores for ranking s. The first is *the actor score*, the probability of reaching vertex s after t iterations[2] according to the model π_θ. The second and more novel score is the value-based *critic score*, an estimate of the state's expected reward. The AC-Score is the sum of these two scores (lines 23-24).

The actor score, $p^t_\theta(s)$, is the sum of probabilities of all prefixes of length t that reach s (rather than the probability of one prefix as in beam search). VBSIX approximates $p^t_\theta(s)$ by performing the summation only over paths that reach s via states in the beam B_{t-1}, which can be done efficiently with a dynamic programming (DP) chart $P_t[s]$ that keeps actor score approximations in each iteration (line 18). This lower-bounds the true $p^t_\theta(s)$ since some prefixes of length t that reach s might have not been discovered.

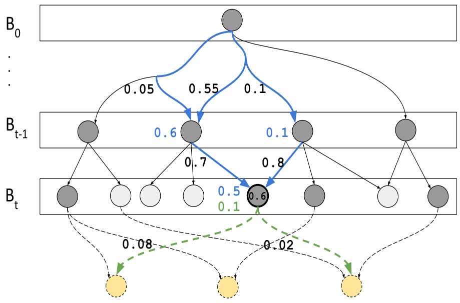

Figure 4: An illustration of scoring and pruning states in step t of VBSIX. Discovered edges are in full edges, undiscovered edges are dashed, correct terminal states are dashed and in yellow, and states that are kept in the beam are in dark grey. The actor scores of the highlighted vertex (0.5) and its parents (0.6, 0.1) are in blue, and its critic score (0.1) is in green.

Contrary to standard beam-search, we want to score search states also with a critic score $\mathbb{E}_{p_\theta}[R(s)]$, which is the sum of the suffix probabilities that lead from s to a correct terminal state:

$$\mathbb{E}_{p_\theta}[R(s)] = \sum_{\tau(s)} p_\theta(\tau(s) \mid s) \cdot R(\tau(s)),$$

where $\tau(s)$ are all possible trajectories starting from s and $R(\tau(s))$ is the reward observed when taking the trajectory $\tau(s)$ from s. Enumerating all trajectories $\tau(s)$ is intractable and so we will approximate $\mathbb{E}_{p_\theta}[R(s)]$ with a trained value network $V_\phi(s, y)$, parameterized by ϕ. Importantly, because we are searching at training time, we can condition V_ϕ on both the current state s and target denotation y. At test time we will use π_θ only, which does not need access to y.

Since the value function and DP chart are used for efficient ranking, the asymptotic run-time complexity of VBSIX is the same as standard beam search ($\mathcal{O}(K \cdot |\mathcal{A}| \cdot L)$). The beam search in Line 3, where we extract programs from the constructed execution space graph, can be done with a small beam size, since it operates over a small space of correct programs. Thus, its contribution to the algorithm complexity is negligible.

Figure 4 visualizes scoring and pruning with the actor-critic score in iteration t. Vertices in B_t are discovered by expanding vertices in B_{t-1}, and each vertex is ranked by the AC-scorer. The highlighted vertex score is 0.6, a sum of the actor score (0.5) and the critic score (0.1). The actor score is the sum of its prefixes $((0.05 + 0.55) \cdot 0.7 + 0.01 \cdot$

---

[2] We score paths in different iterations independently to avoid bias for shorter paths. An MDP state that appears in multiple iterations will get a different score in each iteration.

$0.08 = 0.5$) and the critic score is a value network estimate for the sum of probabilities of outgoing trajectories reaching correct terminal states ($0.02 + 0.08 = 0.1$). Only the top-K states are kept in the beam ($K = 4$ in the figure).

VBSIX leverages execution space in a number of ways. First, since each vertex in execution space compactly represents multiple prefixes, a beam in VBSIX effectively holds more prefixes than in standard beam search. Second, running beam-search over a graph rather than a tree is less greedy, as the same vertex can surface back even if it fell out of the beam.

The value-based approach has several advantages as well: First, evaluating the probability of outgoing trajectories provides look-ahead that is missing from standard beam search. Second (and most importantly), V_ϕ is conditioned on y, which π_θ doesn't have access to, which allows finding correct programs with low model probability, that π_θ can learn from. We note that our two contributions are orthogonal: the critic score can be used in program space, and search in execution space can be done with actor-scores only.

5 Training

We train the model π_θ and value network V_ϕ jointly (Algorithm 2). π_θ is trained using MML over discovered correct programs (Line 4, Algorithm 1). The value network is trained as follows: Given a training example $(c, \mathbf{u}, y)$, we generate a set of correct programs $\mathcal{Z}_{\text{pos}}$ with VBSIX. The value network needs negative examples, and so for every incorrect terminal state z_{neg} found during search with VBSIX we create a single program leading to z_{neg}. We then construct a set of training examples $\mathcal{D}_v$, where each example $((s, y), l)$ labels states encountered while generating programs $z \in \mathcal{Z}$ with the probability mass of correct programs suffixes that extend it, i.e., $l = \sum_{z_t} p_\theta(z_{t\ldots|z|})$, where z_t ranges over all $z \in \mathcal{Z}$ and $t \in [1 \ldots |z|]$ Finally, we train V_ϕ to minimize the log-loss objective: $\sum_{((s,y),l)\in\mathcal{D}_v} l\cdot \log V_\phi(s,y) + (1-l)(\log(1-V_\phi(s,y)))$.

Similar to actor score estimation, labeling examples for V_ϕ is affected by beam-search errors: the labels lower bound the true expected reward. However, since search is guided by the model, those programs are likely to have low probability. Moreover, estimates from V_ϕ are based on multiple examples, compared to probabilities in the DP chart, and are more robust to search errors.

Algorithm 2 Actor-Critic Training

```
procedure TRAIN()
    Initialize $\theta$ and $\phi$ randomly
    while $\pi_\theta$ not converged do
        $(x := (c, \mathbf{u}), y) \leftarrow$ select random example
        $\mathcal{Z}_{\text{pos}} \leftarrow \text{PROGRAMSEARCH}(c, \mathbf{u}, y, \pi_\theta, V_\phi)$
        $\mathcal{Z}_{\text{neg}} \leftarrow$ programs leading to incorrect terminal states
        $\mathcal{D}_v \leftarrow \text{BUILDVALUEEXAMPLES}((\mathcal{Z}_{\text{pos}} \cup \mathcal{Z}_{\text{neg}}), c, y)$
        Update $\phi$ using $\mathcal{D}_v$, update $\theta$ using $(x, \mathcal{Z}_{\text{pos}}, y)$
function BUILDVALUEEXAMPLES($\mathcal{Z}, c, \mathbf{u}, y$)
    for $z \in \mathcal{Z}$ do
        for $t \in [1 \ldots |z|]$ do
            $s \leftarrow [\![z_{1\ldots t}]\!]^{ex}_{c}$
            $L[s] \leftarrow L[s] + p_\theta(z_{t\ldots|z|} \mid c, \mathbf{u}) \cdot R(z)$
    $\mathcal{D}_v \leftarrow \{((s, y), L[s])\}_{s \in L}$
    Return $\mathcal{D}_v$
```

Neural network architecture: We adapt the model proposed by Guu et al. (2017) for SCONE. The model receives the current utterance u^i and program stack ψ, and returns a distribution over the next token. Our value network receives the same input, but also the next utterance u^{i+1}, the world state w^i and target world state y, and outputs a scalar. Appendix A provides a full description.

6 Experiments

6.1 Experimental setup

We evaluated our method on the three domains of SCONE with the standard accuracy metric, i.e., the proportion of test examples where the predicted program has the correct denotation. We trained with VBSIX, and used standard beam search ($K = 32$) at test time for programs' generation. Each test example contains 5 utterances, and similar to prior work we reported the model accuracy on all 5 utterances as well as the first 3 utterances. We ran each experiment 6 times with different random seeds and reported the average accuracy and standard deviation.

In contrast to prior work on SCONE (Long et al., 2016; Guu et al., 2017; Suhr and Artzi, 2018), where models were trained on all sequences of 1 or 2 utterances, and thus were exposed during training to all gold intermediate states, we trained from longer sequences keeping intermediate states latent. This leads to a harder search problem that was not addressed previously, but makes our results incomparable to previous results [3]. In SCENE and TANGRAM, we used the first 4 and 5 utterances as examples. In ALCHEMY, we used the first utterance and 5 utterances.

---

[3] For completeness, we show the performance on these datasets from prior work in Appendix C.

Table 2: Validation accuracy when ablating the different components of VBSIX. The first line presents MML, the last line is VBSIX, and the intermediate lines examine execution space and value-based networks separately.

Training details To warm-start the value network, we trained it for a few thousand steps, and only then start re-ranking with its predictions. Moreover, we gain efficiency by first returning K_0(=128) states with the actor score, and then re-ranking with the actor-critic score, returning K(=32) states. Last, we use the value network only in the last two utterances of every example since we found it has less effect in earlier utterances where future uncertainty is large. We used the Adam optimizer (Kingma and Ba, 2014) and fixed GloVe embeddings (Pennington et al., 2014) for utterance words.

Baselines We evaluated the following training methods (Hyper-parameters are in appendix B):

1. MML: Our main baseline, where search is done with beam search and training with MML. We used randomized beam-search, which adds ϵ-greedy exploration to beam search, which was proposed by Guu et al. (2017) and performed better [4].
2. EXPERT-MML: An alternative way of using the target denotation y at training time, based on imitation learning (Daume et al., 2009; Ross et al., 2011; Berant and Liang, 2015), is to train an *expert policy* $\pi_\theta^{\text{expert}}$, which receives y as input in addition to the parsing state, and trains with the MML objective. Then, our policy π_θ is trained using programs found by $\pi_\theta^{\text{expert}}$. The intuition is that the expert can use y to find good programs that the policy π_θ can train from.
3. VBSIX: Our proposed training algorithm.

We also evaluated REINFORCE, where Monte-Carlo sampling is used as search strategy (Williams, 1992; Sutton et al., 1999). We followed the implementation of Guu et al. (2017), who performed variance reduction with a constant baseline and added ϵ-greedy exploration. We found that REINFORCE fails to discover any correct programs to bootstrap from.

6.2 Results

Table 1 reports test accuracy of VBSIX compared to the baselines. First, VBSIX outperforms all baselines in all cases. MML is the strongest baseline, but even with an increased beam ($K = 64$), VBSIX ($K = 32$) surpasses it by a large margin (more than 20 points on average). On top of the improvement in accuracy, in ALCHEMY and TANGRAM the standard deviation of VBSIX is lower than the other baselines across the 6 random seeds, showing the robustness of our model.

EXPERT-MML performs worse than MML in all cases. We hypothesize that using the denotation y as input to the expert policy $\pi_\theta^{\text{expert}}$ results in many spurious programs, i.e., they are unrelated to the utterance meaning. This is since the expert can learn to perform actions that take it to the target world state while ignoring the utterances completely. Such programs will lead to bad generalization of π_θ. Using a critic at training time eliminates this problem, since its scores depend on π_θ.

Ablations We performed ablations to examine the benefit of our two technical contributions (a) execution space (b) value-based search. Table 2 presents accuracy on the validation set when

---

[4] We did not include meritocratic updates (Guu et al., 2017), since it performed worse in initial experiments.

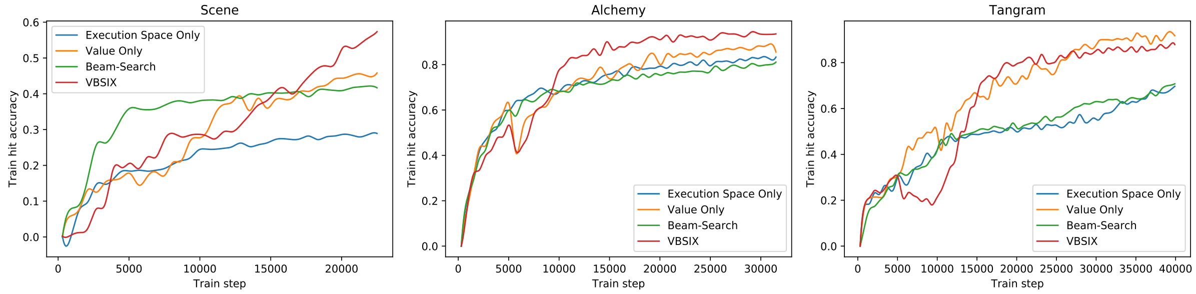

Figure 5: Training hit accuracy on examples with 5 utterances, comparing VBSIX to baselines with ablated components. The results are averaged over 6 runs with different random seeds (best viewed in color)

each component is used separately, when both of them are used (VBSIX), and when none are used (beam-search). We find that both contributions are important for performance, as the full system achieves the highest accuracy in all domains. In SCENE, each component has only a slight advantage over beam-search, and therefore both are required to achieve significant improvement. However, in ALCHEMY and TANGRAM most of the gain is due to the value network.

We also directly measured the *hit accuracy* at training time, i.e., the proportion of training examples where the beam produced by the search algorithm contains a program with the correct denotation, showing the effectiveness of search at training time. In Figure 5, we report train hit accuracy in each training step, averaged across 6 random seeds. The graphs illustrate the performance of each search algorithm in every domain throughout training. The validation accuracy results are correlated with the improvement in train hit-accuracy.

6.3 Analysis

Execution Space We empirically measured two quantities that we expect should reflect the advantage of execution-space search. First, we measured the number of programs stored in the execution space graph compared to beam search, which holds K programs. Second, we counted the average number of states that are connected to correct terminal states in the discovered graph, but fell out of the beam during the search. The property reflects the gain from running search over a graph structure, where the same vertex can resurface. We preformed the analysis on VBSIX over 5-utterance training examples in all 3 domains. The following table summarizes the results:

Property	**SCENE**	**ALCHEMY**	**TANGRAM**
Paths in beam	143903	5892	678
Correct pruned	18.5	11.2	3.8

We found the measured properties and the contribution of execution space in each domain are correlated, as seen in the ablations. Differences between domains are due to the different complexities of their formal languages. As the formal language becomes more expressive, the execution space is more compressed as each state can be reached in more ways. In particular, the formal language in SCENE contains more functions compared to the other domains, and so it benefits the most from execution-space search.

Value Network We analyzed the accuracy of the value network at training time by measuring, for each state, the difference between its expected reward (estimated from the discovered paths) and the value network prediction. Figure 6 shows the average difference in each training step for all encountered states (in blue), and for high reward states only (states with expected reward larger than 0.7, in orange). Those metrics are averaged across 6 runs with different random seeds.

The accuracy of the value network improves during training, except when the policy changes substantially, in which case the value network needs to re-evaluate the policy. When the value network converges, the difference between its predictions and the expected reward is $0.15 - 0.2$ on average. However, for high reward states the difference is higher (~ 0.3). This indicates that the value network has a bias toward lower values, which is expected as most states lead to low rewards. Since VBSIX uses the value network as a beam-search ranker, the value network doesn't need to be exact as long as it assigns higher values to states with higher expected rewards. Further analysis is provided in appendix D.

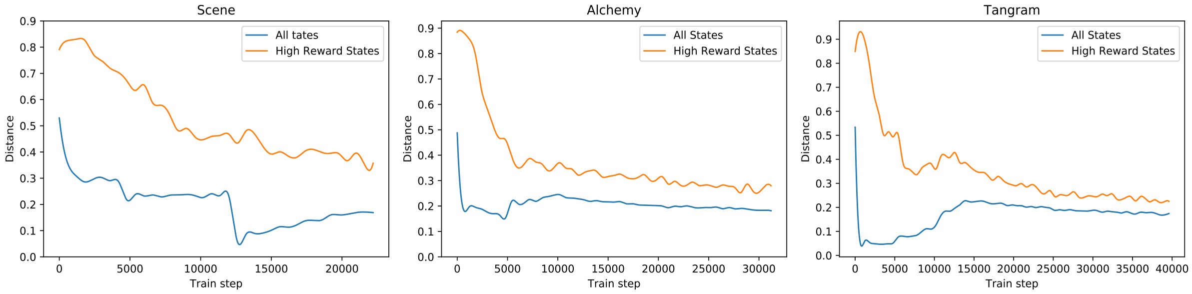

Figure 6: The difference between the prediction of the value network and the expected reward (estimated from the discovered paths) during training. We report the average difference for all of the states (blue) and for the high reward states only (> 0.7, orange). The results are averaged over 6 runs with different random seeds (best viewed in color).

7 Related Work

Training from denotations has been extensively investigated (Kwiatkowski et al., 2013; Pasupat and Liang, 2015; Bisk et al., 2016), with a recent emphasis on neural models (Neelakantan et al., 2016; Krishnamurthy et al., 2017). Improving beam search has been investigated by proposing specialized objectives (Wiseman and Rush, 2016), stopping criteria (Yang et al., 2018), and using continuous relaxations (Goyal et al., 2018).

Bahdanau et al. (2017) and Suhr and Artzi (2018) proposed ways to evaluate intermediate predictions from a sparse reward signal. Bahdanau et al. (2017) used a critic network to estimate expected BLEU in translation, while Suhr and Artzi (2018) used edit-distance between the current world and the goal for SCONE. But, in those works stronger supervision was assumed: Bahdanau et al. (2017) utilized the gold sequences, and Suhr and Artzi (2018) used intermediate worlds states. Moreover, intermediate evaluations were used to compute gradient updates, rather than for guiding search.

Guiding search with both policy and value networks was done in Monte-Carlo Tree Search (MCTS) for tasks with a sparse reward (Silver et al., 2017; T. A. and and Barber, 2017; Shen et al., 2018). In MCTS, value network evaluations are refined with backup updates to improve policy scores. In this work, we gain this advantage by using the target denotation. The use of an actor and a critic is also reminiscent of A^* where states are scored by past cost and an admissible heuristic for future cost (Klein and Manning, 2003; Pauls and Klein, 2009; lee et al., 2016). In semantic parsing, Misra et al. (2018) recently proposed a critic distribution to improve the policy, which is based on prior domain knowledge (that is not learned).

8 Conclusions

In this work, we propose a new training algorithm for mapping instructions to programs given denotation supervision only. Our algorithm exploits the denotation at training time to train a critic network used to rank search states on the beam, and performs search in a compact execution space rather than in the space of programs. We evaluated on three different domains from SCONE, and found that it dramatically improves performance compared to strong baselines across all domains.

VBSIX is applicable to any task that supports graph-search exploration. Specifically, for tasks that can be formulated as an MDP with a deterministic transition function, which allow efficient execution of multiple partial trajectories. Those tasks include a wide range of instruction mapping (Branavan et al., 2009; Vogel and Jurafsky, 2010; Anderson et al., 2018) and semantic parsing tasks (Dahl et al., 1994; Iyyer et al., 2017; Yu et al., 2018). Therefore, evaluating VBSIX on other domains is a natural next step for our research.

Acknowledgments

We thank the anonymous reviewers for their constructive feedback. This work was completed in fulfillment for the M.Sc degree of the first author. A Neural Network Architecture

We adopt the model $\pi_\theta(\cdot)$ proposed by Guu et al. (2017). The model receives the current utterance u^i and the program stack ψ. A bidirectional LSTM (Hochreiter and Schmidhuber, 1997) is used to embed u_i, while ψ is embedded by concatenating the embedding of stack elements. The embedded input is then fed to a feed-forward network with attention over the LSTM hidden states, followed by a softmax layer that predicts a program token. Our value network $V_\phi(\cdot)$ shares the input layer of $\pi_\theta(\cdot)$. In addition, it receives the next utterance u^{i+1}, the current world state w^i and the target world state w^M. The utterance u^{i+1} is embedded with an additional BiLSTM, and world

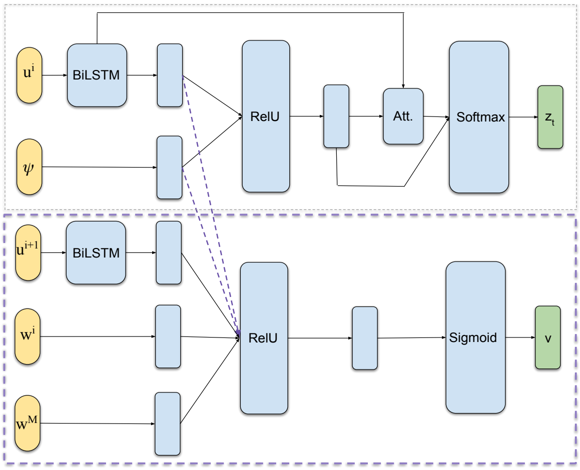

Figure 7: The model proposed by Guu et al. (2017) (top), and our value network (bottom).

states are embedded by concatenating embeddings of SCONE elements. The inputs are concatenated and fed to a feed-forward network, followed by a sigmoid layer that outputs a scalar.

B Hyper-parameters

Table 3 contains the hyper-parameter setting for each experiment. Hyper-parameters of REINFORCE and MML were taken from Guu et al. (2017). In all experiments learning rate was 0.001 and mini-batch size was 8. We explicitly define the following hyper-parameters which are not self-explanatory:

1. *Training steps*: The number of training steps taken.
2. *Sample size*: Number of samples drawn from p_θ in REINFORCE
3. *Baseline*: A constant subtracted from the reward for variance reduction.
4. *Execution beam size*: K in Algorithm 1.
5. *Program bea size*: Size of beam in line 3 of Algorithm 1.
6. *Value ranking start step*: Step when we start ranking states using the critic score.
7. *Value re-rank size*: Size of beam K_0 returned by the actor score before re-ranking with the actor-critic score.

C Prior Work

In prior work on SCONE, models were trained on sequences of 1 or 2 utterances, and thus were exposed during training to all gold intermediate states (Long et al., 2016; Guu et al., 2017; Suhr and Artzi, 2018). Fried et al. (2018) assumed access to the full annotated logical form. In contrast, we trained from longer sequences, keeping the logical form and intermediate states latent. We report the test accuracy as reported by prior work and in this paper, noting that our results are an average of 6 runs, while prior work reports the median of 5 runs.

Naturally, our results are lower compared to prior work that uses much stronger supervision. This is because our setup poses a hard search problem at training time, and also requires overcoming *spuriousness* – the fact that even incorrect programs sometimes lead to high reward.

D Value Network Analysis

We analyzed the ability of the value network to predict expected reward. The reward of a state depends on two properties, (a) *connectivity*: whether there is a trajectory from this state to a correct terminal state, and (b) *model likelihood*: the probability the model assigns to those trajectories. We collected a random set of 120 states in the SCENE domain from, where the real expected reward was very high (> 0.7), or very low ($= 0.0$) and the value network predicted well (less than 0.2 deviation) or poorly (more than 0.5 deviation). For ease of analysis we only look at states from the final utterance.

To analyze connectivity, we looked at states that cannot reach a correct terminal state with a single action (since states in the last utterance can perform one action only, the expected reward is 0). Those are states where either their current and target world differ in too many ways, or the stack content is not relevant to the differences between the worlds. We find that when there are many differences between the current and target world, the value network correctly estimates low expected reward in 87.0% of the cases. However, when there is just one mismatch between the current and target world, the value network tends to ignore it and erroneously predicts high reward in 78.9% of the cases.

To analyze whether the value network can predict the success of the trained policy, we consider states from which there is an action that leads to the target world. While it is challenging to fully interpret the value network, we notice that the network predicts a value that is > 0.5 in 86.1% of the cases where the number of people in the world is no more than 2, and a value that is < 0.5 in

VQD: Visual Query Detection in Natural Scenes

Manoj Acharya[1] **Karan Jariwala**[1] **Christopher Kanan**[1,2,3]

{ma7583, kkj1811, kanan}@rit.edu

Abstract

We propose Visual Query Detection (VQD), a new visual grounding task. In VQD, a system is guided by natural language to localize a *variable* number of objects in an image. VQD is related to visual referring expression recognition, where the task is to localize only *one* object. We describe the first dataset for VQD and we propose baseline algorithms that demonstrate the difficulty of the task compared to referring expression recognition.

1 Introduction

In computer vision, object detection is the task of identifying all objects from a specific closed-set of pre-defined classes by putting a bounding box around each object present in an image, e.g., in the widely used COCO dataset there are 80 object categories and an algorithm must put a box around all instances of each object present in an image (Lin et al., 2014). Recent deep learning based models have significantly advanced the state-of-the-art in object detection (Ren et al., 2015b); however, many applications demand more nuanced detection of objects with specific attributes or objects in relation to each other. Here, we study goal-directed object detection, where the set of possible valid objects is far greater than in the typical object detection problem. Specifically, we introduce the Visual Query Detection (VQD) task (see Fig. 1). In VQD, a system is given a query in natural language and an image and it must produce 0–N boxes that satisfy that query. VQD has numerous applications, ranging from image retrieval to robotics.

VQD is related to the visual referring expression recognition (RER) task (Kazemzadeh et al., 2014); however, in RER every image has only a *single* correct box. In contrast, in VQD there could be no valid outputs for a query or multiple valid outputs, making the task both harder and more useful. As discussed later, existing RER datasets have multiple annotation problems and have significant language bias problems. VQD is also related to Visual Question Answering (VQA), where the task is to answer questions about images in natural language (Malinowski and Fritz, 2014; Antol et al., 2015). The key difference is that in VQD the algorithm must generate image bounding boxes that satisfy the query, making it less prone to the forms of bias that plague VQA datasets.

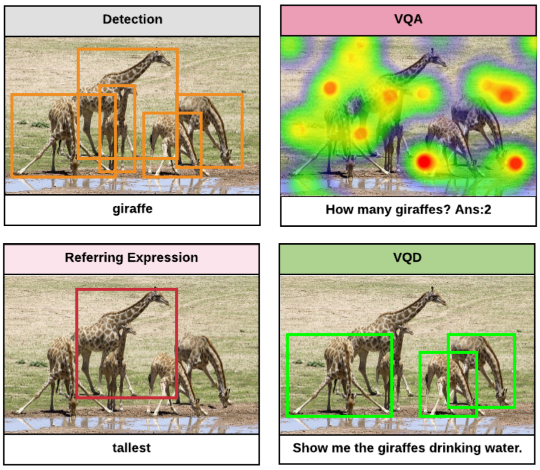

Figure 1: Unlike VQD, object detection cannot deal with attributes and relations. In VQA, often algorithms produce the right answers due to dataset bias without ‘looking’ at relevant image regions. RER datasets have short and often ambiguous prompts, and by having only a single box as an output, they make it easier to exploit dataset biases. VQD requires goal-directed object detection and outputting a variable number of boxes that answer a query.

We make the following contributions:

1. We describe the first dataset for VQD, which will be publicly released.
2. We evaluate multiple baselines on our VQD dataset.

Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related work

Over the past few years, a large amount of work has been done at the intersection of computer vision and natural language understanding, including visual madlibs (Yu et al., 2015; Tommasi et al., 2018), captioning (Farhadi et al., 2010; Kulkarni et al., 2013; Johnson et al., 2016; Liu et al., 2018), and image retrieval (Wan et al., 2014; Li et al., 2016). For VQD, the most related tasks are VQA and RER, which we review in detail.

2.1 Visual Question Answering

VQA systems take in an image and open-ended natural language question and then generate a text-based answer (Antol et al., 2015; Goyal et al., 2017; Acharya et al., 2019; Kafle et al., 2018). Many VQA datasets have been created. However, initial datasets, e.g., VQAv1 (Antol et al., 2015) and COCO-QA (Ren et al., 2015a), exhibited significant language bias in which many questions could be answered correctly without looking at the image, e.g., for VQAv1 it was possible to achieve 50% accuracy using language alone (Kafle and Kanan, 2016). To address the bias issue, the VQAv2 dataset was created with a more balanced distribution for each possible answer to make algorithms analyze the image (Goyal et al., 2017), but it still had bias in the kinds of questions asked, with some questions being scarce, e.g., reasoning questions. Synthetic datasets such as the CLEVR dataset (Johnson et al., 2017) addressed this by being synthetically generated to emphasize hard reasoning questions that are rare in VQAv1 and VQAv2. The TDIUC dataset addresses bias using both synthetically generated and human gathered questions about natural images, with performance evaluated for 12 kinds of questions (Kafle and Kanan, 2017a). While the state-of-the-art has rapidly increased on both synthetic and natural image VQA datasets, many models do not generalize across datasets (Shrestha et al., 2019).

2.2 Referring Expression Recognition

Unlike VQA, RER algorithms must produce evidence to justify their outputs. A RER algorithm outputs a box around the image location matching the input string, making it easier to tell if an algorithm is behaving correctly. The RefCOCO and RefCOCO+ datasets for RER were collected from the two-player 'ReferIt' Game (Kazemzadeh et al., 2014). The first player is asked to describe an outlined object and the second player has to correctly localize it from player one's description. The test datasets are futher split into the 'testA' and 'testB' splits. The split 'testA' contains object categories sampled randomly to be close to the original data distribution, while 'testB' contains objects sampled from the most frequent object categories, excluding categories such as 'sky', 'sand', 'floor', etc. Since, there is a time limit on the game, the descriptions are short, e.g., 'guy in a yellow t-shirt,' 'pink,' etc.

Instead of playing a timed game, to create the RefCOCOg dataset for RER, one set of Amazon Mechanical Turk (AMT) users were asked to generate a description for a marked object in an image and other users marked the region corresponding to the description (Mao et al., 2016). This resulted in more descriptive prompts compared to RefCOCO and RefCOCO+.

The Visual7W dataset for VQA includes a 'pointing' task that is closely related to RER (Zhu et al., 2016). Pointing questions require choosing which box of the four *given* boxes correctly answered a query. Systems did not generate their own boxes, and there is always one correct box.

Cirik et al. (2018) showed that RER datasets suffer from biases caused by their dataset collection procedure. For RefCOCOg, they found that randomly permuting the word in the referring expression caused only about a 5% drop in performance, suggesting that instead of relying on language structure, systems may be using some hidden correlations in language. They further showed that an image only model that ignores the referring expression yielded a precision of 71.2% for top-2 best predictions. They also found that predicting the object category given the image region produced an accuracy of 84.2% for top-2 best predictions. By having 0–N boxes, VQD is harder for an image-only model to perform well.

3 The VQD 1.0 Dataset (VQDv1)

We created VQDv1, the first dataset for VQD. VQDv1 is created synthetically using annotations from Visual Genome (VG), COCO, and COCO Panoptic. While this limits variety, it helps combat some kinds of bias and serves as an initial version of the dataset. VQDv1 has three distinct query categories:

1. Object Presence (e.g., 'Show the dog in the image')
2. Color Reasoning (e.g., 'Which plate is white

Type	# Questions
Simple	391,628
Color	172,005
Positional	57,904
Total	621,537

Table 1: VQDv1 Query Types

Dataset	# Images	# Questions
RefCOCO	19,994	142,209
RefCOCO+	19,992	141,564
RefCOCOg	26,711	85,474
VQDv1	123,287	621,537

Table 2: VQDv1 compared to RER datasets.

in color?')

3. Positional Reasoning (e.g., 'Show the cylinder behind the girl in the picture')

The number of queries per type are given in the Table 1. The dataset statistics and example images and are shown in Fig. 2 and Fig. 3, respectively. We show statistics for VQDv1 compared to RER datasets in Table 2.

All images in VQDv1 are from COCO. The ground truth bounding box annotations are derived from the COCO Panoptic annotations dataset (Kirillov et al., 2018). The questions are generated using multiple templates for each question type, which is an approach that has been used in earlier work for VQA (Kafle and Kanan, 2017a; Kafle et al., 2017). The query objects and their attributes are extracted by integrating the annotations from images that have both COCO and VG annotations. COCO annotations are focused on objects, while VG also has attribute and relationship information, e.g., size, color, and actions for scene objects.

3.1 Object Presence

Object presence questions require an algorithm to determine all instances of an object in an image without any relationship or positional attributes, for example, 'Show me the horse in the image' or 'Where is the chair?' We use all of the COCO 'things' labels and half of the COCO 'stuff' labels to generate these questions, making this task test the same capabilities as conventional object detection. We filter some 'stuff' categories that do not have well defined bounding boxes such as 'water-other', 'floor-stone', etc. We use multiple templates to create variety, e.g., 'Show the <object> in the image', 'Where are the <object> in the picture?' etc.

3.2 Color Reasoning

Color questions test the presence of objects modified by color attributes, e.g., 'Show me the cat which is grey in color' or 'Which blanket is blue in color?' Since, COCO has only object annotations, color attributes are derived from VG's attribute annotations. We align every VG image annotation with COCO annotations to obtain (object, color) annotations for each bounding box. When multiple color attributes for an object are present, the object is assigned a single color from that attribute set.

3.3 Positional Reasoning

Positional reasoning questions test the location of objects with respect to other objects, e.g., 'Show the building behind horses', 'Which people are in front of the lighthouse?', and 'Show the rhino behind elephant.' We again use VG's relationship and attribute annotations to create these questions.

3.4 Generating Counter-Concept Questions

Counter-concept questions have no valid boxes as outputs, and we endeavor to create hard counter-concept questions for each category. We ask 'Show me the zebra' only if there is a similar animal present (e.g., a cow), which was done by using COCO's super-categories. Likewise, 'Show me the donut that is brown in color' is only asked if a brown donut does not exist in the image.

4 Experiments

Our experiments are designed to probe the behavior of models on VQD compared to RER datasets. To facilitate this, we created a variant of our VQDv1 dataset that had only a single correct bounding box.

To evaluate performance for the RER and '1 Obj' version of the VQDv1 dataset, systems only output a single bounding box during test time, so the **Precision@1** metric is used. For the '0-N Obj' version of the VQDv1 dataset, we use the standard PASCAL VOC metric $\mathbf{AP}^{IoU=.50}$ from object detection, which calculates the average precision across the dataset using an intersection over union (IoU) greater than 0.5 criteria for matching with the ground truth boxes.

4.1 Models Evaluated

We implemented and evaluated four models for VQD. All models are built on top of Faster R-CNN with a ResNet-101 backbone whose output bounding boxes pass through Non-Maximal Suppression

	RefCOCO			RefCOCO+			RefCOCOg		VQDv1	
	val	testA	testB	val	testA	testB	val	test	1 Obj.	0–N Obj.
DETECT	38.63	37.82	38.32	38.85	37.85	38.98	50.13	50.03	30.44	26.94
RANDOM	16.51	14.30	19.81	16.67	14.10	20.45	19.87	19.76	9.77	2.38
Query-Blind	33.95	37.28	31.58	34.06	37.34	32.46	39.79	23.34	23.34	6.80
Vision+Query	69.41	**75.52**	**65.28**	**59.83**	**65.21**	**53.02**	**62.52**	**62.06**	**37.55**	**31.03**
SLR	**69.48**	73.71	64.96	55.71	60.74	48.80	60.21	59.63	–	–
SLR	68.95	73.10	64.85	54.89	60.04	49.56	59.33	59.21	–	–

Table 3: Results on RER datasets and two versions of our VQD dataset. The ‘1 Obj’ version is trained and evaluated on queries with only a single box, analogous to RER, and the 0–N version contains the entire VQD dataset. All models use the same object proposals and visual features.

with a threshold of 0.7. This acts as a region proposal generator that provides CNN features for each region.

The four models we evaluate are:

1. **DETECT:** A model that uses the full Faster R-CNN system to detect all trained COCO classes, and then outputs the boxes that have the same label as the first noun in the query.
2. **RANDOM:** Select one random Faster R-CNN proposal.
3. **Query-Blind:** A vision only model that does binary classification of each region proposal’s CNN features using a 3 layer MultiLayer Perceptron(MLP) with 1024-unit hidden ReLU layers.
4. **Vision+Query (V+Q):** A model that does binary classification of each region proposal. The query features are obtained from the last hidden layer of a Gated Recurrent Unit (GRU) network, and then they are concatenated with the CNN features and fed into a 3 layer MLP with 1024-unit hidden ReLU layers.

The primary reason for providing VQDv1 (1 obj.) and the RER results is to put the benefits of the VQD task in context. To aid in this endeavor, we also include comparison results directly from the SLR models (Yu et al., 2017) for RER, which is a recent system for that task.

4.2 Training Details

The Query-Blind and Vision+Query models are trained with binary cross-entropy loss. We use a learning rate of 0.0004, and perform learning rate decay of 0.8 when the training loss plateaus continuously for five epochs. The best model is selected based on the validation loss after training for 50 epochs.

4.3 Results

Our main results are given in Table 3. Although simple, our Vision+Query model performs well across RER datasets, but it can also be applied to VQD tasks. As expected, RANDOM performs poorly on both VQDv1 datasets. DETECT beats RANDOM in the single object VQD setting by a large margin. Since, most of the questions in the RER datasets ask about common COCO categories, choosing one of those objects might be enough to get decent performance; however, DETECT performs poorly when evaluated under 0-N object settings in VQDv1. To handle queries in VQD, models must be able to understand the context and comprehend multiple objects in isolation.

5 Conclusion

In this paper, we described our VQDv1 dataset as a test for visual grounding via goal-directed object detection. VQDv1 has both simple object presence and complex questions with 0–N bounding boxes. While VQDv1 contains only synthetically generated questions, this can help mitigate some forms of bias present in other VQA and RER datasets (Cirik et al., 2018; Kafle and Kanan, 2017b). While it would be expensive, a large, carefully filtered, and well designed human annotated VQD dataset is the next step toward advancing visual grounding research.

Compared to VQA, we argue that it is harder to be right for the *wrong* reasons in VQD because methods must generate bounding boxes. Compared to RER, we argue that it is harder to exploit bias in VQD since there are a variable number of boxes per image, making it considerably more difficult, as demonstrated by our experiments. We believe the VQD approach has considerable value and can be used to advance visual grounding research.

Abstract

Over the last few years, there has been growing interest in learning models for physically grounded language understanding tasks, such as the popular blocks world domain. These works typically view this problem as a single-step process, in which a human operator gives an instruction and an automated agent is evaluated on its ability to execute it. In this paper we take the first step towards increasing the bandwidth of this interaction, and suggest a protocol for including advice, high-level observations about the task, which can help constrain the agents prediction. We evaluate our approach on the blocks world task, and show that even simple advice can help lead to significant performance improvements. To help reduce the effort involved in supplying the advice, we also explore model self-generated advice which can still improve results.

1 Introduction

The problem of constructing an artificial agent capable of understanding and executing human instructions is one of the oldest long-standing AI challenges (Winograd, 1972). This problem has numerous applications in various domains (planning, navigation and assembly) and can help accommodate seamless interaction with personal assistants in many environments. Due to its central role in AI and wide applicability, this problem has seen a surge of interest recently (MacMahon et al., 2006; Branavan et al., 2009; Chen and Mooney, 2011; Tellex et al., 2011; Matuszek et al., 2012; Kim and Mooney, 2013; Misra et al., 2017).

Recent works (Bisk et al., 2016; Tan and Bansal, 2018) focus on exploring deep learning methods for grounding spatial language. In this popular setup, human communication with robots is viewed as a single-step process, in which a natural language (NL) instruction is provided, and an outcome is observed.

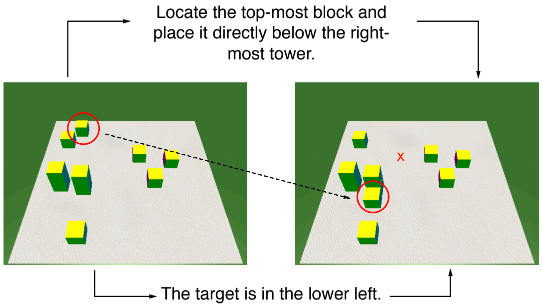

Figure 1: Based on the instruction (upper sentence) the model predicts the coordinates of the block and its target location. The 'x' represents an incorrect prediction, corrected by the provided advice (lower sentence).

Our goal in this paper is to explore different approaches for relaxing the *single step* assumption, and present initial results which we hope would motivate future work in this direction. Similar to interactive dialog systems (Allen et al., 1995; Rybski et al., 2007; Wen et al.), we view this problem as an *interactive* process, in which the human operator can observe the agents' response to their instruction and adjust it by providing advice, a form of online feedback. Specifically, the advice consists of a short sentence, simplifying the user's intent. We utilize two types of advice, one restricting the agent's search space to a general region (*restrictive advice*), and the other telling the agent the appropriate direction (up, down, left, right) to adjust its current prediction (*corrective advice*).

Our focus is on the challenging task of moving blocks on a grid (Winograd, 1972), in which the agent is given only an instruction and the state of the grid, and must predict the coordinates of where a block must be moved. We follow the difficult experimental settings suggested by (Bisk et al., 2016), in which the blocks are unlabeled and can only be referenced by their spatial properties. Fig. 1 describes our settings and uses the advice *"the target is in the lower left"*, to restrict the agents search space after observing the incor-

Proceedings of NAACL-HLT 2019, pages 1962–1967
Minneapolis, Minnesota, June 2 - June 7, 2019.

rect prediction placed the target block in the top half of the board.

To accommodate these settings, we take a two step approach. First, we ground the advice text in the simulated blocks-world environment by training a neural network. In the second step, we integrate the trained advice network into the end-to-end neural model proposed by Bisk et al. Our architecture is described in Fig. 2. The experiments we run show that this end-to-end advice model successfully grounds the meaning of our advice.

We propose four novel interactive advice-based protocols that can be applied on any robot communication architecture, ordered in terms of decreasing human effort. As expected, as human effort lessens, performance does worsen, but all protocols outperform Bisk et al. (whom our model is *identical* to besides the inclusion of advice).

Most notably, we explore the notion of model *self-generated* advice, which significantly reduces/eliminates human effort. In this approach, a model is trained to automatically generate restrictive advice for a given scenario, based on the assumption that it is easier to predict a region containing the target coordinates rather than their exact location. We validate this assumption by developing a neural architecture to predict the restrictive advice and show it can help improve the overall prediction quality, despite having no human assistance.

2 Model

This section describes the architecture we developed for understanding advice, and how to incorporate it into the original Bisk et al. model to make better predictions. We begin by defining the Blocks World task and the types of advice we use. We then introduce a model for grounding the advice and a method for incorporating the pre-trained advice understanding module into the original model. Finally, we discuss an architecture for *advice generation*, a method for self-predicting the advice to avoid any human intervention. Further details of our models and advice generation process are in the Appendix.

2.1 Blocks World Task Definition

Given an input state, consisting of all the block positions on a board, and a NL instruction, the model has to predict the coordinates of the source block to be moved and its target location. We follow the definition by (Bisk et al., 2016) and due to space constraints refer the reader to that paper.

2.2 Advice

The two types of advice we devise in this paper are designed to assist the prediction agent by providing simpler instructions in addition to the original input. The first, restrictive advice, informs the agent about the general region of the source / target coordinates, such as *top left*. These regions are determined by dividing the board into equally sized sections (two halves, four quadrants). The second type of advice, corrective advice, observes the agents' predictions and determines which direction (up, down, left, right) they must be adjusted to get closer to the target. Both of these are representative of information a human could easily provide to a robot in various ways (speech, using assisted devices, etc.), to help correct its predictions. Specific examples are shown below.

Predicted	Target	Advice
-	(-0.5, 0.5, 0.5)	In the top left.
(-0.5, 0.5, 0.9)	(-0.5, 0.5, 0.5)	Move down.

2.3 Advice Grounding

We pre-train a neural network model to accurately understand the advice. For both types of advice, a LSTM-RNN (Hochreiter and Schmidhuber, 1997) is used to read the advice sentence $s = w_1, w_2, ..., w_n$ and output the hidden state representations $\{h_n\}$. Prior to this, a word embedding layer is used to project the input words into high-dimension vectors $\{w_i\}$.

For restrictive advice, the last state from the LSTM h_n is fed along with a random coordinate into a Fully Connected (FC) layer. The network must output a positive prediction if the random coordinate is in the region described by the advice sentence, and negative otherwise.

For corrective advice, the last state from the LSTM h_n is fed along with a random coordinate into a FC layer, and the network must output a coordinate that follows the advice. For example, if the advice is *move the block down*, the predicted coordinate must be below the random input coordinate. If the advice is followed, the network receives 0 loss, otherwise a MSE regression loss.

2.4 End-to-End Training

The pre-trained model from Section 2.3 that understands various advice text is incorporated into

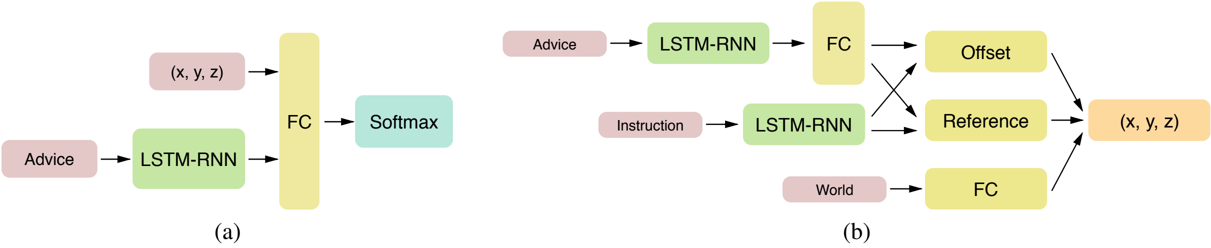

Figure 2: Our advice architectures. (a) Pre-Trained Advice Understanding Model. (b) (Bisk et al., 2016) End-to-End architecture with our pre-trained model. World represents the board state, while offset and reference represent fully connected layers used to identify the offset and reference blocks.

Model	**Source**		**Target**

Table 1: Results for our models compared to previous models evaluated as distance from gold prediction normalized by block length for source and target coordinate prediction.

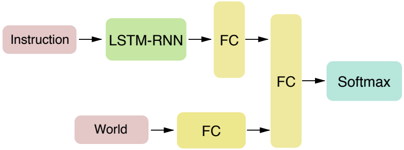

Figure 3: Model for Generating Advice.

the best performing End-to-End RNN architecture proposed in (Bisk et al., 2016) by adding a FC layer to the pre-trained LSTM state h_n and summing it with the LSTM hidden state of the original model (as shown in Figure 2b). We load and freeze the best performing parameters from our pre-trained model into the relevant portion of this end-to-end architecture, and train it on the original task of predicting the coordinates of the source / target location, with the addition of advice input.

2.5 Advice Generation

We use a neural network model to self-generate restrictive advice (as shown in Figure 3), passing the instruction into an embedding layer followed by a LSTM, the board state into a FC layer, concatenating these into a FC layer, and finally using a softmax to classify the input example into a region. We train this architecture and then run it on the test set, generate the appropriate advice based on the region the data is classified in, and use that as test advice input for the end-to-end architecture from section 2.4.

3 Experiments

Next, we present our experiments over our four different advice protocols, each with decreasing human effort and overall performance. In each protocol, we provide advice to the end-to-end model from Section 2.4, whether it is given by a human user or model self-generated. Our results, evaluated on each model's mean and median prediction error, are presented in Table 1. We always compare to the baseline Bisk et al. model, which our model is identical to besides the addition of advice (and we always beat), and the state-of-the-art best non-ensemble Tan and Bansal architecture. Note that Tan and Bansal use an advanced neural architecture and a different training procedure (source prediction trained as classification). We hypothesize that using the advice mechanism over this more complex architecture would lead to further improvements, and leave it for future work.

The pre-trained advice grounding models from Section 2.3 achieve 99.99% accuracy, and are vital, as shown by the poor performance without them (`M4` vs `M5`). These grounding models allow the end-to-end architecture to generalize to the variability in advice utterances.

3.1 Restrictive Advice

When training the end-to-end model from Section 2.4, we provide restrictive advice at training time for only half the examples. For every epoch, a different half set of examples (determined randomly) receive advice. This mechanism gives the model a chance to learn to interpret each example with and without advice, so that it can handle the interactivity without overfitting to one setup. This setup also gave the best performance.

At test time, the advice is provided only whenever the predictions fall in the wrong general region, just like a human would. As seen in Table 1, this model (`M5`) significantly outperforms both baselines (`M1`, `M3`). We note that the performance did not improve much when advice was always provided, showing that this model was able to perform well in its absence and does not rely on it (due to our choice not to provide advice all the time in training). In fact a human would only have to provide restrictive advice for 395/720 examples, and the model always follows it.[1]

3.2 Corrective Advice

We train corrective advice identically to restrictive advice from Section 3.1, except we train in two separate iterations. This is necessary as the model must learn to adjust its predictions based on the advice, which is why it is first trained to make the normal prediction (first iteration), then trained to adjust the prediction (second iteration).

In the first iteration, we train identically to (Bisk et al., 2016) with no advice, but in the second iteration corrective advice is generated based on which direction the predictions must be adjusted to be more accurate. This case is simpler than restrictive advice, since the human operator just has to provide the direction to adjust the predictions, rather than the precise region of the coordinates. However, the performance does worsen (`M5` vs `M6`).

3.3 Retry Advice

In Section 2.5, we introduced a model that was able to self-generate restrictive advice by predicting the general region of the block coordinates given the NL instruction and blocks world. Table 2 shows this model's accuracy on that task when the board is split into 4 regions. As this is a hard problem with low accuracy (`A1`), we instead generate advice for the top 2 most confident predictions (determined by the softmax scores) (`A2`).

We now introduce a new multi-step *retry* advice protocol. In the first step, the model from Section 2.5 self-generates restrictive advice based on the most confident predicted region, which it uses as input in the end-to-end model. If the user believes the coordinate prediction based on this advice is wrong, it can tell the model to "retry", and then the second most likely restrictive advice will be used. Thus, the only human feedback needed now is telling the model to "retry", rather than accurate advice as before. The performance of this (`M7`) still significantly outperforms Bisk et al. and is close to Tan and Bansal on target prediction.

Regions	**Source**	**Target**
`A1` : 4	47%	40%
`A2` : 4, Top 2 Confidence	73%	70%
`A3` : 4, Input-Specific	67%	62%

Table 2: Accuracy of model self-generated advice.

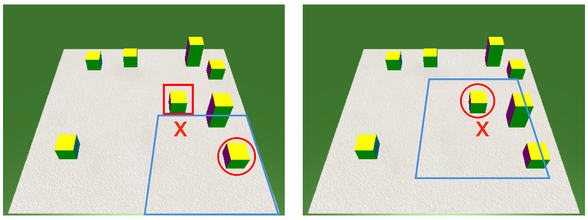
3.4 Model Self-Advice Generation

We now aim to avoid any human interaction, by letting the model completely self-generate the advice. Accomplishing it would allow us to improve the model's performance without additional human effort. We experimented with two approaches. In the first, we generate advice as described in Section 3.3. However, instead of having the user ask the model to "retry", we treat the top 2 confidence regions as a general region, and provide that as advice input as described in Section 3.1. In this case, there is a performance improvement over Bisk et al. with no human effort required (`M8` in Table 1).

Our second approach for self-generated advice aims to improve on some of the shortcomings of the first approach. Previously, when generating the advice, we had decided on four coarse-grained regions, and trained a model to classify each input example into one of these regions. In many cases,

---

[1] We note that the performance does not improve from Bisk et al. if advice is only provided at train time.



(a) (b)

Figure 4: Benefit of Input-Specific Model Self-Generated Advice
(a) The Bisk et al. model would have made a prediction ('x') close to the true block (square). However, the advice region (blue) was incorrect (due to the true block being close to the edge of it) and this led to a significantly worse prediction (circle).
(b) In the input-specific self-generated advice model, the advice region (blue) is centered at the incorrect coordinate prediction ('x'), leading to the true source block being included and a correct prediction (circle).

the true coordinate lay close to the boundary of one of these regions, often resulting in the model predicting the wrong region when self-generating the advice. This incorrect prediction would lead to significantly worse performance (when compared to the model without advice) when running the end-to-end model from Section 3.1, as the advice was incorrect (remember that the model always follows our advice, and the true coordinate is not in the advice region due to the mistake). However, if we had instead chosen our regions to be centered at the true coordinate of each input example, it would be less likely that the model would make an incorrect region prediction (since a small error would still lead to the region containing the correct coordinate). Figure 4 provides a visual explanation of this.

For this reason, we now introduce input-specific model self-generated advice. In this case, we run the Bisk et al. coordinate prediction model in two iterations. In the first iteration, we use the prediction to generate advice for a region (of the same size as in the case of 4 quadrants) centered at the predicted coordinate (see Figure 4b).[2] In the second iteration, we feed in this generated advice just like Section 3.1. This model (`M9`) achieves performance slightly worse than retry advice, and significantly better than Bisk et al., all with no human effort.[3] Table 2 shows the accuracy increase in predicting the advice now (`A3` vs `A1`). It is unsurprising that this approach to self-generating advice performs better, as now the regions are more specific to each coordinate (so there is a higher probability that the true coordinate is actually in the predicted region - see Figure 4).

We hypothesize that the performance improvements in self-generated advice happen since it is easier to predict the general region used to generate the advice rather than the specific coordinates. Previously, we have also shown the benefit of restrictive advice in improving overall coordinate prediction, so it is unsurprising that a high accuracy of advice generation leads to better overall performance. Due to this, we propose that future robot communication works take advantage of predicting and then using model self-generated advice in their end-to-end training procedure.

4 Summary

This paper takes a first step towards a stronger interaction between automated agents and their human operators, for physically grounded language understanding tasks. We focus on the popular blocks task and introduce the notion of advice, Natural Language hints provided by the human operator, correcting the model's predictions. We show that using four versions of this interactive advice driven protocol on an existing robot communication architecture, we can obtain significant performance improvements. The last method, model self-generated advice, shows the benefit of considering advice even when not designing an interactive protocol. Our future work focuses on further increasing the accuracy of the self-generated advice model, so we can achieve better performance with no human effort.

---

[2] We make sure the advice region doesn't exceed the board boundaries.

[3] Note that we must re-train the model from Section 2.3 as there are now significantly more regions. The accuracy of that model is still 99.99%, and the training procedure does not change.

Generating Knowledge Graph Paths from Textual Definitions using Sequence-to-Sequence Models

Abstract

We present a novel method for mapping unrestricted text to knowledge graph entities by framing the task as a sequence-to-sequence problem. Specifically, given the encoded state of an input text, our decoder directly predicts paths in the knowledge graph, starting from the root and ending at the target node following hypernym-hyponym relationships. In this way, and in contrast to other text-to-entity mapping systems, our model outputs hierarchically structured predictions that are fully interpretable in the context of the underlying ontology, in an end-to-end manner. We present a proof-of-concept experiment with encouraging results, comparable to those of state-of-the-art systems.

1 Introduction

Text-to-entity mapping is the task of associating a text with a concept in a knowledge graph (KG) or an ontology (we use two terms, interchangeably). Recent works (Kartsaklis et al., 2018; Hill et al., 2015) use neural networks to project a text to a vector space where the entities of a KG are represented as continuous vectors. Despite being successful, these models have two main disadvantages. First, they rely on a predefined vector space which is used as a gold standard representation for the entities in a KG. Therefore, the quality of these algorithms depends on how well the vector space is represented. Second, these algorithms are not interpretable; hence, it is impossible to understand why a certain text was linked to a particular entity.

To address these issues we propose a novel technique which first represents an ontology concept as a sequence of its ancestors in the ontology (hypernyms) and then maps the corresponding textual description to this unique representation. For example, given the textual description of the concept *swift* ("small bird that resembles a swallow and is noted for its rapid flight"), we map it to the hierarchical sequence of entities in a lexical ontology: *animal* → *chordate* → *vertebrate* → *bird* → *apodiform_bird*. This sequence of nodes constitutes a path.[1]

Our model is based on a sequence-to-sequence neural network (Sutskever et al., 2014) coupled with an attention mechanism (Bahdanau et al., 2014). Specifically, we use an LSTM (Hochreiter and Schmidhuber, 1997) encoder to project the textual description into a vector space and an LSTM decoder to predict the sequence of entities that are relevant to this definition. With this framework we do not need to rely on the pre-existing vector space of the entities, since the decoder explicitly learns topological dependencies between the entities of the ontology. Furthermore, the proposed model is more interpretable for two reasons. First, instead of the closest points in a vector space, it outputs paths; therefore, we can trace all predictions the model makes. Second, the attention mechanism allows to visualise which words in a textual description the model selects while predicting a specific concept in the path. In this paper, we consider rooted tree graphs[2] only and leave the extension of the algorithm for more generic graphs to future work.

We evaluate the ability of our model in generating graph paths for previously unseen textual definitions on seven ontologies (Section 3). We show that our technique either outperforms or performs on a par with a competitive multi-sense LSTM model (Kartsaklis et al., 2018) by better utilising external information in the form of word embeddings. The code and resources for the paper can

---

[1] We only consider hypernymy relations, from the root to the parent node (*apodiform_bird*) of the entity *swift*.

[2] Only single root is allowed. If a tree has more than one root, one can create a dummy root node and connect the roots of the tree to it.

2 Methodology

We assume that an ontology is represented as a rooted tree graph $G = (V, E, T)$, where V is a set of entities (e.g. synsets in WordNet), E is a set of hyponymy edges, and T is a set of textual descriptions such that $\forall v \in V$ there is a $t_v \in T$.

2.1 Node representation

We assume that an ontological concept can be defined by either using a textual description from a dictionary or hypernyms of the defining concept in the ontology. For example, to define the noun *swift* one can use the dictionary definition mentioned previously. Alternatively, the concept of *swift* can be understood from its hypernyms, e.g. in the trivial case one can say that *swift* is an *animal*. This definition is not very useful since *animal* is a hypernym for many other nouns. To provide a more specific definition, one can use a sequence of hypernyms e.g. *animal* → *chordate* → *vertebrate* → *bird* → *apodiform_bird* starting from the most abstract node (root of an ontology) to the most specif (parent node of the noun).

More formally, for each entity $v \neq v_{root} \in V$ we create a path p_v. Each p_v starts from v_{root} and ends with a hypernym of v, i.e., the hierarchical order of entities is preserved. Then the path p_v is aligned with t_v such that each node is defined by a textual definition and a path. This set of aligned representations is used to train the model.

The path representation of an entity ends with its parent node. Therefore, a leaf node will not be present in any of the paths. This is problematic if a novel definition should be attached to a leaf. To alleviate this issue we employ the "dummy source sentences" technique from neural machine translation (NMT) (Sennrich et al., 2016). We create an additional set of paths from the root node to each leaf. As for the textual definition we leave it empty.

2.2 Model

We use a sequence-to-sequence model with an attention mechanism to map a textual description of a node to its path representation.

Encoder. To encode a textual definition $t_v = (w_i)_{i=1}^{N}$, where N is sentence length, we first map each word w_i to a dense embedding e_{w_i} and then use a bi-directional LSTM to project the sequence into a latent representation. The final encoding state is obtained by concatenating the forward and backward hidden states of the bi-LSTM.

Decoder. Decoding the path representation of a node from the latent state of the textual description is done again with an LSTM decoder. Similarly to the encoding stage, we map each symbol in the path $p_v = (s_j)_{j=1}^{M}$ to a dense embedding e_{s_j}, where M is the path length. To calculate the probability of the path symbol s_j at time step j we first represent the path sequence as $h^*_j = \text{LSTM}(e^j_s, h^*_{j-1})$. Then, we concatenate h^*_j with the context vector c_j (defined next) and pass the concatenated representation $[h^*_j; c_j]$ through the softmax function, i.e. $s_j = \max(\text{softmax}(\mathbf{W}[h^*_j; c_j]))$, where $\mathbf{W}$ is a weight parameter. To calculate the context vector c_j we use an attention mechanism, $e_{ji} = v_a^T \tanh(\mathbf{W_a} h_i + \mathbf{U_a} h^*_j)$ and $c_j = \sum_i^N \text{softmax}(e_{ji}) h_i$, where v_a, $\mathbf{W_a}$ and $\mathbf{U_a}$ are the weight parameters, over the words in the text description.

3 Experimental Setup

Ontologies. We experimented with seven graphs four of which are related to the bio-medical domain: Phenotype And Trait Ontology[3] (PATO), Human Disease Ontology (Schriml et al., 2012, HDO), Human Phenotype Ontology (Robinson et al., 2008, HPO) and Gene Ontology[4] (Ashburner et al., 2000, GO). The other three graphs, i.e. $\text{WN}_{\text{animal.n.01}}$[5], $\text{WN}_{\text{plant.n.02}}$ and $\text{WN}_{\text{entity.n.01}}$ are subgraphs of the WordNet 3.0 (Fellbaum, 1998). We present the statistics of the graphs in Table 1.

Ontology Preprocessing. All the ontologies we experimented with are represented as directed acyclic graphs (DAGs). This creates an ambiguity for node path definitions since there are multiple pathways from a root concept to other concepts. We have assumed that a single unambiguous pathway will reduce the complexity of the problem and leave the comparison with ambiguous pathways (which would inevitably involve a more complex model) to future work. To convert a DAG to a tree

---

[3] http://www.obofoundry.org

[4] After prerocessing GO we took its largest connected component.

[5] The subscript in 'WN' indicates the name of the root node of the graph.

Graphs	|V|	Depth	Branch	A.D
PATO	1742	(4.94,10)	(3.95,92)	20
$\text{WN}_{\text{animal.n.01}}$	3999	(6.94,12)	(3.79,52)	26
$\text{WN}_{\text{plant.n.02}}$	4487	(4.70,9)	(5.91,357)	28
HDO	9095	(5.92,12)	(4.59,222)	27
HPO	13348	(6.95,14)	(3.40,32)	24
GO	29682	(6.40,14)	(3.28,172)	21
$\text{WN}_{\text{entity.n.01}}$	74374	(8.01,18)	(4.52,402)	36

Table 1: Statistics of the Graphs. $|\mathbf{V}|$ is the number of nodes, *depth* is the path length from the root of a graph to a node, *branch* is the number of neighbours a node has (leaves were removed from the calculation). The first value in the parentheses corresponds to the average and the second to the maximum value. A.D stands for average number of decisions the model makes to infer a path, i.e A.D = average depth × average branch.

we constrain each entity to have only one parent node. The edges between the other parent nodes are removed.[6]

Path Representations. We also experiment with two path representations. Our first approach, *text2nodes*, uses the label of an entity (cf. Section 1) to represent a path. This is not efficient since the decoder of the model needs to select between all of the entities in an ontology and also requires more parameters in the model. Our second approach, *text2edges*, to reduce the number of symbols for the model to choose from, uses edges to represent the path. To do this we create an artificial vocabulary of the size $\Delta(G)$, where $\Delta(G)$ corresponds to the maximum degree of a node. Each edge in the graph is labeled using the artificial vocabulary. For the example in Section 1, the path would be *animal* −[a]→ *chordate* −[b]→ *vertebrate* −[c]→ *bird* −[d]→ *apodiform_bird* where {a,b,c,d} is the artificial vocabulary. In the resulting path we discard labels for the entities; therefore, the path reduces to: [a]→ [b]→ [c]→ [d].

3.1 Baselines

Bag-of-Words Linear Regression (BOW-LR): To represent a textual definition in a vector space we first use a pre-trained set of word embeddings (Speer et al., 2017) to represent words in the definition and then find the mean of the word embeddings. As for the ontology, we use node2vec (Grover and Leskovec, 2016), to represent each entity in a vector space. To align the two vector spaces we use linear regression.

Multi-Sense LSTM (MS-LSTM): Kartsaklis et al. (2018) proposed a model that achieves state-of-the-art results on the text-to-entity mapping on the *Snomed CT*[7] dataset. The approach uses a novel multi-sense LSTM, augmented with an attention mechanism, to project the definition to the ontology vector space. Additionally, for a better alignment between the two vector spaces, the authors augmented the ontology graph with textual features.

3.2 Evaluation Metric

To perform evaluation of the models described above we used Ancestor-F1 score (Mao et al., 2018). This metric compares the ancestors ($is-a_{model}$) of the predicted node with the ancestors ($is-a_{gold}$) of the gold node in the taxonomy.

$$P = \frac{|is-a_{model} \wedge is-a_{gold}|}{|is-a_{model}|},$$

$$R = \frac{|is-a_{model} \wedge is-a_{gold}|}{|is-a_{gold}|},$$

where P and R are precision and recall, respectively. The Ancestor-F1 is then defined as:

$$2 \times \frac{P \times R}{P + R}.$$

3.3 Intrinsic Evaluation

To verify the reliability of our model on text-to-entity mapping we did a set of experiments on the seven graphs (Section 3) where we map a textual definition of a concept to a path.

To conduct the experiments we randomly sampled 10% of leaves from the graph. From this sample, 90% are used to evaluate the model and 10% are used to tune the model. The remaining nodes in the graph are used for training. We sample leaves for two reasons: (1) to predict a leaf, the model needs to make the maximum number of (correct) predictions and (2) this way we do not change the original topology of the graph. Note that the sampled nodes and their textual definitions are not present in the training data.

Both baselines predict a single entity instead of a path. To have the same evaluation framework for all the models, for each node predicted by the baselines we create[8] a path from the root of the node to the predicted node. However, we want

---

[6] The choice of an edge is performed on random basis.

[7] https://www.snomed.org/snomed-ct

[8] We used NetworkX (https://networkx.github.io) to find a path from predicted node to the root of a graph.

Models	PATO	WN$_{\text{animal.n.01}}$	WN$_{\text{plant.n.02}}$	HDO	HPO	GO	WN$_{\text{entity.n.01}}$

Table 2: Ancestor F1 results. Numbers in bold represent the best performing system on a graph. Models marked with $*$ make use of pre-trained word embedding in their encoder. Lambda (λ) is defined in Section 3.1. We use the same number of epochs, batch size and number of latent dimensions both for MS-LSTM and our models (Appendix C).

to emphasize that this is disadvantageous for our model, since all the symbols in the path are predicted by it and in the case of the baselines only a single node is predicted.

The results are presented in Table 2. Models that are in the last three rows of Table 2 use pre-trained word embeddings (Speer et al., 2017) in the encoder. MS-LSTM and our models that are above the last three rows use randomly initialised word vectors. We had four observations: (1) without pre-trained word embeddings in the encoder our model outperforms the best MS-LSTM$_{\lambda = 0.5}$ only on two of the seven graphs, (2) the text2edges* model outperforms all the other models including MS-LSTM$^{*}_{\lambda=0.5}$, (3) the text2edges model can better exploit pre-trained word embeddings than MS-LSTM, (4) our model performs better when the paths are represented using edges (rather than nodes). We also found that there is a strong negative correlation (Spearman: -0.75, Pearson: -0.80) between A.D. (Table 3) and the Ancestor F1 score for the text2edges* model, meaning that with an increase in A.D. the Ancestor F1 score decreases.

3.4 Error Analysis

We carried out an analysis on the outputs of our best-performing model, i.e. text2edges* with pre-trained word embeddings. One factor that affects the performance is the number of invalid sequences predicted by the text2nodes and text2edges models. An invalid sequence is the path that does not exist in the original graph. This happens because at each time step the decoder outputs a distribution over all the nodes/edges and not just over possible children nodes. We therefore performed a count of the number of invalid sequences produced by the model. The percentage of invalid sequences is in the range of 1.82% - 8.50% (Appendix B), which is relatively low. This analysis was also performed by J. Kusner et al. (2017). To guarantee that the model always produces valid graphs, they use a context-free grammar. A similar method can be adapted in our work.

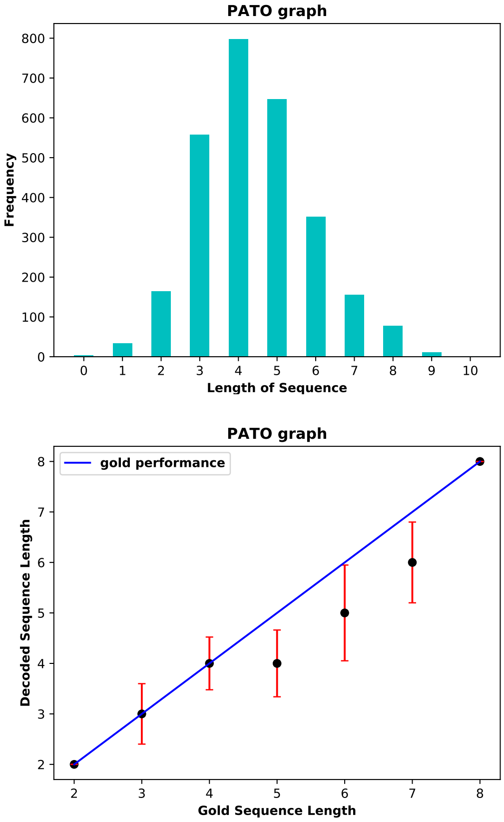

Figure 1: The graph on top shows the length of sequence vs length frequency on a training set. The graph on the bottom shows the length of the gold sequence vs mean length of decoded sequence on the test set.

Another factor that affects the performance is the length of the generated paths which is expected to match the length of the gold path. To test this, we compared the mean length of the generated sequences with the length of the gold path (the graph on the bottom of Figure 1). Also, in the training set, we associate the length of the sequences with their frequencies (the graph on the top of Figure 1). We found that (1) the length of the generated paths are biased towards the more frequent paths in the training data, (2) if the length of a path is not frequent in the training data, the model either under-generates or over-generates the length (Appendix D).

4 Related Work

Text-to-entity mapping is an essential component of many NLP tasks, e.g. fact verification (Thorne et al., 2018) or question answering (Yih et al., 2015). Previous work has approached this problem with pairwise learning-to-rank method (Leaman et al., 2013) or phrase-based machine translation (Limsopatham and Collier, 2015). However, these methods generally ignore ontology's structure. More recent work has viewed the problem of text-to-entity mapping as a projection of a textual definition to a single point in a KG (Kartsaklis et al., 2018; Hill et al., 2015). However, despite potential advantages, such as being more interpretable and less brittle (model predicts multiple related entities instead of one), path-based approaches have received relatively little attention. Instead of predicting a single entity, path-based models, such as the one we proposed in this paper, try to map a textual definition to multiple relevant entities in an external resource.

5 Conclusion and Future Work

We presented a model that maps textual definitions to interpretable ontological pathways. We evaluated the proposed technique on seven semantic graphs, showing that it can perform competitively with respect to existing state-of-the-art text-to-entity systems, while being more interpretable and self-contained. We hope this work will encourage further research on path-based text-to-entity mapping algorithms. A natural next step will be to extend our framework to DAGs. Furthermore, we plan to constrain our model to always predict paths that exist in the graph, as we discussed above.

Acknowledgments

We would like to thank the anonymous reviewers for their comments. Also, we would like to thank Dimitri Kartsaklis and Ehsan Shareghi for helpful discussions and comments. Table 4: Statistics of invalid sequences. Invalid$_{\%}$ is the percentage of invalid sequences and N$_{\text{total}}$ is the total number of sequences that were tested.

C Settings for Models

BOW-LR: To represent an ontology in a vector space we use node2vec https://snap.stanford.edu/node2vec/. For all the graphs the following hyperparameters of the algorithm are the same: *walk-length= 5*, *window-size=5* and *iter=40*. As for the number of dimensions we set it to 128 for PATO, WN$_{\text{animal.n.01}}$, WN$_{\text{plant.n.02}}$, HDO and HPO graphs. For GO and WN$_{\text{entity.n.01}}$ graphs we set it to 256. All the other parameters of node2vec are default.

We do not modify the numberbatch embeddings https://github.com/commonsense/conceptnet-numberbatch. If a word in a textual definition is missing we initilised the embedding for this word with zeros.

For all the graphs to map the textual vector space into an ontology vector space we use the linear regression model from the *scikit-learn* API https://scikit-learn.org/stable/modules/generated/sklearn.linear_model.LinearRegression.html

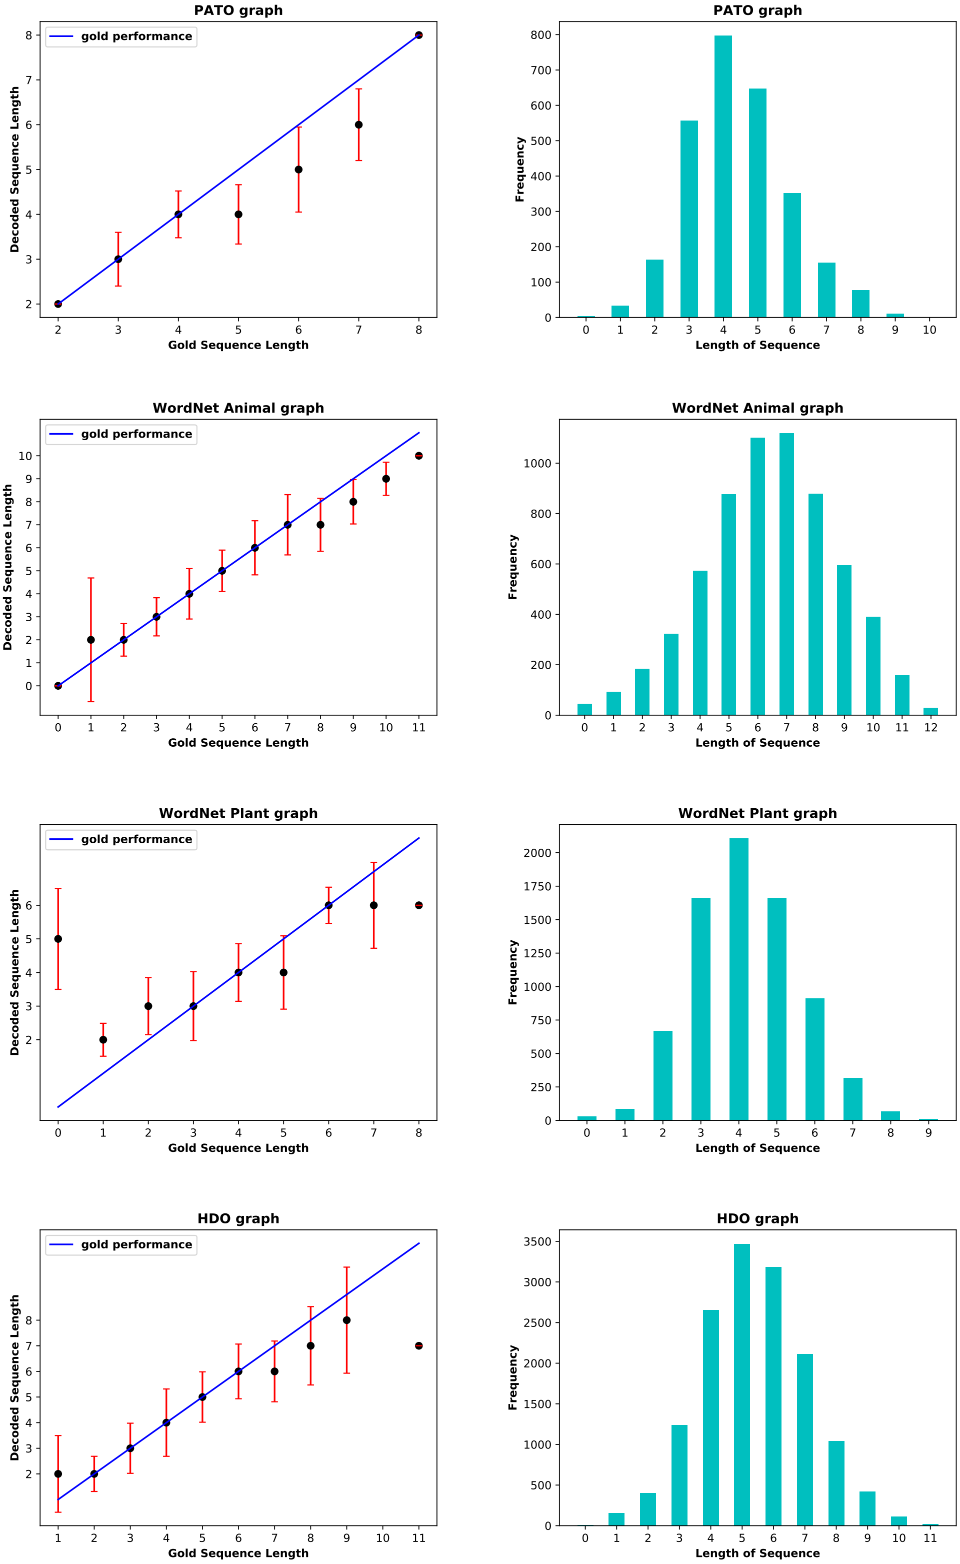

Figure 2: On the left graphs show: length of gold sequence vs mean length of decoded sequence on a test set; On the right graphs show: length of sequence vs length frequency on a training set.

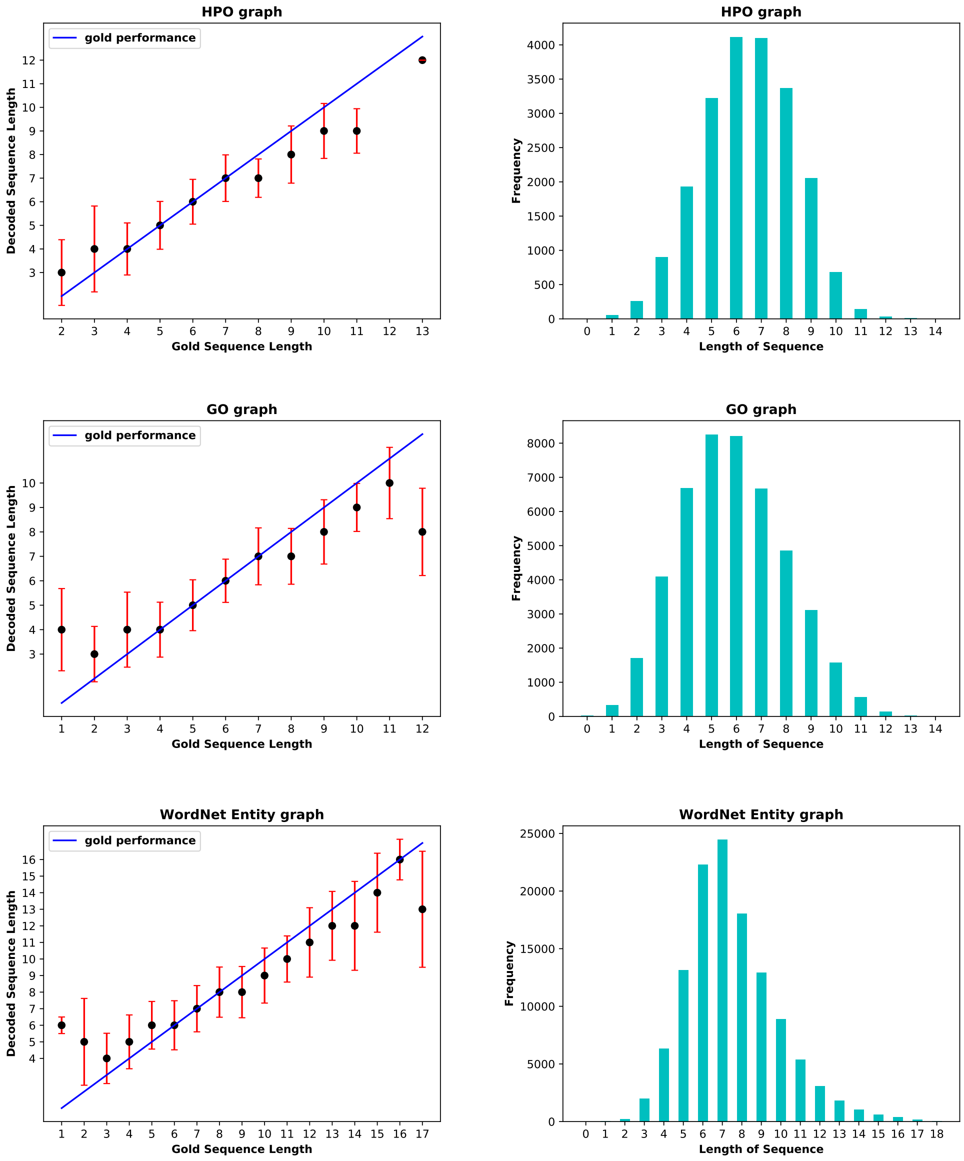

Figure 3: Continuation of Figure 2. On the left graphs show: length of gold sequence vs mean length of decoded sequence on a test set; On the right graphs show: length of sequence vs length frequency on a training set.

MS-LSTM: There are only two hyper-parameters that we vary during the embedding of ontology concepts: λ (we report the values in the paper) and the embedding size of the concepts. We set it to 128 for PATO, $\mathrm{WN}_{\mathrm{animal.n.01}}$, $\mathrm{WN}_{\mathrm{plant.n.02}}$, HDO and HPO graphs. For GO and $\mathrm{WN}_{\mathrm{entity.n.01}}$ graphs we set it to 256.

For all the graphs the model is trained for 300 epochs, dimensions of word embeddings is set to 64 and bi-LSTM is used instead of LSTM. Batch size is set to 16 and the number of latent dimensions in bi-LSTM is set to 128 for the PATO, $\mathrm{WN}_{\mathrm{animal.n.01}}$, $\mathrm{WN}_{\mathrm{plant.n.02}}$, HDO and HPO graphs. For GO and $\mathrm{WN}_{\mathrm{entity.n.01}}$ graphs we set these parameters to 128 and 256 respectively. All the other hyper-parameters are default.

When we use pre-trained word embeddings we reduce (with PCA https://scikit-learn.org/stable/modules/generated/sklearn.decomposition.PCA.html) its dimensions from 300 to 64.

Our Model: For all the graphs the model is trained for 300 epochs, dimensions of word embeddings (also for node/edges embeddings) is set to 64 and bi-LSTM is used in the encoder and LSTM in the decoder. Batch size is set to 16 and the number of latent dimensions in bi-LSTM encoder and LSTM decoder is set to

128 for the PATO, $\text{WN}_{\text{animal.n.01}}$, $\text{WN}_{\text{plant.n.02}}$, HDO and HPO graphs. For GO and $\text{WN}_{\text{entity.n.01}}$ graphs we set these parameters to 128 and 256 respectively. For optimizer we used *RMSProp* (https://www.tensorflow.org/api_docs/python/tf/train/RMSPropOptimizer) with learning rate = 0.001.

When we use pre-trained word embeddings we reduce (with PCA https://scikit-learn.org/stable/modules/generated/sklearn.decomposition.PCA.html) its dimensions from 300 to 64.

D Length of Generated Path

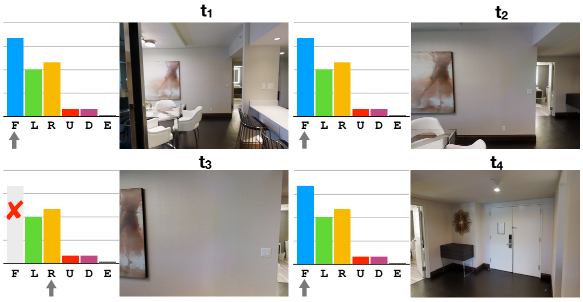
In Figure 2 and 3 the blue line indicates the ideal scenario i.e. mean length of the generated sequences is equal to the gold length. Black dot is the mean of the length of decoded sequences and the red bars are the standard deviation. One can notice that the general trend is following: for short sequences the mode generates (slightly) longer sequences and for the long sequences it generated (slightly) shorter sequences than the gold standard. Another trend is that the sequences of the certain length are matching the gold standard. To understand why this is happening one needs to look at the graph which relate the length of the sequence in the training corpus and the frequency of this length in the corpus. It is become clear there is a correlation between the two. Such as the model tends to generate the sequence of the length that is presented the most in the training data.

Shifting the Baseline:
Single Modality Performance on Visual Navigation & QA

Jesse Thomason **Daniel Gordon** **Yonatan Bisk**
Paul G. Allen School of Computer Science and Engineering
`{jdtho,xkcd,ybisk}@cs.washington.edu`

Abstract

We demonstrate the surprising strength of unimodal baselines in multimodal domains, and make concrete recommendations for best practices in future research. Where existing work often compares against *random* or *majority class* baselines, we argue that unimodal approaches better capture and reflect dataset biases and therefore provide an important comparison when assessing the performance of multimodal techniques. We present unimodal ablations on three recent datasets in visual navigation and QA, seeing an up to 29% absolute gain in performance over published baselines.



Actions: **F**orward, turn **L**eft & **R**ight, tilt **U**p & **D**own, **E**nd

Figure 1: Navigating without vision leads to sensible navigation trajectories in response to commands like "walk past the bar and turn right". At t_3, "forward" is unavailable as the agent would collide with the wall.

1 Introduction

All datasets have biases. Baselines should capture these regularities so that outperforming them indicates a model is actually solving a task. In multimodal domains, bias can occur in any subset of the modalities. To address this, we argue it is not sufficient for researchers to provide random or majority class baselines; instead we recommend presenting results for unimodal models. We investigate visual navigation and question answering tasks, where agents move through simulated environments using egocentric (first person) vision. We find that unimodal ablations (e.g., language only) in these seemingly multimodal tasks can outperform corresponding full models (§4.1).

This work extends observations made in both the Computer Vision (Goyal et al., 2018; Cirik et al., 2018) and Natural Language (Mudrakarta et al., 2018; Glockner et al., 2018; Poliak et al., 2018; Gururangan et al., 2018; Kaushik and Lipton, 2018) communities that complex models often perform well by fitting to simple, unintended correlations in the data, bypassing the complex grounding and reasoning that experimenters hoped was necessary for their tasks.

We ablate models from three recent papers: (1) navigation (Figure 1) using images of real homes paired with crowdsourced language descriptions (Anderson et al., 2018); and (2, 3) navigation and egocentric question answering (Gordon et al., 2018; Das et al., 2018a) in simulation with synthetic questions. We find that unimodal ablations often outperform the baselines that accompany these tasks.

Recommendation for Best Practices: Our findings show that in the new space of visual navigation and egocentric QA, all modalities, even an agent's action history, are strongly informative. Therefore, while many papers ablate either language *or* vision, new results should ablate *both*. Such baselines expose possible gains from unimodal biases in multimodal datasets irrespective of training and architecture details.

2 Ablation Evaluation Framework

In the visual navigation and egocentric question answering tasks, at each timestep an agent receives an observation and produces an action. Actions can move the agent to a new location or heading

Proceedings of NAACL-HLT 2019, pages 1977–1983
Minneapolis, Minnesota, June 2 - June 7, 2019.

	forward	turn left	turn right	tilt up	tilt down	end	start
forward	.36	.22	.22	.02	.02	.16	.00
turn left	.44	.54	.00	.01	.01	.00	.00
turn right	.43	.00	.54	.01	.01	.00	.00
Marginal	.393	.255	.257	.012	.012	.001	.071

Figure 2: $P(act = col|prev = row)$ and marginal action distributions in Matterport training. Peaked distributions enable agents to memorize simple rules like not turning left immediately after turning right, or moving forward an average number of steps.

(e.g., *turn left*), or answer questions (e.g., *answer 'brown'*). At timestep t, a multimodal model $\mathcal{M}$ takes in a visual input $\mathcal{V}_t$ and language question or navigation command $\mathcal{L}$ to predict the next action a_t. The navigation models we examine also take in their action from the previous timestep, a_{t-1}, and 'minimally sensed' world information W specifying which actions are available (e.g., that *forward* is unavailable if the agent is facing a wall).

$$a_t \leftarrow \mathcal{M}(\mathcal{V}_t, \mathcal{L}, a_{t-1}; W) \quad (1)$$

In each benchmark, $\mathcal{M}$ corresponds to the author's released code and training paradigm. In addition to their full model, we evaluate the role of each input modality by removing those inputs and replacing them with zero vectors. Formally, we define the full model and three ablations:

$$\begin{array}{lll} \text{Full Model} & \text{is} & \mathcal{M}(\mathcal{V}_t, \mathcal{L}, a_{t-1}; W) \quad (2) \\ \mathcal{A} & \text{is} & \mathcal{M}(\vec{0}, \vec{0}, a_{t-1}; W) \quad (3) \\ \mathcal{A}+\mathcal{V} & \text{is} & \mathcal{M}(\mathcal{V}_t, \vec{0}, a_{t-1}; W) \quad (4) \\ \mathcal{A}+\mathcal{L} & \text{is} & \mathcal{M}(\vec{0}, \mathcal{L}, a_{t-1}; W) \quad (5) \end{array}$$

corresponding to models with access to $\mathcal{A}$ction inputs, $\mathcal{V}$ision inputs, and $\mathcal{L}$anguage inputs. These ablations preserve the architecture and number of parameters of $\mathcal{M}$ by changing only its inputs.

3 Benchmark Tasks

We evaluate on navigation and question answering tasks across three benchmark datasets: Matterport Room-to-Room (no question answering component), and IQUAD V1 and EQA (question answering that requires navigating to the relevant scene in the environment) (Anderson et al., 2018; Gordon et al., 2018; Das et al., 2018a). We divide the latter two into separate navigation and question answering components. We then train and evaluate models separately per subtask to analyze accuracy.

Figure 3: IQA data construction attempts to make both the question and image necessary for QA.

3.1 Matterport Room-to-Room

An agent is given a route in English and navigates through a discretized map to the specified destination (Anderson et al., 2018). This task includes high fidelity visual inputs and crowdsourced natural language routes.

Published Full Model: At each timestep an LSTM decoder uses a ResNet-encoded image $\mathcal{V}_t$ and previous action a_{t-1} to attend over the states of an LSTM language encoder ($\mathcal{L}$) to predict navigation action a_t (seen in Figure 2).

Published Baseline: The agent chooses a random direction and takes up to five forward actions, turning right when no forward action is available.

3.2 Interactive Question Answering

IQUAD V1 (Gordon et al., 2018) contains three question types: existence (e.g., *Is there a ...?*), counting (e.g., *How many ...?*) where the answer ranges from 0 to 3, and spatial relation: (e.g., *Is there a ... in the ...?*). The data was constructed via randomly generated configurations to weaken majority class baselines (Figure 3). To evaluate the navigation subtask, we introduce a new THOR-Nav benchmark.[1] The agent is placed in a random location in the room and must approach one of *fridge, garbage can,* or *microwave* in response to a natural language question.

Although we use the same full model as Gordon et al. (2018), our QA results are not directly comparable. In particular, Gordon et al. (2018) do not quantify the effectiveness of the QA component independent of the scene exploration (i.e. navigation and interaction). To remove the scene explo-

---

[1] Formed from a subset of IQUAD V1 questions.

ration steps of Gordon et al. (2018), we provide a complete ground-truth view of the environment.[2] We use ground-truth rather than YOLO (Redmon et al., 2016) due to speed constraints.

Nav Full Model: The image and ground-truth semantic segmentation mask $\mathcal{V}_t$, tiled question $\mathcal{L}$, and previous action a_{t-1} are encoded via a CNN which outputs a distribution over actions. Optimal actions are learned via teacher forcing.

Nav Baseline: The agent executes 100 randomly chosen navigation actions then terminates. In AI2THOR (Kolve et al., 2017), none of the kitchens span more than 5 meters. With a step-size of 0.25 meters, we observed that 100 actions was significantly shorter than the shortest path length.

Published QA Full Model: The question encoding $\mathcal{L}$ is tiled and concatenated with a top-down view of the ground truth location of all objects in the scene $\mathcal{V}$. This is fed into several convolutions, a spatial sum, and a final fully connected layer which outputs a likelihood for each answer.

Published QA Baseline: We include the majority class baseline from Gordon et al. (2018).

3.3 Embodied Question Answering

EQA (Das et al., 2018a) questions are programmatically generated to refer to a single, unambiguous object for a specific environment, and are filtered to avoid easy questions (e.g., *What room is the bathtub in?*). At evaluation, an agent is placed a fixed number of actions away from the object.

Published Nav Full Model: At each timestep, a planner LSTM takes in a CNN encoded image $\mathcal{V}_t$, LSTM encoded question $\mathcal{L}$, and the previous action a_{t-1} and emits an action a_t. The action is executed in the environment, and then a lower-level controller LSTM continues to take in new vision observations and a_t, either repeating a_t again or returning control to the planner.

Published Nav Baseline: This baseline model is trained and evaluated with the same inputs as the full model, but does not pass control to a lower-level controller, instead predicting a new action using the planner LSTM at each timestep (i.e., no hierarchical control). Das et al. (2018a) name this baseline *LSTM+Question*.

		Matterport↑ *(%)*		**THOR-Nav↑** *(%)*		**EQA↓** *(m)*

Table 1: Navigation success (Matterport, THOR-Nav) *(%)* and remaining distance to target (EQA) *(m)*. Best unimodal in bold; better than reported baseline; *better than full model.

Published QA Full Model: Given the last five image encodings along the gold standard navigation trajectory, $\mathcal{V}_{t-4} \ldots \mathcal{V}_t$, and the question encoding $\mathcal{L}$, image-question similarities are calculated via a dot product and converted via attention weights to a summary weight $\bar{\mathcal{V}}$, which is concatenated with $\mathcal{L}$ and used to predict the answer. Das et al. (2018a) name this oracle-navigation model *ShortestPath+VQA*.

QA Baseline: Das et al. (2018a) provide no explicit baseline for the VQA component alone. We use a majority class baseline inspired by the data's entropy based filtering.

4 Experiments

Across all benchmarks, unimodal baselines outperform baseline models used in or derived from the original works. Navigating unseen environments, these unimodal ablations outperform their corresponding full models on the Matterport (absolute ↑ 2.5% success rate) and EQA (↓ 0.06m distance to target).

4.1 Navigation

We evaluate our ablation baselines on Matterport,[3] THOR-Nav, and EQA (Table 1),[4] and discover that some unimodal ablations outperform their corresponding full models. For Matterport and THOR-Nav, success rate is defined by proximity to the target. For EQA, we measure absolute distance from the target in meters.

Unimodal Performance: Across Matterport, THOR-Nav, and EQA, either $\mathcal{A}+\mathcal{V}$ or $\mathcal{A}+\mathcal{L}$

---

[2] This approximates the agent having visited every possible location, interacted with all possible objects, and looked in all possible directions before answering.

[3] We report on Matterport-validation since this allows comparing Seen versus Unseen house performance.

[4] For consistency with THOR-Nav and EQA, we here evaluate Matterport using *teacher forcing*.

achieves better performance than existing baselines. In Matterport, the $\mathcal{A}+\mathcal{L}$ ablation performs *better* than the Full Model in unseen environments. The diverse scenes in this simulator may render the vision signal more noisy than helpful in previously unseen environments. The $\mathcal{A}+\mathcal{V}$ model in THOR-Nav and EQA is able to latch onto dataset biases in scene structure to navigate better than chance (for IQA), and the nonhierarchical baseline (in EQA). In EQA, $\mathcal{A}+\mathcal{V}$ also outperforms the Full Model;[5] the latent information about navigation from questions may be too distant for the model to infer.

The agent with access only to its action history ($\mathcal{A}$) outperforms the baseline agent in Matterport and THOR-Nav environments, suggesting it learns navigation correlations that are not captured by simple random actions (THOR-Nav) or programmatic walks away from the starting position (Matterport). Minimal sensing (which actions are available, W) coupled with the *topological* biases in trajectories (Figure 2), help this nearly zero-input agent outperform existing baselines.[6]

Matterport Teacher vs Student forcing With teacher forcing, at each timestep the navigation agent takes the gold-standard action regardless of what action it predicted, meaning it only sees steps along gold-standard trajectories. This paradigm is used to train the navigation agent in THOR-Nav and EQA. Under student forcing, the agent samples the action to take from its predictions, and loss is computed at each time step against the action that would have put the agent on the shortest path to the goal. Thus, the agent sees more of the scene, but can take more training iterations to learn to move to the goal.

Table 2 gives the highest validation success rates across all epochs achieved in Matterport by models trained using student forcing. The unimodal ablations show that the Full Model, possibly because with more exploration and more training episodes, is better able to align the vision and language signals, enabling generalization in unseen environments that fails with teacher forcing.

EQA Navigation Variants Table 3 gives the average final distance from the target ($\mathbf{d_T}$, used as the metric in Table 1) and average minimum distance from target achieved along the path ($\mathbf{d_{min}}$) during EQA episodes for agents starting 10, 30, and 50 actions away from the target in the EQA navigation task. At 10 actions away, the unimodal ablations tend to outperform the full model on both metrics, possibly due to the shorter length of the episodes (less data to train the joint parameters). The $\mathcal{A}+\mathcal{V}$ ablation performs best among the ablations, and ties with or outperforms the Full Model in all but one setting, suggesting that the EQA Full Model is not taking advantage of language information under any variant.

4.2 Question Answering

We evaluate our ablation baselines on IQUAD V1 and EQA, reporting top-1 QA accuracy (Table 4) given gold standard navigation information as $\mathcal{V}$. These decoupled QA models do not take in a previous action, so we do not consider $\mathcal{A}$ ONLY ablations for this task.

Unimodal Performance: On IQUAD V1, due to randomization in its construction, model ab-

---

[5] EQA full & baseline model performances do not exactly match those in Das et al. (2018a) because we use the expanded data updated by the authors `https://github.com/facebookresearch/EmbodiedQA/`.

[6] This learned agent begins to relate to work in minimally sensing robotics (O'Kane and LaValle, 2006).

	Model	IQUAD V1↑ Unseen	IQUAD V1↑ Seen	EQA ↑ Unseen

	Baseline	41.7	41.7	19.8
Uni	$\mathcal{V}$ ONLY	**43.5**	**42.8**	44.2
	$\mathcal{L}$ ONLY	41.7	41.7	**48.8**
Δ	Uni – Base	**+1.8**	**+1.1**	**+29.0**

Table 4: Top-1 QA accuracy. Best unimodal in bold; better than reported baseline.

lations perform nearly at chance.[7] The $\mathcal{V}$ ONLY model with access to the locations of all scene objects only improves by 2% over random guessing.

For EQA, single modality models perform significantly better than the majority class baseline. The vision-only model is able to identify salient colors and basic room features that allow it to reduce the likely set of answers to an unknown question. The language only models achieve nearly 50%, suggesting that despite the entropy filtering in Das et al. (2018a) each question has one answer that is as likely as all other answers combined (e.g. 50% of the answers for *What color is the bathtub?* are *grey*, and other examples in Figure 4).

5 Related Work

Historically, semantic parsing was used to map natural language instructions to visual navigation in simulation environments (Chen and Mooney, 2011; MacMahon et al., 2006). Modern approaches use neural architectures to map natural language to the (simulated) world and execute actions (Paxton et al., 2019; Chen et al., 2018; Nguyen et al., 2018; Blukis et al., 2018; Fried et al., 2018; Mei et al., 2016). In visual question answering (VQA) (Antol et al., 2015; Hudson and Manning, 2019) and visual commonsense reasoning (VCR) (Zellers et al., 2019), input images are accompanied with natural language questions. Given the question, egocentric QA requires an agent to navigate and interact with the world to gather the relevant information to answer the question. In both cases, end-to-end neural architectures make progress on these tasks.

For language annotations, task design, difficulty, and annotator pay can introduce unintended artifacts which can be exploited by models to "cheat" on otherwise complex tasks (Glockner et al., 2018; Poliak et al., 2018). Such issues also occur in multimodal data like VQA (Goyal et al., 2018), where models can answer correctly without looking at the image. In image captioning, work has shown competitive models relying only on nearest-neighbor lookups (Devlin et al., 2015) as well as exposed misalignment between caption relevance and text-based metrics (Rohrbach et al., 2018). Our unimodal ablations of visual navigation and QA benchmarks uncover similar biases, which deep architectures are quick to exploit.

6 Conclusions

In this work, we introduce an evaluation framework and perform the missing analysis from several new datasets. While new state-of-the-art models are being introduced for several of these domains (e.g., Matterport: (Ma et al., 2019a; Ke et al., 2019; Wang et al., 2019; Ma et al., 2019b; Tan et al., 2019; Fried et al., 2018), and EQA: (Das et al., 2018b)), they lack informative, individual unimodal ablations (i.e., ablating *both* language and vision) of the proposed models.

We find a performance gap between baselines used in or derived from the benchmarks examined in this paper and unimodal models, with unimodal models outperforming those baselines across all benchmarks. These unimodal models can even outperform their multimodal counterparts. In light of this, we recommend all future work include unimodal ablations of proposed multimodal models to vet and highlight their learned representations.

Abstract

The task of retrieving clips within videos based on a given natural language query requires cross-modal reasoning over multiple frames. Prior approaches such as sliding window classifiers are inefficient, while text-clip similarity driven ranking-based approaches such as segment proposal networks are far more complicated. In order to select the most relevant video clip corresponding to the given text description, we propose a novel extractive approach that predicts the start and end frames by leveraging cross-modal interactions between the text and video - this removes the need to retrieve and re-rank multiple proposal segments. Using recurrent networks we encode the two modalities into a joint representation which is then used in different variants of start-end frame predictor networks. Through extensive experimentation and ablative analysis, we demonstrate that our simple and elegant approach significantly outperforms state of the art on two datasets and has comparable performance on a third.

1 Introduction

Clip Localization is the task of selecting the relevant span of temporal frames in a video corresponding to a natural language description and has recently piqued interest in research that lies at the intersection of visual and textual modalities. An example of this task is demonstrated in Figure 1. It requires cross-modal reasoning to ground free-form text inside the video and calls for models capable of segmenting a video into action segments (Singh et al., 2016; Yeung et al., 2016; Xu et al., 2017) as well as measuring multi-modal semantic similarity (Karpathy and Fei-Fei, 2015).

This task is inherently discriminative, i.e., there is only a single most relevant clip pertaining to a given query in the corresponding video. However, most prior works (Hendricks et al., 2017, 2018; Liu et al., 2018; Chen et al., 2018; Zhang et al., 2018) explore this as a ranking task over a fixed number of moments by uniformly sampling clips within a video. Moreover, these approaches are restrictive in scope since they use predefined clips as candidates for a video and cannot be easily extended to videos with considerable variance in length.

Figure 1: Clip Extraction task for the given query '*the biker jumps to another ramp near the camera*'

Gao et al. (2017); Xu et al. (2019) apply two-stage methods which rank candidate clips using a learned similarity metric. Gao et al. (2017); Ge et al. (2019) propose a sliding window approach with alignment and offset regression learning objective, but it is limited by the coarseness of the windows and is thus inefficient and inflexible. Xu et al. (2019) address this through a query-guided segment proposal network (QSPN). However, the similarity metric used by these approaches is difficult to learn as it is sensitive to the choice of negative samples (Yu et al., 2018) and it still does not consider the discriminative nature of the task.

Hence, we propose an elegant and fairly simple extractive approach. Our technique is similar to text-based Machine Comprehension (Chen et al., 2017) but in a multimodal setting where the video is analogous to the text passage and the target-clip is analogous to the text span corresponding to the correct answer. We verify empirically that

Minneapolis, Minnesota, June 2 - June 7, 2019.

our method significantly outperforms prior work on two benchmark datasets - TACoS, ActivityNet and comparably well on the third, Charades-STA. Our flexible, modular approach to *Extractive Clip Localization (ExCL)* can easily be extended to incorporate attention models and different variants of encoders for both visual and text modality to improve performance further.

2 Approach

Our model comprises of three modular parts - a text encoder, a video encoder and a span predictor as shown in Figure 2. We use a bidirectional text LSTM as the text encoder with pretrained GloVE (Pennington et al., 2014) embeddings as input, and use the last hidden state ($\mathbf{h}^T$) as sentence-embedding. Simpler variants such as bag-of-words, and other approaches such as InferSent (Conneau et al., 2017) or Skip-Thought (Kiros et al., 2015) could also be used. We use a bidirectional LSTM with I3D features (Carreira and Zisserman, 2017) as the video encoder which captures temporal context at each time-step ($\mathbf{h}_t^V$). Note that this could also be substituted by C3D features (Tran et al., 2014) or self-attentive networks (Kim et al., 2018). Finally, we compare the variants of span-predictor networks which output scores $S_{\text{start}}(t), S_{\text{end}}(t) \in \mathbb{R}^1$ respectively.

2.1 Training objectives

We consider two modes of training our networks, one which uses a classification loss (ExCL-clf) and another which uses a regression loss (ExCL-reg).

ExCL-clf: The scores are normalized using SoftMax to give $P_{\text{start}}(t), P_{\text{end}}(t)$, and trained using negative log-likelihood loss:

$$L(\theta) = -\frac{1}{N}\sum_{i}^{N} \log(P_{\text{start}}(t_s^i)) + \log(P_{\text{end}}(t_e^i)) \tag{1}$$

where N is number of text-clip pairs and t_s^i, t_e^i are the ground-truth start and end frame indices for the i^{th} pair. During inference we predict the span of frames $(\hat{t}_s, \hat{t}_e)$ for each query by maximizing the joint probability of start and end frames.

$$\text{span}(\hat{t}_s, \hat{t}_e) = \underset{\hat{t}_s,\hat{t}_e}{\text{argmax}}\, P_{\text{start}}(\hat{t}_s)P_{\text{end}}(\hat{t}_e) \tag{2}$$

$$= \underset{\hat{t}_s,\hat{t}_e}{\text{argmax}}\, S_{\text{start}}(\hat{t}_s) + S_{\text{end}}(\hat{t}_e) \tag{3}$$

$$\text{s.t. } \hat{t}_s \leq \hat{t}_e \tag{4}$$

ExCL-reg: The classification approach is limited to predicting start and end times of clip at discretized intervals, while the true target is a continuous value. In order to directly model this as a regression problem, we formulate start and end time prediction by computing an expectation over the probability distribution given by SoftMax outputs:

$$t_s = \mathbb{E}_{P_{\text{start}}}[t] \tag{5}$$

$$= \sum_{t_s=1}^{T} t_s P_{\text{start}}(t_s) \tag{6}$$

$$t_e = \mathbb{E}_{P_{\text{start}}}[\mathbb{E}_{P_{\text{end|start}}}[t]] \tag{7}$$

$$= \sum_{t_s=1}^{T} P_{\text{start}}(t_s) \sum_{t_e=1}^{T} P_{\text{end|start}}(t_e) \tag{8}$$

Here the above equations t_s, t_e refer to the actual time values corresponding to each index. $P_{\text{end|start}}(t_e)$ is computed by a SoftMax over masked logits:

$$P_{\text{end|start}} = \text{SoftMax}(\mathbb{1}[t_e \geq t_s]S_{\text{end}}(t))$$

Finally we train the networks using regression losses such as mean squared error and absolute error. We find that using absolute error and first normalizing the values of time to $t_s, t_e \in [0, 1]$ yields better results.

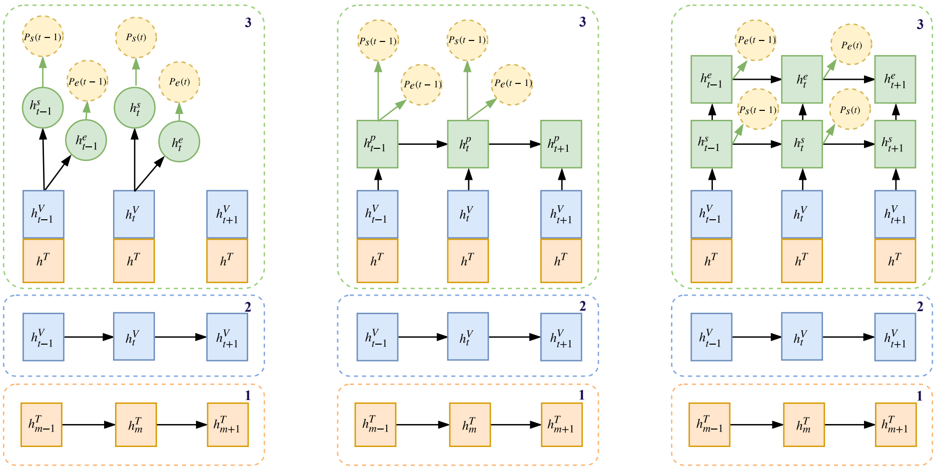
2.2 Span Predictor Variants

We implement the following variants of the span predictor network:

MLP predictor: At each time step t, we pass concatenated video-encoder features with sentence embeddings into two multi-layered perceptrons (MLPs) to obtain scores $S_{\text{start}}(t), S_{\text{end}}(t)$.

$$S_{\text{start}}(t) = \text{MLP}_{\text{start}}([\mathbf{h}_t^V; \mathbf{h}^T]) \tag{9}$$

$$S_{\text{end}}(t) = \text{MLP}_{\text{end}}([\mathbf{h}_t^V; \mathbf{h}^T]) \tag{10}$$



(a) MLP predictor (b) Tied-LSTM predictor (c) Conditioned-LSTM predictor

Figure 2: Our model consists of three modules: a text sentence encoder (orange, denoted by [1]), a video encoder (blue, denoted by [2]) and three variants of span predictor (green, denoted by [3]) - MLP, Tied-LSTM and Conditioned-LSTM to predict start and end probabilities for each frame. We use bidirectional LSTMs for the text and video encoders.

Tied LSTM predictor: Here, we send concatenated video encoder output and sentence embedding to a bidirectional LSTM as input at each step in order to capture recurrent cross-modal interactions. The hidden states ($\mathbf{h}_t^P$) concatenated with the original inputs are then fed to a MLP with $\tanh$ activation in hidden layers to predict start and end scores.

$$h_t^P = \text{LSTM}([\mathbf{h}_t^V;\mathbf{h}^T], \mathbf{h}_{t-1}^P) \tag{11}$$

$$S_{\text{start}}(t) = \text{MLP}_{\text{start}}([\mathbf{h}_t^P;\mathbf{h}_t^V;\mathbf{h}^T]) \tag{12}$$

$$S_{\text{end}}(t) = \text{MLP}_{\text{end}}([\mathbf{h}_t^P;\mathbf{h}_t^V;\mathbf{h}^T]) \tag{13}$$

Conditioned LSTM predictor: Note that in the previous two approaches the end-frame predictor is not conditioned in any way on the start predictor. Here we use two bidirectional LSTMs: LSTM_{end} takes as input the hidden states $\mathbf{h}_t^{P_0}$ of $\text{LSTM}_{\text{start}}$ and produces $\mathbf{h}_t^{P_1}$ as output. The respective hidden states are then used in a similar way as the tied LSTM method to generate start and end scores.

$$\mathbf{h}_t^{P_0} = \text{LSTM}_{\text{start}}([\mathbf{h}_t^V;\mathbf{h}^T], \mathbf{h}_{t-1}^{P_0}) \tag{14}$$

$$\mathbf{h}_t^{P_1} = \text{LSTM}_{\text{end}}(\mathbf{h}_t^{P_0}, \mathbf{h}_{t-1}^{P_1}) \tag{15}$$

$$S_{\text{start}}(t) = \mathbf{W}_s([\mathbf{h}_t^{P_0};\mathbf{h}_t^V;\mathbf{h}^T]) + \mathbf{b}_s \tag{16}$$

$$S_{\text{end}}(t) = \mathbf{W}_e([\mathbf{h}_t^{P_1};\mathbf{h}_t^V;\mathbf{h}^T]) + \mathbf{b}_e \tag{17}$$

3 Datasets

We evaluate our models on three datasets. Note that we do not evaluate our models on DiDeMo/TEMPO (Hendricks et al., 2017, 2018) as these datasets only provide coarse fixed-size moments, thus reducing the problem essentially to ranking a fixed set of candidates. We choose the following datasets because each has unique properties such as visual variance, richness of vocabulary and variance in query lengths.

MPII TACoS: This dataset (Rohrbach et al., 2014) has been built on top of the MPII Cooking Activities dataset. It consists of detailed temporally aligned text descriptions of cooking activities. The average length of videos is 5 minutes. A significant challenge in TACoS dataset is that descriptions span over only a few seconds because of the atomic nature of queries such as 'takes out the knife' and 'chops the onion' (8.4% of them are less than 1.6s long). Such short queries allow a smaller margin of error. We use the train/test split as provided by Gao et al. (2017) *here*. Coupled with lesser visual variance to distinguish activities, fine-grained actions and descriptions which can often have high word overlap, this is a challenging dataset.

ActivityNet Captions: ActivityNet (Caba Heilbron et al., 2015) is a large-scale open domain activity recognition, segmentation and prediction dataset based on YouTube videos additionally augmented with dense temporally annotated captions (Krishna et al., 2017). The average length is 2 minutes, but they are much more diverse in content, with videos that span over 200 activity classes and annotations which use a richer vocabulary. There are 10,024 and 5,044 train and test set videos. We use the same train/test split as provided by the authors. Our reported results have 3,370 missing videos which could not be downloaded.

Charades-STA: The Charades dataset was introduced with action classification, localization and video description annotations (Sigurdsson et al., 2016). Gao et al. (2017) extend this to include sentence level temporal annotation to create the Charades-STA dataset which contains 12,408 training, and 3,720 test sentence level annotations. In Charades-STA, average length of videos is 30 seconds and query length (number of frames) has much lower variance (3.7s) as compared to TACoS (39.5s) and ActivityNet (78.1s).

4 Experiments

4.1 Feature Extraction

We downsample the videos at a frame rate of 5 frames per second and extract I3D RGB (Carreira and Zisserman, 2017) visual features pretrained on Kinetics dataset. We use a fine-tuned version for Charades available *here*.

4.2 Implementation Details

We use pre-trained GloVE embeddings of 300 dimensions. The extracted visual features have 1024 dimensions. For TACoS, Charades-STA, and ActivityNet we use a vocabulary size of 1438, 3720 and 10,000 respectively. We considered batch sizes of 16, 32, 64 and single-layer LSTM hidden sizes of 128, 256, 512. The video and span predictors are bidirectional LSTMs with 256 and 128 hidden units respectively while queries are encoded by a 256-dimensional bidirectional LSTM. The MLP based span predictors have 256 hidden dimensions and use $\tanh$ activation in hidden layers. For all datasets, we train the model with a batch size of 32 for 30 epochs using Adam optimizer with a learning rate of 0.001 and early stopping. We apply a dropout of 0.5 to all the abovementioned LSTMs during training. We measure our model performance primarily using *localization accuracy* which is defined to be intersection over union (IoU) at threshold values of 0.3, 0.5, 0.7 to compare with past work which reports Recall@1, IoU=$\{0.3, 0.5, 0.7\}$.

4.3 Experimentation and Ablative Analysis

We compare the different training objectives (labeled ExCL-clf for classification and ExCL-reg for regression) and evaluate the usefulness of recurrent encoders for video representations by removing the video LSTM (labeled ExCL-clf/reg 1-$\{a, b, c\}$). We also perform ablative analysis of a range of span predictor networks. We compare the performance of our proposed model with three baselines which are the current SOTA for the different datsets. (i) Activity Concepts based Localizer (ACL) proposed in Ge et al. (2019) for TACoS (ii) Segment Proposal Network approach proposed in (Xu et al., 2019) for ActivityNet and (iii) Moment Alignment Network (MAN) via Iterative Graph Adjustment approach proposed in (Zhang et al., 2018) for Charades-STA. While we significantly beat the first two baselines for TACoS and Activity Net respectively, we attain comparable performance with the third for Charades-STA. It is to be noted that since the approach in (Zhang et al., 2018) depends on ranking fixed number of segments in each video, it is not scalable to the other two datasets which have longer videos with greater variance in their lengths.

4.4 Results

Our results in Table 1 confirm our hypothesis that extractive models work better.

We find that across all datasets, models without recurrent architectures (ExCL 1-a) perform significantly worse, demonstrating the importance of temporal context provided by LSTMs in either video encoder (ExCL 2-a) or span predictors (ExCL 1-b). With ExCL 2-a we see that if the visual context is captured well using recurrent architectures in the video LSTM, then even with a MLP span predictor we get a significant improvement in performance. Furthermore, if we add LSTM span predictors along with the video LSTM (ExCL 2-$\{b, c\}$) we obtain an additional boost in performance. However, without a recurrent visual encoder, a recurrent span predictor is essential to capture both uni-modal and cross-modal interactions (ExCL 1-$\{b,\ c\}$). When comparing the regression learning objective with classification, we do not notice a substantial gain in performance thereby indicating that not much information is lost if the continuous nature of the labels is not considered. In terms of span predictors, tied LSTM generally performs well across all datasets,

Table 1: Clip Localization Accuracy at IoU = $\{0.3, 0.5, 0.7\}$ for TACoS, Charades-STA and ActivityNet. Here ExCL-clf represents the classification loss model and ExCL-reg represents the regression loss model. ExCL-$\{$clf/reg$\}$ 1-m refer to models run without a video LSTM encoder, while ExCL-$\{$clf/reg$\}$ 2-m include the video LSTM. $m = a, b, c$ refer to MLP, tied LSTM and conditioned LSTM span predictor networks respectively.

and any difference with conditioned LSTM is negligible. This benefit is more pronounced when using the regression objective, possibly because conditioning is already captured in the formulation as given by Equation 7.

While Xu et al. (2019) note a significant difference in performance between Charades-STA and ActivityNet captions, performance is similar on both the datasets in our model. We hypothesize that their model fails to work well when there is large variability in the query lengths, as explained in Section 3. We also find TACoS to be a significantly more challenging benchmark, similar to Ge et al. (2019).

5 Conclusion

In conclusion, our main contribution is an extractive model for clip localization based on text queries as opposed to ranking driven approaches used in the past. Our results show that this elegant and fairly simple approach works much better empirically on three very different benchmark datasets, with tied LSTM span predictor generally giving best results. It is to be noted that these datasets previously had three different architectures as their respective SOTA, and our work naturally lays the foundation for training a single generalizable model across datasets and possibly related tasks as the next step. Furthermore, our approach is modular, making it trivial to insert different architectures for the encoders and span-predictors. Other future directions of this work include adding temporal attention in order to handle more complicated temporal references and extending this approach to work for longer, and thereby more challenging videos such as movies.

Abstract

Machine learning has shown promise for automatic detection of Alzheimer's disease (AD) through speech; however, efforts are hampered by a scarcity of data, especially in languages other than English. We propose a method to learn a correspondence between independently engineered lexicosyntactic features in two languages, using a large parallel corpus of out-of-domain movie dialogue data. We apply it to dementia detection in Mandarin Chinese, and demonstrate that our method outperforms both unilingual and machine translation-based baselines. This appears to be the first study that transfers feature domains in detecting cognitive decline.

1 Introduction

Alzheimer's disease (AD) is a neurodegenerative disease affecting 5.7 million people in the US (Association et al., 2018), and is the most common cause of dementia. Although no cure yet exists, early detection of AD is crucial for an effective treatment to delay or prepare for its effects (Dubois et al., 2016). One of the earliest symptoms of AD is speech impairment, including a difficulty in finding words and changes to grammatical structure (Taler and Phillips, 2008). These early signs can be detected by having the patient perform a picture description task, such as the *Cookie Theft* task from the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 1983).

Previous models have applied machine learning to automatic detection of AD, for example, Fraser et al. (2016) extracted a wide variety of lexicosyntactic and acoustic features to classify AD and obtained 82% accuracy on the DementiaBank (DB) dataset. However, clinical studies of AD are expensive, so datasets of patient data are often scarce. Noorian et al. (2017) augmented DB with more a much larger corpus of normative data and improved the classification accuracy to 93% on DB. Similar linguistic differences between healthy and AD speech have been observed in Mandarin Chinese (Lai et al., 2009), but machine learning has not yet been applied to detecting AD in Mandarin.

Daume III (2007) proposed a simple way of combining features in different domains, assuming that the same features are extracted in each domain. In our case, ensuring consistency of features across domains is challenging because of the grammatical differences between Mandarin and English. For example, Mandarin doesn't have determiners or verb tenses, and has classifiers, which don't exist in English (Chao, 1965). Another method trains a classifier jointly on multiple domains with different features on each domain, by learning a projection to a common subspace (Duan et al., 2012). However, this method only accepts labelled samples in each domain, and cannot make use of unlabelled, out-of-domain data. Other work from our broader group (Fraser et al., 2019) combined English and French data by extracting features based on conceptual "information units" rather than words, thus limiting the effects of multilingual differences.

In the current work, we train an *unsupervised* model to detect dementia in Mandarin, requiring only the English DB dataset and a large parallel Mandarin-English corpus of normative dialogue. We extract lexicosyntactic features in Mandarin and English using separate pipelines, and use the OpenSubtitles corpus of bilingual parallel movie dialogues to learn a correspondence between the different feature sets. We combine this correspondence model with a classifier trained on DB to predict dementia on Mandarin speech. To evaluate our system, we apply it to a dataset of speech from Mandarin-speakers with dementia, and demon-

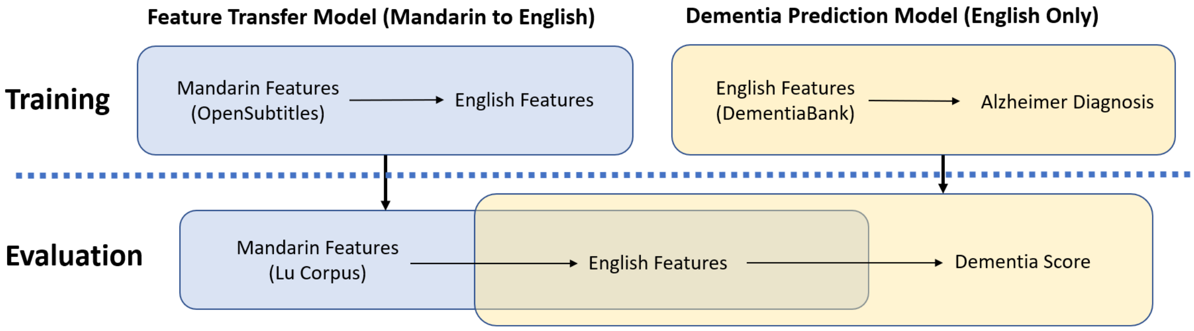

Figure 1: Diagram of our model. We train two separate models: the first is trained on OpenSubtitles and learns to map Mandarin features to English features; the second is trained on DementiaBank and predicts dementia given English features. During evaluation, the two models are combined to predict dementia in Mandarin.

strate that our method outperforms several baselines.

2 Datasets

We use the following datasets:

- **DementiaBank** (Boller and Becker, 2005): a corpus of *Cookie Theft* picture descriptions, containing 241 narrations from healthy controls and 310 from patients with dementia. Each narration is professionally transcribed and labelled with part-of-speech tags. In this work, we only use the narration transcripts, and neither the part-of-speech tags or raw acoustics.

- **Lu Corpus** (MacWhinney et al., 2011): contains 49 patients performing the *Cookie theft* picture description, category fluency, and picture naming tasks in Taiwanese Mandarin. The picture description narrations were human-transcribed; patient diagnoses are unspecified but exhibit various degrees of dementia.

- **OpenSubtitles2016** (Lison and Tiedemann, 2016): a corpus of parallel dialogues extracted from movie subtitles in various languages. We use the Traditional Chinese / English language pair, which contains 3.3 million lines of dialogue.

The Lu Corpus is missing specifics of diagnosis, so we derive a *dementia score* for each patient using the category fluency and picture naming tasks. For each category fluency task, we count the number of unique items named; for the picture naming tasks, we score the number of pictures correctly named, awarding partial credit if a hint was given. We apply PCA to the scores across all tasks, and assign the first principal component to be the *dementia score* for each patient. This gives a relative ordering of all patients for degree of dementia, which we treat as the ground-truth for evaluating our models.

3 Methodology

3.1 Feature Extraction

We extract a variety of lexicosyntactic features in Mandarin and English, including type-token-ratio, the number of words per sentence, and proportions of various part-of-speech tags[1]. A detailed description of the features is provided in the supplementary materials (Section A.1). In total, we extract 143 features in Mandarin and 185 in English. To reduce sparsity, we remove features in both languages that are constant for more than half of the dataset.

Due to the size of the OpenSubtitles corpus, it was computationally unfeasible to run feature extraction on the entire corpus. Therefore, we randomly select 50,000 narrations from the corpus, where each narration consists of between 1 to 50 contiguous lines of dialogue (about the length of a *Cookie Theft* narration).

For English, we train a logistic regression classifier to classify between dementia and healthy controls on DB, using our features as input. Using L1 regularization and 5-fold CV, our model achieves 77% classification accuracy on DB. This is slightly lower than the 82% accuracy reported

---

[1] The feature extraction pipeline is open-source, available at: `https://github.com/SPOClab-ca/COVFEFE`. The `lex` and `lex_chinese` pipelines were used for English and Chinese, respectively.

by Fraser et al. (2016), but it does not include any acoustic features as input.

3.2 Feature Transfer

Next, we use the OpenSubtitles corpus to train a model to transform Mandarin feature vectors to English feature vectors. For each target English feature, we train a separate ElasticNet linear regression (Zou and Hastie, 2005), using the Mandarin features of the parallel text as input. We perform a hyperparameter search independently for each target feature, using 3-fold CV to minimize the MSE.

3.3 Regularization

Although the output of the ElasticNet regressions may be given directly to the logistic regression model to predict dementia, this method has two limitations. First, the model considers each target feature separately and cannot take advantage of correlations between target features. Second, it treats all target feature equally, even though some are noisier than others. We introduce two regularization mechanisms to address these drawbacks: reduced rank regression and joint feature selection.

Reduced Rank Regression

Reduced rank regression (RRR) trains a single linear model to predict all the target features: it minimizes the sum of MSE across all target features, with the constraint that the rank of the linear mapping is bounded by some given R (Izenman, 1975). Following recommended procedures (Davies, 1982), we standardize the target features and find the best value of R with cross validation. However, this procedure did not significantly improve results so it was not included in our best model.

Joint Feature Selection

A limitation of the above models is that they are not robust to noisy features. For example, if some English feature is useful for predicting dementia, but cannot be accurately predicted using the Mandarin features, then including this feature might hurt the overall performance. A desirable English feature in our pipeline needs to not only be useful for predicting dementia in English, but also be reconstructable from Mandarin features.

We modify our pipeline as follows. After training the ElasticNet regressions, we sort the target features by their R^2 (coefficient of determination) measured on the training set, where higher values indicate a better fit. Then, for each K between 1 and the number of features, we select only the top K features and re-train the DB classifier (3.1) to only use those features as input. The result of this experiment is shown in Figure 2.

4 Experiments

4.1 Baseline Models

We compare our system against two simple baselines:

1. **Unilingual baseline:** using the Mandarin features, we train a linear regression to predict the dementia score. We take the mean across 5 cross-validation folds.
2. **Translate baseline:** The other intuitive way to generate English features from a Mandarin corpus is by using translation. We use Google Translate[2] to translate each Mandarin transcript to English. Then, we extract features from the translated English text and feed them to the dementia classifier described in section 3.1.

4.2 Evaluation Metric

We evaluate each model by comparing the Spearman's rank-order correlation ρ (Spearman, 1904) between the ground truth dementia scores and the model's predictions. This measures the model's ability to rank the patients from the highest to the lowest severities of dementia, without requiring a threshold value.

4.3 Experimental Results

Model	**Spearman ρ**
Baselines	
Unilingual	0.385
Google Translate	0.366
Our models	
Feature Transfer	0.319
+ RRR	0.354
+ JFS	**0.549**

Table 1: Baselines compared with our models, evaluated on the Lu corpus. RRR: Reduced rank regression (3.3), JFS: Joint feature selection (3.3).

---

[2] `https://translate.google.com/`

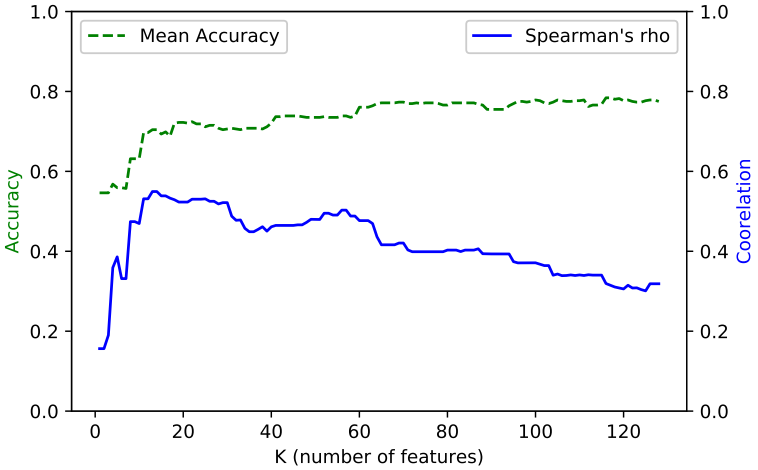

Figure 2: Accuracy of DementiaBank classifier model and Spearman's ρ on Lu corpus, using only the top K English features ordered by R^2 on the OpenSubtitles corpus. Spearman's ρ is maximized at $K = 13$, achieving a score of $\rho = 0.549$. DementiaBank accuracy generally increases with more features.

Our best model achieves a Spearman's ρ of 0.549, beating the translate baseline (n = 49, p = 0.06). Joint feature selection appears to be crucial, since the model performs worse than the baselines if we use all of the features. This is the case no matter if we predict each target feature independently or all at once with reduced rank regression. RRR does not outperform the baseline model, probably because it fails to account for the noisy target features in the correspondence model and considers each feature equally important. We did not attempt to use joint feature selection and RRR at the same time, because the multiplicative combination of hyperparameters K and R would produce a multiple comparisons problem using the small validation set.

Using joint feature selection, we find that the best score is achieved when we use $K = 13$ target features (Figure 2). With $K < 13$, performance suffers because the DementiaBank classifier is not given enough information to make accurate classifications. With $K > 13$, the accuracy for the DementiaBank classifier improves; however, the overall performance degrades because it is given noisy features with low R^2 coefficients. A list of the top features is given in Table 2 in the supplementary materials.

In our experiments, the correspondence model worked better when absolute counts were used for the Chinese CFG features (e.g., the number of $NP \rightarrow PN$ productions in the narration) rather than ratio features (e.g., the proportion of CFG productions that were $NP \rightarrow PN$). When ratios were used for source features, the R^2 coefficients for many target features decreased. A possible explanation is that the narrations have varying lengths, and dividing features by the length introduces a nonlinearity that adversely affects our linear models. However, more experimentation is required to examine this hypothesis.

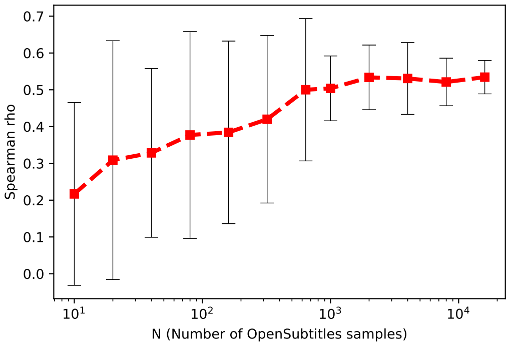

Figure 3: Ablation experiment where a various number of OpenSubtitles samples were used for training. The error bars indicate the two standard deviation confidence interval.

4.4 Ablation Study

Next, we investigate how many parallel OpenSubtitles narrations were necessary to learn the correspondence model. We choose various training sample sizes from 10 to 50,000 and, for each training size, we train and evaluate the whole model from end-to-end 10 times with different random seeds (Figure 3). As expected, the Spearman's ρ increased as more samples were used, but only 1000-2000 samples were required to achieve comparable performance to the full model.

5 Conclusion

We propose a novel method to use a large parallel corpus to learn mappings between engineered features in two languages. Combined with a dementia classifier model for English speech, we constructed a model to predict dementia in Mandarin Chinese. Our method achieves state-of-the-art results for this task and beats baselines based on unilingual models and Google Translate. It is successful despite the stark differences between English and Mandarin, and the fact that the parallel corpus is out-of-domain for the task. Lastly, our method does not require any Mandarin data for training, which is important given the difficulty of acquiring sensitive clinical data.

Future work will investigate the use of automatic speech recognition to reduce the need for manual transcripts, which are impractical in a clinical setting. Also, our model only uses lexicosyntactic features, and ignores acoustic features (e.g., pause duration) which are significant for dementia detection in English. Finally, it remains to apply this method to other languages, such as French (Fraser et al., 2019), for which datasets have recently been collected.

A Appendices

A.1 Description of Lexicosyntactic Features

We extract 185 lexicosyntactic features in English and 143 in Mandarin Chinese. We use Stanford CoreNLP to do constituency parsing and part-of-speech tagging (Klein and Manning, 2003; Levy and Manning, 2003). We also use `wordfreq` (Speer et al., 2018) for word frequency statistics in both languages. Our features are similar to the set of features used by Fraser et al. (2016), which the reader can refer to for a more thorough description.

The following features are extracted in English:

- **Narrative length:** Number of words and sentences in narration.
- **Vocabulary richness:** Type-token ratio, moving average type-token ratio (with window sizes of 10, 20, 30, 40, and 50 words), Honoré's statistic, and Brunét's index.
- **Frequency metrics:** Mean word frequencies for all words, nouns, and verbs.
- **POS counts:** Counts and ratios of nouns, verbs, inflected verbs, determiners, demonstratives, adjectives, adverbs, function words, interjections, subordinate conjunctions, and coordinate conjunctions. Also includes some special ratios such as pronoun / noun and noun / verb ratios.
- **Syntactic complexity:** Counts and mean lengths of clauses, T-units, dependent clauses, and coordinate phrases as computed by Lu's syntactic complexity analyzer (Lu, 2010).
- **Tree statistics:** Max, median, and mean heights of all CFG parse trees in the narration.
- **CFG ratios:** Ratio of CFG production rule count for each of the 100 most common CFG productions from the constituency parse tree.

The following features are extracted in Mandarin Chinese:

- **Narrative length:** Number of sentences, number of characters, and mean sentence length.
- **Frequency metrics:** Type-token ratio, mean and median word frequencies.
- **POS counts:** For each part-of-speech category, the number of it in the utterance and ratio of it divided by the number of tokens. Also includes some special ratios such as pronoun / noun and noun / verb ratios.
- **Tree statistics:** Max, median, and mean heights of all CFG parse trees in the narration.
- **CFG counts:** Number of occurrences for each of the 60 most common CFG production rules from the constituency parse tree.

A.2 Top Joint Features

Table 2 lists the top English features for joint feature selection (most reconstructable from Chinese features), ordered by R^2 coefficients on the OpenSubtitles corpus. The top performing model uses the first 13 features.

#	**Feature Name**	R^2
1	Number of words	0.894
2	Number of sentences	0.828
3	Brunét's index	0.813
4	Type token ratio	0.668
5	Moving average TTR (50 word window)	0.503
6	Moving average TTR (40 word window)	0.461
7	Moving average TTR (30 word window)	0.411
8	Average word length	0.401
9	Moving average TTR (20 word window)	0.360
10	Moving average TTR (10 word window)	0.328
11	NP → PRP	0.294
12	Number of nouns	0.233
13	Mean length of clause	0.225
14	PP → IN NP	0.224
15	Total length of PP	0.222
16	Complex nominals per clause	0.220
17	Noun ratio	0.213
18	Pronoun ratio	0.208
19	Number of T-units	0.207
20	Number of PP	0.205
21	Number of function words	0.198
22	Subordinate / coordinate clauses	0.193
23	Mean word frequency	0.193
24	Number of pronouns	0.191
25	Average NP length	0.188

Abstract

Recent work has shown that visual context improves cross-lingual sense disambiguation for nouns. We extend this line of work to the more challenging task of cross-lingual *verb sense* disambiguation, introducing the MultiSense dataset of 9,504 images annotated with English, German, and Spanish verbs. Each image in MultiSense is annotated with an English verb and its translation in German or Spanish. We show that cross-lingual verb sense disambiguation models benefit from visual context, compared to unimodal baselines. We also show that the verb sense predicted by our best disambiguation model can improve the results of a text-only machine translation system when used for a multimodal translation task.

1 Introduction

Resolving lexical ambiguity remains one of the most challenging problems in natural language processing. It is often studied as a word sense disambiguation (WSD) problem, which is the task of assigning the correct sense to a word in a given context (Kilgarrif, 1998). Word sense disambiguation is typically tackled using only *textual context*; however, in a multimodal setting, *visual context* is also available and can be used for disambiguation. Most prior work on visual word sense disambiguation has targeted noun senses (Barnard and Johnson, 2005; Loeff et al., 2006; Saenko and Darrell, 2008), but the task has recently been extended to verb senses (Gella et al., 2016, 2019). Resolving sense ambiguity is particularly crucial for translation tasks, as words can have more than one translation, and these translations often correspond to word senses (Carpuat and Wu, 2007; Navigli, 2009). As an example consider the verb *ride*, which can translate into German as *fahren* (ride a bike) or *reiten* (ride a horse). Recent work on multimodal machine translation has partly addressed lexical ambiguity by using visual information, but it still remains unresolved especially for the part-of-speech categories such as verbs (Specia et al., 2016; Shah et al., 2016; Hitschler et al., 2016; Lala and Specia, 2018). Prior work on cross-lingual WSD has been limited in scale and has only employed textual context (Lefever and Hoste, 2013), even though the task should benefit from visual context, just like monolingual WSD.

Target:	Drei Männer **reiten** auf einem Elefanten.
Output:	Drei Jungs **fahren** auf einem Elefanten.

Figure 1: An example of a verb sense translation error (shown in **bold red**) by the English-German neural translation system of Sennrich et al. (2017).

Visual information has been shown to be useful to map words across languages for bilingual lexicon induction. For this, images are used as a pivot between languages or visual information is combined with cross-lingual vector spaces to learn word translations across languages (Bergsma and Van Durme, 2011; Kiela et al., 2015; Vulic et al., 2016). However, as with other grounding or word similarity tasks, bilingual lexicon induction has so far mainly targeted nouns and these approaches was shown to perform poorly for other word categories such as verbs. Recent work by Gella et al. (2017) and Kádár et al. (2018) has shown using image as pivot between languages can lead to better multilingual multimodal representations and can have successful applications in crosslingual retrieval and

Proceedings of NAACL-HLT 2019, pages 1998–2004
Minneapolis, Minnesota, June 2 - June 7, 2019.

multilingual image retrieval.

In this paper, we introduce the MultiSense dataset of 9,504 images annotated with English verbs and their translations in German and Spanish. For each image in MultiSense, the English verb is translation-ambiguous, i.e., it has more than one possible translation in German or Spanish. We propose a series of disambiguation models that, given an image and an English verb, select the correct translation of the verb. We apply our models on MultiSense and find that multimodal models that fuse textual context with visual features outperform unimodal models, confirming our hypothesis that cross-lingual WSD benefits from visual context.

Cross-lingual WSD also has a clear application in machine translation. Determining the correct sense of a verb is important for high quality translation output, and sometimes text-only translation systems fail when the correct translation would be obvious from visual information (see Figure 1). To show that cross-lingual visual sense disambiguation can improve the performance of translation systems, we annotate a part of our MultiSense dataset with English image descriptions and their German translations. There are two existing multimodal translation evaluation sets with ambiguous words: the Ambiguous COCO dataset (Elliott et al., 2017) contains sentences that are "possibly ambiguous", and the Multimodal Lexical Translation dataset is restricted to predicting single words instead of full sentences (Lala and Specia, 2018). This type of resource is important for multimodal translation because it is known that humans use visual context to resolve ambiguities for nouns and gender-neutral words (Frank et al., 2018). MultiSense contains sentences that are known to have ambiguities, and it allows for sentence-level and verb prediction evaluation. Here, we use the verbs predicted by our visual sense disambiguation model to constrain the output of a neural translation system and demonstrate a clear improvement in Meteor, BLEU, and verb accuracy over a text-only baseline.

2 MultiSense Dataset

Images Paired with Verb Translations The MultiSense dataset pairs sense-ambiguous English verbs with images as visual context and contextually appropriate German and Spanish translations. Table 1 shows examples of images taken from MultiSense with their Spanish and German translations. To compile the dataset, we first chose a set of English verbs which had multiple translations into German and Spanish in Wiktionary, an online dictionary. Then we retrieved 150 candidate images from Google Images using queries that included the target English verb. We constructed the verb phrases by extracting the 100 most frequent phrases for each verb from the English Google syntactic n-grams dataset (Lin et al., 2012), which we then manually filtered to remove redundancies, resulting in 10 phrases per verb. Examples of verb phrases for *blow* include *blowing hair*, *blowing a balloon*, and *blowing up a bomb*. We filtered the candidate images using crowdworkers on Amazon Mechanical Turk, who were asked to remove images that were irrelevant to the verb phrase query. Overall pairwise agreement for this image filtering task was 0.763. Finally, we employed native German and Spanish speakers to translate the verbs into their language, given the additional visual context.

This resulted in a dataset of 9,504 images, covering 55 English verbs with 154 and 136 unique translations in German and Spanish, respectively. We divided the dataset into 75% training, 10% validation and 15% test splits.

Sentence-level Translations We also annotated a subset of MultiSense with sentence-level translations for English and German. This subset contains 995 image–English description–German translation tuples that can be used to evaluate the verb sense disambiguation capabilities of multimodal translation models. We collected the data in four-steps: (1) crowdsource English descriptions of the images using the gold-standard MultiSense verb as a prompt; (2) manually post-edit the English descriptions to ensure they contain the correct verb; (3) crowdsource German translations, given the English descriptions, the German gold-standard MultiSense verb, and the image; (4) manually post-edit the German translations to ensure they contain the correct verb. Figure 1 shows an example of an image paired with its English description and German translation.

3 Verb Sense Disambiguation Modeling

We propose three models for cross-lingual verb sense disambiguation, based on the visual input, the textual input, or using both inputs. Each model is trained to minimize the negative log probability of predicting the correct verb translation.

Spanish	mandar	hinchar	explotar
German	zublasen	aufblasen	detonieren

Table 1: Images for the English verb *blow* annotated with translations in Spanish and German. The images correspond to the uses of *blowing with a hair dryer* and *blowing a balloon*, and *blowing up a bomb*.

3.1 Unimodal Visual Model

Visual features have been shown to be useful for learning semantic representations of words (Lazaridou et al., 2015), bilingual lexicon learning (Kiela et al., 2015), and visual sense disambiguation (Gella et al., 2016), amongst others. We propose a model that learns to predict the verb translation using only visual input. Given an image **I**, we extract a fixed feature vector from a Convolutional Neural Network, and project it into a hidden layer $\mathbf{h}_v$ with the learned matrix $\mathbf{W}_i \in \mathbb{R}^{h \times 512}$ (Eqn. 1). The hidden layer is projected into the output vocabulary of v verbs using the learned matrix $\mathbf{W}_o \in \mathbb{R}^{h \times v}$, and normalized into a probability distribution using a softmax transformation (Eqn. 2).

$$\mathbf{h}_v = \mathbf{W}_i \cdot \texttt{CNN}(\mathbf{I}) + \mathbf{b}_i \tag{1}$$

$$\mathbf{y} = \texttt{softmax}(\mathbf{W}_o \cdot \mathbf{h}_v + \mathbf{b}_o) \tag{2}$$

3.2 Unimodal Textual Model

Each image in MultiSense is associated with the query phrase that was used to retrieve it. Given a query phrase with N words, we embed each word as a d-dimensional dense vector, and represent the phrase as the average of its embeddings E. We then project the query representation into a hidden layer with the learned matrix $\mathbf{W}_q \in \mathbb{R}^{h \times d}$ (Eqn. 3). The hidden layer is projected into an output layer and normalized to a probability distribution, in the same manner as the unimodal visual model.

$$\mathbf{h}_q = \mathbf{W}_q \cdot \left(\frac{1}{N} \sum_{i}^{N} \mathrm{E}[w_i] \right) + \mathbf{b}_q \tag{3}$$

3.3 Multimodal Model

We also propose a multimodal model that integrates the visual and textual features to predict the correct verb sense. In our multimodal model, we concatenate the inputs together before projecting them into a hidden layer with a learned matrix $\mathbf{W}_h \in \mathbb{R}^{h \times (512+h)}$ (Eqn. 4). We follow the same steps as the unimodal models to project the multimodal hidden layers into the output label space.

$$\mathbf{h}_{early} = \mathbf{W}_h \cdot [\texttt{CNN}(\mathbf{I})\ ;\ \mathbf{h}_q] + \mathbf{b}_h \tag{4}$$

	Chance	Majority	Text	Image	MM
German	0.7	2.8	49.1	52.1	**55.6**
Spanish	0.7	4.0	52.7	50.3	**56.0**

Table 2: Cross-lingual verb sense disambiguation accuracy of our unimodal models and the multimodal model. We also show the performance of a random chance baseline and a majority label baseline.

4 Verb Disambiguation Experiments

Our experiments are designed to determine whether the integration of textual and visual features yields better cross-lingual verb sense disambiguation than unimodal models.

4.1 Setup and Evaluation

We embed the textual queries using pre-trained $d = 300$ dimension word2vec embeddings (Mikolov et al., 2013). We represent images in the visual model using the features extracted from the 512D `pool5` layer of a pre-trained ResNet-34 CNN (He et al., 2016). All our models have a $h = 128$ dimension hidden layer. The German models have an output vocabulary of $v = 154$ verbs, and the Spanish models have a vocabulary of $v = 136$ verbs. All of our models are trained using SGD with minibatches of 16 samples and a learning rate of 0.0001.

We evaluate the performance of our models by measuring the accuracy of the predicted verb against the gold standard. We also compare against chance and majority label baselines. Our preliminary experiments show that with better visual representation we achieve better acccuracy scores similar to others who observed better visual representation contributes to better downstream tasks such as image description (Fang et al., 2015), multimodal machine translation (Specia et al., 2016) and representation learning (Kádár et al., 2018).

4.2 Results

We present the results in Table 2. The chance and majority label baselines perform very poorly. The unimodal textual model performs better than the

Source	A large herd of sheep is **blocking** the road.	A woman smiles as she **brushes** her long, dark hair.
Target	Eine große Herde Schafe **blockiert** die Straße.	Eine Frau lächelt während sie sich ihre dunklen langen Haare **bürstet** .
Baseline	Eine große Herde Schafe **kriecht** die Straße entlang.	Eine Frau lächelt , als sie ihren langen und dunklen Haaren **putzt** .
+WSD	Eine große Herde Schafe **blockieren** die Straße.	Eine Frau lächelt , als sie ihr lange , dunklen Haaren **bürsten** .

Table 3: The visual verb sense predictions ("blockieren", "bürsten") successfully constrains the decoder to predict the correct sense of the verb ("block", "brush") in the German translation **(+WSD)**. The incorrect verb in the baseline translation is shown in **bold red.**

Model	German	Spanish
Textual	schauen	mirar
Visual	tragen	**buscar**
MM	**suchen**	**buscar**

Figure 2: Examples of the Top-1 predictions of our unimodal and multimodal models. Only the early fusion multimodal model predicts the correct verb sense for both languages (shown in bold).

unimodal visual model for German verb sense disambiguation, but we find the opposite for Spanish unimodal verb sense disambiguation. However, the early fusion multimodal model outperforms the best unimodal model for both German and Spanish. This confirms that cross-lingual verb sense disambiguation benefits from multimodal supervision compared to unimodal supervision.

4.3 Discussion

We analyzed the outputs of our models in order to understand where multimodal features helped in identifying the correct verb translation and the cases where they failed. In Figure 2, we show an example that illustrates how varying the input (textual, visual, or multimodal) affects the accuracy of the verb prediction. We show the top verb predicted by our models for both German and Spanish. The top predicted verb using text-only visual features is incorrect. The unimodal visual features model predicts the correct Spanish verb but the incorrect German verb. However, when visual information is added to textual features, models in both the languages predict the correct label.

	Meteor	BLEU	VAcc
Baseline NMT	38.6	17.8	22.9
+ Predicted Verb	40.0	18.5	49.5
+ Oracle Verb	40.4	19.1	77.7
Caglayan et al.	46.1	25.8	29.3
Helcl & Libovický	42.5	22.3	25.1

Table 4: Translation results: Meteor and BLEU are standard text-similarity metrics; verb accuracy (VAcc) counts how often the model proposal contains the gold standard German verb.

5 Machine Translation Experiments

We also evaluate our verb sense disambiguation model in the challenging downstream task of multimodal machine translation (Specia et al., 2016). We conduct this evaluation on the sentence-level translation subset of MultiSense. We evaluate model performance using BLEU (Papineni et al., 2002) and Meteor scores (Denkowski and Lavie, 2014) between the MultiSense reference description and the translation model output. We also evaluate the verb prediction accuracy of the output against the gold standard verb annotation.

5.1 Models

Our baseline is an attention-based neural machine translation model (Hieber et al., 2017) trained on the 29,000 English-German sentences in Multi30k (Elliott et al., 2016). We preprocessed the text with punctuation normalization, tokenization, and lowercasing. We then learned a joint byte-pair-encoded vocabulary with 10,000 merge operations to reduce sparsity (Sennrich et al., 2016).

Our approach uses the German verb predicted by the unimodal visual model (Section 3.1) to constrain the output of the translation decoder (Post and Vilar, 2018). This means that our approach does not directly use visual features, instead it uses the output of the visual verb sense disambiguation model to guide the translation process.

We compare our approach against two state-of-the-art multimodal translation systems: Caglayan et al. (2017) modulate the target language word embeddings by an element-wise multiplication with a learned transformation of the visual data; Helcl and Libovický (2017) use a double attention model that learns to selectively attend to a combination of the source language and the visual data.

5.2 Results

Table 4 shows the results of the translation experiment. Overall, the Meteor scores are much lower than on the Multi30k test sets, where the state-of-the-art single model scores 51.6 Meteor points compared to 46.1 Meteor we obtained. This gap is most likely due evaluating the models on an out-of-domain dataset with out-of-vocabulary tokens. Using the predicted verb as a decoding constraint outperforms the text-only translation baseline by 1.4 Meteor points. In addition, the translation output of our model contains the correct German verb 27% more often than the text-only baseline model. These results show that a multimodal verb sense disambiguation model can improve translation quality in a multimodal setting.

We also calculated the upper bound of our approach by using the gold standard German verb as the lexical constraint. In this oracle experiment we observed a further 0.4 Meteor point improvement over our best model, and a further 27% improvement in verb accuracy. This shows that: (1) there are further improvements to be gained from improving the verb disambiguation model, and (2) the OOV rate in German means that we cannot achieve perfect verb accuracy.

6 Conclusions

We introduced the MultiSense dataset of 9,504 images annotated with an English verb and its translation in Spanish and German. We proposed a range of cross-lingual visual sense disambiguation models and showed that multimodal models that fuse textual and visual features outperform unimodal models. We also collected a set of image descriptions and their translations, and showed that the output of our cross-lingual WSD system boosts the performance of a text-only translation system on this data. MultiSense is publicly available at `https://github.com/spandanagella/multisense`

Subword-Level Language Identification for Intra-Word Code-Switching

Manuel Mager[1], **Özlem Çetinoğlu**[1] and **Katharina Kann**[2]

Abstract

Language identification for code-switching (CS), the phenomenon of alternating between two or more languages in conversations, has traditionally been approached under the assumption of a single language per token. However, if at least one language is morphologically rich, a large number of words can be composed of *morphemes* from more than one language (intra-word CS). In this paper, we extend the language identification task to the subword level, such that it includes splitting mixed words while tagging each part with a language ID. We further propose a model for this task, which is based on a segmental recurrent neural network. In experiments on a new Spanish–Wixarika dataset and on an adapted German–Turkish dataset, our proposed model performs slightly better than or roughly on par with our best baseline, respectively. Considering only mixed words, however, it strongly outperforms all baselines.

1 Introduction

In settings where multilingual speakers share more than one language, mixing two or more languages within a single piece of text, for example a tweet, is getting increasingly common (Grosjean, 2010). This constitutes a challenge for natural language processing (NLP) systems, since they are commonly designed to handle one language at a time.

Code-switching (CS) can be found in multiple non-exclusive variants. For instance, sentences in different languages can be mixed within one text, or words from different languages can be combined into sentences. CS can also occur on the subword level, when speakers combine morphemes from different languages (*intra-word CS*). This last phenomenon can mostly be found if at least one of the languages is morphologically rich. An example for intra-word CS between the Romance language Spanish and the Yuto-Aztecan language Wixarika[1] is shown in Figure 1.

(a)	*ne'iwa*	*pecansadoxɨ*
	WIX	MIXED

	my.brother	you-are	tired	PPFV

'My brother, you are tired.'

Figure 1: Intra-word CS between Spanish and Wixarika, **(a)** standard LID for CS, **(b)** our task. PPFV stands for past perfective.

CS language identification (LID) , i.e., predicting the language of each token in a text, has attracted a lot of attention in recent years (cf. Solorio et al. (2014); Molina et al. (2016)). However, intra-word mixing is mostly not handled explicitly: words with morphemes from more than one language are simply tagged with a `mixed` label.

While this works reasonably well for previously studied language pairs, overlooking intra-word CS leads to a major loss of information for highly polysynthetic languages. A mixed word is unknown for NLP systems, yet a single word contains much more information, cf. Figure 1 (b). Furthermore, we find intra-word CS to be much more frequent for Spanish–Wixarika than for previously studied language pairs, such that it is crucial to handle it.

Motivated by these considerations, we extend the LID task to the subword level (from (a) to (b) in Figure 1). We introduce a new CS dataset for Spanish–Wixarika (ES–WIX) and modify an existing German–Turkish (DE–TR) CS corpus (Çetinoğlu, 2016) for our purposes. We then intro-

---

[1] Wixarika, also known as Huichol, is a polysynthetic Mexican indigenous language.

Proceedings of NAACL-HLT 2019, pages 2005–2011
Minneapolis, Minnesota, June 2 - June 7, 2019.

duce a segmental recurrent neural network (SegRNN) model for the task, which we compare against several strong baselines. Our experiments show clear advantages of SegRNNs over all baselines for intra-word CS.

2 Related Work

The task of LID for CS has been frequently studied in the last years (Al-Badrashiny and Diab, 2016; Rijhwani et al., 2017; Zhang et al., 2018), including two shared tasks on the topic (Solorio et al., 2014; Molina et al., 2016). The best systems (Samih et al., 2016; Shirvani et al., 2016) achieved over 90% accuracy for all language pairs. However, intra-word CS was not handled explicitly, and often systems even failed to correctly assign the `mixed` label. For Nepali–English, Barman et al. (2014) correctly identified some of the mixed words with a combination of linear kernel support vector machines and a k-nearest neighbour approach. The most similar work to ours is Nguyen and Cornips (2016), which focused on detecting intra-word CS for Dutch–Limburgish (Nguyen et al., 2015). The authors utilized Morfessor (Creutz and Lagus, 2002) to segment all words into morphemes and Wikipedia to assign LID probabilities to each morpheme. However, their task definition and evaluation are on the word level. Furthermore, as this method relies on large monolingual resources, it is not applicable to low-resource languages like Wixarika, which does not even have its own Wikipedia edition.

Subword-level LID consists of both segmentation and tagging of words. An earlier approach to handle a similar scenario was the connectionist temporal classification (CTC) model developed by Graves et al. (2006). The disadvantage of this model was the lack of prediction of the segmentation boundaries that are necessary for our task. Kong et al. (2016) later proposed the SegRNN model that segments and labels jointly, with successful applications on automatic glossing of polysynthetic languages (Micher, 2017, 2018). Segmentation of words into morphemes alone has a long history in NLP (Harris, 1951), including semi- or unsupervised methods (Goldsmith, 2001; Creutz and Lagus, 2002; Hammarström and Borin, 2011; Grönroos et al., 2014), as well as supervised ones (Zhang and Clark, 2008; Ruokolainen et al., 2013; Cotterell et al., 2015; Kann et al., 2018).

3 Task and Data Description

3.1 Task Description

Formally, the task of subword-level LID consists of producing two sequences, given an input sequence of tokens $X = \langle x_1, \ldots, x_i, \ldots, x_{|X|} \rangle$. The first sequence contains all words and splits $X^s = \langle x_1^s, \ldots, x_i^s, \ldots, x_{|X|}^s \rangle$, where each x_i^s is an m-tuple of variable length $0 < m \leq |x_i|$, where $|x_i|$ is the number of characters in x_i. The second sequence is such that $T^s = \langle t_1^s, \ldots, t_i^s, \ldots, t_{|X|}^s \rangle$, where $|T^s| = |X^s| = |X|$ and each $t_i^s \in T^s$ is an n-tuple of tags from a given set of LID tags. An input–output example for a DE–TR mixed phrase is shown in Figure 2.

Input	⟨ ‘Yerim’,	‘seni’,	‘,’,	‘danke’,	‘Schatzym’⟩
Output	⟨ (Yerim),	(seni),	(,),	(danke),	(Schatzy, m)⟩
	⟨ (TR),	(TR),	(OTHER),	(DE),	(DE, TR)⟩

Figure 2: Subword-level LID in German–Turkish.

3.2 Datasets

German–Turkish The German–Turkish Twitter Corpus (Çetinoğlu and Çöltekin, 2016) consists of 1029 tweets with 17K tokens. They are manually normalized, tokenized, and annotated with language IDs. The language ID tag set consists of `TR` (Turkish), `DE` (German), `LANG3` (other language), `MIXED` (intra-word CS), `AMBIG` (ambiguous language ID in context), and `OTHER` (punctuation, numbers, emoticns, symbols, etc.). Named entities are tagged with a combination of `NE` and their language ID: `NE.TR`, `NE.DE`, `NE.LANG3`. In the original corpus, some Turkish and mixed words undergo a morphosyntactic split,[2] with splitting points not usually corresponding to language boundaries. For the purpose of subword-level LID, these morphosyntactic splits are merged back into single words. We then manually segment `MIXED` words at language boundaries, and replace their labels with more fine-grained language ID tags. The total percentage of mixed words is 2.75%. However, the percentage of sentences with mixed words is 15.66%. The complete dataset statistics can be found in Table 1.

Spanish–Wixarika Our second dataset consists of 985 sentences and 8K tokens in Spanish and Wixarika. Wixarika is spoken by approximately

Table 2: Number of tokens classified by language tags seen in the Spanish-Wixarika dataset. We show the total number of *Tokens* per tag, their proportion (*%*) with the total tokens, the *Unique* word types, and the proportion (*Unique %*) of them with the total number of unique word types.

$50,000$ people in the Mexican states of Durango, Jalisco, Nayarit and Zacatecas (Leza and López, 2006) and is polysynthetic, with most morphemes ocurring in verbs. The data is collected from public postings and comments from Facebook accounts. To ensure the public characteristic of these posts, we manually collect data that is accessible publicly without being logged in to Facebook, to comply with the terms of use and privacy of the users. These posts and comments are taken from 34 users: 14 women, 10 men, and the rest does not publically reveal their gender. None of them have publically mentioned their age. To get a dataset that focuses on the LID task, we only consider threads where the CS phenomenon appears. We replace usernames with `@username` in order to preserve privacy. Afterwards, we tokenize the text, segment mixed words, and add language IDs to words and segments.

The tag set is parallel to that of German–Turkish: `ES` (Spanish), `WIX` (Wixarika), `EN` (English), `AMBIG` (ambiguous) `OTHER` (punctuation, numbers, emoticons, etc), `NE.ES`, `NE.WIX` and `NE.EN` (named entities). Mixed words are segmented and each segment is labeled with its corresponding language (`ES`, `WIX`, `EN`). Table 2 shows a detailed description of the dataset. The percentage of mixed words is higher than in the DE–TR dataset: 3.13% of the tokens and 4.26% of the types. The most common combination is Spanish roots with Wixarika affixes. Furthermore, 16.55% of the sentences contain mixed words.

We split the DE–TR corpus and the ES–WIX corpus into training and test sets of sizes 800:229 and 770:216, respectively. Error analysis and hyperparameter tuning are done on the training set via 5-fold cross-validation. We present results on the test sets. Both datasets are available at `https://www.ims.uni-stuttgart.de/institut/mitarbeiter/ozlem/NAACL2019.html`

4 Experiments

Our main system is a neural architecture that jointly solves the segmentation and language identification tasks. We compare it to multiple pipeline systems and another joint system.

4.1 SegRNN

We suggest a SegRNN (Kong et al., 2016) would be the best fit for our task because it models a joint probability distribution over possible segmentations of the input and labels for each segment.

The model is trained to optimize the following objective, which corresponds to the joint log-likelihood of the segment lengths e and the language tags t:

$$\mathcal{L}(\theta) = \sum_{(x,t,e)\in\mathcal{D}} - \log p(t, e|x) \qquad (1)$$

$\mathcal{D}$ denotes the training data, θ is the set of model parameters, x the input, t the tag sequence and e the sequence of segment lengths.

Our inputs are single words.[3] As hyperparame-

---

[3] We also experimented with entire phrases as inputs, and the achieved scores were slightly worse than for word-based inputs.

Table 3: Segmentation and LID test results for mixed words only.

ters we use: 1 RNN layer, a 64-dimensional input layer, 32 dimensions for tags, 16 for segments, and 4 for lengths. For training, we use Adam (Kingma and Ba, 2014).

4.2 Baselines

BiLSTM+Seq2Seq/BiLSTM+CRF Our first baselines are pipelines. First, the input text is tagged with language IDs. Language IDs of a mixed word are directly predicted as a combination of all language ID tags of the word (i.e., `WIX_ES`). Second, a subword-level model segments words with composed language ID tags. For word-level tagging, we use a hierarchical bidirectional LSTM (**BiLSTM**) that incorporates both token- and character-level information (Plank et al., 2016), similar to the winning system (Samih et al., 2016) of the Second Code-Switching Shared Task (Molina et al., 2016). [4] For the subword level, we use two supervised segmentation methods: a **CRF** segmenter proposed by Ruokolainen et al. (2013), that models segmentation as a labeling problem and a sequence-to-sequence (**Seq2Seq**) model trained with an auxiliary task as proposed by Kann et al. (2018).

CRFTag+Seq2Seq/CRFTag+CRF Since our datasets might be small for training neural networks, we substitute the BiLSTM with a CRF tagger (Müller et al., 2013, **CRFTag**) in the first step. For segmentation, we use the same two approaches as for the previous baselines.

CharBiLSTM We further employ a BiLSTM to tag each character with a language ID. For training, each character inherits the language ID of the word or segment it belongs to. At prediction time, if the characters of a word have different language IDs, the word is split.

4.3 Metrics

We use two metrics for evaluation. First, we follow Kong et al. (2016) and calculate precision (P), recall (R), and F1, using segments as units (an unsegmented word corresponds to one segment). We also report a tagging accuracy (Char Acc.) by assigning a language ID to each character and calculating the ratio of correct language tags over all characters.

	DE–TR			ES–WIX		
	Seg. F1	Tag. F1	Char Acc.	Seg. F1	Tag. F1	Char Acc.
SegRNN	**98.7**	94.0	93.6	97.8	**92.5**	**92.4**
BiLSTM+Seq2Seq	98.6	**95.1**	94.3	**98.1**	90.9	90.7
BiLSTM+CRF	**98.7**	94.9	**94.4**	97.9	87.8	90.6
CRFTag+Seq2Seq	98.4	93.7	93.1	97.7	90.4	90.1
CRFTag+CRF	98.4	93.7	93.1	97.6	90.3	90.1
CharBiLSTM	87.7	88.0	92.5	89.7	87.9	91.3

Table 4: Test set results for entire datasets.

4.4 Results and Discussion

Table 4 shows all test results for the entire datasets. We find the following: (i) For ES–WIX, SegRNN performs slightly better for tagging than the best baseline, both in terms of F1 and character accuracy. For DE–TR, SegRNN and BiLSTM+CRF are the best segmentation models, but the BiLSTM models slightly outperform SegRNN for tagging. (ii) The CRF pipelines perform slightly worse than the best word-level BiLSTM models for both datasets and all evaluations.

Table 3 shows the results of tagging and segmentation only for the mixed words in our datasets. Here, we can see that: (i) Our SegRNN model achieves the best performance for segmentation. Differences to the other approaches are $\geq$ 10%, showing clearly why these models are good for the task when the number of words belonging to two languages is high. (ii) The pipeline BiLSTM models work best for tagging of the DE–TR data with a slight margin, but underperform

---

[4] For all BiLSTM models input dimension is 100 with a hidden layer size of 100. For training we use a stochastic gradient descent (Bottou, 2010), 30 epochs, with a learning rate of 0.1. A 0.25 dropout factor is applied.

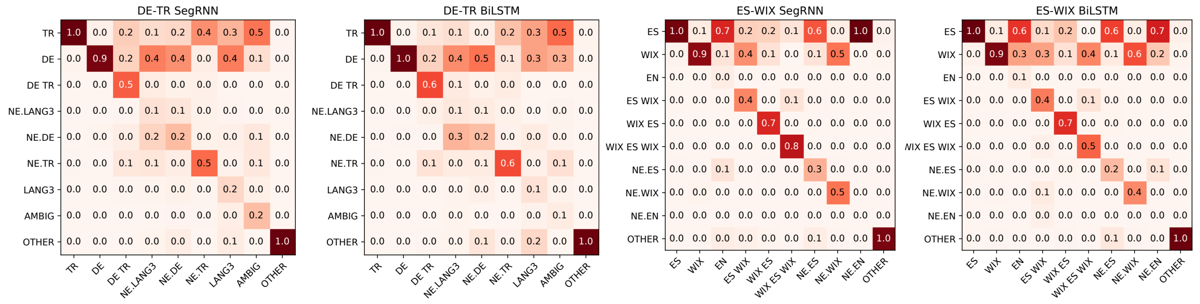

Figure 3: Confusion matrices of the two best models on both datasets. The x axis represents tags seen in the gold standard, and the y axis shows the corresponding predicted tags. Values are rounded up, therefore not all columns add up to 1.

on the ES–WIX dataset as compared to the SegRNN models. (iii) Both CRFTag models achieve very low results for both segmentation and tagging. (iv) CharBiLSTM performs better than the CRFTag models on both tasks, but is worse than all other approaches in our experiments.

More generally, we further observe that recall on mixed words for the DE–TR pair is low for all systems, as compared to ES–WIX. This effect is especially strong for the CRFTag and CharBiLSTM models, which seem to be unable to correctly identify mixed words. While this tendency can also be seen for the ES–WIX pair, it is less extreme. We suggest that the better segmentation and tagging of mixed words for ES–WIX might mostly be due to the higher percentage of available examples of mixed words in the training set for ES–WIX.

Overall, we conclude that SegRNN models seem to work better on language pairs that have more intra-word CS, while pipeline approaches might be as good for language pairs where the number of mixed words is lower.

Error analysis. Figure 3 shows confusion matrices for SegRNN and BiLSTM+Seg2Seg. Both models achieve good results assigning monolingual tags (`ES`, `WIX`, `DE`, `TR`) and punctuation symbols (`OTHERS`). The hardest labels to classify are named entities (`NE`, `NE.TR`, `NE.TR`, `NE.WIX`, `NE.ES`), as well as third language and ambiguous tags (`LANG3`, `EN`, `AMBIG`). Performance on multilingual tags (`DE TR`, `WIX ES`, `ES WIX`, `WIX ES WIX`) is mixed. For `DE TR`, BiLSTM+Seq2Seq gets slightly better classifications, but for the ES–WIX tags SegRNN achieves better results.

Regarding oversegmentation problems, BiLSTM+Seq2Seq (0.8% for DE–TR and 2.0% for ES–WIX) slightly underperforms SegRNN (0.7% for DE–TR and 1.13% for ES–WIX). The BiLSTM+Seq2Seq (2.4%) makes fewer undersegmentation errors for DE–TR than SegRNN (2.7%). However, for ES–WIX, SegRNN performs better with 3.81% undersegmentation errors compared to 4.2% of BiLSTM+Seq2Seq.

5 Conclusion

In this paper, we extended the LID task to the subword level, which is particularly important for code-switched text in morphologically rich languages. We further proposed a SegRNN model for the task and compared it to several strong baselines. Investigating the behaviour of all systems, we found that pipelines including a BiLSTM tagger work well for tagging DE–TR, where the number of mixed tokens is not that high, but that our proposed SegRNN approach performs better than all other systems for ES–WIX. Also, SegRNNs have clear advantages over all baselines if we consider mixed words only. Our subword-level LID datasets for ES–WIX and DE–TR are publicly available.

Acknowledgments

We would like to thank Mohamed Balabel, Sam Bowman, Agnieszka Falenska, Ilya Kulikov and Phu Mon Htut for their valuable feedback. We also want to thank Jeffrey Micher for his help with the setup of the SegRNN code. Abstract

Current research on spoken language translation (SLT) has to confront with the scarcity of sizeable and publicly available training corpora. This problem hinders the adoption of neural end-to-end approaches, which represent the state of the art in the two parent tasks of SLT: automatic speech recognition and machine translation. To fill this gap, we created MuST-C, a multilingual speech translation corpus whose size and quality will facilitate the training of end-to-end systems for SLT from English into 8 languages. For each target language, MuST-C comprises at least 385 hours of audio recordings from English TED Talks, which are automatically aligned at the sentence level with their manual transcriptions and translations. Together with a description of the corpus creation methodology (scalable to add new data and cover new languages), we provide an empirical verification of its quality and SLT results computed with strong baseline system on each language direction.

1 Introduction

Besides the increased computing power, the recent surge of neural end-to-end approaches to natural language processing tasks has been stoked by the increased availability of data. For instance, when supported by sizeable training corpora, the robustness and the strong generalization capabilities of neural networks led to their dominance over previous paradigms both in automatic speech recognition (ASR (Chiu et al., 2018)) and machine translation (MT (Bojar et al., 2018)).

Compared to its two parent research areas, spoken language translation (SLT) has not shown such a steady progress yet. Despite recent claims by big industry players about the effectiveness of end-to-end learning (Weiss et al., 2017; Jia et al., 2018), its adoption does not yet represent the mainstream solution to the SLT task. One of the main obstacles to a stable dominance of the end-to-end paradigm also in this area is the scarcity of training corpora. While cascade ASR+MT solutions can exploit the wealth of task-specific data available for each of the two tasks,[1] the situation for end-to-end model training is much less favourable. As shown in Table 1, few publicly available corpora exist, their language coverage is rather limited and, most importantly, their size is often too small (less than 100 hours of translated audio) for training data-hungry neural models.[2]

Table 1: Publicly available SLT corpora. The two most recent resources (also known as *IWSLT18* and *Augmented LibriSpeech*) are also the largest ones. Though considerably smaller, the *Fisher and Callhome* corpus described in (Post et al., 2013) is among the most widely used ones in previous research.

To circumvent the problem, neural SLT approaches currently rely on: *i)* large proprietary corpora (Jia et al., 2018), *ii)* multitask learning

---

[1] In resource-rich conditions, ASR and MT training often builds on thousands of hours of transcribed speech and tens of millions of parallel sentences, respectively.

[2] Besides the corpora reported in Table 1, several smaller (< 4 hours) freely-available datasets have been created (*e.g.* the IWSLT evaluation campaign development and test sets from 2010 to 2017 and the Griko-Italian corpus by Boito et al. (2018)).

Proceedings of NAACL-HLT 2019, pages 2012–2017
Minneapolis, Minnesota, June 2 - June 7, 2019.

(Weiss et al., 2017; Anastasopoulos and Chiang, 2018; Bérard et al., 2018), *iii)* encoder/decoder pre-training (Bansal et al., 2018; Bérard et al., 2018), *iv)* synthesized speech data (Bérard et al., 2016), or *v)* machine-translated target text data (Bérard et al., 2018). Though effective, solutions *ii)* and *iii)* assume the availability of ASR and MT data, which is not always guaranteed (especially in low-resource language settings). Solutions *iv)* and *v)*, instead, rely on training material derived from sub-optimal automatic data creation/augmentation procedures. This situation calls for initiatives towards the creation of large, high-quality multilingual corpora suitable to explore end-to-end SLT in more favorable conditions similar to condition *i)*. Along this direction, our contributions are:

- A large ($\sim$400 hours of speech per language) multilingual corpus for SLT from English into 8 languages (German, Spanish, French, Italian, Dutch, Portuguese, Romanian and Russian);
- An empirical verification of its quality;
- ASR, MT and SLT results computed with strong baseline systems on each language direction.

2 Corpus Creation Methodology

Must-C was created pursuing high quality as well as large size, speaker variety (male/female, native/non-native) and coverage in terms of topics and languages. To achieve these objectives, similar to (Niehues et al., 2018), we started from English TED Talks, in which a variety of speakers discuss topics spanning from business to science and entertainment. Most importantly, the fact that TED talks are often manually transcribed and translated sets ideal conditions for creating an SLT corpus from high-quality text material. Although the initial data are similar to those used to build the IWSLT18 corpus, our methodology is different. Inspired by Kocabiyikoglu et al. (2018), it exploits automatic alignment procedures, first at the text level (between transcriptions and translations) and then with the corresponding audio segments.

More in detail, for each target language L_i, the (English-L_i) section of MuST-C is created as follows. First, for all the English talks available from the TED website,[3] we download the videos and the HTML files containing the manual transcriptions and their translation into L_i.[4]

Then, the plain text transcription and the translation of each talk are split at the sentence level based on strong punctuation marks and aligned using the Gargantua sentence alignment tool (Braune and Fraser, 2010). This step produces a bilingual text corpus aligned at the sentence level.

In the third step, the English side of this bilingual corpus is aligned to the corresponding audio track extracted from the video. This is done using Gentle,[5] an off-the-shelf English forced-aligner built on the Kaldi ASR toolkit (Povey et al., 2011).

Next, the audio-text alignments are processed to create a YAML file containing time information (*i.e.* start and duration) for each sentence. In this processing step, two filters are applied to weed out potentially noisy segments, or entire talks, based on the number of words that were not aligned by Gentle. First, entire talks are discarded if the proportion of unrecognized words is equal or greater than 15% of the total. This threshold was determined after a manual analysis of 73 talks (those with the highest percentage of unrecognized words). The analysis showed that these cases are representative of different types of noise like: *i)* non-English speech, *ii)* long silences, *iii)* music, non-transcribed songs and videos played during the talk, and *iv)* wrong transcriptions (*e.g.* captions from other talks in the material downloaded from the TED website). The second rule applies to the single sentences of the talks that passed the first filter, and removes those in which none of the words was aligned by Gentle.[6]

In the last step, the log Mel 40-dimensional filter-bank features – commonly used as input representation for ASR (Graves et al., 2013) and SLT (Weiss et al., 2017) – are extracted from the

---

[3] `www.ted.com` – dump of April 2018.

[4] All talks have manual captions, which were also translated into many languages by volunteers. The language coverage of the translations depends on several factors like the age of the talk (the old ones often have more translations), the popularity of its topic and the availability of volunteer translators for a given language.

[5] `github.com/lowerquality/gentle`

[6] The effectiveness of this filtering criterion was manually verified on random samples. More aggressive solutions will be explored for future releases of the corpus.

Table 2: Statistics for each section of MuST-C.

aligned audio using the XNMT tool (Neubig et al., 2018).[7]

Table 2 provides basic statistics for the 8 sections of the MuST-C corpus. Comparing the 4^{th} column with the numbers reported in Table 1, it is worth noting that, in terms of hours of transcribed/translated speech, each section is larger than any existing publicly available SLT resource.

3 Experiments

In this section we present two sets of experiments, which are respectively aimed to: *i)* empirically assess the quality of the MuST-C corpus (Section 3.3) and *ii)* compute baseline ASR, MT, and SLT results for future comparisons (Section 3.4).

In these experiments, the *audio-transcription* alignments of MuST-C are used to train and evaluate ASR models, *transcription-translation* alignments are used for the MT models, and *audio-translation* alignments are used for the SLT models.

3.1 ASR, MT and SLT Models

ASR and SLT. For our experiments in ASR and SLT we use the same neural architecture. This setting allows us to use the encoder of the ASR models to initialize the weights of the SLT encoders and achieve a faster convergence (Bansal et al., 2018). Our SLT architecture is a variant of the system proposed by Bérard et al. (2018), which we re-implemented in the fairseq toolkit (Gehring et al., 2017). The system relies on an attentional encoder-decoder model that takes in input sequences of audio features and outputs the target sequence at the character level. The encoder processes the input with two consecutive fully-connected layers to expand the size of the representation, followed by two 2D strided convolutional layers that reduce the sequence length. The output of the convolutions is then processed by three stacked LSTMs (Hochreiter and Schmidhuber, 1997). The decoder consists of a two-layered deep transition (Pascanu et al., 2014) LSTM with an attention network based on the general soft attention score (Luong et al., 2015). The final output of the decoder is a function of the concatenation of the LSTM output, the context vector and the previous-character embedding.

MT. For the MT experiments we use the open source version of ModernMT.[8] The system is based on the Transformer (Vaswani et al., 2017) architecture, which represents the state of the art in NMT (Bojar et al., 2018). The encoder consists of a stack of 6 layers, each containing a sequence of two sub-layers, a self-attention network based on multi-head attention, and a position-wise feed-forward layer. The decoder layers have an additional sub-layer: between the self attention and the position-wise feed-forward layer they have an encoder-decoder multi-head attention. All the sub-layers in both the encoder and decoder are preceded by layer normalization and are followed by residual connections.

3.2 Data Processing and Evaluation Metrics

In our experiments, texts are tokenized and punctuation is normalized. Furthermore, the English texts are lowercased, while the target language texts are split into characters still preserving the word boundaries. For MT, we segment the English words with the BPE algorithm (Sennrich et al., 2015) using a maximum of $30K$ merge operations. The output generation of all models is performed using beam search with a beam size of 5.

ASR performance is measured with word error rate (WER) computed on lower-cased, tokenized texts without punctuation. MT and SLT results are computed with BLEU (Papineni et al., 2002).

3.3 Experiment 1: Corpus Quality

As observed in Section 2, each section of MuST-C is larger than any other existing publicly available SLT corpus. The usefulness of a resource, however, is not only a matter of size but also of quality (in this case, the quality of the *audio-transcription-translation* alignments). For an empirical verification of this aspect, we experimented with two comparable datasets. One is

---

[7] `github.com/neulab/xnmt`

[8] `www.modernmt.eu`

the TED-derived English-German IWSLT18 corpus (Niehues et al., 2018), which is built following a pipeline that performs segment extraction and alignment based on time information (*i.e.* start and end position of each segment in the SubRip Text (SRT) files) instead of text-level alignments. The other is the English-German subset of MuST-C derived from the same TED Talks used to build the IWSLT18 corpus. On one side (MuST-C), the number of segments, their length, and the overall corpus quality depend on text-level alignments. On the other side (IWSLT18), they depend on matching time stamps. This strategy, however, has some drawbacks. First, as pointed out by (Niehues et al., 2018; Liu et al., 2018; Di Gangi et al., 2018), the use of time information brings some noise in the corpus. Second, it often results in utterance-level alignment (based on speakers' pauses in the original audio). Compared to sentence-level alignment, this level of granularity can be sub-optimal during model training (*e.g.* for MT and SLT, learning from complete sentences is easier than learning from phrases). Finally, time information about the recorded speech is not always available: bypassing this need would make the method replicable on other data (not only TED-like).

Though initialized with the same set of $1,619$ talks, the two pipelines produce different corpora. As shown in Table 3, our approach filters out 58 entire talks ($\sim$3.6% of the total) but the final number of segments, their corresponding audio duration and their average length (in words) are larger.

Corpus	#Talk	#Sent	Hours	src w	tgt w
IWSLT18	1,619	176K	280	2.7M	2.5M
MuST-C	1,561	179K	313	3.3M	3.1M

Table 3: Statistics of the English-German corpora created by applying the IWSLT18 and MuST-C pipelines to the same initial set of $1,619$ TED Talks.

Each corpus was divided into training, development and test. Development and test contain segments from randomly selected common talks (*i.e.* those preserved by the MuST-C pipeline). Their size is respectively $2.3K$ (from 28 talks) and $2.1K$ segments (from 26 talks). The test portions were concatenated to create a balanced test set ($4.2K$ segments) containing half of the instances from the IWSLT18 corpus and half from MuST-C. The remaining material was used to separately train ASR, MT and SLT models on homogeneous data from either of the two corpora (*i.e.* three systems per corpus). All the systems are evaluated on the common test set.

Training set	ASR (↓)	MT (↑)	SLT (↑)
IWSLT18	42.15	24.90	8.94
MuST-C	32.05	25.46	12.25

Table 4: Performance of ASR, MT and SLT systems trained with En-De IWSLT18 and MuST-C data.

Tgt	ASR (↓)	MT (↑)	SLT (↑)
De	27.00	28.09	12.93
Es	26.61	34.16	18.20
Fr	25.81	42.23	22.29
It	26.38	30.40	14.95
Nl	26.55	33.43	18.20
Pt	28.00	32.44	17.10
Ro	27.61	28.16	13.35
Ru	26.97	18.30	7.22

Table 5: Baseline ASR, MT and SLT results for each language direction.

Table 4 shows that the models trained on MuST-C data achieve better results on the balanced test set in all the three tasks. In particular: *i)* a reduction of 10.1 WER points in ASR indicates a higher quality of *audio-transcription* alignments, *ii)* a BLEU increase of 0.56 points in MT indicates a similar quality for *transcription-translation* alignments, and *iii)* a BLEU increase of 3.31 points in SLT indicates a higher quality of *audio-translation* alignments. We consider these results as evidence of the reliability of our corpus creation methodology. Being the same for all the language pairs, we expect this procedure to end up in comparable quality for all the 8 sections of MuST-C.

3.4 Experiment 2: Baseline Results

We finally present baseline results computed, for all the three tasks, on each section of MuST-C. Also for these experiments, development and test data are created with segments from talks that are common to all the languages. Their size is respectively $1.4K$ (from 11 talks) and $2.5K$ segments (from 27 talks). The remaining data (of variable size depending on the language pairs) are used for training. For the sake of replicability, these splits are preserved in the released version of MuST-C.

The results in Table 5 lead to the following observations. First, though not directly comparable since they are computed on different test sets, English-German results are in line (actually higher, since they are produced by models built on larger training data) with those presented in Section 3.3. This indicates that the level of quality observed in the previous experiments with a subset of the training data is preserved by the whole material released for this language pair. Second, looking at the other language pairs, ASR, MT and SLT results are comparable with the English-German scores. Besides normal fluctuations in the optimization of the neural models, performance differences are coherent with: *i)* the relative difficulty of each target language (*e.g.* Russian is more difficult due to high inflection) and *ii)* the variable quantity of training data available (*e.g.* French has the largest training set, see Table 2). Overall, these explainable differences suggest that our corpus creation methodology yields homogeneous quality for all the languages covered by MuST-C.

4 Conclusion and Future Work

We presented MuST-C, a *Mu*ltilingual *S*peech *T*ranslation *C*orpus built to address the need of resources for training data-hungry neural SLT models. To the best of our knowledge, to date MuST-C is the largest publicly available corpus of this kind. In its current version, it comprises the English transcription and the translations into 8 target languages of at least 385 hours of speech (up to 504) per language. Thanks to a scalable corpus creation procedure initialized with constantly expanding TED talks data, future extensions will increase the coverage of the already present target languages and introduce new ones.

MuST-C is released under a Creative Commons license, Attribution - Non Commercial - No Derivatives (CC BY NC ND 4.0 International), and is freely downloadable at `mustc.fbk.eu`

Abstract

Critical to natural language generation is the production of correctly inflected text. In this paper, we isolate the task of predicting a fully inflected sentence from its partially lemmatized version. Unlike traditional morphological inflection or surface realization, our task input does not provide "gold" tags that specify what morphological features to realize on each lemmatized word; rather, such features must be inferred from sentential context. We develop a neural hybrid graphical model that explicitly reconstructs morphological features before predicting the inflected forms, and compare this to a system that directly predicts the inflected forms without relying on any morphological annotation. We experiment on several typologically diverse languages from the Universal Dependencies treebanks, showing the utility of incorporating linguistically-motivated latent variables into NLP models.

1 Introduction

NLP systems are often required to generate grammatical text, e.g., in machine translation, summarization, dialogue, and grammar correction. One component of grammaticality is the use of contextually appropriate closed-class morphemes. In this work, we study **contextual inflection**, which has been recently introduced in the CoNLL-SIGMORPHON 2018 shared task (Cotterell et al., 2018) to directly investigate context-dependent morphology in NLP. There, a system must inflect partially lemmatized tokens in sentential context. For example, in English, the system must reconstruct the correct word sequence *two cats are sitting* from partially lemmatized sequence *two _cat_ are sitting*. Among other things, this requires: (1) identifying *cat* as a noun in this context, (2) recognizing that *cat* should be inflected as plural to agree with the nearby verb and numeral, and (3) realizing this inflection as the suffix *s*. Most past work in supervised computational morphology—including the previous CoNLL-SIGMORPHON shared tasks on morphological reinflection (Cotterell et al., 2017)—has focused mainly on step (3) above.

As the task has been introduced into the literature only recently, we provide some background. Contextual inflection amounts to a highly constrained version of language modeling. Language modeling predicts all words of a sentence from scratch, so the usual training and evaluation metric—perplexity—is dominated by the language model's ability to predict *content*, which is where most of the uncertainty lies. Our task focuses on just the ability to reconstruct certain missing parts of the sentence—inflectional morphemes and their orthographic realization. This refocuses the modeling effort from semantic coherence to morphosyntactic coherence, an aspect of language that may take a back seat in current language models (see Linzen et al., 2016; Belinkov et al., 2017). Contextual inflection does not perfectly separate grammaticality modeling from content modeling: as illustrated in Tab. 1, mapping *two cats _be_ sitting* to the fully-inflected *two cats were sitting* does not require full knowledge of English grammar—the system does not have to predict the required word order nor the required auxiliary verb *be*, as these are supplied in the input. Conversely, this example does still require predicting some content—the semantic choice of past tense is *not* given by the input and must be guessed by the system.[1]

The primary contribution of this paper is a novel structured neural model for contextual inflection. The model first predicts the sequence of morphological tags from the partially lemmatized sequence and, then, it uses the predicted tag and lemma to inflect the word. We use this model

---

[1] This morphological feature is *inherent* in the sense of Booij (1996).

Target:	`two`	`cats`	`were`	`sitting`

Table 1: Example data entry: the target word *be* should be properly inflected into *were* to fit the sentential context.

to evince a simple point: models are better off jointly predicting morphological tags from context than directly learning to inflect lemmata from sentential context. Indeed, none of the participants in the 2018 shared task jointly predicted tags with the inflected forms. Comparing our new model to several competing systems, we show our model has the best performance on the majority of languages. We take this as evidence that predicting morphological tags jointly with inflecting is a better method for this task. Furthermore, we provide an analysis discussing the role of morphological complexity in model performance.

2 Joint Tagging and Inflection

Given a language, let $\mathcal{M}$ be a set of morphological tags in accordance with the Universal Dependencies annotation (Nivre et al., 2016). Each $m \in \mathcal{M}$ has the form $m = \langle t, \sigma \rangle$, where t is a part of speech, and the slot σ is a set of attribute–value pairs that represent morphosyntactic information, such as number, case, tense, gender, person, and others. We take $t \in \mathcal{T}$, the set of universal parts of speech described by Petrov et al. (2012). A sentence consists of a finite word sequence $\mathbf{w}$ (we use boldface for sequence variables). For every word w_i in the sequence, there is a corresponding analysis in terms of a morphological tag $m_i \in \mathcal{M}$ and a lemma ℓ_i. In general, w_i is determined by the pair $\langle \ell_i, m_i \rangle$.[2] Using this notation, Cotterell et al. (2018)'s shared task is to predict a sentence $\mathbf{w}$ from its partially lemmatized form $\boldsymbol{\ell}$, inferring $\mathbf{m}$ as an intermediate latent variable. Our dataset (§3) has all three sequences for each sentence.

2.1 A Structured Neural Model

Consider an extreme case when *all* words are lemmatized.[3] We introduce a structured neural model for contextual inflection, as follows:

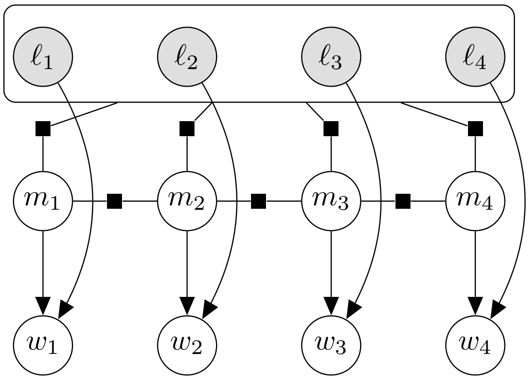

Figure 1: Our structured neural model shown as a hybrid (directed–undirected) graphical model. We omitted several arcs for convenience; namely, every morphological tag m_i depends on the entire sequence $\boldsymbol{\ell}$.

$$p(\mathbf{w}, \mathbf{m} \mid \boldsymbol{\ell}) = \left(\prod_{i=1}^{n} p(w_i \mid \ell_i, m_i) \right) p(\mathbf{m} \mid \boldsymbol{\ell}) \tag{1}$$

In other words, the distribution is over interleaved sequences of one-to-one aligned inflected words and morphological tags, conditioned on a lemmatized sequence, all of length n. This distribution is drawn as a hybrid (directed–undirected) graphical model (Koller and Friedman, 2009) in Fig. 1. We define the two conditional distributions in the model in §2.2 and §2.3, respectively.

2.2 A Neural Conditional Random Field

The distribution $p(\mathbf{m} \mid \boldsymbol{\ell})$ is defined to be a conditional random field (CRF; Lafferty et al., 2001). In this work, our CRF is a conditional distribution over morphological taggings of an input sequence. We define this conditional distribution as

$$p(\mathbf{m} \mid \boldsymbol{\ell}) = \frac{1}{Z(\boldsymbol{\ell})} \prod_{i=1}^{n} \psi\left(m_i, m_{i-1}, \boldsymbol{\ell}\right) \tag{2}$$

where $\psi(\cdot, \cdot, \cdot) \geq 0$ is an arbitrary potential, $Z(\boldsymbol{\ell})$ normalizes the distribution, and m_0 is a distinguished start-of-sequence symbol.

---

[2] Although w_i can sometimes be computed by concatenating ℓ_i with m_i-specific affixes, it can also be irregular.

[3] In case of partially lemmatized sequence we still train the model to predict the tags over the entire sequence, but evaluate it only for lemmatized slots.

In this work, we opt for a recurrent neural potential—specifically, we adopt a parameterization similar to the one given by Lample et al. (2016). Our potential ψ is computed as follows. First, the sequence $\boldsymbol{\ell}$ is encoded into a sequence of word vectors using the strategy described by Ling et al. (2015): word vectors are passed to a bidirectional LSTM (Graves et al., 2005), where the corresponding hidden states are concatenated at each time step. We simply refer to the hidden state $\mathbf{h}_i \in \mathbb{R}^d$ as the result of said concatenation at the i-th step. Using $\mathbf{h}_i$, we can define the potential function as $\psi(m_i, m_{i-1}) = \exp\left(A_{m_i,m_{i-1}} + \mathbf{o}_{m_i}^\top \mathbf{h}_i\right)$, where $A_{m_i,m_{i-1}}$ is a transition weight matrix and $\mathbf{o}_{m_i} \in \mathbb{R}^d$ is a morphological tag embedding; both are learned.

2.3 The Morphological Inflector

The conditional distribution $p(w_i \mid \ell_i, m_i)$ is parameterized by a neural encoder–decoder model with hard attention from Aharoni and Goldberg (2017). The model was one of the top performers in the 2016 SIGMORPHON shared task (Cotterell et al., 2016); it achieved particularly high accuracy in the low-resource setting. Hard attention is motivated by the observation that alignment between the input and output sequences is often monotonic in inflection tasks. In the model, the input lemma is treated as a sequence of characters, and encoded using a bidirectional LSTM (Graves and Schmidhuber, 2005), to produce vectors $\mathbf{x}_j$ for each character position j. Next the word $w_i = \mathbf{c} = c_1 \cdots c_{|w_i|}$ is generated in a decoder character-by-character:

$$p(c_j \mid \mathbf{c}_{<j}, l_i, m_i) = \text{softmax}\left(\mathbf{W} \cdot \phi(\mathbf{z}_1, \ldots, \mathbf{z}_j) + \mathbf{b}\right) \quad (3)$$

where $\mathbf{z}_j$ is the concatenation of the current attended input $\mathbf{x}_j$ alongside morphological features, m_i, and an embedding of the previously generated symbol c_{j-1}; and finally ϕ is an LSTM over the sequence of $\mathbf{z}_j$ vectors. The decoder additionally predicts a type of operation.[4] The distribution in Eq. (3), strung together with the other conditionals, yields a joint distribution over the entire character sequence:

$$p(\mathbf{c} \mid \ell_i, m_i) = \prod_{j=1}^{|w_i|} p(c_j \mid \mathbf{c}_{<j}, \ell_i, m_i) \quad (4)$$

For instance, to map the lemma *talk* to its past form *talked*, we feed in `POS=V;Tense=PAST <w> t a l k </w>` and train the network to output `<w> t a l k e d </w>`, where we have augmented the orthographic character alphabet Σ with the feature–attribute pairs that constitute the morphological tag m_i.

2.4 Parameter Estimation and Decoding

We optimize the log-likelihood of the training data with respect to all model parameters. As Eq. (1) is differentiable, this is achieved with standard gradient-based methods. For decoding we use a greedy strategy where we first decode the CRF, that is, we solve the problem $\mathbf{m}^\star = \text{argmax}_{\mathbf{m}} \log p(\mathbf{m} \mid \boldsymbol{\ell})$, using the Viterbi (1967) algorithm. We then use this decoded $\mathbf{m}^\star$ to generate forms from the inflector. Note that finding the one-best string under our neural inflector is intractable, and for this reason we use greedy search.

3 Experiments

Dataset. We use the Universal Dependencies v1.2 dataset (Nivre et al., 2016) for our experiments. We include all the languages with information on their lemmata and fine-grained grammar tag annotation that also have `fasttext` embeddings (Bojanowski et al., 2017), which are used for word embedding initialization.[5]

Evaluation. We evaluate our model's ability to predict: (i) the correct morphological tags from the lemma context, and (ii) the correct inflected forms. As our evaluation metric, we report 1-best accuracy for both tags and word form prediction.

Configuration. We use a word and character embedding dimensionality of 300 and 100, respectively. The hidden state dimensionality is set to 200. All models are trained with Adam (Kingma and Ba, 2014), with a learning rate of 0.001 for 20 epochs.

Baselines. We use two baseline systems: (1) the CoNLL–SIGMORPHON 2018 subtask 2 neural encoder–decoder with an attention mechanism ("SM"; Cotterell et al. (2018)), where the encoder represents a target form context as a concatenation of its lemma, its left and right word forms, their

---

[4] The model can be viewed as a transition system trained over aligned character-level strings to learn sequences of operations (`write` or `step`).

[5] We also choose mainly non-Wikipedia datasets to reduce any possible intersection with the data used for the *FastText* model training

lemmata and tag representations, and then the decoder generates the target inflected form character-by-character; and (2) a monolingual version of the best performing system of the shared task ("CPH"; Kementchedjhieva et al. (2018)) that augments the above encoder–decoder with full (sentence-level) left and right contexts (comprising of forms, their lemmata and morphological tags) as well as predicts morphological tags for a target form as an auxiliary task.[6] In both cases, the hyperparameters are set as described in Cotterell et al. (2018). We additionally evaluate the SIGMORPHON baseline system on prediction of the target form without any information on morphological tags ("DIRECT").

4 Results and Discussion

Tab. 2 presents the accuracy of our best model across all languages.[7] Below we highlight two main lessons from our error analysis that apply to a wider range of generation tasks, e.g., machine translation and dialog systems.

Directly Predicting Morphology. Tab. 2 indicates that all systems that make use of morphological tags outperform the DIRECT baseline on most languages. The comparison of our hybrid model with latent morphological tags to the direct form generation baseline in SM suggests that we should be including linguistically-motivated latent variables into models of natural language generation. We observe in Tab. 2 that predicting the tag together with the form (joint) often improves performance. The most interesting comparison here is with the multi-task CPH method, which includes morphology into the model without joint modeling; our model achieves higher results on 7/10 languages.

Morphological Complexity Matters. We observed that for languages with rich case systems, e.g., the Slavic languages (which exhibit a lot of fusion), the agglutinative Finno-Ugric languages, and Basque, performance is much worse. These languages present a broader decision space and often require inferring which morphological categories need to be in agreement in order to make an accurate prediction. This suggests that generation in languages with more morphological complexity will be a harder problem for neural models to solve. Indeed, this problem is under-explored, as the field of NLP tends to fixate on generating English text, e.g., in machine translation or dialogue system research.

Error Analysis. We focused error analysis on prediction of agreement categories. Our analysis of adjective–noun agreement category prediction suggests that our model is able to infer adjective number, gender, and case from its head noun. Verb gender, which appears only in the past tense of many Slavic languages, seems to be harder to predict. Given that the linear distance between the subject and the verb may be longer, we suspect the network struggles to learn longer-distance dependencies, consistent with the findings of Linzen et al. (2016). Overall, automatic inference of agreement categories is an interesting problem that deserves more attention, and we leave it for future work.

We also observe that most uncertainty comes from morphological categories such as noun number, noun definiteness (which is expressed morphologically in Bulgarian), and verb tense, all of which are inherent (Booij, 1996)[8] and typically cannot be predicted from sentential context if they do not participate in agreement.[9] On the other hand, aspect, although being closely related to tense, is well-predicted since it is mainly expressed as a separate lexeme. But, in general, it is still problematic to make a prediction in languages where aspect is morphologically marked or highly mixed with

---

[6] It has been shown to improve the model's performance.

[7] The accuracy numbers are on average higher than the ones achieved in terms of the CoNLL–SIGMORPHON 2018 subtask 2 since we did not filter out tokens that are typically not inflected (such as articles or prepositions).

[8] Such categories exist in most languages that exhibit some degree of morphological complexity.

[9] Unless there is no strong signal within a sentence such as *yesterday*, *tomorrow*, or *ago* as in the case of tense.

tense as in Basque.

We additionally compared 1-best and 10-best predictions for tags. Most mispredictions existing in 1-best lists are due to inherent categories mentioned above (that allow multiple plausible options that can fit the sentential context). Indeed, the problem is usually solved by allowing system to output 10-best lists. There, precision@10 is on average 8 points higher than precision@1.

Finally, our analysis of case category prediction on nouns shows that more common cases such as the nominative, accusative, and genitive are predicted better, especially in languages with fixed word order. On the other hand, cases that appear less frequently and on shifting positions (such as the instrumental), as well as those not associated with specific prepositions, are less well predicted. In addition, we evaluated the model's performance when *all* forms are replaced by their corresponding lemmata (as in *two cat be sit*). For freer word order languages such as Polish or Latin, we observe a substantial drop in performance because most information on inter-word relations and their roles (expressed by means of case system) is lost.

5 Related Work

The primary evaluation for most contemporary language and translation modeling research is perplexity, BLEU (Papineni et al., 2002), or METEOR (Banerjee and Lavie, 2005). Undoubtedly, such metrics are necessary for extrinsic evaluation and comparison. However, relatively few studies have focused on intrinsic evaluation of the model's mastery of grammaticality. Recently, Linzen et al. (2016) investigated the ability of an LSTM language model to capture sentential structure, by evaluating subject–verb agreement with respect to number, and showed that under strong supervision, the LSTM is able to approximate dependencies.

Taking it from the other perspective, a truer measure of grammatical competence would be a task of mapping a meaning representation to text, where the meaning representation specifies all necessary semantic content—content lemmata, dependency relations, and "inherent" closed-class morphemes (semantic features such as noun number, noun definiteness, and verb tense)—and the system is to realize this content according to the morphosyntactic conventions of a language, which means choosing word order, agreement morphemes, function words, and the surface forms of all words. Such tasks have been investigated to some extent—generating text from tectogrammatical trees (Hajic et al., 2002; Ptáček and Žabokrtský, 2006) or from an AMR graph (Song et al., 2017). Belz et al. (2011) organized a related surface realization shared task on mapping unordered and uninflected dependency trees to properly ordered inflected sentences. The generated sentences were afterwards assessed by human annotators, making the task less scalable and more time consuming. Although our task is not perfectly matched to grammaticality modeling, the upside is that it is a "lightweight" task that works directly on text. No meaning representation is required. Thus, training and test data in any language can be prepared simply by lemmatizing a naturally occurring corpus.

Finally, as a morphological inflection task, the form generation task is closely related to previous SIGMORPHON shared tasks (Cotterell et al., 2016, 2017). There, most neural models achieve high accuracy on many languages at type-level prediction of the form from its lemma and slot. The current task is more challenging in that the model has to perform token-level form generation and inherently infer the slot from the contextual environment. Our findings are in line with those from the CoNLL-SIGMORPHON 2018 shared task (Cotterell et al., 2018) and provide extra evidence of the utility of morphosyntactic features.

6 Conclusion

This work proposed a method for contextual inflection using a hybrid architecture. Evaluation over several diverse languages showed consistent improvements over state of the art. Our analysis demonstrated that the contextual inflection can be a highly challenging task, and the inclusion of morphological features prediction is an important element in such a system. We also highlighted two types of morphological categories, contextual and inherent, in which the former relies on agreement and the latter comes from a speaker's intention.

A Robust Abstractive System for Cross-Lingual Summarization

Abstract

We present a robust neural abstractive summarization system for cross-lingual summarization. We construct summarization corpora for documents automatically translated from three low-resource languages, Somali, Swahili, and Tagalog, using machine translation and the New York Times summarization corpus. We train three language-specific abstractive summarizers and evaluate on documents originally written in the source languages, as well as on a fourth, unseen language: Arabic. Our systems achieve significantly higher fluency than a standard copy-attention summarizer on automatically translated input documents, as well as comparable content selection.

1 Introduction

Cross-lingual summarization is a little-explored task combining the difficulties of automatic summarization with those of machine translation. The goal is to summarize in one language a document available only in another language. Wan et al. (2010) describe two approaches: summarize then translate, and translate then summarize. They argue that summarize-then-translate is preferable to avoid both the computational expense of translating more sentences and sentence extraction errors caused by incorrect translations.

However, summarize-then-translate can only be used when the source language is high-resource (Wan et al. used English as the source, for example); if the source language is one of the thousands of low-resource languages in the world, there are no summarization corpora available. Language-independent techniques, such as TextRank (Mihalcea), might be used, but there may be serious difficulties in their application, such as morphologically rich languages that render token-based similarity measures useless. In such a case, translate-then-summarize is the only possible approach.

We address this scenario through the development of a neural abstractive summarization system that fluently summarizes potentially disfluent, automatically-translated documents by generating short, simple phrases to replace awkward input phrases resulting from difficult to translate source documents. Our novel combination of existing building block systems results in a summarization solution that can be easily applied to new low-resource languages. We use machine translation on the New York Times annotated corpus of document/summary pairs to create summarization corpora for documents automatically translated from three low-resource languages, Somali, Swahili, and Tagalog. We use these corpora to train cross-lingual summarizers for these source languages, with English as the target. We also evaluate our systems on a fourth source language, Arabic. Our experiments show that our abstractive summarizers produce more fluent English summaries from automatically-translated documents, and that this improvement generalizes across source languages.

Our main contributions are as follows:

- We create summarization corpora for automatically translated Somali, Swahili, and Tagalog documents: noisy English input documents paired with clean English reference summaries.
- We present a method for producing cross-lingual summarization systems for low resource languages where no summarization corpora currently exist, providing a potential summarization solution for thousands of such languages.
- Our novel approach of training on noisy input with clean references outperforms a standard copy-attention abstractive summarizer on real-world Somali, Swahili, and Tagalog documents.
- Our evaluation on Arabic documents demonstrates that our robust abstractive summarizers

generalize to unseen languages.

2 Related Work

Cross-Lingual Summarization. Orăsan and Chiorean (2008) extractively summarized Romanian news articles and automatically translated the summaries into English. Their experiments showed that the poor quality of the translations turned reasonable Romanian summaries into barely legible English ones.

The most extensively investigated source-target language pair is English-to-Chinese. Wan et al. (2010) used a predicted translation quality score as a feature in extracting sentences for their summaries. Wan (2011) translated the English sentences into Chinese and represented sentences in the extraction stage by both the original English and the Chinese translation. Yao et al. (2015) scored aligned phrases from the original English documents and the Chinese translations to perform sentence extraction and compression based on both salience and translation quality. Zhang et al. (2016) parsed the original English documents into predicate-argument structures that were aligned with their Chinese translations and generated the summary from these structures. Finally, Wan et al. (2018) experimented with extracting and ranking multiple candidate summaries.

Abstractive Summarization. Rush et al. (2015) presented the first neural abstractive summarization model, a convolutional neural network encoder and feed-forward network decoder with attention, which learned to generate news headlines from the lead sentences of their articles; Chopra et al. (2016) extended their work using a recurrent network for the decoder. Nallapati et al. (2016) improved on the RNN encoder-decoder with attention model by adding linguistically-motivated part of speech and named entity type embeddings, as well as a pointer-network (Vinyals et al., 2015) to allow copying of rare or out-of-vocabulary words from the input document. In this work, we use See et al.'s (2017) definition of the pointer-generator network, which adds a coverage vector and coverage penalty to prevent repetition in generated words.

The New York Times annotated corpus (Sandhaus, 2008) was first used for neural abstractive summarization by Paulus et al. (2018), who used attention over the decoder's previous predictions to both prevent repetition and to allow for coherent longer summaries. Celikyilmaz et al. (2018) also used the New York Times corpus, training multiple, collaborating encoders to encode long documents one paragraph at a time.

3 Data

We use the New York Times (hereafter *NYT*) summarization corpus (Sandhaus, 2008), consisting of 650k articles and their human-written abstractive summaries. We follow the train/test/validation split and preprocessing steps used by Paulus et al. (2018), with one exception: we do not anonymize named entities. We first translate 112k articles from the NYT corpus into each of our three low-resource languages, Somali, Swahili, and Tagalog, using neural machine translation. Of the 112k articles, 100k are taken from the training set, 6k from validation, and 6k from test. We then translate the articles back into noisy English, again using neural machine translation. Figure 1 shows an example noisy English article.

We pair each noisy English article with the clean English reference summary corresponding to the clean English article that generated it. Thus our abstractive summarization model learns to take a "bad" English input document with translation errors and disfluencies and produce a "good" English summary. For simplicity, we refer to the corpus created by translating into Somali and back as the *Somali NYT corpus*, and similarly with Swahili and Tagalog, but all three corpora are in (noisy) English, not Somali, Swahili, or Tagalog.

4 Models

4.1 Machine Translation

We use neural machine translation systems built on the Marian framework (Junczys-Dowmunt

	BLEU

et al., 2018) to translate the NYT corpus into Somali, Swahili, and Tagalog, and back to English. The systems were developed at the University of Edinburgh and were trained on a mix of clean, human-curated parallel data (about 23k sentences for Somali and Swahili and 51k for Tagalog); noisy, web-crawled parallel data (Somali only, about 354k sentences); and synthetic, backtranslated parallel data created from monolingual sources including news articles, the Common Crawl, and Wikipedia (250-600k sentences). Table 1 shows the performance of the machine translation systems for each of the three languages on held-out test sets of 500 sentences taken from the clean, human-curated parallel data.

4.2 Abstractive Summarization

For our abstractive summarizers (hereafter *abstractors*), we implemented See et al.'s (2017) pointer-generator network in PyTorch (Paszke et al., 2017). We pre-train for 12 epochs on the unmodified NYT corpus to obtain a baseline system. Table 2 shows the performance of this baseline on the unmodified NYT test set; our baseline underperforms the more complex systems of Paulus et al. (2018) and Celikyilmaz et al. (2018), but we are more interested in the improvements our fluency-focused approach makes over this baseline than in the baseline's performance compared to state-of-the-art systems. We use each of the three noisy English corpora to train the baseline system for another 8 epochs, producing three language-specific abstractors. We also train a fourth, mixed-language abstractor using 100k articles randomly selected from the Somali, Swahili, and Tagalog training sets, evenly split among the three.

5 Evaluation

5.1 Noisy NYT Evaluation.

Table 3 shows the performance of our abstractors on the Somali, Swahili, and Tagalog NYT test sets. Differences among the language-specific systems are not statistically significant, and the more general mixed model achieved the best scores[1]. However, we found that abstractors trained solely on one language and tested on another significantly ($p < 0.05$) underperformed the mixed model, which was trained on all three languages, suggesting that training on some same-language data is still important.

We also trained a bigram language model on the entire set of NYT reference summaries and

---

[1] These results are shown in Appendix A, along with all combinations of the language-specific models on the three languages.

Table 5: Average human-rated content and fluency scores on Somali, Swahili, and Tagalog weblog entries.

calculated the average perplexity of our abstractors' output as a proxy for fluency (Table 4). We see that Somali is the most difficult overall, but all three language-specific systems and the mixed model produce more fluent English across source languages than does the base model.

5.2 Weblog Evaluation.

We perform a human evaluation on 20 Somali, 20 Swahili, and 20 Tagalog weblog entries that we automatically translate into English using the same neural machine translation systems we used to create our noisy NYT corpora. Unlike our NYT data, which we translated from English into the low-resource languages, these weblogs are real-world Somali, Swahili, and Tagalog documents – this evaluation demonstrates the performance of our system in a real use-case. Figure 2 shows a Swahili weblog entry and its summaries[2]. This example shows the advantage of our approach: unlike a machine translation system, which must translate every part of its input, our abstractor is able to delete most of the long, rambling, and disfluent blog entry, instead summing it up fluently with the generated phrase "comments on his plans" and the repurposed phrase "to vie for".

We use five human judges, all native English speakers and none of whom are the authors. The judges were shown a translated document and a summary and asked to rate the content and fluency of the summary on a scale of 1–3 (Table 5). Our human judges rated our abstractors higher in both fluency and content, and we see again that while the language-specific systems are more fluent on their own languages than are the language-specific systems for the other languages, the mixed model still performs the best. We also see that, while our improvement in content is more modest, our improvement in fluency – the goal of this work – is significant. The judges achieved substantial agreement (Fleiss's $\kappa = 0.72$).

5.3 DUC 2004 Arabic Evaluation.

Finally, we evaluate our system on a new language: Arabic. We use the DUC 2004 Task 3 test set, which consists of real-world Arabic news articles translated into English, each paired with four human-written summaries.

Table 6 shows the performance of our abstractors on the Arabic data, demonstrating their ability to generalize and improve the fluency of input documents automatically translated from a previously unseen language, yielding a significant improvement in ROUGE. Compared to the 28 DUC 2004 systems, our performance would have ranked 1st on summarizing the machine-translated documents; despite our use of these lower-quality, *au-*

tomatically-translated documents, we performed extremely well even in comparison with the DUC 2004 systems on high-quality, *human*-translated documents: we would have ranked 1st, 4th, and 5th on ROUGE-1, -2, and -L, respectively. Figure 3 compares the baseline system and our abstractors on the Arabic data[3].

6 Discussion

We find that the NYT-base model tends to copy heavily from the beginning of its input documents. Since it was trained entirely on clean English news articles, it is understandable that it tries to copy the *lead* sentence, but in both examples, it copies errors: the confusing run-on sentence "not special seats' kinondoni without drugs is possible" (shown in yellow in Figure 2) and the phrase "signed by" (shown in green in Figure 3), whose subject is missing. In contrast, our abstractors are able to correctly identify the important information in the input documents and produce fluent summaries presenting this information. In Figure 3, Abs-mix deletes the unnecessary "washington 10-23" and produces the verb "agree" in the plural form, agreeing with its plural subject. More dramatically, in Figure 2, Abs-mix identifies "kinondoni without drugs" as Mange Kimambi's campaign platform and succinctly summarizes this using both the purely generated phrase "comments on his plans" and the repurposed – but still fluent and correct – "to vie for."

The main limitation of our approach is that it assumes the existence of a machine translation system for the source language. Although our abstractors are able to handle errorful, disfluent translations, for extremely low-resource languages, there may be no translations of any kind available; in such a case, another approach, such as cross-lingual word embeddings, is necessary.

7 Conclusion

We have presented a robust abstractive summarization system for the task of cross-lingual summarization, taking advantage of an abstractive system's ability to delete difficult to translate phrases and generate new text to use instead. Our straightforward method allows us to produce summarization systems for low resource languages where no summarization corpora are currently available, providing a potential summarization solution for thousands of such languages. Our experiments demonstrate that, by using our novel approach of training on noisy English documents and clean English reference summaries, the model learns to produce fluent summaries from disfluent inputs. Further, we have shown that, while training a system for a specific source language gives strong performance, the abstractive fluency of these systems generalize to other source languages.

A Appendix: Language-Specific Abstractor Performance on Noisy NY

Table 7 expands Table 3, showing the performance of each of our four abstractors on the Somali, Swahili, and Tagalog NYT test sets. As discussed in Section 5.1, the differences among the three language-specific abstractors are not statistically significant on any of the three languages. However, the differences between the mixed model and the two language-specific models *not* trained on a given test language are significant ($p < 0.05$). That is, the difference between Abs-mix and Abs-sw and the difference between Abs-mix and Abs-tl are significant on the Somali test set, the difference between Abs-mix and Abs-so and the difference between Abs-mix and Abs-tl are significant on the Swahili test set, and the difference between Abs-mix and Abs-so and the difference between Abs-mix and Abs-sw are significant on the Tagalog test set.

Abstract

The explicit use of syntactic information has been proved useful for neural machine translation (NMT). However, previous methods resort to either tree-structured neural networks or long linearized sequences, both of which are inefficient. Neural syntactic distance (NSD) enables us to represent a constituent tree using a sequence whose length is identical to the number of words in the sentence. NSD has been used for constituent parsing, but not in machine translation. We propose five strategies to improve NMT with NSD. Experiments show that it is not trivial to improve NMT with NSD; however, the proposed strategies are shown to improve translation performance of the baseline model (+2.1 (En–Ja), +1.3 (Ja–En), +1.2 (En–Ch), and +1.0 (Ch–En) BLEU).

1 Introduction

In recent years, neural machine translation (NMT) has been developing rapidly and has become the de facto approach for machine translation. To improve the performance of the conventional NMT models (Sutskever et al., 2014; Bahdanau et al., 2014), one effective approach is to incorporate syntactic information into the encoder and/or decoder of the baseline model.

Based on how the syntactic information is represented, there are two categories of syntactic NMT methods: (1) those that use tree-structured neural networks (NNs) to represent syntax structures (Eriguchi et al., 2016; Hashimoto and Tsuruoka, 2017), and (2) those that use linear-structured NNs to represent linearized syntax structures (Li et al., 2017; Ma et al., 2017, 2018). For the first category, there is a direct corresponding relationship between the syntactic structure and the NN structure, but the complexity of NN structures usually makes training inefficient. In contrast, for the second category, syntactic structures are linearized and represented using linear-structured recurrent neural networks (RNNs), but the linearized sequence can generally be quite long and therefore training efficiency is still a problem. Although using a shorter sequence may improve the efficiency, some syntactic information is lost.

We propose a method of using syntactic information in NMT that overcomes the disadvantages of both methods. The basis of our method is the neural syntactic distance (NSD), a recently proposed concept used for constituent parsing (Shen et al., 2018; Gómez-Rodríguez and Vilares, 2018). NSD makes it possible to represent a constituent tree as a sequence whose length is identical to the number of words in the sentence (almost) without losing syntactic information. However, there are no previous studies that use NSD in NMT. Moreover, as demonstrated by our experiments, using NSD in NMT is far from straightforward, so we propose five strategies and verify the effects empirically. The strategies are summarized below.

- Extend NSD to dependency trees, which is inspired by the dependency language model (Shen et al., 2010).
- Use NSDs as input sequences[1], where an NSD is regarded as a linguistic input feature (Sennrich and Haddow, 2016).
- Use NSDs as output sequences, where the NMT and prediction of the NSD are simultaneously trained through multi-task learning (Firat et al., 2016).
- Use NSD as positional encoding (PE), which is a syntactic extension of the PE of the Transformer (Vaswani et al., 2017).
- Add a loss function for NSD to achieve

---

[1] Throughout this paper, ”input” means the input of an encoder or a decoder rather than the input of the NMT model (i.e., only source sentences), and ”output” is similar.

Proceedings of NAACL-HLT 2019, pages 2032–2037
Minneapolis, Minnesota, June 2 - June 7, 2019.

distance-aware training (Shen et al., 2018).

2 Neural Syntactic Distance (NSD)

The NSD was firstly proposed by Shen et al. (2018). This is the first method of linearizing a constituent tree with a sequence of length n, without loss of information, where n is the number of words in the sentence.

Formally, given the sentence $\mathbf{w} = (w_1, \ldots, w_n)$, for any pairs of contiguous words (w_i, w_{i+1}), we can define an NSD $d(w_i)$,[2] where $i \in [1, n-1]$. In Shen et al. (2018), the NSD $d_S(w_i)$ is defined as the height of the lowest common ancestor (LCA) of the words.[3] Subsequently, in Gómez-Rodríguez and Vilares (2018), the NSD $d_G(w_i)$ was defined as the number of the common ancestors of the words. To make the definition complete, we define $d(w_n)$ as follows:[4]

$$d_S(w_n) = H, \quad d_G(w_n) = 0, \tag{1}$$

where H is the height of the constituent tree. It is easy to prove that

$$d_S(w_i) + d_G(w_i) = H, \quad i \in [1, n]. \tag{2}$$

We call d_S and d_G the *absolute* NSD.

Furthermore, Gómez-Rodríguez and Vilares (2018) define the *relative* NSD as follows:

$$d_R(w_i) = \begin{cases} d_G(w_1), & i = 1, \\ d_G(w_i) - d_G(w_{i-1}), & i \in [2, n]. \end{cases} \tag{3}$$

Figure 1 illustrates these NSDs. It is easy to see the one-to-one correspondence relationship between the constituent tree and the (absolute or relative) NSDs.

The effectiveness of all different NSDs has been proven on constituent parsing. However, there has been no attempt to use NSD in machine translation.

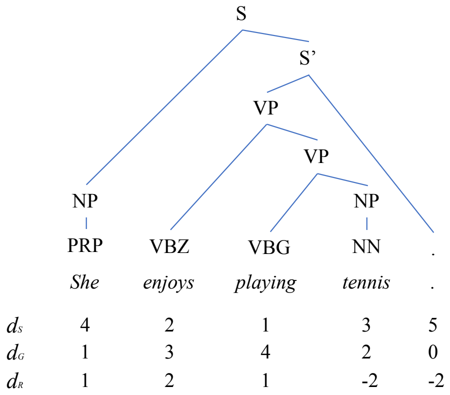

Figure 1: Example of different NSDs. This example is from Shen et al. (2018).

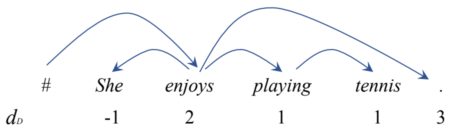

Figure 2: Example of dependency NSDs. "#" is the root. Dependency labels are omitted.

3 Strategies to improve NMT with NSD

3.1 Dependency NSD

There are many previous studies on using dependency trees to improve NMT (Nguyen Le et al., 2017; Wu et al., 2017). Therefore, we extend NSD to dependency trees. Formally, the dependency NSD between two nodes is defined as follows:

$$d_D(w_i) = i - h(i), \tag{4}$$

where $h(i)$ is the index of the head of w_i, and we let the index of root be 0. Note that $d_D(w_i)$ can be either positive or negative, representing the directional information. Figure 2 gives an example.

3.2 NSDs as Input Sequences

It is easy to see that for $\mathbf{w} = (w_1, \ldots, w_n)$, the lengths of d_S, d_G, d_R and d_D are all n. Denoting the NSD sequence as $\mathbf{d} = (d_1, \ldots, d_n)$, we can see that $d_i \in \mathbb{Z}, i \in [1, n]$, so we can obtain a sequence of embedding vectors $\mathbf{e}^d = (e_1^d, \ldots, e_n^d)$ as follows:

$$e_i^d = E_d[d_i^d + (\max(\mathbf{d}) - \min(\mathbf{d}) + 1)]. \tag{5}$$

We call E_d the distance embedding matrix and call $\mathbf{e}^d$ the syntactic embedding sequence. Note that $\mathbf{d}$ can be the NSD on either the source side or the target side, so there are two possible E_d, which are

---

[2] Note that NSD is defined between two contiguous words. For convenience of notation, we use $d(w_i)$ rather than $d(w_i, w_{i+1})$ to denote an NSD.

[3] In Shen et al. (2018), NSD is defined as a real number that is a function of LCA. However, in practice, NSD is simply identical to the depth of the LCA.

[4] $d_S(w_n)$ and $d_G(w_n)$ are undefined in both of the original papers. We give the definitions here to enable the use of NSD in NMT later.

denoted as E_d^s and E_d^t, respectively. The embeddings are calculated as follows:

$$x_i^s = f_{emb}(E_w^s[w_i^s], e_i^{ds}), \tag{6}$$
$$x_i^t = f_{emb}(E_w^t[w_i^t], e_i^{dt}), \tag{7}$$

where e_i^{ds} and e_i^{dt} are defined in Eq. 5 on the source side and target side, respectively, and E_w^s and E_w^t are the word embedding matrices on both sides, respectively. Inspired by Sennrich and Haddow (2016), function f_{emb} is used to combine two vectors. This function has many different options, such as:

$$f_{emb}^{\|}(x, e) = x \| e, \tag{8}$$
$$f_{emb}^{+}(x, e) = x + e, \tag{9}$$
$$f_{emb}^{Wb}(x, e) = W_f \cdot (x \| e) + b_f, \tag{10}$$

where $x, e, b_f \in \mathbb{R}^d$ and $W_f \in \mathbb{R}^{d \times 2d}$. The operator "$\|$" is the concatenation of two vectors.

When NSD is used as the input sequence on the target side, there is one problem: $\mathbf{e}^{dt}$ is unknown during testing. For this case, we use NSDs for both the input and output sequences, let the decoder predict NSD on-the-fly using the strategy introduced in Section 3.3, and use the predicted NSD to calculate $\mathbf{e}^{dt}$.

3.3 NSDs as Output Sequences

An NSD can be used to form the output sequence to improve NMT using the idea of multi-task learning. Specifically, we train the model to predict the NSD sequence. When NSD is used as the output sequence of the *encoder*, we minimize the distance (e.g., cross entropy $\mathcal{L}_{dist}^{ent}$, see Section 3.5 for details) between the predicted and the golden NSD sequences. When NSD is used as the output sequence of the *decoder*, besides minimizing the distance, we use the predicted NSD as the input of the next time step.

Denote the hidden vector as $\mathbf{h} = (h_1, \ldots, h_n)$. For the encoder, $h_i = h_i^s$ and $n = n_s$, while for the decoder, $h_i = h_i^t$ and n is the current time step of decoding. Then, we can obtain a sequence of predicted syntactic distance $\hat{\mathbf{d}} = (\hat{d}_1, \ldots, \hat{d}_n)$, which is calculated as follows:

$$p(\hat{d}_i \mid h_i) = \mathrm{softmax}(W_d \cdot h_i + b_d), \tag{11}$$

where W_d and b_d are parameters to be learned. By minimizing the distance between $\hat{d}_i$ and d_i, NSD can be used to enhance NMT.

3.4 NSD as Positional Encoding (PE)

PE is used by the Transformer (Vaswani et al., 2017) to encode the positions of words. Formally, it is defined as follows:

$$x_i' = x_i + PE(i), \tag{12}$$
$$PE(i)_{2k} = \sin(i/10000^{2k/d}), \tag{13}$$
$$PE(i)_{2k+1} = \cos(i/10000^{2k/d}), \tag{14}$$

where x_i can be either x_i^s or x_i^t, and d is the dimension of the embedding vector. Similarly, we define syntactic PE as follows:

$$PE(i)_{2k} = \sin\left(\frac{i + \max(\mathbf{d}) - \min(\mathbf{d})}{{\lambda_{SPE}}^{2k/d}} \cdot 2\pi\right), \tag{15}$$

$$PE(i)_{2k+1} = \cos\left(\frac{i + \max(\mathbf{d}) - \min(\mathbf{d})}{{\lambda_{SPE}}^{2k/d}} \cdot 2\pi\right), \tag{16}$$

where λ_{SPE} is a hyperparameter to be tuned. In this way, the periods of these two functions vary from 1 to λ_{SPE}. We define syntactic PE in this way because (1) according to a quantitative analysis of the experimental datasets, we found that the ranges of possible values are quite different between NSD and word positions, so we tuned λ_{SPE} instead of fixed it to 10000 as in Eqs. 13 and 14, and (2) d_i may be negative, so we adjust it to be positive.

3.5 Distance-aware Training

Instead of using conventional cross-entropy loss function during training, we use the following loss function to make the NMT model learn NSD better:

$$\mathcal{L} = \mathcal{L}_{NMT} + \mathcal{L}_{dist} + \mathcal{L}_{dist}^{ent}. \tag{17}$$

The first item is the cross-entropy loss of the NMT model, which is

$$\mathcal{L}_{NMT} = -\sum_{\langle \mathbf{w}^s, \mathbf{w}^t \rangle \in \mathcal{D}} \log p(\mathbf{w}^t \mid \mathbf{w}^s), \tag{18}$$

where $\mathcal{D}$ is the training dataset. The second item is the distance-aware loss, which is inspired by Shen et al. (2018) and is as follows:

$$\mathcal{L}_{dist} = \sum_{\langle \mathbf{w}^s, \mathbf{w}^t \rangle \in \mathcal{D}} (\mathcal{L}_{dist}^s(\mathbf{w}^s) + \mathcal{L}_{dist}^t(\mathbf{w}^t)),$$

$$\mathcal{L}_{dist}^s(\mathbf{w}^s) = \sum_{i=1}^{n_s} (d_i - \hat{d}_i)^2 + \sum_{i,j>i} [1 - \mathrm{sign}(d_i - d_j)(\hat{d}_i - \hat{d}_j)]^+, \tag{19}$$

and $\mathcal{L}^{t}_{dist}$ can be defined similarly. The third item is the cross-entropy loss for NSD, which is as follows:

$$\mathcal{L}^{ent}_{dist} = \sum_{\langle \mathbf{w}^s, \mathbf{w}^t \rangle \in \mathcal{D}} (\mathcal{L}^{ent(s)}_{dist}(\mathbf{w}^s) + \mathcal{L}^{ent(t)}_{dist}(\mathbf{w}^t)),$$
$$\mathcal{L}^{ent(s)}_{dist}(\mathbf{w}^s) = -\sum_{d_i \in \mathbf{d}^s} p(d_i \mid h_i) \log p(\hat{d}_i \mid h_i), \tag{20}$$

and $\mathcal{L}^{ent(t)}_{dist}$ can be defined similarly.

4 Experiments

4.1 Configuration

We experimented on two corpora: (1) ASPEC (Nakazawa et al., 2016), using the top 100K sentence pairs for training En–Ja models and top 1M sentence pairs for training Ja–En models, and (2) LDC,[5] which contains about 1.2M sentence pairs, for training En–Ch and Ch–En models. To tackling the problem of memory consumption, sentences longer than 150 were filtered out, so that models can be trained successfully. Chinese sentences were segmented by the Stanford segmentation tool.[6] For Japanese sentences, we followed the preprocessing steps recommended in WAT 2017.[7]

The test set is a concatenation of NIST MT 2003, 2004, and 2005. Constituent trees are generated by the parser of Kitaev and Klein (2018)[8], and dependency trees are generated by the parser of Dyer et al. (2015)[9]. Note that although we only used syntactic information of English in our experiments, our method is also applicable to other languages.

We implemented our method on `OpenNMT`[10] (Klein et al., 2017), and used the Transformer as our baseline. As far as we know, there are no previous studies on using syntactic informations in the Transformer.

The vocabulary sizes for all languages are $50,000$. Both the encoder and decoder have 6 layers. The dimensions of hidden vectors and word embeddings are 512. The multi-head attention has 8 heads, and the dropout probability is 0.1 (Srivastava et al., 2014). The number of training epochs was fixed to 50, and we used the model which performs the best on the development set for testing.

As for optimization, we used the Adam optimizer (Kingma and Ba, 2014), with $\beta_1 = 0.9, \beta_2 = 0.998$, and $\epsilon = 10^{-9}$. Warmup and decay strategy for learning rate of Vaswani et al. (2017) are also used, with $8,000$ warmup steps. We also used the label smoothing strategy (Szegedy et al., 2016) with $\epsilon_{ls} = 0.1$.

4.2 Experimental Results

Table 1 compares the effects of the strategies. We evaluate the proposed strategies using character-level BLEU (Papineni et al., 2002) for Chinese and Japanese, and case-insensitive BLEU for English.

Comparison of different NSDs. The first five rows of Table 1 compare the results of using different NSDs. When NSD was used at the source side (En–Ja/En–Ch), all kinds of NSDs improved translation performance. This indicates that NSD can be regarded as a useful linguistic feature to improve NMT. In contrast, when NSD was used at the target side (Ja–En/Ch–En), d_S and d_G hurt the performance. This is because the values of d_S and d_G are volatile. A tiny change of syntactic structure often causes a big change of d_S and d_G. Since the model has to predict the NSD during decoding, once there is one error, the subsequent predictions will be heavily influenced. The use of d_R and d_D remedies this problem. Furthermore, the effects of d_S and d_G are similar, because they are equivalent in nature (refer to Eq. 2).

NSD as PE. Rows 5 to 8 of Table 1 evaluate the use of dependency NSD (d_D) as syntactic PE. Note that for all the experiments, we used not only the syntactic PE but the conventional PE. Experiment results show that this strategy is indeed useful. When the dominators of Eqs. 15 and 16, λ_{SPE}, were set to 10^4, there was no improvement. When they were set to 40, the improvement was remarkable. This indicates that our design of syntactic PE is reasonable.

NSD as input/output and source/target sequences. Rows 8 to 12 of Table 1 are the results of using dependency NSD (i.e., d_D) as the input and/or output sequences on both sides. First, for the choice of f_{emb}, we can see that $f^{||}_{emb}$ and f^{+}_{emb} are similar, while f^{Wb}_{emb} yields better performance. This is because the model has to learn W_f and

Table 1: Comparison of strategies. I/O: use NSDs as the input or output sequences. Functions $f_{emb}^{\Vert}$, f_{emb}^{+}, and f_{emb}^{Wb} are defined in Eqs. 8 to 10, respectively. SPE: use NSD as syntactic PE. Numbers are the values of λ_{SPE} in Eqs. 15 and 16. Loss: items used in the final loss function. Note that when NSD is used as the input sequence of the source language, $\mathcal{L}_{dist} + \mathcal{L}_{dist}^{ent} \equiv 0$, because the parsing tree is fixed.

b_f, which increases the model capacity. Second, performance improved for using NSDs both as input and output sequences, and combining both obtained further improvement. Third, NSDs improved the performance both on the source and the target sides. All these results indicate the robustness of NSDs.

Effects of distance-aware training. The last three rows compare the different effects of the items in the loss function. When only $\mathcal{L}_{NMT}$ are used, the performance is extremely poor. This is within expectations, because with only $\mathcal{L}_{NMT}$, weights related to NSDs are kept to the initial values and were not updated, and hence detrimental to learning. Adding $\mathcal{L}_{dist}^{ent}$ improves the results significantly, but the improvement is lower than that of $\mathcal{L}_{dist}$. This is because training with $\mathcal{L}_{dist}^{ent}$ treats different values of NSDs equally, while $\mathcal{L}_{dist}$ penalizes larger differences between the predicted NSD and the golden NSD more severely.

5 Conclusion

We proposed five strategies to improve NMT with NSD. We found relative NSDs and dependency NSDs are able to improve the performance consistently, while absolute NSDs hurt the performance for some cases. The improvement obtained by using NSDs is general in that NSDs can be used at both the source side and target side, both as input sequences and output sequences. Using NSDs as syntactic PE is also useful, and training with a distance-aware loss function is quite important.

Measuring Immediate Adaptation Performance for Neural Machine Translation

Abstract

Incremental domain adaptation, in which a system learns from the correct output for each input immediately after making its prediction for that input, can dramatically improve system performance for interactive machine translation. Users of interactive systems are sensitive to the speed of adaptation and how often a system repeats mistakes, despite being corrected. Adaptation is most commonly assessed using corpus-level BLEU- or TER-derived metrics that do not explicitly take adaptation speed into account. We find that these metrics often do not capture immediate adaptation effects, such as zero-shot and one-shot learning of domain-specific lexical items. To this end, we propose new metrics that directly evaluate immediate adaptation performance for machine translation. We use these metrics to choose the most suitable adaptation method from a range of different adaptation techniques for neural machine translation systems.

1 Introduction

Incremental domain adaptation, or *online* adaptation, has been shown to improve statistical machine translation and especially neural machine translation (NMT) systems significantly (Turchi et al., 2017; Karimova et al., 2018) (*inter-alia*). The natural use case is a computer-aided translation (CAT) scenario, where a user and a machine translation system collaborate to translate a document. Each user translation is immediately used as a new training example to adapt the machine translation system to the specific document.

Adaptation techniques for MT are typically evaluated by their corpus translation quality, but such evaluations may not capture prominent aspects of the user experience in a collaborative translation scenario. This paper focuses on directly measuring the speed of lexical acquisition for in-domain vocabulary. To that end, we propose three related metrics that are designed to reflect the responsiveness of adaptation.

An ideal system would immediately acquire in-domain lexical items upon observing their translations. Moreover, one might expect a neural system to generalize from one corrected translation to related terms. Once a user translates “bank” to German “Bank” (*institution*) instead of “Ufer” (*shore*) in a document, the system should also correctly translate “banks” to “Banken” instead of “Ufer” (the plural is identical to the singular in German) in future sentences. We measure both one-shot vocabulary acquisition for terms that have appeared once in a previous target sentence, as well as zero-shot vocabulary acquisition for terms that have not previously appeared.

Our experimental evaluation shows some surprising results. Methods that appear to have comparable performance using corpus quality metrics such as BLEU can differ substantially in zero-shot and one-shot vocabulary acquisition. In addition, we find that *fine-tuning* a neural model tends to improve one-shot vocabulary recall while *degrading* zero-shot vocabulary recall.

We evaluate several adaptation techniques on a range of online adaptation datasets. Fine tuning applied to all parameters in the NMT model maximizes one-shot acquisition, but shows a worrisome degradation in zero-shot recall. By contrast, fine tuning with group lasso regularization, a technique recently proposed to improve the space efficiency of adapted models (Wuebker et al., 2018), achieves an appealing balance of zero-shot and one-shot vocabulary acquisition as well as high corpus-level translation quality.

2 Measuring Immediate Adaptation

2.1 Motivation

For interactive, adaptive machine translation systems, *perceived* adaptation performance is a crucial property: An error in the machine translation output which needs to be corrected multiple times can cause frustration, and thus may compromise acceptance of the MT system by human users. A class of errors that are particularly salient are lexical choice errors for domain-specific lexical items. In the extreme, NMT systems using subword modeling (Sennrich et al., 2015) can generate "hallucinated" words—words that do not exist in the target language—which are especially irritating for users (Lee et al., 2018; Koehn and Knowles, 2017). Users of adaptive MT have a reasonable expectation that in-domain vocabulary will be translated correctly after the translation of a term or some related term has been corrected manually.

Arguably, more subtle errors, referring to syntax, word order or more general semantics are less of a focus for immediate adaptation, as these types of errors are also harder to pinpoint and thus to evaluate[1] (Bentivogli et al., 2016). Traditional metrics for evaluating machine translation outputs, e.g. BLEU and TER, in essence try to measure the similarity of a hypothesized translation to one or more reference translations, taking the full string into account.

Due to significant improvements in MT quality with neural models (Bentivogli et al., 2016) (*inter-alia*), more specialized metrics, evaluating certain desired behaviors of systems become more useful for specific tasks. For example, Wuebker et al. (2016) show, that NMT models, while being better in most respects, still fall short in the handling of content words in comparison with phrase-based MT. This observation is also supported by Bentivogli et al. (2016), who show smaller gains for NMT for translation of nouns, an important category of content words.

Another reason to isolate vocabulary acquisition as an evaluation criterion is that interactive translation often employs local adaptation via prefix-decoding (Knowles and Koehn, 2016; Wuebker et al., 2016), which can allow the system to recover syntactic structure or resolve local ambiguities when given a prefix, but may still suffer from poor handling of unknown or domain-specific vocabulary.

In this work, we therefore focus on translation performance with respect to content words, setting word order and other aspects aside.

2.2 Metrics

We propose three metrics: one to directly measure one-shot vocabulary acquisition, one to measure zero-shot vocabulary acquisition, and one to measure both. In all three, we measure the recall of target-language content words so that the metrics can be computed automatically by comparing translation hypotheses to reference translations without the use of models or word alignments[2].

We define content words as those words that are not included in a fixed stopword list, as used for example in query simplification for information retrieval. Such lists are typically compiled manually and are available for many languages.[3] For western languages, content words are mostly nouns, main verbs, adjectives or adverbs.

For the i-th pair of source sentence and reference translation, $i = 1, \dots, |\mathcal{G}|$, of an ordered test corpus $\mathcal{G}$, we define two sets $\mathcal{R}_{0,i}$ and $\mathcal{R}_{1,i}$ that are a subset of the whole set of unique[4] content words (i.e. types) of the reference translation for i. $\mathcal{R}_{0,i}$ includes a word if its first occurrence in the test set is in the i-th reference of $\mathcal{G}$, and $\mathcal{R}_{1,i}$ if its second occurrence in the test set is in the i-th reference of $\mathcal{G}$. The union $\mathcal{R}_{0,i} \cup \mathcal{R}_{1,i}$ includes content words occurring for either the first or second time.

To measure zero-shot adaptation in a given hypothesis $\mathcal{H}_i$, also represented as a set of its content words, we propose to evaluate the number of word types that were immediately translated correctly:

$$\text{R0} = \frac{|\mathcal{H}_i \cap \mathcal{R}_{0,i}|}{|\mathcal{R}_{0,i}|}.$$

To measure one-shot adaptation, where the system correctly produces a content word after ob-

---

[1] Some practitioners observed that these subtle errors become harder to spot due the improved fluency of NMT systems (Burchardt, 2017).

[2] In each of the data sets considered in this work, the average number of occurrences of content words ranges between 1.01 and 1.11 per sentence. We find this sufficiently close to 1 to evaluate in a bag-of-words fashion and not consider alignments.

[3] For German we used the list available here: `https://github.com/stopwords-iso`.

[4] All proposed metrics operate on the set-level, without clipping (Papineni et al., 2002) or alignment (Banerjee and Lavie, 2005; Kothur et al., 2018), as we have found this simplification effective.

	Reference	Hypothesis	R0	R1	R0+1
1.	The [dog] [bites] the [lady]	A [terrier] [bites] the [person]	1/3	0/0	1/3
2.	The [man] [bites] the [dog]	The [dog] [bites] the [man]	1/1	2/2	3/3
		Total	2/4	2/2	4/6

Figure 1: Example for calculating R0, R1, and R0+1 on a corpus of two sentences. Content words are written in brackets, the corpus-level score is given below the per-segment scores. In the example, the denominator for R1 is 2 due to the two repeated words *dog* and *bites* in the reference.

serving it exactly once, we propose:

$$\text{R1} = \frac{|\mathcal{H}_i \cap \mathcal{R}_{1,i}|}{|\mathcal{R}_{1,i}|}.$$

This principle can be extended to define metrics Rk, $k > 1$ to allow more "slack" in the adaptation, but we leave that investigation to future work.

Finally, we define a metric that measures both zero- and one-shot adaptation:

$$\text{R0+1} = \frac{|\mathcal{H}_i \cap [\mathcal{R}_{0,i} \cup \mathcal{R}_{1,i}]\,|}{|\mathcal{R}_{0,i} \cup \mathcal{R}_{1,i}|}.$$

All metrics can either be calculated for single sentences as described above, or for a full test corpus by summing over all sentences, e.g. for R0:

$$\frac{\sum_{i=1}^{|\mathcal{G}|} |\mathcal{H}_i \cap \mathcal{R}_{0,i}|}{\sum_{i=1}^{|\mathcal{G}|} |\mathcal{R}_{0,i}|}.$$

Figure 1 gives an example calculation of all three metrics across a two-sentence corpus.

3 Related Work

An important line of related work is concerned with estimating the *potential* adaptability of a system given a source text only, the so-called repetition rate (Cettolo et al., 2014). The metric is inspired by BLEU, and uses a sliding window over the source text to count singleton N-grams.

The modus operandi for our metrics is most similar to HTER (Snover et al., 2006), since we are also assuming a single, targeted reference translation[5] for evaluation.

The introduction of NMT brought more aspects of translation quality evaluation into focus, such as discourse-level evaluation (Bawden et al., 2017), or very fine-grained evaluation of specific aspects of the translations (Bentivogli et al., 2016), highlighting the differences between phrase-based and NMT systems.

Online adaptation for (neural) machine translation has been thoroughly explored using BLEU (Turchi et al., 2017), simulated keystroke and mouse action ratio (Barrachina et al., 2009) for effort estimation (Peris and Casacuberta, 2018), word prediction accuracy (Wuebker et al., 2016), and user studies (Denkowski et al., 2014; Karimova et al., 2018) (all *inter-alia*). In (Simianer et al., 2016) immediate adaptation for hierarchical phrase-based MT is specifically investigated, but they also evaluate their systems using human-targeted BLEU and TER.

Regularization for segment-wise continued training in NMT has been explored by Khayrallah et al. (2018) by means of knowledge distillation, and with the group lasso by Wuebker et al. (2018), as used in this paper.

Most relevant to our work, in the context of document-level adaptation, Kothur et al. (2018) calculate accuracy for novel words based on an automatic word alignment. However, they do not focus on zero- and one-shot matches, but instead aggregate counts over the full corpus.

4 Online Adaptation

NMT systems can be readily adapted by fine-tuning (also called continued training) with the same cross-entropy loss ($\mathcal{L}$) as used for training the parameters of the baseline system, which also serves as the starting point for adaptation (Luong and Manning, 2015). Following Turchi et al. (2017), we perform learning from each example i using (stochastic) gradient descent, using the current source x_i and reference translation y_i as a batch of size 1:

$$\theta_i \leftarrow \theta_{i-1} - \gamma \nabla \mathcal{L}(\theta_{i-1}, x_i, y_i). \qquad (1)$$

Evaluation is carried out using simulated post-editing (Hardt and Elming, 2010), first translating the source using the model with parameters θ_{i-1}, before performing the update described

---

[5] A reference translation which was produced from post-editing output of the to-be-evaluated MT system.

above with the now revealed reference translation. The machine translation system effectively only trains for a single iteration for any given data set.

The naïve approach, updating all parameters θ of the NMT model, while being effective, can be infeasible in certain settings[6], since tens of millions of parameters are updated depending on the respective model. While some areas of a typical NMT model can be stored in a sparse fashion without loss (source- and target embeddings), large parts of the model cannot. We denote this type of adaptation as *full*.

A light-weight alternative to adaptation of the full parameter set is to introduce a second bias term in the final output layer of the NMT model, which is trained in isolation, freezing the rest of the model (Michel and Neubig, 2018). This merely introduces a vector in the size of the output vocabulary. This method is referred to as *bias*.

Another alternative is freezing parts of the model (Thompson et al., 2018), for example determining a subset of parameters by performance on a held-out set (Wuebker et al., 2018). In our experiments we use two systems using this method, *fixed* and *top*, the former being a pre-determined fixed selection of parameters, and the latter being the topmost encoder and decoder layers in the *Transformer* NMT model (Vaswani et al., 2017).

Finally, a data-driven alternative to the fixed freezing method was introduced to NMT by Wuebker et al. (2018), implementing tensor-wise ℓ_1/ℓ_2 group lasso regularization, allowing the learning procedure to select a fixed number of parameters after each update. This setup is referred to as *lasso*.

5 Experiments

5.1 Neural Machine Translation Systems

We adapt an English→German NMT system based on the Transformer architecture trained with an in-house NMT framework on about 100M bilingual sentence pairs. The model has six layers in the encoder, three layers in the decoder, each with eight attention heads with dimensionality 256, distinct input and output embeddings, and vocabulary sizes of around 40,000. The vocabularies are generated with byte-pair encoding (Sennrich et al., 2015). For adaptation we use a learning rate γ of 10^{-2} (for the *bias* adaptation a learning rate of 1.0 is used), no dropout, and no label-smoothing. We use a tensor-wise ℓ_2 normalization to 1.0 for all gradients (gradient clipping). Updates for a sentence pair are repeated until the perplexity on that sentence pair is ≤ 2.0, for a maximum of three repetitions. The *fixed* adaptation scheme, which involves selecting a subset of parameters on held-out data following Wuebker et al. (2018), uses about two million parameters excluding all embedding matrices, in addition to potentially the full source embeddings, but in practice this is limited to about 1M parameters. The *top* scheme only adapts the top layers for both encoder and decoder. For the *lasso* adaptation, we allow 1M parameters excluding the embeddings, for which we allow 1M parameters in total selected from all embedding matrices. This scheme also always includes the previously described second bias term in the final output layer.

Method	BLEU	SBLEU	TER
baseline	40.3	49.3	45.2
bias	40.4	49.5	45.0
full	47.0	**55.9**	44.0
lasso	46.3	54.3	42.6
fixed	**47.1**	55.5	**41.0**
top	43.2	54.0	49.5

Table 1: Results on the *Autodesk* test set for traditional MT quality metrics. *SBLEU* refers to an average of sentence-wise BLEU scores as described by Nakov et al. (2012). The best result in each column is denoted with bold font.

Since the proposed metrics operate on words, the machine translation outputs are first converted to full-form words using *sentencepiece* (Kudo and Richardson, 2018), then tokenized and truecased with the tokenizer and truecaser distributed with the *Moses* toolkit (Koehn et al., 2007).

5.2 Results

Tables 1 and 2 show the performance of different adaptation techniques on the *Autodesk* dataset (Zhechev, 2012), a public post-editing software domain dataset for which incremental adaptation is known to provide large gains for corpus-level metrics. BLEU, sentence BLEU, and TER scores (Table 1) are similar for *full* adaptation, sparse adaptation with group *lasso*, and adaptation of a *fixed* subset of parameters. However (in Table 2),

---

[6] For example in setups where a large number of these adapted models need to be stored and transferred.

Method	R0	R1	R0+1
baseline	39.3	44.9	41.0
bias	39.3	45.3	41.1
full	35.8	**55.0**	41.6
lasso	**40.3**	48.6	**42.8**
fixed	35.8	52.3	40.8
top	35.6	50.3	40.0

Table 2: Results on the *Autodesk* test set for the proposed metrics R0, R1, and R0+1.

lasso substantially outperforms the other methods in zero-shot (R0), and combined zero- and one-shot recall of content words (R0+1).

Zero-shot recall is considerably degraded relative to the non-adapted baseline for both *full* and adaptation of a fixed subset of tensors (*fixed* and *top*). That is, terms never observed before during online training are translated correctly less often than they would be with an unadapted system, despite the data set's consistent domain. These approaches trade off long-term gains in BLEU and high one-shot recall for low zero-shot recall, which could be frustrating for users who may perceive the degradation in quality for terms appearing for the first time in a document. The *lasso* technique is the only one that shows an improvement in R0 over the baseline. However, *lasso* has considerably lower one-shot recall compared to the other adaptation methods, implying that it often must observe a translated term more than once to acquire it.

Appendix A shows similar experiments for several other datasets.

5.3 Analysis

For a better understanding of the results described in the previous section, we conduct an analysis varying the units of the proposed metrics, while focusing on *full* and *lasso* adaptation.

For the first variant, only truly novel words are taken into account, i.e. words in the test set that do not appear in the training data. Results for these experiments are depicted in Table 3. It is apparent that the findings of Table 2 are confirmed, and that relative differences are amplified. This can be explained by the reduced number of total occurrences considered, which is only 310 words in this data set. It is also important to note that all of these words are made up of known subwords[7], since our NMT system does not include a copying mechanism and is thus constrained to the target vocabulary.

Method	R0	R1	R0+1
baseline	27.1	40.7	29.9
full	26.1	**63.0**	33.8
lasso	**31.9**	53.1	**36.3**

Table 3: Results on *Autodesk* data calculating the metrics only for truly novel content words, i.e. ones that do not occur in the training data.

Method	R0	R1	R0+1
baseline	**44.1**	48.1	45.5
full	40.4	**54.6**	45.4
lasso	43.7	51.7	**46.5**

Table 4: Results on *Autodesk* data calculating the metrics with subwords.

Further results using the raw subword output[8] of the MT systems are depicted in Table 4: R0 for the *lasso* method is degraded only slightly below the baseline (-1%, compared to +2% for the regular metric), the findings for R1 and R0+1 remain the same as observed before. Compared to the results for novel words this indicates that the improvement in terms of R0 for *lasso* mostly come from learning new combinations of subwords.

A discussion of the adaptation behavior over time, with exemplified differences between the metrics, can be found in Appendix B.

6 Conclusions

To summarize: In some cases, the strong gains in corpus-level translation quality achieved by fine tuning an NMT model come at the expense of zero-shot recall of content words. This concerning impact of adaptation could affect practical user experience. Existing regularization methods mitigate this effect to some degree, but there may be more effective techniques for immediate adaptation that have yet to be developed.

The proposed metrics R0, R1, and R0+1 are useful for measuring immediate adaptation performance, which is crucial in adaptive CAT systems.

---

[7] The test set does not contain any unknown characters.

[8] Note that this includes all tokens, not just parts of content words.

A Additional Results

Table 5 contains results for additional English→German datasets, namely patents (Wäschle and Riezler, 2012) (*Patent*), transcribed public speeches (Cettolo et al., 2012) (*TED*), and two proprietary user data sets, one from the financial domain (*User 1*) and the other being technical documentation (*User 2*). The same pattern is observed in almost all cases: *lasso* outperforms the other adaptation techniques in zero-shot recall (R0) and combined recall (R0+1), while *full* has the highest one-shot recall (R1) on two out of five test sets, being close runner-up to *lasso* on all others. Overall however, we observe that zero-shot recall R0 is degraded by adaptation, while one-shot recall is improved. We also find that adaptation with the light-weight *bias* method often does not deviate much from the baseline. In contrast, the results for the traditional MT metrics are predominantly positive. For adaptation, the *lasso* method provides the best tradeoff in terms of performance throughout the considered metrics.

B Learning Curves

We are also interested in the behavior of the adaptation methods over time. To this end, in Figure 2, we plot the difference in cumulative scores[9] of two adapted systems (*full* and *lasso*) to the baseline for the proposed metrics as well as the BLEU score.

As evident from comparing the curves for BLEU and R0, the BLEU score and the proposed metric give disparate signals for this data. Specifically, there are two distinct dips in the curves for R0 (as well as R0+1) and BLEU:

1. The degradation in R0 around segment 800 is due to significant noise in segment 774, which has a strong impact on the adapted systems, while the baseline system is not affected. The *full* system's score drops by about 50% at segment 775 (i.e. after adaptation) relative to the cumulative score difference at the previous segment and never recovers after that.
2. The dip in the BLEU score at segment 752, observable for both adapted systems, depicting a relative degradation of about 10%, is due to a pathological repetition of a single character in the output of the adapted MT systems for this segment, which has a large impact on the score.

The dip observed with R0 is also noticeable in BLEU, but much less pronounced at 4% relative for *full* and 2% relative for *lasso*. The dip in BLEU on the other hand is not noticeable with R0, R1, or R0+1.

---

[9] For each sentence i in the data set, the metrics for all systems are calculated up to the ith sentence. The difference for the adapted systems is then calculated by subtracting the baseline score.

Abstract

Despite some empirical success at correcting exposure bias in machine translation, scheduled sampling algorithms suffer from a major drawback: they incorrectly assume that words in the reference translations and in sampled sequences are aligned at each time step. Our new differentiable sampling algorithm addresses this issue by optimizing the probability that the reference can be aligned with the sampled output, based on a soft alignment predicted by the model itself. As a result, the output distribution at each time step is evaluated with respect to the whole predicted sequence. Experiments on IWSLT translation tasks show that our approach improves BLEU compared to maximum likelihood and scheduled sampling baselines. In addition, our approach is simpler to train with no need for sampling schedule and yields models that achieve larger improvements with smaller beam sizes.[1]

1 Introduction

Neural machine translation (NMT) models are typically trained to maximize the likelihood of reference translations (Sutskever et al., 2014; Bahdanau et al., 2015). While simple and effective, this objective suffers from the exposure bias problem (Ranzato et al., 2015): the model is only exposed to reference target sequences during training, but has to rely on its own predictions at inference. As a result, errors can accumulate along the generated sequence at inference time.

This is a well-known issue in sequential decision making (Langford and Zadrozny, 2005; Cohen and Carvalho, 2005; Kääriäinen and Langford, 2006, i.a.) and it has been addressed in past work by incorporating the previous decoding choices into the training scheme, using imitation learning (Daumé et al., 2009; Ross et al., 2011; Bengio et al., 2015; Leblond et al., 2018) and reinforcement learning (Ranzato et al., 2015; Bahdanau et al., 2016) techniques. In this paper, we focus on a simple and computationally inexpensive family of approaches, known as Data as Demonstrator (Venkatraman et al., 2015) and scheduled sampling (Bengio et al., 2015; Goyal et al., 2017). The algorithms use a stochastic mixture of the reference words and model predictions with an annealing schedule controlling the mixture probability. Despite their empirical success in various sequence prediction tasks, they are based on an assumption that does not hold for machine translation: they assume that words in the reference translations and in sampled sequences are aligned at each time step, which results in weak and sometimes misleading training signals.

In this paper, we introduce a differentiable sampling algorithm that exposes machine translation models to their own predictions during training, and allows for differences in word order when comparing model outputs with reference translations. We compute the probability that the reference can be aligned with the sampled output using a soft alignment predicted based on the model states, so that the model will not be punished too severely for producing hypotheses that deviate from the reference, as long as the hypotheses can still be aligned with the reference.

Experiments on three IWSLT tasks (German-English, English-German and Vietnamese-English) show that our approach significantly improves BLEU compared to both maximum likelihood and scheduled sampling baselines. We also provide evidence that our approach addresses exposure bias by decoding with varying beam sizes, and show that our approach is simpler to train than scheduled sampling as it requires no annealing schedule.

2 Approach

Our approach is designed to optimize the standard sequence-to-sequence model for translating a source sentence $\boldsymbol{x}$ into a target sentence $\boldsymbol{y}$ (Bahdanau et al., 2015). This model computes the probability of $\boldsymbol{y}$ given $\boldsymbol{x}$ as:

$$P(\boldsymbol{y} \mid \boldsymbol{x}) = \prod_{t=1}^{T} p(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}; \theta) \quad (1)$$

where θ represents the model parameters. Given $\boldsymbol{x}$, the model first produces a sequence of hidden representations $\boldsymbol{h}_{1...T}$: $\boldsymbol{h}_t = f(\boldsymbol{y}_{<t}, \boldsymbol{x})$, where T is the length of $\boldsymbol{y}$, and f is usually an encoder-decoder network. At each time step t, the hidden representation $\boldsymbol{h}_t$ is fed to a linear projection layer $\boldsymbol{s}_t = \boldsymbol{W}\boldsymbol{h}_t + \boldsymbol{b}$ to obtain a vector of scores $\boldsymbol{s}_t$ over all possible words in the vocabulary $\mathcal{V}$. Scores are then turned into a conditional probability distribution: $p(\cdot \mid \boldsymbol{y}_{<t}, \boldsymbol{x}; \theta) = \mathrm{softmax}(\boldsymbol{s}_t)$.

The traditional maximum likelihood (ML) objective maximizes the log-likelihood of the training data $\mathcal{D} \equiv \{(\boldsymbol{x}^{(n)}, \boldsymbol{y}^{(n)})\}_{n=1}^{N}$ consisting of N pairs of source and target sentences:

$$\mathcal{J}_{ML}(\theta) = \sum_{n=1}^{N} \sum_{t=1}^{T} \log p(y_t^{(n)} \mid \boldsymbol{y}_{<t}^{(n)}, \boldsymbol{x}^{(n)}; \theta) \quad (2)$$

At test time, prefixes $\boldsymbol{y}_{<t}$ are subsequences generated by the model and therefore contain errors. By contrast, in ML training, prefixes $\boldsymbol{y}_{<t}$ are subsequences of reference translations. As a result, the model is never exposed to its own errors during training and errors accumulate at test time. This mismatch is known as the exposure bias problem (Ranzato et al., 2015).

2.1 Limitations in Scheduled Sampling

Bengio et al. (2015) introduced the scheduled sampling algorithm to address exposure bias. Scheduled sampling gradually replaces the reference words with sampled model predictions in the prefix used at training time. An annealing schedule controls the probability of using reference words vs. model predictions. The training objective remains the same as the ML objective, except for the nature of the prefix $\hat{\boldsymbol{y}}_{<t}$, which contains a mixture of reference and predicted words:

$$\mathcal{J}_{SS}(\theta) = \sum_{n=1}^{N} \sum_{t=1}^{T} \log p(y_t^{(n)} \mid \hat{\boldsymbol{y}}_{<t}^{(n)}, \boldsymbol{x}^{(n)}; \theta) \quad (3)$$

Despite the empirical success of scheduled sampling, one limitation is that the discontinuity of the argmax operation makes it impossible to penalize errors made in previous steps, which can lead to slow and unstable training. We address this issue using a continuous relaxation to the greedy search and sampling process, similarly to Goyal et al. (2017), which we describe in Section 2.2.

Another limitation of scheduled sampling is that it incorrectly assumes that the reference and predicted sequence are aligned by time indices which introduces additional noise to the training signal.[2] We address this problem with a novel differentiable sampling algorithm with an alignment based objective called soft aligned maximum likelihood (SAML). It is used in combination with maximum likelihood to define our training objective $\mathcal{J} = \mathcal{J}_{ML} + \mathcal{J}_{SAML}$, where $\mathcal{J}_{ML}$ is computed based on reference translations, and $\mathcal{J}_{SAML}$ is computed based on sampled translations of the same input sentences. We define $\mathcal{J}_{SAML}$ in Section 2.3.

2.2 Differentiable Sampling

To backpropagate errors made in the previous decoding steps, we use a continuous relaxation of the discrete sampling operation similar to Goyal et al. (2017), except that we use the Straight-Through (ST) Gumbel-Softmax estimator (Jang et al., 2017; Bengio et al., 2013) instead of Gumbel-Softmax (Jang et al., 2017; Maddison et al., 2014) to better simulate the scenario at inference time.[3]

The Gumbel-Softmax is derived from the Gumbel-Max trick (Maddison et al., 2014), an algorithm for sampling one-hot vector $z \in \mathbb{R}^k$ from a categorical distribution $(p_1, ..., p_k)$:

$$z = \text{one-hot}(\arg\max_i(\log p_i + \beta g_i)) \quad (4)$$

where g_i is the Gumbel noise drawn i.i.d from $\mathrm{Gumbel}(0,1)$[4], and β is a hyperparameter controlling the scale of the noise. Here, the trick is used to approximate the discontinuous argmax function with the differentiable softmax:

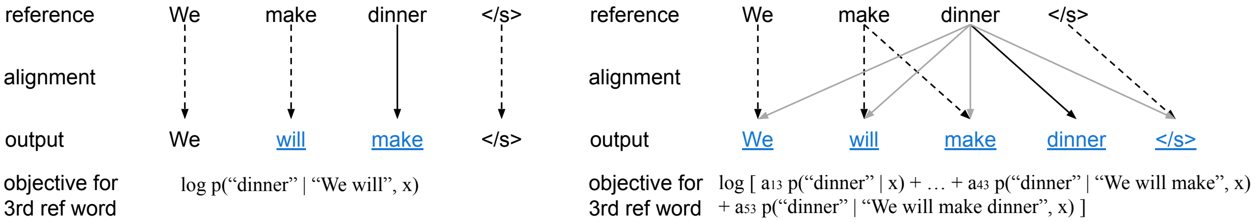
$$\tilde{z} = \mathrm{softmax}((\log p_i + \beta g_i)/\tau) \quad (5)$$

---

[2] https://nlpers.blogspot.com/2016/03/a-dagger-by-any-other-name-scheduled.html

[3] The Straight-Through estimator consistently outperforms the Gumbel-Softmax in preliminary experiments.

[4] $g_i = -\log(-\log(u_i))$ and $u_i \sim \mathrm{Uniform}(0,1)$.



(a) Scheduled Sampling Objective (b) SAML Objective

Figure 1: Difference between objectives used in scheduled sampling (left) and our approach (right), when computing the contribution to the objective of the reference word "dinner". The schedule sampling hypothesis uses a mixture of the reference (black) and sampled (blue underlined) words, while the entire hypothesis sequence is sampled in our approach.

where τ is the temperature parameter. As τ diminishes to zero, $\tilde{z}$ becomes the same as one-hot sample z.

The Straight-Through Gumbel-Softmax maintains the differentiability of the Gumbel-Softmax estimator while allowing for discrete sampling by taking different paths in the forward and backward pass. It uses argmax to get the one-hot sample z in the forward pass, but uses its continuous approximation $\tilde{z}$ in the backward pass. While ST estimators are biased, they have been shown to work well in latent tree learning (Choi et al., 2018) and semi-supervised machine translation (Niu et al., 2019).

2.3 Soft Aligned Maximum Likelihood

The soft aligned maximum likelihood (SAML) is defined as the probability that the reference can be aligned with the sampled output using a soft alignment predicted by the model:

$$P_{SAML}(\boldsymbol{y} \mid \boldsymbol{x}) = \prod_{t=1}^{T} \sum_{j=1}^{T'} a_{tj} \cdot p(y_t \mid \tilde{\boldsymbol{y}}_{<j}, \boldsymbol{x}; \theta) \tag{6}$$

where T is the length of the reference sequence, T' is the length of the sampled sequence, a_{tj} is the predicted soft alignment between the reference word y_t and sampled prefix $\tilde{\boldsymbol{y}}_{<j}$.

Training with the SAML objective consists in maximizing:

$$\mathcal{J}_{SAML}(\theta) = \sum_{n=1}^{N} \log P_{SAML}(\boldsymbol{y}^{(n)} \mid \boldsymbol{x}^{(n)}) \tag{7}$$

The conditional probability of the next word $p(y_t \mid \tilde{\boldsymbol{y}}_{<j}, \boldsymbol{x}; \theta)$ is computed as follows:

$$p(\cdot \mid \tilde{\boldsymbol{y}}_{<j}, \boldsymbol{x}; \theta) = \mathrm{softmax}(\boldsymbol{W}\tilde{\boldsymbol{h}}_j + \boldsymbol{b}) \tag{8}$$

where $\boldsymbol{W}$ and $\boldsymbol{b}$ are model parameters. $\tilde{\boldsymbol{h}}_j$ is the hidden representation at step j conditioned on the source sequence $\boldsymbol{x}$ and the preceding words $\tilde{\boldsymbol{y}}_{<j}$ sampled from the model distribution using differentiable sampling:

Task	sentences (K)			vocab (K)	
	train	dev	test	src	tgt
de-en	153.3	7.0	6.8	113.5	53.3
vi-en	121.3	1.5	1.3	23.9	50.0

Table 1: We evaluate on two translation tasks.

$$\tilde{\boldsymbol{h}}_j = f(\tilde{\boldsymbol{y}}_{<j}, \boldsymbol{x}) \tag{9}$$

We compute the soft alignment a_{tj} between y_t and $\tilde{\boldsymbol{y}}_{<j}$ based on the model's hidden states:

$$a_{tj} = \frac{\exp(score(\tilde{\boldsymbol{h}}_j, \boldsymbol{e}_{y_t}))}{\sum_{i=1}^{T'} \exp(score(\tilde{\boldsymbol{h}}_i, \boldsymbol{e}_{y_t}))} \tag{10}$$

where $\boldsymbol{e}_{y_t}$ is the embedding of the reference word y_t. The *score* function captures the similarity between the hidden state $\tilde{\boldsymbol{h}}_j$ and the embedding $\boldsymbol{e}_{y_t}$. We use the dot product here as it does not introduce additional parameters:

$$score(\boldsymbol{h}, \boldsymbol{e}) = \boldsymbol{h}^\top \boldsymbol{e} \tag{11}$$

Figure 1 illustrates how the resulting objective differs from scheduled sampling: (1) it is computed over sampled sequences as opposed to sequences that contain a mixture of sampled and reference words, and (2) each reference word is soft-aligned to the sampled sequence.

3 Experiments

Data We evaluate our approach on IWSLT 2014 German-English (de-en) as prior work (Goyal et al., 2017), as well as two additional tasks: IWSLT 2014 English-German (en-de) and IWSLT

Method	**Anneal**	**de-en**	**en-de**	**vi-en**
Baseline	No	$27.41_{\pm 0.26}$	$22.64_{\pm 0.13}$	$23.59_{\pm 0.13}$
+SS	Yes	$27.47_{\pm 0.28}$	$22.56_{\pm 0.17}$	$23.97_{\pm 0.39}$
+DSS	Yes	$27.30_{\pm 0.24}$	$22.47_{\pm 0.20}$	$23.68_{\pm 0.35}$
+SS	No	$22.91_{\pm 0.21}$	$17.78_{\pm 0.20}$	$19.57_{\pm 0.19}$
+SAML	No	$\mathbf{27.94}_{\pm 0.12}$	$\mathbf{23.30}_{\pm 0.19}$	$\mathbf{24.60}_{\pm 0.35}$

Table 2: BLEU scores of our approach (SAML) and three baselines including the maximum likelihood (ML) baseline, scheduled sampling (SS), and differentiable scheduled sampling (DSS). The *Anneal* column indicates whether the sampling rate is annealed. For each task, we report the mean and standard deviation over 5 runs with different random seeds. SAML achieves the best BLEU scores and is simpler to train than SS and DSS, as it requires no annealing schedule.

2015 Vietnamese-English (vi-en). For de-en and en-de, we follow the preprocessing steps in Ranzato et al. (2015). For vi-en, we use the data preprocessed by Luong and Manning (2015), with test2012 for validation and test2013 for testing. Table 1 summarizes the data statistics.

Setup Our translation models are attentional RNNs (Bahdanau et al., 2015) built on Sockeye (Hieber et al., 2017). We use bi-directional LSTM encoder and single-layer LSTM decoder with 256 hidden units, embeddings of size 256, and multilayer perceptron attention with a layer size of 256. We apply layer normalization (Ba et al., 2016) and label smoothing (0.1). We add dropout to embeddings (0.1) and decoder hidden states (0.2). For ST Gumbel-Softmax, we use temperature $\gamma = 1$ and noise scale $\beta = 0.5$. The decoding beam size is 5 unless stated otherwise. We train the models using the Adam optimizer (Kingma and Ba, 2015) with a batch size of 1024 words. We checkpoint models every 1000 updates. The initial learning rate is 0.0002, and it is reduced by 30% after 4 checkpoints without validation perplexity improvement. Training stops after 12 checkpoints without improvement. For training efficiency, we first pre-train a baseline model for each task using only $\mathcal{J}_{ML}$ and fine-tune it using different approaches. In the fine-tuning phase, we inherit all settings except that we initialize the learning rate to 0.00002 and set the minimum number of checkpoints before early stopping to 24. We fine-tune each randomly seeded model independently.

Baselines We compare our model against three baselines: (1) a standard baseline trained with the ML objective, and models fine-tuned with (2) scheduled sampling (**SS**) (Bengio et al., 2015) and (3) differentiable scheduled sampling (**DSS**) (Goyal et al., 2017). In SS and DSS, the probability of using reference words ϵ_s is annealed using inverse sigmoid decay (Bengio et al., 2015): $\epsilon_s = k/(k + \exp(i/k))$ at the i-th checkpoint with $k = 10$.

Results Table 2 shows that the SAML improves over the ML baseline by +0.5 BLEU on de-en, +0.7 BLEU on en-de, and +1.0 BLEU on vi-en task. In addition, SAML consistently improves over both the scheduled sampling and differentiable scheduled sampling on all tasks. All improvements are significant with $p < 0.002$. Interestingly, differentiable scheduled sampling performs no better than scheduled sampling in our experiments, unlike in Goyal et al. (2017).

Unlike scheduled sampling, our approach does not require an annealing schedule, and it is therefore simpler to train. We verify that the annealing schedule is needed in scheduled sampling by training a contrastive model with the same objective as scheduled sampling, but without annealing schedule (Table 2). We set the sampling rate to 0.5. The contrastive model hurts BLEU scores by at least 4.0 points compared to both the ML baseline and models fine-tuned with scheduled sampling, confirming that scheduled sampling needs the annealing schedule to work well.

We further examine the performance gain of different approaches over the baseline with varying beam sizes (Figure 2). Our approach yields larger BLEU improvements when decoding with greedy search and smaller beams, while there is no clear pattern for scheduled sampling models. These results support the hypothesis that our approach mitigates exposure bias, as it yields bigger improvements in settings where systems have fewer opportunities to recover from early errors.

4 Related Work

Daumé et al. (2009) first addressed exposure bias in an imitation learning framework by training a classifier on examples generated using a mixture of the ground truth and the model's current predictions. DAgger (Ross et al., 2011) is a similar algorithm which differs in how the training examples are generated and aggregated. Both al-

Figure 2: Improvements from our method (SAML), scheduled sampling (SS), and differentiable scheduled sampling (DSS) over the maximum likelihood (ML) baseline when decoding with varying beam sizes (average of 5 runs). The SAML model consistently yields the largest improvements with smaller beams.

gorithms require an expert policy, which produces the best next token given any model predicted prefix, and assume that policy can be efficiently computed from the reference. However, for structured prediction tasks such as machine translation with large vocabulary and complex loss functions, it is intractable to find the best next token given any prefix. For time series modeling, the Data as Demonstrator algorithm (Venkatraman et al., 2015) derives the expert policy directly from the reference sequences which are aligned with the sampled sequences at each time step. Scheduled sampling algorithms (Bengio et al., 2015; Goyal et al., 2017) use the same strategy to train neural sequence-to-sequence models for a broader range of language generation tasks, even though the time alignment between reference and sampled sequences does not hold. Leblond et al. (2018) proposed to complete a predicted prefix with all possible reference suffixes and picking the reference suffix that yields the highest BLEU-1 score. However, they found that this approach performs well only when the prefix is close to the reference.

Reinforcement learning (RL) algorithms (Bahdanau et al., 2016; Sutton and Barto, 2018; Van Hasselt et al., 2016) address exposure bias by directly optimizing a sentence-level reward for the model generated sequences. Evaluation metrics such as BLEU can be used as rewards, but they are discontinuous and hard to optimize. Techniques such as policy gradient (Williams, 1992) and actor-critic (Sutton and Barto, 2018; Degris et al., 2012) are thus required to find an unbiased estimation of the gradient to optimize the model. Due to the high variance of the gradient estimation, training with RL can be slow and unstable (Henderson et al., 2018; Wu et al., 2018). Recent alternatives use data augmentation to incorporate the sentence-level reward into the training objective more efficiently (Norouzi et al., 2016).

Finally, our SAML loss shares the idea of flexible reference word order with the bag-of-word loss introduced by Ma et al. (2018) to improve source coverage. However, their loss is computed with teacher forcing and therefore does not address exposure bias.

5 Conclusion

We introduced a differentiable sampling algorithm which exposes a sequence-to-sequence model to its own predictions during training and compares them to reference sequences flexibly to backpropagate reliable error signals. By soft aligning reference and sampled sequences, our approach consistently improves BLEU over maximum likelihood and scheduled sampling baselines on three IWSLT tasks, with larger improvements for greedy search and smaller beam sizes. Our approach is also simple to train, as it does not require any sampling schedule.

Abstract

We consider the problem of making efficient use of heterogeneous training data in neural machine translation (NMT). Specifically, given a training dataset with a sentence-level feature such as noise, we seek an optimal *curriculum*, or order for presenting examples to the system during training. Our curriculum framework allows examples to appear an arbitrary number of times, and thus generalizes data weighting, filtering, and fine-tuning schemes. Rather than relying on prior knowledge to design a curriculum, we use reinforcement learning to learn one automatically, jointly with the NMT system, in the course of a single training run. We show that this approach can beat uniform baselines on Paracrawl and WMT English-to-French datasets by +3.4 and +1.3 BLEU respectively. Additionally, we match the performance of strong filtering baselines and hand-designed, state-of-the-art curricula.

1 Introduction

Machine Translation training data is typically heterogeneous: it may vary in characteristics such as domain, translation quality, and degree of difficulty. Many approaches have been proposed to cope with heterogeneity, such as filtering (Duh et al., 2013) or down-weighting (Wang et al., 2017) examples that are likely to be noisy or out of domain. A powerful technique is to control the curriculum—the order in which examples are presented to the system—as is done in fine-tuning (Freitag and Al-Onaizan, 2016), where training occurs first on general data, and then on more valuable in-domain data. Curriculum based approaches generalize data filtering and weighting[1] by allowing examples to be visited multiple times or not at all; and they additionally potentially enable steering the training trajectory toward a better global optimum than might be attainable with a static attribute-weighting scheme.

Devising a good curriculum is a challenging task that is typically carried out manually using prior knowledge of the data and its attributes. Although powerful heuristics like fine-tuning are helpful, setting hyper-parameters to specify a curriculum is usually a matter of extensive trial and error. Automating this process with meta-learning is thus an attractive proposition. However, it comes with many potential pitfalls such as failing to match a human-designed curriculum, or significantly increasing training time.

In this paper we present an initial study on meta-learning an NMT curriculum. Starting from scratch, we attempt to match the performance of a successful non-trivial *reference curriculum* proposed by Wang et al. (2018), in which training gradually focuses on increasingly cleaner data, as measured by an external scoring function. Inspired by Wu et al. (2018), we use a reinforcement-learning (RL) approach involving a learned agent whose task is to choose a corpus bin, representing a given noise level, at each NMT training step. A challenging aspect of this task is that choosing only the cleanest bin is sub-optimal; the reference curriculum uses all the data in the early stages of training, and only gradually anneals toward the cleanest. Furthermore, we impose the condition that the agent must learn its curriculum in the course of a single NMT training run.

We demonstrate that our RL agent can learn a curriculum that works as well as the reference, obtaining a similar quality improvement over a random-curriculum baseline. Interestingly, it does so using a different strategy from the reference. This result opens the door to learning more sophisticated curricula that exploit multiple data at-

tributes and work with arbitrary corpora.

2 Related Work

Among the very extensive work on handling heterogeneous data in NMT, the closest to ours are techniques that re-weight (Chen et al., 2017) or re-order examples to deal with domain mismatch (van der Wees et al., 2017; Sajjad et al., 2017) or noise (Wang et al., 2018).

The idea of a curriculum was popularized by Bengio et al. (2009), who viewed it as a way to improve convergence by presenting heuristically-identified easy examples first. Several recent papers (Kocmi and Bojar, 2017; Zhang et al., 2019; Platanios et al., 2019) explore similar ideas for NMT, and verify that this strategy can reduce training time and improve quality.

Work on meta-learning a curriculum originated with Tsvetkov et al. (2016), who used Bayesian optimization to learn a linear model for ranking examples in a word-embedding task. This approach requires a large number of complete training runs, and is thus impractical for NMT. More recent work has explored bandit optimization for scheduling tasks in a multi-task problem (Graves et al., 2017), and reinforcement learning for selecting examples in a co-trained classifier (Wu et al., 2018). Finally, Liu et al. (2018) apply imitation learning to actively select monolingual training sentences for labeling in NMT, and show that the learned strategy can be transferred to a related language pair.

3 Methods

The attribute we choose to learn a curriculum over is noise. To determine a per-sentence noise score, we use the *contrastive data selection* (CDS) method defined in Wang et al. (2018). Given the parameters θ_n of an NMT model trained on a noisy corpus, and parameters θ_c of the same model fine-tuned on a very small trusted corpus, the score $s(e,f)$ for a translation pair e,f is defined as:

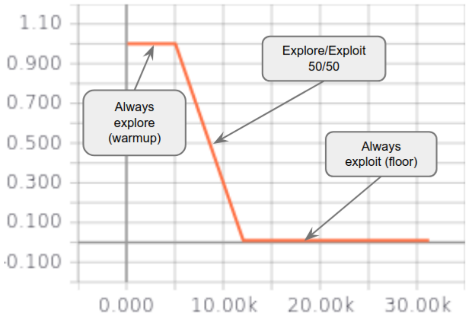

Figure 2: Linearly-decaying ϵ-greedy exploration.

$$s(e,f) = \log p_{\theta_c}(f|e) - \log p_{\theta_n}(f|e) \qquad (1)$$

Wang et al. (2018) show that this correlates very well with human judgments of data quality. They use the CDS score in a heuristic, online schedule that slowly anneals from sampling mini-batches from all the training data to sampling only from the highest-scoring (cleanest) data. Our goal is to replace this heuristic curriculum with a learned one.

Q-learning for NMT Curricula

Our agent uses deep Q-learning (DQN) (Mnih et al., 2015) which is a model-free reinforcement learning procedure. The agent receives an *observation* from the environment and conditions on it to produce an *action* which is executed upon the environment. It then receives a *reward* representing the goodness of the executed action. The agent chooses actions according to a state-action value (Q) function, and attempts to learn the Q-function so as to maximize expected total rewards.

In our setup, the environment is the NMT system and its training data, as illustrated in Figure 1. We divide the training data into a small number of equal-sized *bins* according to CDS scores. At each step, the agent selects a bin (action) from which a mini-batch is sampled to train the NMT system.

Our RL agent must balance exploration (choosing an action at random) versus exploitation (choosing the action which maximizes the Q-function). In our setup, this is done using a linearly-decaying ϵ-greedy exploration strategy (Figure 2). This strategy has three phases: (1) The warmup period where we always explore; (2) the decay period where the probability of exploration decreases and exploitation increases; (3) the floor where we almost always exploit. Since we do not want to exploit an uninformed Q-function, the duration of exploration needs to be set carefully. In our experiments, we found that longer decays were useful and the best performance was achieved when the decay was set to about 50% of the expected NMT training steps.

Observation Engineering

The *observation* is meant to be a summary of the state of the environment. The NMT parameters are too numerous to use as a sensible observation at each time step. Inspired by Wu et al. (2018), we propose an observation type which is a function of the NMT system's current performance at various levels of noise. We first create a *prototype batch* by sampling a fixed number of prototypical sentences from each bin of the training data. At each time step, the observation is the vector containing sentence-level log-likelihoods produced by the NMT system for this prototype batch.

Since the observations are based on likelihood, a metric which aggressively decays at the beginning of NMT training, we use an NMT warmup period to exclude this period from RL training. Otherwise, the initial observations would be unlike any that occur later.

Reward Engineering

Our objective is to find a curriculum which maximizes the likelihood of the NMT system on a development set. The RL *reward* that directly corresponds to this goal would be the highest likelihood value reached during an NMT training run. However, as we use only one NMT training run, having a single reward per run is infeasible. To provide a denser signal to the RL agent, we define the reward at a step to be the change in likelihood since the most recent previous step for which development-set likelihood is available. This has the desired property that the sum of per-step rewards maximized by the RL agent is equal to the NMT maximum-likelihood objective (on development data). We rely on the WMT warmup period described in the previous section to eliminate spuriously large rewards at the beginning of training.

4 Experimental Setup

Our NMT model is similar to RNMT+ (Chen et al., 2018), but with only four layers in both encoder and decoder. Rewards (dev-set log-likelihood) are provided approximately every 10 training steps by an asynchronous process.

We use the DQN agent implementation in Dopamine,[2] which includes an experience replay buffer to remove temporal correlations from the observations, among other DQN best practices. Due to the sparse and asynchronous nature of our rewards, we store observation, action transitions in a temporary buffer until a new reward arrives. At this point, transitions are moved from the temporary buffer to the DQN agent's replay buffer. The RL agent is trained after each NMT training step by sampling an RL mini-batch from the replay buffer. Our RL hyper-parameter settings are listed in the appendix.

Following Wang et al. (2018), we use the Paracrawl and WMT English-French corpora for our experiments. These contain 290M and 36M training sentences respectively. WMT is relatively clean, while a large majority of Paracrawl sentence pairs contain noise. We process both corpora with BPE, using a vocabulary size of 32k. Both corpora are split into 6 equal-sized bins according to their noise level, as provided by CDS score. In both settings, the WMT newstest 2010-2011 corpus is used as trusted data for CDS scores, which are computed using the models and procedure described in Wang et al. (2018). For the *prototype batch* used to generate observations, we extracted the 32 sentences whose CDS scores are closest to the mean in each bin, giving a total of 192 sentences. We use WMT 2012-2013 for development and WMT 2014 for test, and report tokenized, naturally-cased BLEU scores from the test checkpoint closest to the highest-BLEU dev checkpoint. To combat variance caused by sampling different batches per bin (which produces somewhat different results even when bins are visited in fixed order), all models were run twice with different random seeds, and the model with the best score on the dev set was chosen.

5 Results

Our results are presented in Table 1. **Uniform baselines** consist of:

- *Uniform* – standard NMT training
- *Uniform (6-bins)* – sample a bin uniformly at random, and then sample a mini-batch from that bin

---

[2] `github.com/google/dopamine`

	Paracrawl	**WMT**
Uniform baselines		
Uniform	34.1	37.1
Uniform (6-bins)	34.8	-
Uniform (bookends)	35.0	34.8
Heuristic baselines		
Filtered (20%/33%)	37.0	38.3
Fixed ϵ-schedule	36.9	37.7
Online	37.5	37.7
Learned curricula		
Q-learning (bookends)	36.8	36.3
Q-learning (6-bins)	37.5	38.4

Table 1: BLEU scores on Paracrawl and WMT En-Fr datasets with uniform, heuristic and learned curricula.

- *Uniform (bookends)* – as Uniform (6-bins) but uniformly sampling over just the best and worst bin.

Surprisingly, 6-bins performs better than the standard NMT baseline. We hypothesize that this can be attributed to more homogeneous mini-batches.

Heuristic baselines are:

- *Filtered* – train only on the highest-quality data as determined by CDS scores: top 20% of the data for Paracrawl, top 33% for WMT.
- *Fixed ϵ-schedule* – we use the ϵ-decay strategy of our best RL experiment, but always choose the cleanest bin when we exploit.
- *Online* – the online schedule from Wang et al. (2018) adapted to the 6-bin setting. We verified experimentally that our performance matched the original schedule, which did not use hard binning.

Learned curricula were trained over 2 bookend (worst and best) bins and all 6 bins. On the Paracrawl dataset, in the 2-bin setting, the learned curriculum beats all uniform baselines and almost matches the optimized filtering baseline.[3] With 6-bins, it beats all uniform baselines by up to 2.5 BLEU and matches the hand-designed online baseline of Wang et al. (2018). On WMT, with 2 bins, the learned curriculum beats the 2-bin baseline, but not the uniform baseline over all data. With 6 bins, the learned curriculum beats the uniform baseline by 1.5 BLEU, and matches the filtered baseline, which in this case outperforms the online curriculum by 0.6 BLEU.

Observation Reward	Default	Fixed
Default	**37.5**	37.5
Fixed	32.5	-

Table 2: BLEU scores on ablation experiments with fixed rewards or observations on the Paracrawl En-Fr dataset.

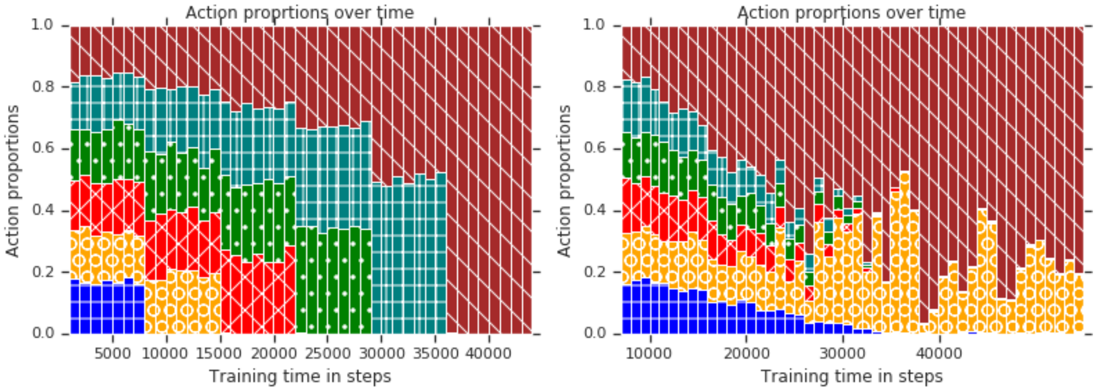
Our exploration strategy for Q-learning (see Figure 2) forces the agent to visit all bins during initial training, and only gradually rely on its learned policy. This mimics the gradual annealing of the online curriculum, so one possibility is that the agent is simply choosing the cleanest bin whenever it can, and its good performance comes from the enforced period of exploration. However, the fact that the agent beats the fixed ϵ-schedule (see Table 1) described above on both corpora makes this unlikely.

6 Analysis

Task-specific reward and observation engineering is critical when building an RL model. We performed ablation experiments to determine if the rewards and observations we have chosen contain information which aids us in the curriculum learning task. Table 2 shows the results of our experiments. The fixed reward experiments were conducted by replacing the default delta-perplexity based reward with a static reward which returns a reward of one when the cleanest bin was selected and zero otherwise. The fixed observation experiments used a static vector of zeroes as input at all time steps. Using fixed observations matches the performance of dynamic observations, from which we can draw two conclusions. First, the agent's good performance is due to associating higher rewards with better bins, but it learns to do so slowly (partly modulated by its ϵ-greedy schedule) so that it avoids the sub-optimal strategy of choosing only the best bin. Second, its ability to distinguish among bins is not impeded by the use of an observation vector that slowly evolves through time and never returns to previous states.

---

[3] The clean data available in the 2-bin setup is limited to the best bin (16%), while filtering uses slightly more data (20%).



(a) Online

(b) RL learned

Figure 3: Online policy from Wang et al. (2018) compared to the RL policy. Each color/pattern represents a bin (blue is the noisiest bin, dark red is the cleanest; bins lower on the vertical axis contain more noise) and length along the vertical axis is proportional to the number of times each bin was selected at a given step during training.

6.1 What did the agent learn?

Figure 3 shows a coarse visualization of the hand-optimized policy of Wang et al. (2018), adapted to our 6-bin scenario, compared to the Q-learning policy on the same scenario. The former, by design, telescopes towards the clean bins. Note that the latter policy is masked by the agent's exploration schedule, which slowly anneals toward nearly complete policy control, beginning at step 30,000. After this point, the learned policy takes over and continues to evolve. This learned policy has little in common with the hand-designed one. Instead of focusing on a mixture of the clean bins, it focuses on the cleanest bin and the second-to-noisiest. We hypothesize that returning to the noisy bin acts as a form of regularization, though this requires further study.

7 Conclusion

We have presented a method to learn a curriculum for presenting training samples to an NMT system. Using reinforcement learning, our approach learns the curriculum jointly with the NMT system during the course of a single NMT training run. Empirical analysis on the Paracrawl and WMT English-French corpora shows that this approach beats the uniform sampling and filtering baselines. In addition, we were able to match a state-of-the-art hand designed curriculum on Paracrawl and beat it on WMT.

We see this a first step toward enabling NMT systems to manage their own training data. In the future, we intend to improve our approach by eliminating the static exploration schedule and binning strategy, and extend it to handle additional data attributes such as domain, style, and grammatical complexity.

Acknowledgements

The authors would like to thank Wei Wang for his advice and help in replicating the CDS baselines.

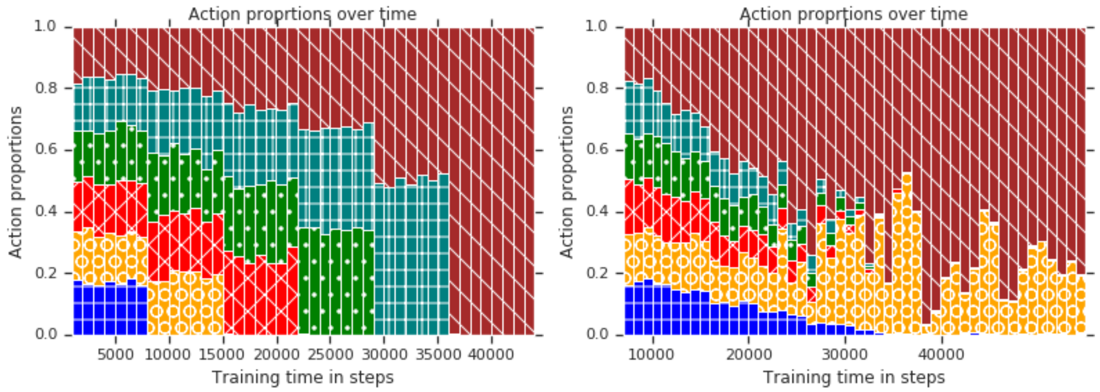
A Appendix

A.1 Q-learning hyper-parameters

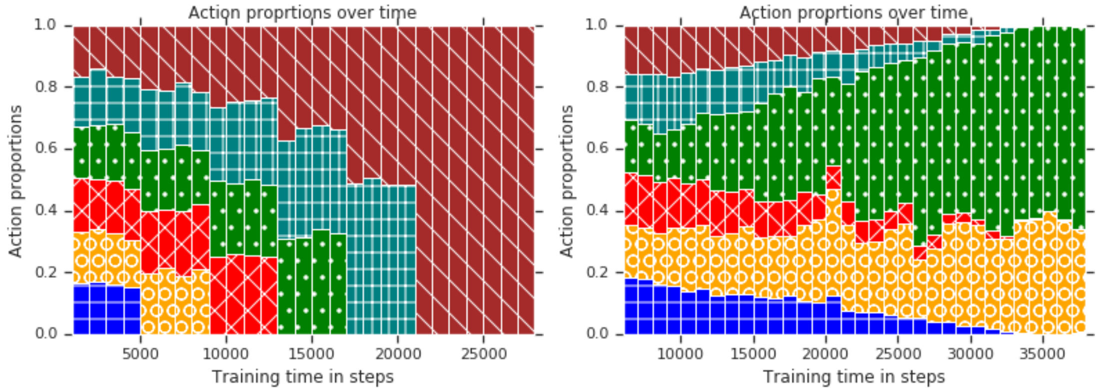
- Observations: We sample 32 prototype sentences from each bin to create a *prototype batch* of 192 sentences.
- Q-networks: The two Q-networks were MLPs with 2 x 512-d hidden layers each. A $\tanh$ activation function was used.
- RL optimizer: We used RMSProp with a learning rate of 0.00025 and a decay of 0.95 and no momentum.
- NMT warmup : 5000 steps (no transitions from this period are recorded).
- Stack size: We do not stack our observations for the RL agent (i.e., stack size = 1).
- Exploration strategy : We use a linearly decaying epsilon function with decay period set to 25k steps. The decay floor was set to 0.01.
- Discount gamma : 0.99
- Update horizon : 2
- Minimum number of transitions in replay buffer before training starts: 3000



(a) Telescoping

(b) RL learned

Figure 4: Policies learned by the RL agent on the Paracrawl En-Fr corpus compared against the telescoping policy from Wang et al. (2018). Lower bins on the vertical axis contain more noise.



(a) Telescoping

(b) RL learned

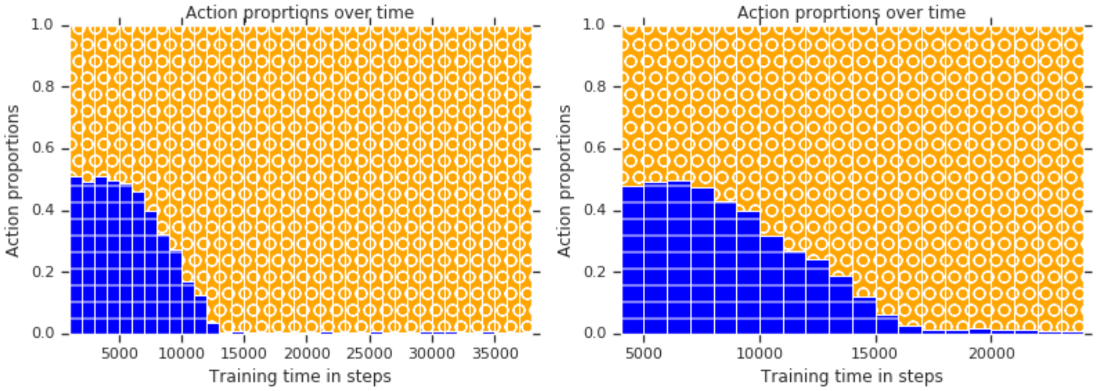
Figure 5: Policies learned by the RL agent on the WMT En-Fr corpus compared against the telescoping policy from Wang et al. (2018). Lower bins on the vertical axis contain more noise.

- Update period (how often the online Q-network is trained): 4 steps
- Target update period (how often the target Q-network is trained): 100 steps
- The window for the delta-perplexity reward was 1.

A.2 Learned Policies

Figures 4, 5 and 6 show coarse representations of the policies learned by the Q-learning agent on the Paracrawl and WMT English-French datasets. Each column in the figures represents the relative proportion of actions taken (bins selected) averaged over a thousand steps and the actions go from noisy to clean on the y-axis. Each policy starts from a uniform distribution over actions. Some salient aspects of the learned policies are listed below.

1. All learned curricula differ significantly from the hand-designed policies.
2. The RL curriculum learned for Paracrawl (Figure 4) focus on two bins during exploitation (choose action using the trained Q-function). Surprisingly, these are not the two cleanest bins but a mixture of the cleanest and the second-to-noisiest bin.
3. The RL curriculum learned for WMT (Figure 4) is closer to a uniform distribution over actions for a long duration. This makes sense since the data from WMT is mostly homogeneous with respect to noise. When the agent does decide to exploit some bins more often, they are not the cleanest ones, but the 1st and 4th bin instead.
4. Figure 6 shows the policies learned on the bookend task for Paracrawl and WMT; the



(a) RL Learned (Paracrawl)

(b) RL learned (WMT)

Figure 6: Policies learned by the RL agent on the 2-bin task on the Paracrawl and WMT En-Fr datasets. Lower bins on the vertical axis contain more noise.

only two bins available contain the noisiest and cleanest portion of the corpus. The RL agent very quickly learns that there is an optimal bin to choose in this task and converges to consistently exploiting it. We consider this a sanity check of curriculum learning methods.

Overcoming Catastrophic Forgetting During Domain Adaptation of Neural Machine Translation

Abstract

Continued training is an effective method for domain adaptation in neural machine translation. However, in-domain gains from adaptation come at the expense of general-domain performance. In this work, we interpret the drop in general-domain performance as *catastrophic forgetting* of general-domain knowledge. To mitigate it, we adapt Elastic Weight Consolidation (EWC)—a machine learning method for learning a new task without forgetting previous tasks. Our method retains the majority of general-domain performance lost in continued training without degrading in-domain performance, outperforming the previous state-of-the-art. We also explore the full range of general-domain performance available when some in-domain degradation is acceptable.

1 Introduction

Neural Machine Translation (NMT) performs poorly without large training corpora (Koehn and Knowles, 2017). Domain adaptation is required when there is sufficient data in the desired language pair but insufficient data in the desired *domain* (the topic, genre, style or level of formality). This work focuses on the supervised domain adaptation problem where a small in-domain parallel corpus is available for training. Continued training (Luong and Manning, 2015; Sennrich et al., 2015) (also called fine-tuning), where a model is first trained on general-domain data and then domain adapted by training on in-domain data, is a popular approach in this setting as it leads to empirical improvements in the targeted domain.

One downside of continued training is that the adapted model's ability to translate general-domain sentences is severely degraded during adaptation (Freitag and Al-Onaizan, 2016). We interpret this drop in general-domain performance as *catastrophic forgetting* (Goodfellow et al., 2013) of general-domain translation knowledge. Degradation of general-domain performance may be problematic when the domain adapted NMT system is used to translate text outside its target domain, which can happen if there is a mismatch between the data available for domain-specific training and the test data. Poor performance may also concern end users of these MT systems who are expecting good performance on 'easy' generic sentences.[1]

Elastic Weight Consolidation (EWC) (Kirkpatrick et al., 2017) is a method for training neural networks to learn a new task without forgetting previously learned tasks. We extend EWC to continued training in NMT (see §3): Our first task is to translate general-domain sentences, and our second is to translate domain-specific sentences (without forgetting how to translate general-domain sentences). EWC works by adding a per-parameter regularizer, based on the Fisher Information matrix, while training on the second task. At a high level, the regularization term keeps parameters which are important to general-domain performance close to the initial general-domain model values during continued training, while allowing parameters less important to general-domain performance to adapt more aggressively to the in-domain data.

We show that when adapting general-domain models to the domain of patents, EWC can substantially improve the retention of general-domain performance (up to 18.1 BLEU) without degrading in-domain translation quality. Our proposed method outperforms the previous state-of-the-art method (Dakwale and Monz, 2017) at retaining general-domain performance while adapting to a new domain.

---

Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related Work

A few prior studies address the drop in general-domain NMT performance during continued training. Freitag and Al-Onaizan (2016) found that ensembling general- and in-domain models provides most of the in-domain gain from continued training while retaining most of the general-domain performance. Ensembling doubles memory and computational requirements at translation time, which may be impractical for some applications and does not address our more fundamental goal of building a single model that is robust across domains. Chu et al. (2017) found that mixing general-domain data with the in-domain data used for continued training improved general-domain performance of the resulting models, at the expense of training time.

Dakwale and Monz (2017) share our goal of improving the general-domain performance of continued training. They introduce two novel approaches which use the initial, general-domain model to supervise the in-domain model during continued training. The first, *multi-objective fine-tuning*, which they denote MCL, trains the network with a joint objective of standard log-likelihood loss plus a second term based on knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) of the general-domain model. The second, *multiple-output layer fine tuning*, adds new parameters to the output layer during continued training that are specific to the new domain. They found both methods performed similarly, significantly outperforming ensembling in the more challenging case where domain shift is significant, so we select the simpler MCL as our baseline.

We do not assume that the domain of input sentences is known, thus we do not compare to methods such as LHUC (Vilar, 2018). Our work applies a regularization term to continued training, similar to Miceli Barone et al. (2017) and Khayrallah et al. (2018), but for the purpose of retaining general-domain performance as opposed to improving in-domain performance.

3 Method

Compared to Kirkpatrick et al. (2017), we present a more general derivation of EWC to address the fact that our tasks are not independent. We also show that the diagonal of the Fisher matrix used in EWC is intractable to compute for sequence-to-sequence models with large vocabularies. Instead we propose to approximate it with the diagonal of the *empirical Fisher* (Martens, 2014), which can be computed efficiently using gradients from back-propagation.

At a high level, our method works as follows:

1. Train on the general-domain data, resulting in parameters $\hat{\theta}^G$.
2. Compute the diagonal of the empirical Fisher matrix $\bar{F}$. $\bar{F}_{i,i}$ estimates how important the i^{th} parameter $\hat{\theta}_i^G$ is to the general-domain translation task.
3. Initialize parameters to $\hat{\theta}^G$ and train on in-domain data, using an EWC regularization term which incorporates the diagonal of $\bar{F}$.

Intuitively, the regularization term during continued training keeps a parameter θ_i close to corresponding general-domain parameter $\hat{\theta}_i^G$ if the model's general-domain performance is sensitive to that parameter (i.e., large $\bar{F}_{i,i}$). Parameters to which general-domain performance is less sensitive (i.e., small $\bar{F}_{i,i}$) are allowed to be updated more aggressively to fit the in-domain data.

3.1 Bayesian Rationale for EWC

For the following discussions, let X be the set of all well-formed source sentences and Y be the set of all possible sequences of target words. Training data D consists of translations (x, y). We assume $x \in X$ is drawn from a true underlying distribution of source sentences Q_x, and $y \in Y$ is drawn from a true conditional distribution of correct translations $Q_{y|x}$. Our model, parameterized by θ, computes the conditional probability $P_{y|x} \triangleq P(y|x;\theta)$, which estimates $Q_{y|x}$. Our dataset D is assumed to have come from two distinct tasks: general-domain translation with data D^G and in-domain translation with data D^S(domain-specific). Without loss of generality, $p(D){=}p(D^G)p(D^S|D^G)$. Applying Bayes rule to $\log p(\theta|D)$ and simplifying gives:

$$\log p(\theta|D) = \log p(D^S|D^G,\theta) + \log p(\theta|D^G) - \log p(D^S|D^G) \quad (1)$$

We aim to maximize Equation 1 for θ:

$$\hat{\theta}^* = \arg\max_{\theta} \left[\log p(D^S|D^G,\theta) + \log p(\theta|D^G)\right] \quad (2)$$

3.2 Approximating $\log p(\boldsymbol{\theta}|D^G)$

To efficiently compute Equation 2, we first approximate $p(\theta|D^G)$ as a multivariate Gaussian[2] with mean $\hat{\theta}^G$, obtained by training the network on D^G with standard negative log likelihood (NLL) loss, and diagonal precision matrix (inverse of the covariance matrix) given by the diagonal of the Fisher Information Matrix F:

$$F = E_{P_{x,y}}\left[\nabla \log p(x,y|\theta) \nabla \log p(x,y|\theta)^T\right]$$

$$= E_{Q_x}\left[E_{P_{y|x}}\left[\nabla \log p(y|x,\theta) \nabla \log p(y|x,\theta)^T\right]\right]$$

This is the expected variance of the likelihood function's gradient at θ.[3] The magnitude of $F_{i,i}$ indicates the model's sensitivity to parameter θ_i, on the general-domain translation task. Note that the first expectation is taken with respect to the true distribution of x and can be approximated by training samples. The second expectation is taken with respect to the model distribution $P_{y|x}$, which is impractical for a large sequence-to-sequence model as it requires summing over all possible output sequences.

We approximate the true Fisher with the empirical Fisher $\bar{F}$ (Martens, 2014), where y is not enumerated but fixed to be the training labels:

$$\bar{F} = \frac{1}{|D^G|} \sum_{(x,y)\in D^G} \nabla \log p(y|x,\theta) \nabla \log p(y|x,\theta)^T$$

Thus we approximate maximizing $\log p(\theta|D^G)$ in Equation 2 by minimizing $\sum_i \bar{F}_{i,i}\left[\theta_i - \hat{\theta}_i^G\right]^2$. Note that the diagonal of $\bar{F}$ is easily computed from backpropagation gradients.

3.3 Approximating $\log p(D^S|D^G, \boldsymbol{\theta})$

Tasks are assumed to be independent in the original EWC work (Kirkpatrick et al., 2017), which is unrealistic in the continued training scenario since both tasks are translation in the same language.[4] Since we assume source sentences in D^G and D^S are sampled independently, all dependencies can be attributed to $Q_{y|x}$, representing knowledge of translation (i.e., $D^G \perp\!\!\!\perp D^S \mid Q_{y|x}$). $Q_{y|x}$ is unknown, so we approximate it with our general-domain model ($\hat{\theta}^G$). Furthermore, we will regularize continued training such that θ stays in a region near $\hat{\theta}^G$. Thus we assume $D^G \perp\!\!\!\perp D^S \mid \theta$ during continued training. This allows us to approximate $\log p(D^S|D^G,\theta)$ in Equation 2 with $\log p(D^S|\theta)$, which is simply the likelihood function on D^S.

De	Ru	Zh	De	Ru	Zh
323 M	730 M	584 M	3.2 M	0.81 M	0.80 M

Table 1: # English words in the training corpora.

3.4 EWC Loss

Combining the approximations above results in the EWC loss used in continued training:

$$L_{EWC}(\theta) = L_{NLL}^S(\theta) + \lambda \sum_i \bar{F}_{i,i}\left[\theta_i - \hat{\theta}_i^G\right]^2 \quad (3)$$

Where $L_{NLL}^S(\theta)$ is the standard NLL loss on D^S and λ is a hyper-parameter which weights the importance of the general-domain task. Note that the left-hand side of Equation 3 is still the loss over both the general- and in-domain translation tasks, but the right-hand side is based only on in-domain data. All information from the general-domain data has been collapsed into the second term, which is in the form of a regularizer.

4 Experiments

Our general-domain training data is the concatenation of the parallel portions of the WMT17 news translation task (Bojar et al., 2017) and OpenSubtitles18 (Lison et al., 2018) corpora. For De↔En and Ru↔En, we use `newstest2017` and the final 2500 lines of OpenSubtitles as our test set. We use `newstest2016` and the penultimate 2500 lines of OpenSubtitles as the development set. For Zh↔En, we use the final and penultimate 4000 lines of the UN portion of the WMT data and the final and penultimate 2500 lines of OpenSubtitles as our test and development sets, respectively.

We use the World Intellectual Property Organization (WIPO) COPPA-V2 corpus (Junczys-Dowmunt et al., 2016) as our in-domain dataset. The WIPO data consist of parallel sentences from international patent application abstracts. WIPO De↔En data are large enough to train strong in-domain systems (Thompson et al., 2018), so we truncate to 100k lines to simulate a more interesting domain adaptation scenario.

We reserve 3000 lines each for in-domain development and test sets. We apply the Moses tok-

[2] For background, see MacKay (1992).

[3] See Martens (2014) for detailed derivation.

[4] The fact that continued training works is strong evidence that the in-domain translations are *not* independent of the general-domain translations.

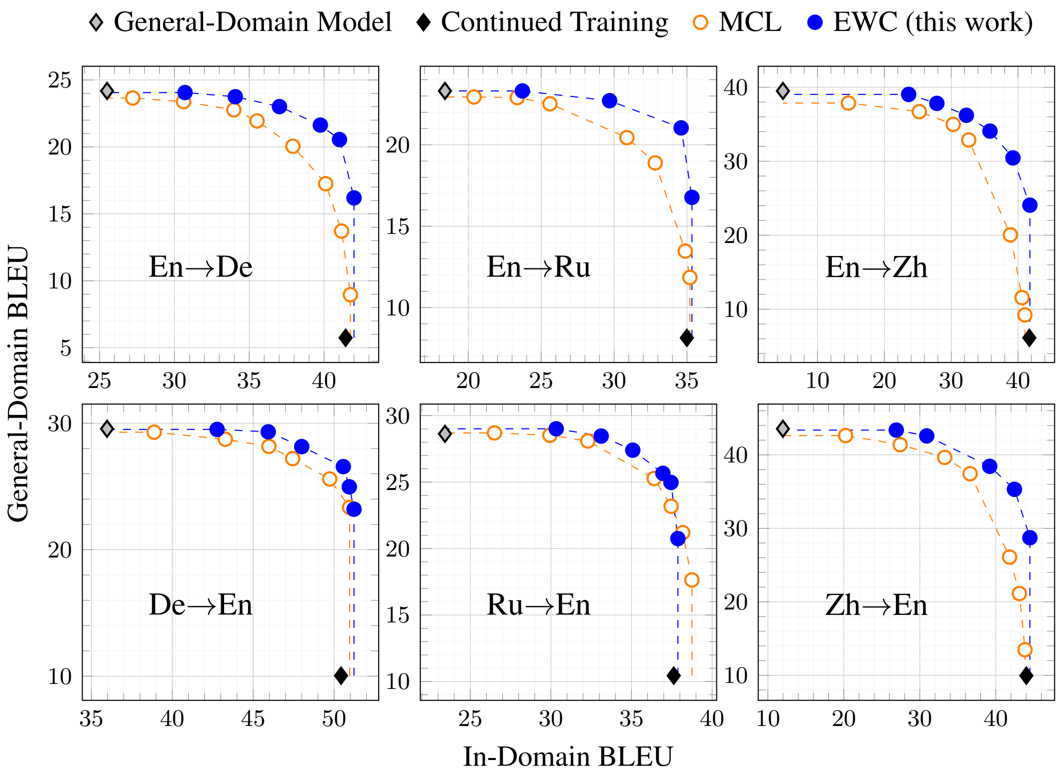

Figure 1: Performance trade-off for MCL and EWC: Convex hull of grid search over learning rate and regularization amount. x-axis is in-domain BLEU and y-axis is general-domain BLEU, so the desired operating point is the top right corner. Initial general-domain model (GD) and continued training (CT) points are shown for comparison.

enizer (Koehn et al., 2007) and byte-pair encoding (BPE) (Sennrich et al., 2016). We train separate BPE models for the source and target languages, each with a vocabulary size of approximately 30k. BPE is trained on the out-of-domain corpus only and then applied to the training, development, and test data for both out-of-domain and in-domain datasets. Token counts for corpora are shown in Table 1.

We implemented[5] both EWC and MCL in Sockeye (Hieber et al., 2017). To avoid floating point issues, we normalize the empirical Fisher diagonal to have a mean value of 1.0 instead of dividing by the number of sentences. For efficiency, we compute gradients for a batch of sentences prior to squaring and accumulating them. Fisher regularization is implemented as weight decay (towards $\hat{\theta}^G$) in Adam (Kingma and Ba, 2014).

Preliminary experiments in Ru→En found no meaningful difference in general-domain or in-domain performance when computing the diagonal of $\bar{F}$ on varying amounts of data ranging from 500k sentences to the full dataset. We also tried computing the diagonal of $\bar{F}$ on held-out data, as there is some evidence that estimating Fisher on held out data reduces overfitting in natural gradient descent (Pascanu and Bengio, 2013). However, we again found no meaningful differences. All results presented herein estimate the the diagonal of $\bar{F}$ on 500k training data sentences, which took less than an hour on a GTX 1080 Ti GPU.

We use a two-layer LSTM network with hidden unit size 512. The general-domain models are trained with a learning rate of 3E-4. We use dropout (0.1) on both RNN inputs and states. We compute lower-cased `multi-bleu.perl`. We use label smoothing (0.1) for all experiments except with MCL, because MCL explicitly regularizes the output distribution.

MCL uses an interpolation of the cross entropy between the output distribution of the model being trained and the general-domain models output distribution (scaled by α) and the standard training loss (scaled by $1-\alpha$). For MCL, we do a grid search over learning rates (10^{-4}, 10^{-5}, 10^{-6}) and α values of (0.1, 0.3, 0.5, 0.7, 0.9). For EWC, we do a grid search over the same learning rates and weight decay values of (10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}).

---

[5] `github.com/thompsonb/sockeye_ewc`

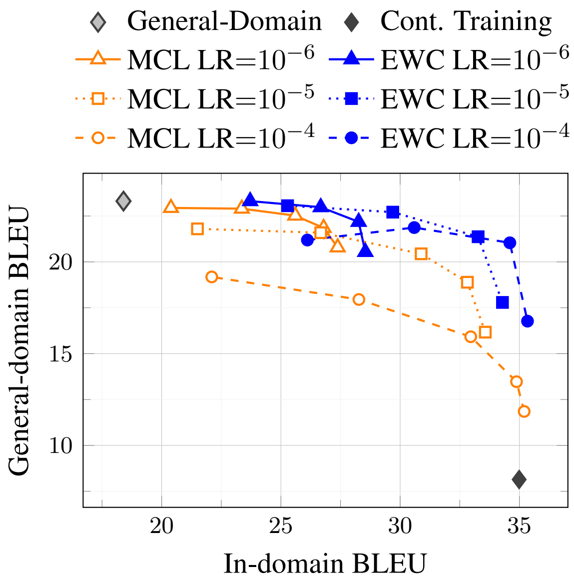

Figure 2: En→Ru results for various learning rates, for both MCL and EWC. Regularization amount increases from left to right for each trace. General-domain and continued training points shown for reference.

5 Results

We present the full in- and general-domain performance trade-off[6] for both EWC and MCL in Figure 1. This is computed by taking the convex hull of a grid search over learning rate and regularization amount for each method. EWC outperforms MCL at all operating points with the exception of Ru→En, where MCL provides a small in-domain performance improvement at lower general-domain performance; this was also observed in Khayrallah et al. (2018).

Figure 2 shows an example result (for En→Ru) of the grid search prior to taking the convex hull. We see similar trends between the three pairs of MCL/EWC curves at corresponding learning rates, but in each case EWC is further up/right, indicating better performance. Note that for both EWC and MCL, both learning rate and regularization amount have a large impact on final in- and general-domain performance.

General-domain gains for *no* in-domain performance degradation are presented in Table 2. Our method provides large general-domain gains (between 8.0 and 18.1 BLEU), regaining the majority of general-domain performance lost in continued training and substantially outperforming MCL.

Langs	GD	CT	MCL	EWC
En→De	24.2	5.7	9.0 (+3.2)	16.2 **(+10.5)**
De→En	29.6	10.0	23.3 (+13.3)	26.6 **(+16.5)**
En→Ru	23.3	8.1	11.8 (+3.7)	16.8 **(+8.6)**
Ru→En	28.6	10.4	21.2 (+10.8)	21.5 **(+11.1)**
En→Zh	39.5	6.1	6.1 (+0.0)	24.1 **(+17.9)**
Zh→En	43.5	9.9	9.9 (+0.0)	28.7 **(+18.8)**

Table 2: General-domain BLEU for: general-domain model prior to adaptation (GD), standard continued training (CT), and best performing MCL and EWC models with *no* in-domain degradation compared to CT (delta from CT). Best improvement over CT bolded.

6 Conclusion

We interpret the general-domain performance drop experienced during continued training as catastrophic forgetting of general-domain knowledge and demonstrate that it can be largely mitigated by applying Elastic Weight Consolidation.

We present the full trade-off for in- and general-domain performance and show that our method outperforms MCL (Dakwale and Monz, 2017) at all operating points in five of six language pairs. Our method is able to regain the majority of the general-domain performance lost during continued training without compromising in-domain performance and without an additional memory or computational burden at translation-time.

Our method retains the advantages of continued training while addressing one of its main shortcomings and can be used in practical situations to avoid poor performance when general-domain input is encountered, even when in-domain performance and translation efficiency are both critical.

Short-Term Meaning Shift: A Distributional Exploration

Marco Del Tredici* **Raquel Fernández*** **Gemma Boleda**†
*University of Amsterdam †Universitat Pompeu Fabra
{m.deltredici|raquel.fernandez}@uva.nl
gemma.boleda@upf.edu

Abstract

We present the first exploration of meaning shift over short periods of time in online communities using distributional representations. We create a small annotated dataset and use it to assess the performance of a standard model for meaning shift detection on short-term meaning shift. We find that the model has problems distinguishing meaning shift from referential phenomena, and propose a measure of contextual variability to remedy this.

1 Introduction

Semantic change has received increasing attention in empirical Computational Linguistics / NLP in the last few years (Tang, 2018; Kutuzov et al., 2018). Almost all studies so far have focused on meaning shift in long periods of time—decades to centuries. However, the genesis of meaning shift and the mechanisms that produce it operate at much shorter time spans, ranging from the online agreement on words' meaning in dyadic interactions (Brennan and Clark, 1996) to the rapid spread of new meanings in relatively small communities of people in (Wenger, 1998; Eckert and McConnell-Ginet, 1992). This paper is, to the best of our knowledge, the first exploration of the latter phenomenon—which we call **short-term meaning shift**—using distributional representations.

More concretely, we focus on meaning shift arising within a period of 8 years, and explore it on data from an online community of speakers, because there the adoption of new meanings happens at a fast pace (Clark, 1996; Hasan, 2009). Indeed, short-term shift is usually hard to observe in standard language, such as the language of books or news, which has been the focus of long-term shift studies (e.g., Hamilton et al., 2016; Kulkarni et al., 2015), since it takes a long time for a new meaning to be widely accepted in the standard language.

Our contribution is twofold. First, we create a small dataset of short-term shift for analysis and evaluation, and qualitatively analyze the types of meaning shift we find.[1] This is necessary because, unlike studies of long-term shift, we cannot rely on material previously gathered by linguists or lexicographers. Second, we test the behavior of a standard distributional model of semantic change when applied to short-term shift. Our results show that this model successfully detects most shifts in our data, but it overgeneralizes. Specifically, the model gets confused with contextual changes due to speakers in the community often talking about particular people and events, which are frequent on short time spans. We propose to use a measure of contextual variability to remedy this and showcase its potential to spot false positives of referential nature like these. We thus make progress in understanding the nature of semantic shift and towards improving computational models thereof.

2 Related Work

Distributional models of semantic change are based on the hypothesis that a change in context of use mirrors a change in meaning. This in turn stems from the Distributional Hypothesis, that states that similarity in meaning results in similarity in context of use (Harris, 1954). Therefore, all models (including ours) spot semantic shift as a change in the word representation in different time periods. Among the most widely used techniques are Latent Semantic Analysis (Sagi et al., 2011; Jatowt and Duh, 2014), Topic Modeling (Wijaya and Yeniterzi, 2011), classic distributional representations based on co-occurence matrices of target words and context terms (Gulordava and Baroni, 2011). More recently, researchers have used

Proceedings of NAACL-HLT 2019, pages 2069–2075
Minneapolis, Minnesota, June 2 - June 7, 2019.

word embeddings computed using the skip-gram model by Mikolov et al. (2013). Since embeddings computed in different semantic spaces are not directly comparable, time related representations are usually made comparable either by aligning different semantic spaces through a transformation matrix (Kulkarni et al., 2015; Azarbonyad et al., 2017; Hamilton et al., 2016) or by initializing the embeddings at t_{i+1} using those computed at t_i (Kim et al., 2014; Del Tredici et al., 2016; Phillips et al., 2017; Szymanski, 2017). We adopt the latter methodology (see Section 3.2).

Unlike most previous work, we focus on the language of online communities. Recent studies of this type of language have investigated the spread of new forms and meanings (Del Tredici and Fernández, 2017, 2018; Stewart and Eisenstein, 2018), competing lexical variants (Rotabi et al., 2017), and the relation between conventions in a community and the social standing of its members (Danescu-Niculescu-Mizil et al., 2013). None of these works has analyzed the ability of a distributional model to capture these phenomena, which is what we do in this paper for short-term meaning shift. Kulkarni et al. (2015) consider meaning shift in short time periods on Twitter data, but without providing an analysis of the observed shift nor systematically assessing the performance of the model, as we do here.

Evaluation of semantic shift is difficult, due to the lack of annotated datasets (Fremann and Lapata, 2016). For this reason, even for long-term shift, evaluation is usually performed by manually inspecting the n words whose representation changes the most according to the model under investigation (Hamilton et al., 2016; Kim et al., 2014). Our dataset allows for a more systematic evaluation and analysis, and enables comparison in future studies.

3 Experimental Setup

3.1 Data

We exploit user-generated language from an online forum of football fans, namely, the r/LiverpoolFC subreddit, one of the many communities hosted by the Reddit platform.[2] Del Tredici and Fernández (2018) showed that this subreddit presents many characteristics that favour the creation and spread of linguistic innovations, such as a topic that reflects a strong external interest and high density of the connections among its users. This makes it a good candidate for our investigation. We focus on a short period of eight years, between 2011 and 2017. In order to enable a clearer observation of short-term meaning shift, we define two non-consecutive time bins: the first one (t_1) contains data from 2011–2013 and the second one (t_2) from 2017.[3] We also use a large sample of community-independent language for the initialization of the word vectors, namely, a random crawl from Reddit in 2013. Table 1 shows the size of each sample.

3.2 Model

We adopt the model proposed by Kim et al. (2014), a representative method for computing diachronic meaning shift.[4] While other methods might be equally suitable (see Section 2), we expect our results not to be method-specific, because they concern general properties of short-term shift, as we show in Sections 4 and 5. In the model by Kim et al. (2014), word embeddings for the first time bin t_1 are initialized randomly; then, given a sequence of time-related samples, embeddings for t_i are initialized using the embeddings of t_{i-1} and further updated. If at t_i the word is used in the same contexts as in t_{i-1}, its embedding will only be marginally updated, whereas a major change in the context of use will lead to a stronger update of the embedding. The model makes embeddings across time bins directly comparable.

We implement the following steps: First, we create randomly initialized word embeddings with the large sample Reddit$_{13}$ to obtain meaning representations that are community-independent. We then use these embeddings to initialize those in LiverpoolFC$_{13}$, update the vectors on this sample, and thus obtain embeddings for time t_1. This step adapts the general embeddings to the LiverpoolFC community. Finally, we initialize the word embeddings for LiverpoolFC$_{17}$ with those of t_1, train on this sample, and get embeddings for t_2.

The vocabulary is defined as the intersection of the vocabularies of the three samples

---

[2] `https://www.reddit.com`. We downloaded Reddit data using the Python package Praw: `https://pypi.python.org/pypi/praw/`.

[3] These choices ensure that the samples in these two time bins are approximately of the same size – see Table 1. The r/LiverpoolFC subreddit exists since 2009, but very little content was produced in 2009–2010.

[4] The model was implemented using the Python package Gensim: `https://pypi.python.org/pypi/gensim/`.

sample	time bin	million tokens
Reddit_{13}	2013	~900
LiverpoolFC_{13}	2011–13	8.5
LiverpoolFC_{17}	2017	11.9

Table 1: Time bin and size of the datasets.

(Reddit_{13}, LiverpoolFC_{13}, LiverpoolFC_{17}), and includes 157k words. For Reddit_{13}, we include only words that occur at least 20 times in the sample, so as to ensure meaningful representations for each word, while for the other two samples we do not use any frequency threshold: Since the embeddings used for the initialization of LiverpoolFC_{13} encode community-independent meanings, if a word doesn't occur in LiverpoolFC_{13} its representation will simply be as in Reddit_{13}, which reflects the idea that if a word is not used in a community, then its meaning is not altered within that community. We train with standard skip-gram parameters (Levy et al., 2015): window 5, learning rate 0.01, embedding dimension 200, hierarchical softmax.

3.3 Evaluation dataset

Our dataset consists of 97 words from the r/LiverpoolFC subreddit with annotations by members of the subreddit —that is, community members with domain knowledge (needed for this task) but no linguistic background.

To ensure that we would get enough cases of semantic shift to enable a meaningful analysis, we started out from content words that increase their relative frequency between t_1 and t_2.[5] A threshold of 2 standard deviations above the mean yielded $\sim$200 words. The first author manually identified 34 semantic shift candidates among these words by analyzing their contexts of use in the r/LiverpoolFC data. Semantic shift is defined here as a change in the ontological type that a word denotes, which takes place when the word starts to be used to denote an entity which is different from the one originally denoted and the new use spreads among the members of a community (see examples in Sec. 4). We added two types of confounders: 33 words with a significant frequency increase but not marked as meaning shift candidates, and 33 words with constant frequency between t_1 and t_2, included as a sanity check. All words have absolute frequency in range [50–500].

The participants were shown the 100 words (in randomized order) together with randomly chosen contexts of usage from each time period (μ=4.7 contexts per word) and, for simplicity, were asked to make a binary decision about whether there was a change in meaning. In order to have the redditors familiarize with the concept of meaning change, we first provide them with an intuitive, non-technical definition, and then a set of cases that exemplify it. The instructions to participants can be found in the project's GitHub repository (see footnote 1).

Semantic shift is arguably a graded notion. In line with a suggestion by Kutuzov et al. (2018) to account for this fact, we aggregate the annotations into a graded *semantic shift index*, ranging from 0 (no shift) to 1 (shift) depending on how many subjects spotted semantic change. The shift index is exclusively based on the judgments of the redditors, and does not consider the preliminary candidate selection done by us. Overall, 26 members of r/LiverpoolFC participated in the survey, and each word received on average 8.8 judgements. Further details about the dataset are in Appendix A.

4 Types of Meaning Shift

We identify three main types of shift in our data via qualitative analysis of examples with a shift index > 0.5: metonymy, metaphor, and meme.

Metonymy. In metonymic shifts, a highly salient characteristic of an entity is used to refer to it. Among these cases are, for example, *'highlighter'*, which in t_2 occurs in sentences like *'we are playing with the highlighter today'*, or *'what's up with the hate for this kit? This is great, ten times better than the highlighter'*, used to talk about a kit in a colour similar to that of a highlighter pen; or *'lean'*, in *'I hope a lean comes soon!'*, *'Somebody with speed…make a signing…Cuz I need a lean'*, used to talk about hiring players due to new hires typically leaning on a Liverpool symbol when posing for a photo right after signing for the club. Particularly illustrative is the 'F5' example shown in Table 2. While 'F5' is initially used with its common usage of shortcut for refreshing a page (1), it then starts to denote the act of refreshing in order to get the latest news about the possible transfer of a new

---

[5] Frequency increase has been shown to positively correlate with meaning change (Wijaya and Yeniterzi, 2011; Kulkarni et al., 2015); although it is not a necessary condition, it is a reasonable starting point, as a random selection of words would contain very few positive examples. Our dataset is thus biased towards precision over recall.

(1)	*Damn, after losing the F5 key on my keyboard [...]*	16 Jun
(2)	*[he is] so close, F5 tapping is so intense right now*	18 Jun
(3)	*Don't think about it too much, man. Just F5*	1 Jul
(4)	*Literally 4am I slept and just woke up and thought it was f5 time*	3 Jul
(5)	*this was a happy f5*	3 Jul
(6)	*what is an F5?*	3 Jul
(7)	*I'm leaving the f5 squad for now*	5 Jul
(8)	*I made this during the f5 madness*	6 Sep

Table 2: Examples of use of 'F5' with time stamps, which illustrate the speed of the meaning shift process. All the examples are from LiverpoolFC$_{17}$.

player to LiverpoolFC (2). This use catches on and many redditors use it to express their tension while waiting for good news (3-5),[6] though not all members are aware of the new meaning of the word (6). When the transfer is almost done, someone leaves the *'F5 squad'* (7), and after a while, another member recalls the period in which the word was used (8).

Metaphor. Metaphorical shifts lead to a broadening of the original meaning of a word through analogy. For example, in t_2 *'shovel'* occurs in sentences such as *'welcome aboard, here is your shovel'* or *'you boys know how to shovel coal'*: the team is seen as a train that is running through the season, and every supporter is asked to figuratively contribute by shoving coal into the train boiler.

Meme. Finally, memes are another prominent source of meaning shift. In this case, fans use a word to make jokes and be sarcastic, and the new usage quickly spreads within the community. As an example, while Liverpool was about to sign a new player named Van Dijk, redditors started to play with the homography of the first part of the surname with the common noun 'van', its plural form 'vans', and the shoes brand 'Vans': '*Rumour has it Van Djik was wearing these vans in the van*' or '*How many vans could Van Dijk vear if Van Dijk could vear vans*'. Jokes of this kind are positively received in the community ('*Hahah I love it. Anything with vans is instant karma!*') and quickly become frequent in it.

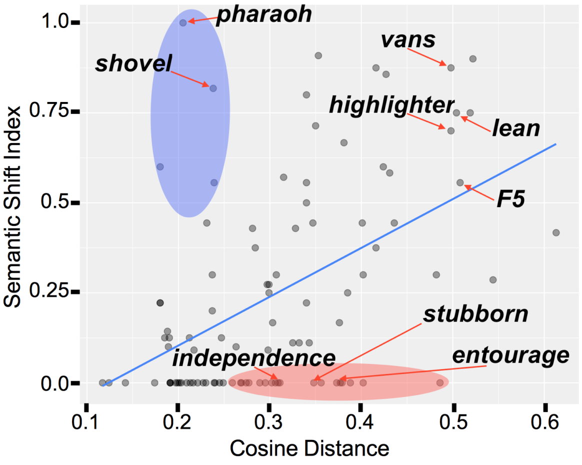

Figure 1: Semantic shift index vs. cosine distance in the evaluation dataset (Pearson's $r = 0.49$, $p < 0.001$). Red horizontal ellipsis: false positives; blue vertical ellipsis: false negatives.

5 Modeling Results and Analysis

The positive correlation between cosine distance and semantic shift index (Pearson's r= 0.49, $p < 0.001$, see Figure 1) confirms the hypothesis that meaning shift is mirrored by a change in context of use. However, we also find systematic deviations.

5.1 False negatives

A small, but consistent group is that of words that undergo semantic shift but are not captured by the model (blue vertical ellipsis Figure 1; shift index>0.5, cosine distance<0.25). These are all metaphorical shifts; in particular, cases of extended metaphor (Werth, 1994), where the metaphor is developed throughout the whole text. For instance, besides the *'shovel'* example mentioned in Section 4, we find *'pharaoh'*, the nickname of an Egyptian player who joined Liverpool in 2017, used in sentences like *'approved by our new Pharaoh Tutankhamun'*, or *'our dear Egyptian Pharaoh, let's hope he becomes a God'*. Despite the metaphoric usage, the local context of these words is similar to the literal one, and so the model does not spot the meaning shift. We expect this to happen in long-term shift models, too, but we are not aware of results confirming this.

5.2 False positives

A larger group of problematic cases is that of words that do *not* undergo semantic shift despite showing relatively large differences in context between t_1 and t_2 (red horizontal ellipsis in Figure 1; shift index=0, cosine distance>0.25). Manual in-

---

[6] Here the semantic change is accompanied by a change in the part of speech, and 'F5' becomes a denominal verb.

spection reveals that most of these "errors" are due to a referential effect: words are used almost exclusively to refer to a specific person or event in t_2, and so the context of use is different from the contexts in t_1. For instance, *'stubborn'* is almost always used to talk about a coach who was not there in 2013 but only in 2017; *'entourage'*, for the entourage of a particular star of the team; *'independence'* for the political events in Catalonia (Spain). In all these cases, the meaning of the word stays the same, despite the change in context. In line with the Distributional Hypothesis, the model spots the context change, but it is not sensitive to its nature. We expect long-term shift to not be as susceptible to referential effects like these because embeddings are aggregated over a larger and more varied number of occurrences.

We expect that in referential cases the contexts of use will be *narrower* than for words with actual semantic shift, as they are specific to one person or event. Hence, a measure of *contextual variability* should help spot false positives. To test this hypothesis, we define contextual variability as follows: For a target word, we create a vector for each of its contexts (5 words on both sides of the target) in t_2 by averaging the embeddings of the words occurring in it, and define variability as the average pairwise cosine distance between context vectors.[7] We find that contextual variability is indeed significantly correlated with semantic shift in our dataset (Pearson's $r = 0.55$, $p < 0.001$), while it is independent from cosine distance (Pearson's $r = 0.18$, $p > 0.05$). These two aspects are thus complementary. While both shift words and referential cases change context of use in t_2, context variability captures the fact that only in referential cases words occur in a restricted set of contexts. Figure 2 shows this effect visually. This result can inform future models of short-term meaning shift.

6 Conclusion

The goal of this initial study was to bring to the attention of the NLP community **short-term meaning shift**, an under-studied problem in the field. Our hope is that it will spark further research into a phenomenon which, besides being of theoretical interest, has potential practical implications for NLP downstream tasks concerned with user-generated language, as modeling how word meanings rapidly change in communities would allow a better understanding of what their members say. Future research should experiment with other datasets (reddits from other domains, other online communities) and also alternative models that address the challenges described here.

A Further Details on Evaluation Dataset

For our experiment, we considered content words only, which we identified by using the external list of common words available at `https://www.wordfrequency.info/free.asp`.

Three words were discarded from the initial list after analysis of the redditor data: 'discord' and 'owls' due to the homonymy with proper names not detected during survey's implementation; 'tracking' because the chosen examples clearly mislead the judgements of the redditors.

As detailed in Section 3.3, 26 members of r/LiverpoolFC participated in the survey, and each word received on average 8.8 judgements. We computed inter-annotator agreement as Krippendorff's alpha, and obtained $\alpha = 0.58$, a relatively low value but common in semantic tasks (Artstein and Poesio, 2008).

The results of the annotation validate our initial word sampling procedure:

- the words that present a significant increase in frequency and were annotated as meaning shift by us received an average shift annotation of 0.72 (± 0.15);
- the words that present a significant increase in frequency but that were *not* annotated as meaning shift by us received an average shift annotation of 0.15 (± 0.16);
- the words that keep a constant frequency between t_1 and t_2, and we don't consider examples of meaning shift, got 0.07 (± 0.12).

Detecting Derogatory Compounds – An Unsupervised Approach

Abstract

We examine the new task of detecting derogatory compounds (e.g. *curry muncher*). Derogatory compounds are much more difficult to detect than derogatory unigrams (e.g. *idiot*) since they are more sparsely represented in lexical resources previously found effective for this task (e.g. Wiktionary). We propose an unsupervised classification approach that incorporates linguistic properties of compounds. It mostly depends on a simple distributional representation. We compare our approach against previously established methods proposed for extracting derogatory unigrams.

1 Introduction

Abusive or offensive language is commonly defined as hurtful, derogatory or obscene utterances made by one person to another person.[1] Examples are (1)-(3). In the literature, closely related terms include *hate speech* (Waseem and Hovy, 2016) or *cyber bullying* (Zhong et al., 2016). While there may be nuanced differences in meaning, they are all compatible with the general definition above.

(1) stop editing this, you **dumbass**.
(2) Just want to slap the **stupid** out of these **bimbos**!!!
(3) Go lick a pig you arab muslim piece of **scum**.

Due to the rise of user-generated web content, in particular on social media networks, the amount of abusive language is also steadily growing. NLP methods are required to focus human review efforts towards the most relevant microposts.

A substantial amount of abusive utterances comprises derogatory words (e.g. *bimbo* or *scum*). Automatic extraction methods of such words are required since new derogatory words constantly enter language. Wiegand et al. (2018a) extracted a large list of such expressions and demonstrated its importance for text classification.

In this work, we focus on a subtype of derogatory terms, namely derogatory compounds (e.g. *booze hound*, *curry muncher*, *fault finder*). Distinguishing such multi-word expressions from non-derogatory ones (e.g. *fox hound*, *mile muncher*, *branch finder*) is more difficult than classifying unigrams since they are only sparsely represented in general-purpose lexical resources which have previously been found an effective source from which to learn abusive language, such as Wiktionary.[2] For example, while 97% of the derogatory unigrams of the gold standard lexicon in Wiegand et al. (2018a) are contained in Wiktionary, less than 17% of the derogatory compounds used as our gold standard in this work can be found.

Despite their sparsity in lexical resources derogatory compounds are a frequent phenomenon, particularly in German data, which is why we study this task on that language. On the German benchmark corpus for abusive language detection, the *GermEval corpus* (Wiegand et al., 2018b), we found that of the abusive microposts in the test set that include at least one derogatory expression, 39% contain a derogatory compound.

In our work, we focus on noun-noun compounds. Each compound (e.g. *curry muncher*) comprises two constituents, a modifier (i.e. *curry*) and a head (i.e. *muncher*). On the GermEval corpus, 77% of the derogatory compounds are noun-noun compounds. We only consider compounds whose constituents are <u>not</u> derogatory. 58% of the derogatory compounds on the GermEval corpus fall under this category. Given publicly available lists of derogatory unigrams, the detection of derogatory compounds containing derogatory constituents (e.g. *mother<u>fucker</u>*) is rather trivial.

Proceedings of NAACL-HLT 2019, pages 2076–2081
Minneapolis, Minnesota, June 2 - June 7, 2019.

There even exist abusive word generators employing such compounds.[3]

We present the first study to detect derogatory noun-noun compounds and propose an unsupervised classification approach based on distributional information that does not require any properly labeled training data. We demonstrate that linguistic features that have previously been found effective for the classification of derogatory unigrams are notably less effective for the detection of derogatory compounds. We created a new dataset of derogatory compounds which will be made **publicly available**.[4]

Our task is framed as a **binary classification problem**. Each given compound is to be classified out of context as either derogatory or not. For the sake of accessibility, we use English translations of our German compounds in this paper.

2 Related Work

Lexical knowledge for the detection of abusive language has only received little attention in previous work (Schmidt and Wiegand, 2017), the notable exceptions are Razavi et al. (2010) who present a manually-compiled lexicon, Gitari et al. (2015) who bootstrap *hate verbs* and Wiegand et al. (2018a) who induce a lexicon of derogatory words. In all these researches, however, derogatory compounds are not explicitly addressed.

3 Data

We built a **gold standard of derogatory compounds** to train and test classifiers. We inspected a range of websites containing derogatory word lists.[5] Since ambiguity is a massive problem in these lists[6] which makes them hardly usable for abusive language detection (Wiegand et al., 2018a), we manually extracted noun-noun compounds which we considered **unambiguously** derogatory. In order to produce non-derogatory compounds, we randomly sampled from the COW16 corpus (Schäfer, 2015) for each derogatory compound (e.g. *booze hound*) other compounds sharing the same head (e.g. *fox hound*, *stag hound*). Since among those putative non-derogatory instances, there could well be further derogatory compounds, we manually annotated them as well. We limited the set of compounds sharing the same head, which we henceforth call **head group**, to 20 compounds. Thus, we hope to avoid any biases towards particular heads.

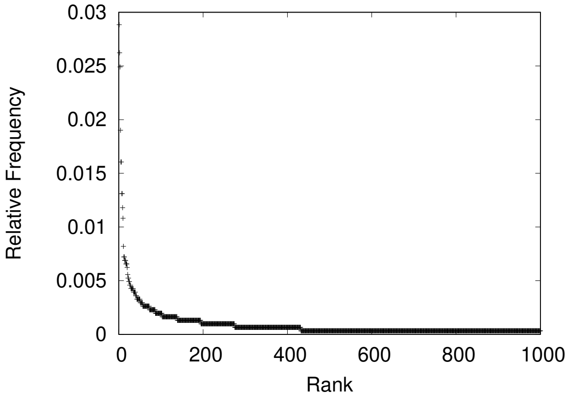

Figure 1: Head distribution of derogatory compounds.

Property	Freq
total compounds	3500
derogatory compounds	382
head groups (*each group contains 20 compounds*)	175
average no. of derogatory compounds in head group	2.2

Table 1: Some statistics of the gold standard.

We also looked at the natural distribution of heads on derogatory compounds. As a proxy we considered the union of all derogatory compounds found on the above websites.[5] Figure 1 plots the frequency rank of the heads against the relative frequency of a particular head. The plot suggests that the heads follow a power-law distribution (Zipf, 1965). As a consequence, one cannot assume that this task could be solved by looking up heads in a finite lexicon with words that often form derogatory compounds in combination with different modifiers.

On a sample of 600 compounds, we measured a substantial agreement of Cohen's $\kappa = 0.61$ (Landis and Koch, 1977) between 2 annotators. Our final dataset (Table 1) comprises 3,500 compounds with only 11% being derogatory.

We also created a **gold standard of derogatory unigram words** in order to examine in how far derogatory compounds can be detected by a classifier trained on derogatory unigrams. For this lexicon, we manually translated the *base lexicon* from Wiegand et al. (2018a) to German.

[6] These lists contain many compounds commonly used in a non-offensive manner, e.g. *Colatrinker (coke drinker)*.

4 Method

Our method does not require any labeled training data. In the first step (§4.1), we apply high-precision diagnostics for the detection of derogatory compounds. The output are rankings in which derogatory compounds should be ranked highest. In the second step (§4.2), we combine and re-rank the output of those diagnostics. Our method largely relies on a distributional representation of our compounds. We induced embeddings of our compounds using Word2Vec (Mikolov et al., 2013) on the COW16 corpus, which with its 30B tokens is one of the largest German corpora. Since we exclusively work on German data and German compounds occur as closed compounds, e.g. *Milchbube (milk sop)* or *Schnapsdrossel (booze hound)*, we can employ standard tokenization[7] for inducing embeddings for our compounds.

4.1 Individual High-Precision Diagnostics

Negative Polarity (NEG). Derogatory words form a subset of negative polar expressions. Due to their sparsity, however, derogatory compounds are rarely part of any sentiment lexicon (containing polar expressions). We, therefore, rank all our compounds according to their cosine similarity to a centroid embedding-vector computed from all negative polar expressions from the German PolArt sentiment lexicon (Klenner et al., 2009).

Compound Occurrence vs. Constituent Occurrence (COMCON). Derogatory compounds can be creative word constructions (e.g. *booze hound*, *oxygen thief*, *keyboard warrior*). Consequently, their constituents are often not semantically related. For instance, in *booze hound*, *booze* bears no common semantic relation to *hound*. Therefore, the corpus frequency of a derogatory compound should be much higher than its constituents co-occurring in a sentence (i.e. with other words occurring in between). Such co-occurrences should be coincidental.

We capture this by the following formula (frequencies are computed on the COW16 corpus):

$$COMCON = \frac{\text{\# compound mentions in corpus}}{\text{\# constituents co-occurring in sentence}} \tag{1}$$

In prose, COMCON ranks all compounds by the ratio of observed compound mentions and constituent co-occurrences in a sentence. For derogatory compounds, there should be a high frequency of compound mentions but only a low frequency of the constituents co-occurring in a sentence. Therefore, COMCON will have a high score. While there is a similarly high frequency of compound mentions for non-derogatory compounds, there is also a high frequency of the constituents co-occurring in a sentence since these constituents are usually semantically related (e.g. *landowner* or *circus clown*). This should result in COMCON producing comparably lower scores.

Derogatory Compound Must Be Person (PERSON). We rank our compounds with regard to how likely they represent a person since many non-derogatory compounds represent either objects or animals (e.g. *booze hound* vs. *sight hound*, *fox hound*, *stag hound*). We first compute a centroid vector representing persons. Then, we rank compounds by their similarity to that vector.

As a proxy for persons, we took embeddings of words representing professions, e.g. *banker*, *lawyer*, *salesman*. We also experimented with personal pronouns as a proxy for persons. However, we found them unsuitable since they are also often used as referring expressions to other entities, such as animals. Professions, on the other hand, can only refer to humans. The list of professions we used was created ad-hoc. It should be reproducible in any arbitrary language. *The full list is included in the supplementary notes.*[4]

Outlier Compound(s) in Head Group (OUT). In most head groups, derogatory compounds represent a clear minority with only 1 or 2 compounds. The derogatory compounds are also often semantically different from the non-derogatory compounds (*keyboard warrior* vs. *rajput warrior*, *ninja warrior*, *samurai warrior*). This is particularly true if the non-derogatory compounds are very homogeneous. From that observation we derive a diagnostic in which we determine the semantic outlier(s) for each head group. First, we compute for each compound the average pairwise similarity to all other compounds within its head group. The resulting score of a compound (converted to a <u>dis</u>similarity score by taking its inverse) is then multiplied by a weight representing the homogeneity of all compounds within that head group.[8] (*Pseudocode is provided in the supplementary notes.*[4]) This is done since for head

---

[7] Any alphanumeric string separated by spaces is considered a token.

[8] The homogeneity weight is the average pairwise similarity of all compounds belonging to the same head group.

groups that are heterogeneous (e.g. ***legacy hunter***, *job hunter*, *autograph hunter*), there are less obvious outliers.

4.2 Combination and Reranking

Combination (COMB). Negative polarity is a pre-requisite for being derogatory (Sood et al., 2012; Dinakar et al., 2012; Gitari et al., 2015). Therefore, we base our combination on the ranking of NEG. From that ranking we remove all those compounds which have not co-occurred at the high ranks of at least one of the other diagnostics (COMCON, OUT, PERSON).[9] Compounds that are highly ranked by several diagnostics should more likely represent derogatory compounds.

Re-Ranking by PageRank (PRANK). We observed that among the top ranks of COMB, the derogatory compounds are semantically similar (e.g. *dwarf tosser*, *mischief maker*, *slimeball*) while the non-derogatory compounds are semantically different from each other (e.g. *biker club*, *spirit bear*). Therefore, we run personalized PageRank (Agirre and Soroa, 2009) to further improve the ranking by enforcing the compounds on the high ranks to be distributionally similar. We build a word-similarity graph where our compounds are nodes and edges encode cosine-similarities of their embeddings. PageRank then produces a ranking of nodes where the highest ranked nodes are the ones most highly connected. In personalized PageRank prior information is added. A biased graph is constructed in which attention is drawn towards particular regions of interest. This is achieved by assigning re-entrance weights to the individual nodes. As prior information, we set the nodes representing the compounds returned by COMB with a uniform re-entrance weight (α)[10] while all other nodes receive a weight of 0.

Label Propagation (LP). While previous diagnostics were designed to isolate a few derogatory compounds with a high precision, LP aims for increasing recall. We define some high-precision seeds for the two categories of our task and then propagate the labels to the unlabeled compounds by using label propagation (Talukdar et al., 2008). The algorithm operates on the same word-similarity graph that we used for PRANK. We define highly ranked compounds from PRANK as derogatory seeds and lowly ranked compounds as non-derogatory seeds. Unlike the previous diagnostics, the output of LP is a binary categorization rather than a ranking. In order to make this output comparable to the other diagnostics, we converted the output of LP to a ranking. This is achieved by ranking the compounds predicted as derogatory according to the confidence score provided by the classifier.

5 Experiments

Table 2 shows the precision at rank n (P@n) of different rankings as measured on our compound gold standard. For LP, we consider the top 50 compounds from PRANK as derogatory seeds and the bottom 500 as non-derogatory seeds.[11] As a baseline we add a randomized ranking (RAND).

PRANK produces a very high precision on the high ranks, outperforming the individual rankings and COMB. We also tested a modification, PRANK$_{NEG}$, which applies personalized PageRank on the output of NEG, which is the strongest individual ranking. Since PRANK outperforms PRANK$_{NEG}$, we conclude that the high precision of PRANK also depends on the combination of the individual rankings. LP manages to notably raise scores on the lower ranks (e.g. P@300) which proves the advantage of LP over PRANK.

Table 3 compares our proposed method (LP) against supervised classifiers. We evaluate the entire classification output (with F1-measure) rather than a ranking. The classifiers are trained on our unigram or compound gold standard (§3). For the latter case, we conducted 10-fold crossvalidation. 500 of the 3500 compounds were reserved as a development set on which we tuned hyperparameters of the supervised classifiers. (*The supplementary notes*[4] *contain more details.*) As features we consider word embeddings and the linguistic features from Wiegand et al. (2018a). They are based on knowledge that is expensive to produce, such as sentiment views, polar intensity, or information from Wiktionary.[12]

Table 3 shows that learning from the compound gold standard is more effective than learning from the existing unigram gold standard. Given the

---

[9] We took top 350 from all these rankings which resembles the number of derogatory compounds on our dataset.

[10] Following Manning et al. (2008), we set $\alpha = 0.1$.

[11] The ratio of derogatory and non-derogatory compounds should vaguely reflect the class distribution.

[12] The method WSUP from Wiegand et al. (2018a) was not considered because of its poor performance on compounds.

Table 4: Comparison of compositional approaches.

strong performance of embeddings, we also examined the performance of (publicly available) off-the-shelf embeddings[13] and found that the high classification scores can be mainly ascribed to the large corpus on which we induced our embeddings (i.e. COW16).

Our unsupervised approach (LP) is almost on a par with the most complex SVM. This is particularly appealing since we produced that classifier without manually labeled training data and those manually-created resources required for the linguistic features.

Compound embeddings are the most predictive information for our task, but even from the large COW16 corpus, we only obtained embeddings for 60% of our compounds.[14] In Table 4, we evaluate compositional information, which can also be used for compounds that lack an embedding. We apply an SVM with the best previous feature set (of which embeddings are the main contributor) on the constituents of the compounds. Moreover, we train an LSTM on the sequence of characters of the compound. Table 4 shows that information drawn from units other than the compound itself is less effective. The feature combination of head, modifier and compound is not effective either.

Instead of applying embeddings on constituents and concatenating them, we also examine a sophisticated compositional model (*Wmask*) based on a masking process that takes into account the variation of a constituent depending on whether it is a head or a modifier (Dima, 2015). Table 5 shows the performance of the two best previous classifiers where compounds lacking an embedding are represented by an embedding approximated by Wmask (rather than a dummy vector). The table shows that the two classifiers can be improved by adding the approximated embeddings.

Classifier	SVM (embed.+ling.)		LP

6 Conclusion

We examined the new task of detecting derogatory compounds and proposed an unsupervised approach incorporating linguistic properties of compounds that mostly depend on a distributional representation. Our method outperforms linguistic features previously shown to be effective for the detection of derogatory unigrams and it is on a par with a far more expensive state-of-the-art supervised approach. Features defined on the constituents of a compound and training a classifier on derogatory unigrams are far less effective.

Acknowledgements

Personalized Neural Embeddings for Collaborative Filtering with Text

Guangneng Hu
Department of Computer Science and Engineering
Hong Kong University of Science and Technology, Hong Kong, China
`njuhgn@gmail.com`

Abstract

Collaborative filtering (CF) is a core technique for recommender systems. Traditional CF approaches exploit user-item relations (e.g., clicks, likes, and views) only and hence they suffer from the data sparsity issue. Items are usually associated with unstructured text such as article abstracts and product reviews. We develop a Personalized Neural Embedding (PNE) framework to exploit both interactions and words seamlessly. We learn such embeddings of users, items, and words jointly, and predict user preferences on items based on these learned representations. PNE estimates the probability that a user will like an item by two terms—behavior factors and semantic factors. On two real-world datasets, PNE shows better performance than four state-of-the-art baselines in terms of three metrics. We also show that PNE learns meaningful word embeddings by visualization.

1 Introduction

Recommender systems are widely used in e-commerce platforms, such as to help consumers buy products at Amazon, watch videos on Youtube, and read articles on Google News. They are useful to alleviate the information overload and improve user satisfaction. Given history records of consumers such as the product transactions and movie watching, collaborative filtering (CF) is among the most effective approaches based on the simple intuition that if users rated items similarly in the past then they are likely to rate items similarly in the future (Sarwar et al., 2001).

History records include both implicit (e.g., purchase and clicks) and explicit (e.g., likes/dislikes and ratings) feedback which can be represented as a user-item interaction matrix. Typically, observed user-item interactions are incomplete with a large portion remaining not recorded. The goal of recommendation is to predict user preferences on these missing interactions. This setting requires to complete the partial observed rating matrix. Matrix Factorization (MF) techniques which can learn latent factors for users and items are the main cornerstone for CF (Mnih and Salakhutdinov, 2008; Koren, 2008; Koren et al., 2009). It is effective and flexible to integrate with additional data sources (Hu et al., 2015). Recently, neural networks like Multilayer Perceptron (MLP) are used to learn an interaction function from data with the power of learning highly nonlinear relationships between users and items (Dziugaite and Roy, 2015; Cheng et al., 2016; He et al., 2017; Hu et al., 2018b). MF and neural CF exploit user-item behavior interactions only and hence they both suffer from the data sparsity and cold-start issues.

Items are usually associated with unstructured text, like news articles and product reviews. These additional sources are essential for recommendation beyond user-item interactions since they contain independent and diverse information. Hence, they provide an opportunity to alleviate the data sparsity issue (Ganu et al., 2009; Hu et al., 2018a). For application domains like recommending research papers and news articles, the unstructured text associated with the item is its text content (Wang and Blei, 2011; Wang et al., 2015; Bansal et al., 2016). For some domains like recommending products, the unstructured text associated with the item is its user reviews which justify the rating behavior (McAuley and Leskovec, 2013; He and McAuley, 2016). These methods adopt topic modelling techniques and neural networks to exploit the item content leading to performance improvement.

A typical way of exploiting text content is to firstly extract a feature vector for each document by averaging word embeddings in the document, and then to learn a text factor corresponding to this feature vector (Hu and Dai, 2017). These embed-

Proceedings of NAACL-HLT 2019, pages 2082–2088
Minneapolis, Minnesota, June 2 - June 7, 2019.

dings are pre-trained from a large corpus such as Wikipedia. This approach separates the extraction of text feature from the learning of user-item interaction. These two processes cannot benefit from each other and errors in the previous step maybe propagate to the successive steps. Another way is to learn a topic vector using topic modelling (Wang and Blei, 2011; McAuley and Leskovec, 2013; Bao et al., 2014) by aligning behavior factors and topic factors with a link function such as softmax and offset.

Recently, neural networks are used to learn a representation from the text using autoencoders (Wang et al., 2015; Zhang et al., 2016), recurrent networks (Bansal et al., 2016), and convolutional networks (Zheng et al., 2017; Catherine and Cohen, 2017). These methods treat different words in the document as equal importance and do not match word semantics with the specific user. Instead, we achieve to learn a personalized word embedding with the guidance of user-item interactions. That is, the importance of words is learned to match user preferences. The attention mechanism can be used to learn these importance weights. Memory Networks (MemNet) have been used in recommendation to model item content (Hu et al., 2018c; Huang et al., 2017), capture user neighborhood (Ebesu et al., 2018), and learn latent relationships (Tay et al., 2018). We follow this thread to adapt a MemNet to match word semantics with user preferences.

In this paper, we propose a novel neural framework to exploit relational interactions and text content seamlessly. The proposed Personalized Neural Embedding (PNE) model fuses semantic representations learnt from unstructured text with behavior representations learnt from user-item interactions jointly for effective estimation of user preferences on items. PNE estimates the preference probability by two kinds of factors. The *behavior factor* is to capture the personalized preference of a user to an item learned from behavior interactions. The *semantic factor* is to capture the high-level representation attentively extracted from the unstructured text by matching word semantics with user preferences.

To model the behavior factor, we adopt a neural CF approach, which learns the user-item nonlinear interaction relationships using a neural network (CFNet). To model the semantic factor, we adopt a memory network to match word semantics with the specific user via the attention mechanism inherent in the memory module (MemNet), determining which words are highly relevant to the user preferences. PNE integrates relational interactions with unstructured text by bridging neural CF and memory networks. PNE can also learn meaningful word embeddings.

2 Approach

We present PNE to jointly learn representations of users, items, and words. PNE seamlessly captures nonlinear user-item interaction relationships and matches word semantics with user preferences.

Denote the set of users by $\mathcal{U}$ and items by $\mathcal{I}$. We use a rating matrix $\boldsymbol{Y} \in \mathbb{R}^{|\mathcal{U}| \times |\mathcal{I}|}$ to describe user-item interactions where each entry $y_{ui} \in \{0, 1\}$ is 1 (observed entries) if user u has an interaction with item i and 0 (unobserved entries) otherwise. Usually the interaction matrix is very sparse since a user $u \in \mathcal{U}$ only consumed a very small subset of all items. For the task of item recommendation, each user is only interested in identifying $topK$ items (typically K is small e.g. tens or hundreds). Items are ranked by their predicted scores:

$$\hat{y}_{ui} = f(u, i|\Theta), \tag{1}$$

where f is an interaction function and Θ denotes model parameters.

2.1 Architecture

PNE consists of a CF network (CFNet) to learn a nonlinear interaction function and of a memory network (MemNet) to match word semantics with user preferences. The information flow in PNE goes from the input (u, i) to the output $\hat{y}_{ui}$ through the following five modules.

1. *Input:* $(u, i) \rightarrow (\vec{e}_u, \vec{e}_i)$ This module encodes user-item interaction indices. We adopt the one-hot encoding. It takes user u and item i, and maps them into one-hot encodings $\vec{e}_u \in \{0, 1\}^{|\mathcal{U}|}$ and $\vec{e}_i \in \{0, 1\}^{|\mathcal{I}|}$ where only the element corresponding to that user/item index is 1 and all others are 0.

2. *Embedding:* $(\vec{e}_u, \vec{e}_i) \rightarrow \boldsymbol{x}_{ui}$ This module firstly embeds one-hot encodings into continuous representations $\boldsymbol{x}_u = \boldsymbol{P}^T \vec{e}_u$ and $\boldsymbol{x}_i = \boldsymbol{Q}^T \vec{e}_i$ by embedding matrices $\boldsymbol{P} \in \mathbb{R}^{|\mathcal{U}| \times d}$ and $\boldsymbol{Q} \in \mathbb{R}^{|\mathcal{I}| \times d}$ respectively, where d is the latent dimension. It then concatenates them as $\boldsymbol{x}_{ui} = [\boldsymbol{x}_u, \boldsymbol{x}_i]$ to be the input of following CFNet and MemNet modules.

3. *CFNet:* $\boldsymbol{x}_{ui} \rightarrow z_{ui}^{behavior}$ This module is a CF approach to exploit user-item interactions. It takes continuous representations from the embedding

Dataset	#user	#item	#rating	#word	#density	avg. words
Amazon	8,514	28,262	56,050	1,845,387	0.023%	65.3
Cheetah	15,890	84,802	477,685	612,839	0.035%	7.2

Table 1: Datasets and statistics.

module and then transforms to a final *behavior factor* representation:

$$\boldsymbol{z}_{ui}^{\text{behavior}} = \text{ReLU}(\boldsymbol{W}\boldsymbol{x}_{ui} + \boldsymbol{b}), \tag{2}$$

where $\text{ReLU}(x) = \max(0, x)$ is an activation function, and $\boldsymbol{W}$ and $\boldsymbol{b}$ are connection weights and biases.

4. *MemNet:* $\boldsymbol{x}_{ui} \to \boldsymbol{z}_{ui}^{semantic}$ This module is to model the item content with the guidance of user-item interaction. The item content is modelled by memories. It takes representations from both the embedding module and the review text d_{ui} associated with the corresponding user-item (u, i) into a final *semantic factor* representation:

$$\boldsymbol{z}_{ui}^{\text{semantic}} = \sum\nolimits_{j:\, w_j \in d_{ui}} \text{Softmax}(a_j^{u,i})\boldsymbol{c}_j, \tag{3}$$

where the external memory slot $\boldsymbol{c}_j$ is an embedding vector for word w_j by mapping it with an external memory matrix $\boldsymbol{C}$. The attentive weight $a_j^{u,i}$ encodes the relevance of user u to word w_j by content-based addressing:

$$a_j^{u,i} = \boldsymbol{x}_{ui}^T \boldsymbol{m}_j^{u,i}, \tag{4}$$

where memory $\boldsymbol{m}_j^{u,i}$ is concatenated from internal memory slots $\{\boldsymbol{m}_j^u, \boldsymbol{m}_j^i\}$ which are mapped from word w_j by internal memory matrices $\boldsymbol{A}^u$ for user attention and $\boldsymbol{A}^i$ for item attention.

5. *Output:* $\boldsymbol{z}_{ui} \to \hat{y}_{ui}$ This module predicts the recommendation score $\hat{y}_{ui}$ for a given user-item pair based on the representation of both behavior factor and semantic factor from CFNet and MemNet respectively: $\boldsymbol{z}_{ui} = [\boldsymbol{z}_{ui}^{\text{behavior}}, \boldsymbol{z}_{ui}^{\text{semantic}}]$. The output is the probability that the input pair is a positive interaction. This is achieved by a logistic layer:

$$\hat{y}_{ui} = \frac{1}{1 + \exp(-\boldsymbol{h}^T \boldsymbol{z}_{ui})}, \tag{5}$$

where $\boldsymbol{h}$ is model parameter.

2.2 Learning

We adopt the binary cross-entropy loss:

$$\mathcal{L}(\Theta) = -\sum_{(u,i)\in\mathcal{S}} y_{ui} \log \hat{y}_{ui} + (1 - y_{ui}) \log(1 - \hat{y}_{ui}), \tag{6}$$

where $\mathcal{S} = \boldsymbol{Y}^+ \cup \boldsymbol{Y}^-$ is the union of observed interactions and randomly sampled negative examples. Model parameters $\Theta = \{\boldsymbol{P}, \boldsymbol{Q}, \boldsymbol{W}, \boldsymbol{b}, \boldsymbol{A}, \boldsymbol{h}\}$ where we use a single word embedding matrix $\boldsymbol{A}$ by sharing all memory matrices $\boldsymbol{A}^u$, $\boldsymbol{A}^i$, and $\boldsymbol{C}$ in order to reduce model complexity. The objective function can be optimized by stochastic gradient descent.

Baselines	Shallow method	Deep method
CF	BPR	MLP
CF w/ text	HFT, TBPR	LCMR, PNE (ours)

Table 2: Categorization of recommender approaches.

3 Experiment

In this section, we evaluate PNE on two datasets with five baselines in terms of three metrics.

3.1 Datasets

We evaluate on two real-world datasets. The public **Amazon** products (McAuley and Leskovec, 2013) and a company **Cheetah** Mobile news (Hu et al., 2018c; Liu et al., 2018) (see Table 1). We preprocess the data following the strategy in (Wang and Blei, 2011). The size of word vocabulary is 8,000.

3.2 Evaluation protocol

We adopt leave-one-out evaluation (Hu et al., 2018b) and use three ranking metrics: hit ratio (HR), normalized discounted cumulative gain (NDCG), and mean reciprocal rank (MRR).

We compare with five baselines (see Table 2).

- BPR (Rendle et al., 2009) is a latent factor model based on matrix factorization.
- HFT (McAuley and Leskovec, 2013) adopts topic distributions to learn latent factors from text reviews.
- TBPR (Hu and Dai, 2017) extends BPR by integrating text content via word embedding features. Word embeddings used in TBPR are pre-trained by GloVe (Pennington et al., 2014).

TopK	Metric	Method					
		BPR	HFT	TBPR	MLP	LCMR	PNE

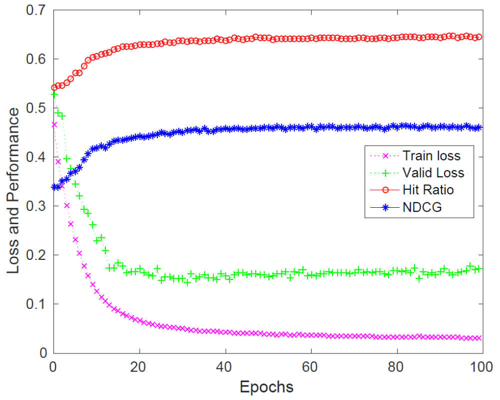

Figure 2: Loss and performance@10.

- MLP (He et al., 2017) is a neural CF approach. Note that, CFNet of PNE is an MLP with only one hidden layer.

- LCMR (Hu et al., 2018c) is a deep model for CF with unstructured text. Note that, MemNet of PNE is the same with the local MemNet of LCMR with only one-hop hidden layer.

Our method is implemented by TensorFlow (Abadi et al., 2016). Parameters are randomly initialized from Gaussian with optimizer Adam (Kingma and Ba, 2015). Learning rate is 0.001, batch size is 128, the ratio of negative sampling is 1.

3.3 Results

Results on two datasets are shown in Table 3 and Table 4, respectively. We have some observations. First, PNE outperforms the neural CF method MLP on two datasets in terms of three ranking metrics. On Amazon dataset, PNE obtains a large improvement in performance gain with relative 12.3% HR@10, 7.7% NDCG@10, and 6.2% MRR@5. On Cheetah Mobile dataset, PNE obtains a large improvement in performance gain with relative 5.0% HR@5, and 4.2% NDCG@5, and 3.9% MRR@5. Since the CFNet component of PNE is a neural CF method (with only one hidden layer), results show the benefit of exploiting unstructured text to alleviate the data sparsity issue faced by CF methods (BPR and MLP).

Second, PNE outperforms the traditional hybrid methods HFT and TBPR on two datasets in terms of three ranking metrics. On Amazon dataset, PNE obtains a significantly large improvement in performance gain with relative 55.0% HR@5, 28.9% NDCG@5, and 20.4% MRR@5. On Cheetah Mobile dataset, PNE still obtains reasonably large improvements with relative 17.5% HR@10, 1.8% NDCG@10, and 1.9% MRR@10. Compared with traditional hybrid methods which integrate the text content using topic modelling or word embeddings, results show the benefit of integrating text information through memory networks (and exploiting the interaction data through neural CF).

Last, PNE outperforms neural hybrid method LCMR by a large margin on Amazon dataset with relative improvements of 16.2% HR@5, 9.6% NDCG, and 7.4% MRR@5. PNE obtains reasonable improvements on Cheetah Mobile dataset with relative improvements of 3.1% HR@5, 2.8% NDCG, and 2.7% MRR. The design of CFNet of PNE is

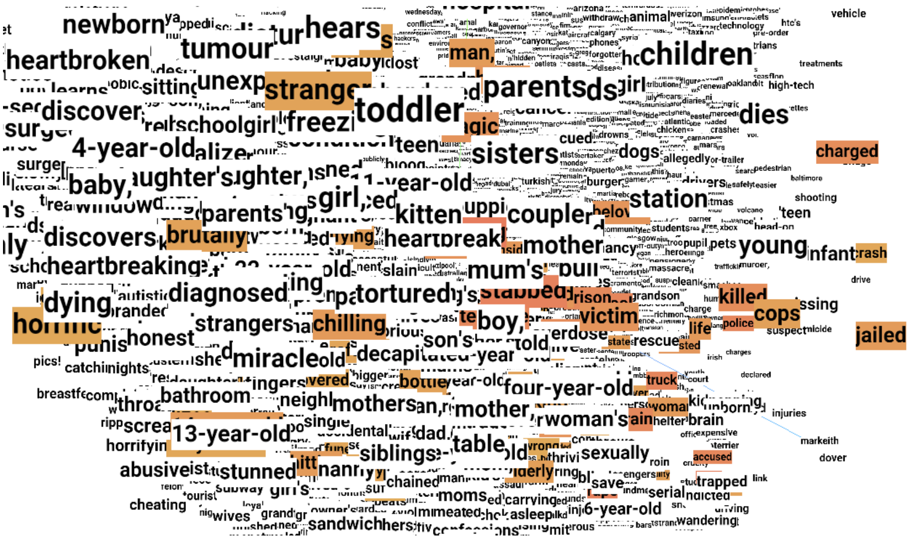

Figure 3: Visualization of word embeddings.

more reasonable than that of centralized memory module of LCMR which is equivalent to use a softmax activation between two hidden layers. The results show the effectiveness of fusing strategy in PNE to exploit unstructured text via MemNet and the interaction data via CFNet.

3.4 Analysis

We first evaluate the effects of the dimensionality of the embedding space. The x-axis in Figure 1 is the dimension of user/item and hence the dimensionality of input to CFNet is double since we adopt concatenation. It clearly indicates that the embedding should not be too small due to the possibility of information loss and the limits of expressiveness. The dimension 75 (and hence $d = 150$) is a good tradeoff between recommendation performance and computation burden.

We next show optimization curves of performance and loss (averaged over all examples) against iterations on Cheetah Mobile dataset in Figure 2. The model learns quickly in the first 20 iterations and improves slowly until 50, while training losses continue to go down and valid losses stabilize. The average time per epoch of PNE takes 68.1s and as a reference it is 34.5s for MLP using one NVIDIA TITAN Xp GPU.

3.5 Visualization

We visualize the learned word embeddings $\boldsymbol{A}$. We show that we can learn meaningful semantics for word embeddings such that words are to cluster when they have relevant semantics. We give an example to show the neighbors of the word “drug” in the 3D space by projecting the high-dimensional word vectors using TensorFlow [1] as shown in Figure 3. The top nearest neighbors of *drug* are: *shot, shoots, gang, murder, killing, rape, stabbed, truck, school, police, teenage*. We can see they are highly semantic relevant. We may also infer that school teenagers have close relationships to the drug issue from the Cheetah News corpus. This should raise a concern for society and it shows the society impact of natural language processing (Hovy and Spruit, 2016). Try our trained word embeddings [2].

4 Conclusion

We showed that relational interactions can be effectively integrated with unstructured text under a neural embedding model. Our method attentively focuses relevant words to match user preferences with user and item attentions (semantic factor) and captures nonlinear relationships between users and items (behavior factor). Experiments show better performance than five baselines on two real-world datasets in terms of three ranking metrics. We learn meaningful word embeddings and rethink the society impact of language processing technology.

Abstract

A growing number of state-of-the-art transfer learning methods employ language models pretrained on large generic corpora. In this paper we present a conceptually simple and effective transfer learning approach that addresses the problem of catastrophic forgetting. Specifically, we combine the task-specific optimization function with an auxiliary language model objective, which is adjusted during the training process. This preserves language regularities captured by language models, while enabling sufficient adaptation for solving the target task. Our method does not require pretraining or finetuning separate components of the network and we train our models end-to-end in a single step. We present results on a variety of challenging affective and text classification tasks, surpassing well established transfer learning methods with greater level of complexity.

1 Introduction

Pretrained word representations captured by Language Models (LMs) have recently become popular in Natural Language Processing (NLP). Pretrained LMs encode contextual information and high-level features of language, modeling syntax and semantics, producing state-of-the-art results across a wide range of tasks, such as named entity recognition (Peters et al., 2017), machine translation (Ramachandran et al., 2017) and text classification (Howard and Ruder, 2018).

However, in cases where contextual embeddings from language models are used as additional features (e.g. ELMo (Peters et al., 2018)), results come at a high computational cost and require task-specific architectures. At the same time, approaches that rely on fine-tuning a LM to the task at hand (e.g. ULMFiT (Howard and Ruder, 2018)) depend on pretraining the model on an extensive vocabulary and on employing a sophisticated slanted triangular learning rate scheme to adapt the parameters of the LM to the target dataset.

We propose a simple and effective transfer learning approach, that leverages LM contextual representations and does not require any elaborate scheduling schemes during training. We initially train a LM on a Twitter corpus and then transfer its weights. We add a task-specific recurrent layer and a classification layer. The transferred model is trained end-to-end using an auxiliary LM loss, which allows us to explicitly control the weighting of the pretrained part of the model and ensure that the distilled knowledge it encodes is preserved.

Our contributions are summarized as follows: 1) We show that transfer learning from language models can achieve competitive results, while also being intuitively simple and computationally effective. 2) We address the problem of catastrophic forgetting, by adding an auxiliary LM objective and using an unfreezing method. 3) Our results show that our approach is competitive with more sophisticated transfer learning methods. We make our code widely available. [1]

2 Related Work

Unsupervised pretraining has played a key role in deep neural networks, building on the premise that representations learned for one task can be useful for another task. In NLP, pretrained word vectors (Mikolov et al., 2013; Pennington et al., 2014) are widely used, improving performance in various downstream tasks, such as part-of-speech tagging (Collobert et al., 2011) and question answering (Xiong et al., 2016). These pretrained word vectors serve as initialization of the embedding layer and remain frozen during training, while our pretrained language model also initializes the hidden layers of the model and is fine-tuned to each

classification task.

Aiming to learn from unlabeled data, Dai and Le (2015) use unsupervised objectives such as sequence autoencoding and language modeling for as pretraining methods. The pretrained model is then fine-tuned to the target task. However, the fine-tuning procedure of the language model to the target task does not include an auxiliary objective. Ramachandran et al. (2017) also pretrain encoder-decoder pairs using language models and fine-tune them to a specific task, using an auxiliary language modeling objective to prevent catastrophic forgetting. This approach, nevertheless, is only evaluated on machine translation tasks; moreover, the seq2seq (Sutskever et al., 2014) and language modeling losses are weighted equally throughout training. By contrast, we propose a weighted sum of losses, where the language modeling contribution gradually decreases. ELMo embeddings (Peters et al., 2018) are obtained from language models and improve the results in a variety of tasks as additional contextual representations. However, ELMo embeddings rely on character-level models, whereas our approach uses a word-level LM. They are, furthermore, concatenated to pretrained word vectors and remain fixed during training. We instead propose a fine-tuning procedure, aiming to adjust a generic architecture to different end tasks.

Moreover, BERT (Devlin et al., 2018) pretrains language models and fine-tunes them on the target task. An auxiliary task (next sentence prediction) is used to enhance the representations of the LM. BERT fine-tunes masked bi-directional LMs. Nevertheless, we are limited to a uni-directional model. Training BERT requires vast computational resources, while our model only requires 1 GPU. We note that our approach is not orthogonal to BERT and could be used to improve it, by adding an auxiliary LM objective and weighing its contribution.

Towards the same direction, ULMFiT (Howard and Ruder, 2018) shows impressive results on a variety of tasks by employing pretrained LMs. The proposed pipeline requires three distinct steps, that include (1) pretraining the LM, (2) fine-tuning it on a target dataset with an elaborate scheduling procedure and (3) transferring it to a classification model. Our proposed model is closely related to ULMFiT. However, ULMFiT trains a LM and fine-tunes it to the target dataset, before transferring it to a classification model. While fine-tuning the LM to the target dataset, the metric (e.g. accuracy) that we intend to optimize cannot be observed. We propose adopting a multi-task learning perspective, via the addition of an auxiliary LM loss to the transferred model, to control the loss of the pretrained and the new task simultaneously. The intuition is that we should avoid catastrophic forgetting, but at the same time allow the LM to distill the knowledge of the prior data distribution and keep the most useful features.

Multi-Task Learning (MTL) via hard parameter sharing (Caruana, 1993) in neural networks has proven to be effective in many NLP problems (Collobert and Weston, 2008). More recently, alternative approaches have been suggested that only share parameters across lower layers (Sogaard and Goldberg, 2016). By introducing part-of-speech tags at the lower levels of the network, the proposed model achieves competitive results on chunking and CCG super tagging. Our auxiliary language model objective follows this line of thought and intends to boost the performance of the higher classification layer.

3 Our Model

We introduce **SiATL**, which stands for **Si**ngle-step **A**uxiliary loss **T**ransfer **L**earning. In our proposed approach, we first train a LM. We then transfer its weights and add a task-specific recurrent layer to the final classifier. We also employ an auxiliary LM loss to avoid catastrophic forgetting.

LM Pretraining. We train a word-level language model, which consists of an embedding LSTM layer (Hochreiter and Schmidhuber, 1997), 2 hidden LSTM layers and a linear layer. We want to minimize the negative log-likelihood of the LM:

$$L(\hat{p}) = -\frac{1}{N}\sum_{n=1}^{N}\sum_{t=1}^{T^n}\log\hat{p}(x_t^n|x_1^n, ..., x_{t-1}^n) \quad (1)$$

where $\hat{p}(x_t^n|x_1^n, ..., x_{t-1}^n)$ is the distribution of the t^{th} word in the n^{th} sentence given the $t-1$ words preceding it and N is total number of sentences.

Transfer & auxiliary loss. We transfer the weights of the pretrained model and add one LSTM with a self-attention mechanism (Lin et al., 2017; Bahdanau et al., 2015).

In order to adapt the contribution of the pretrained model to the task at hand, we introduce an auxiliary LM loss during training. The joint loss is the

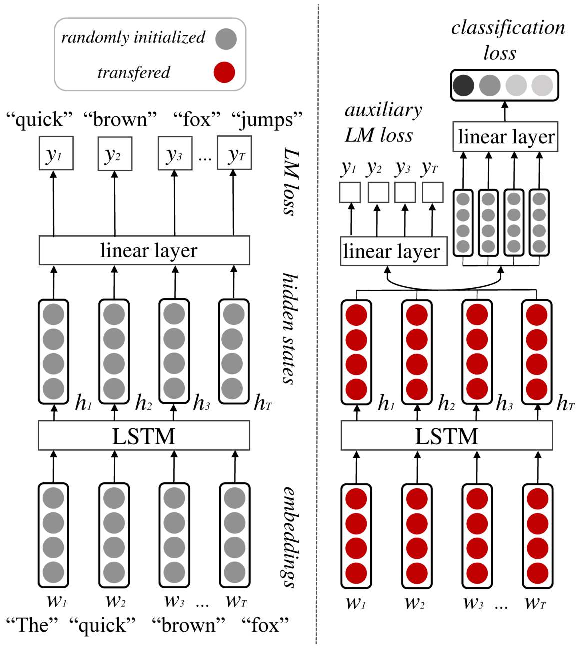

Figure 1: High-level overview of our proposed TL architecture. We transfer the pretrained LM add an extra recurrent layer and an auxiliary LM loss.

weighted sum of the task-specific loss L_{task} and the auxiliary LM loss L_{LM}, where γ is a weighting parameter to enable adaptation to the target task but at the same time keep the useful knowledge from the source task. Specifically:

$$L = L_{task} + \gamma L_{LM} \tag{2}$$

Exponential decay of γ. An advantage of the proposed TL method is that the contribution of the LM can be explicitly controlled in each training epoch. In the first few epochs, the LM should contribute more to the joint loss of SiATL so that the task-specific layers adapt to the new data distribution. After the knowledge of the pretrained LM is transferred to the new domain, the task-specific component of the loss function is more important and γ should become smaller. This is also crucial due to the fact that the new, task-specific LSTM layer is randomly initialized. Therefore, by backpropagating the gradients of this layer to the pretrained LM in the first few epochs, we would add noise to the pretrained representation. To avoid this issue, we choose to initially pay attention to the LM objective and gradually focus on the classification task. In this paper, we use an exponential decay for γ over the training epochs.

Sequential Unfreezing. Instead of fine-tuning all the layers simultaneously, we propose unfreezing them sequentially, according to Howard and Ruder (2018); Chronopoulou et al. (2018). We first fine-tune only the extra, randomly initialized LSTM and the output layer for $n-1$ epochs. At the n^{th} epoch, we unfreeze the pretrained hidden layers. We let the model fine-tune, until epoch $k-1$. Finally, at epoch k, we also unfreeze the embedding layer and let the network train until convergence. The values of n and k are obtained through grid search. We find the sequential unfreezing scheme important, as it minimizes the risk of overfitting to small datasets.

Optimizers. While pretraining the LM, we use Stochastic Gradient Descent (SGD). When we transfer the LM and fine-tune on each classification task, we use 2 different optimizers: SGD for the pretrained LM (embedding and hidden layer) with a small learning rate, in order to preserve its contextual information. As for the new, randomly initialized LSTM and classification layers, we employ Adam (Kingma and Ba, 2015), in order to allow them to train fast and adapt to the target task.

4 Experiments and Results

4.1 Datasets

To pretrain the language model, we collect a dataset of 20 million English Twitter messages, including approximately 2M unique tokens. We use the 70K most frequent tokens as vocabulary. We evaluate our model on five datasets: *Sent17* for sentiment analysis (Rosenthal et al., 2017), *PsychExp* for emotion recognition (Wallbott and Scherer, 1986), *Irony18* for irony detection (Van Hee et al., 2018), *SCv1* and *SCv2* for sarcasm detection (Oraby et al., 2016; Lukin and Walker, 2013). More details about the datasets can be found in Table 1.

4.2 Experimental Setup

To preprocess the tweets, we use *Ekphrasis* (Baziotis et al., 2017). For the generic datasets, we use NLTK (Loper and Bird, 2002). For the *NBoW* baseline, we use *word2vec* (Mikolov et al., 2013) 300-dimensional embeddings as features.

Table 2: Ablation study on various downstream datasets. Average over five runs with standard deviation. *BoW* stands for Bag of Words, *NBoW* for Neural Bag of Words. *P-LM* stands for a classifier initialized with our pretrained LM, *su* for sequential unfreezing and *aux* for the auxiliary LM loss. In all cases, F_1 is employed.

For the neural models, we use an LM with an embedding size of 400, 2 hidden layers, 1000 neurons per layer, embedding dropout 0.1, hidden dropout 0.3 and batch size 32. We add Gaussian noise of size 0.01 to the embedding layer. A clip norm of 5 is applied, as an extra safety measure against exploding gradients. For each text classification neural network, we add on top of the transferred LM an LSTM layer of size 100 with self-attention and a softmax classification layer. In the pretraining step, SGD with a learning rate of 0.0001 is employed. In the transferred model, SGD with the same learning rate is used for the pretrained layers. However, we use Adam (Kingma and Ba, 2015) with a learning rate of 0.0005 for the newly added LSTM and classification layers. For developing our models, we use PyTorch (Paszke et al., 2017) and Scikit-learn (Pedregosa et al., 2011).

5 Results & Discussion

Baselines and Comparison. Table 2 summarizes our results. The top two rows detail the baseline performance of the BoW and NBoW models. We observe that when enough data is available (e.g. *Sent17*), baselines provide decent results. Next, the results for the generic classifier initialized from a pretrained LM (*P-LM*) are shown with and without sequential unfreezing, followed by the results of the proposed model SiATL. SiATL is also directly compared with its close relative ULMFiT (trained on Wiki-103 or Twitter) and the state-of-the-art for each task; ULMFiT also fine-tunes a LM for classification tasks. The proposed SiATL method consistently outperforms the baselines, the *P-LM* method and ULMFiT in all datasets. Even though we do not perform any elaborate learning rate scheduling and we limit ourselves to pretraining in Twitter, we obtain higher results in two Twitter datasets and three generic.

Auxiliary LM objective. The effect of the auxiliary objective is highlighted in very small datasets, such as *SCv1*, where it results in an impressive boost in performance (7%). We hypothesize that when the classifier is simply initialized with the pretrained LM, it overfits quickly, as the target vocabulary is very limited. The auxiliary LM loss, however, permits refined adjustments to the model and fine-grained adaptation to the target task.

Exponential decay of γ. For the optimal γ interval, we empirically find that exponentially decaying γ from 0.2 to 0.1 over the number of training epochs provides best results for our classification tasks. A heatmap of γ is depicted in Figure 3. We observe that small values of γ should be employed, in order to scale the LM loss in the same order of magnitude as the classification loss over the training period. Nevertheless, the use of exponential decay instead of linear decay does not provide a significant improvement, as our model is not sensitive to the way of decaying hyperparameter γ.

Sequential Unfreezing. Results show that sequential unfreezing is crucial to the proposed method, as it allows the pretrained LM to adapt to the target word distribution. The performance improvement is more pronounced when there is a mismatch between the LM and task domains, i.e., the non-Twitter domain tasks. Specifically for the *PsychExp* and *SCv2* datasets, sequentially unfreezing yields significant improvement in F_1 building upon our intuition.

Number of training examples. Transfer learning is particularly useful when limited training data are available. We notice that for our largest dataset

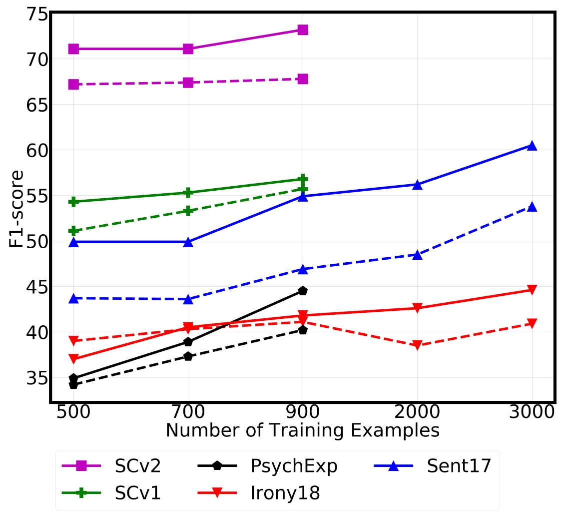

Figure 2: Results of SiATL, our proposed approach (continuous lines) and ULMFiT (dashed lines) for different datasets (indicated by different markers) as a function of the number of training examples.

Sent17, SiATL outperforms ULMFiT only by a small margin when trained on all the training examples available (see Table 2), while for the small *SCv2* dataset, SiATL outperforms ULMFiT by a large margin and ranks very close to the state-of-the-art model (Ilic et al., 2018). Moreover, the performance of SiATL vs ULMFiT as a function of the training dataset size is shown in Figure 2. Note that the proposed model achieves competitive results on less than 1000 training examples for the *Irony18, SCv2, SCv1* and *PsychExp* datasets, demonstrating the robustness of SiATL even when trained on a handful of training examples.

Catastrophic forgetting. We observe that SiATL indeed provides a way of mitigating catastrophic forgetting. Empirical results that are shown in Table 2 indicate that by only adding the auxiliary language modeling objective, we obtain better results on all downstream tasks. Specifically, a comparison of the *P-LM + aux* model and the *P-LM* model shows that the performance of SiATL on classification tasks is improved by the auxiliary objective. We hypothesize that the language model objective acts as a regularizer that prevents the loss of the most generalizable features.

6 Conclusions and Future Work

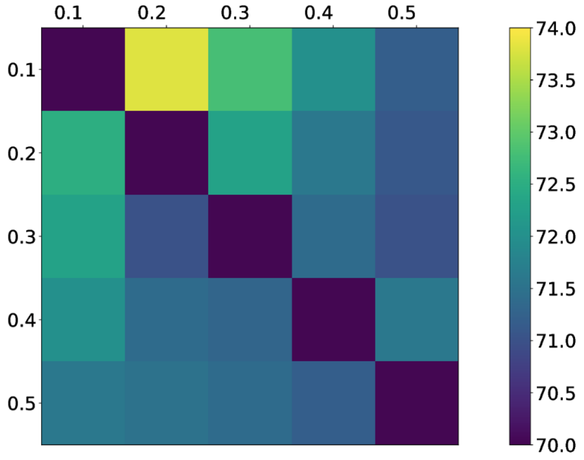

Figure 3: Heatmap of the effect of γ to F_1-score, evaluated on *SCv2*. The horizontal axis depicts the initial value of γ and the vertical axis the final value of γ.

We introduce SiATL, a simple and efficient transfer learning method for text classification tasks. Our approach is based on pretraining a LM and transferring its weights to a classifier with a task-specific layer. The model is trained using a task-specific functional with an auxiliary LM loss. SiATL avoids catastrophic forgetting of the language distribution learned by the pretrained LM. Experiments on various text classification tasks yield competitive results, demonstrating the efficacy of our approach. Furthermore, our method outperforms more sophisticated transfer learning approaches, such as ULMFiT in all tasks.

In future work, we plan to move from Twitter to more generic domains and evaluate our approach to more tasks. Additionally, we aim at exploring ways for scaling our approach to larger vocabulary sizes (Kumar and Tsvetkov, 2019) and for better handling of out-of-vocabulary words (OOV) (Mielke and Eisner, 2018; Sennrich et al., 2015) in order to be applicable to diverse datasets.

Finally, we want to explore approaches for improving the adaptive layer unfreezing process and the contribution of the language model objective (value of γ) to the target task.

Acknowledgments

We would like to thank Katerina Margatina and Georgios Paraskevopoulos for their helpful suggestions and comments. This work has been partially supported by computational time granted from the Greek Research & Technology Network (GR-NET) in the National HPC facility - ARIS. Also, the authors would like to thank NVIDIA for supporting this work by donating a TitanX GPU.

Abstract

Tweets are short messages that often include specialized language such as hashtags and emojis. In this paper, we present a simple strategy to process emojis: replace them with their natural language description and use pretrained word embeddings as normally done with standard words. We show that this strategy is more effective than using pretrained emoji embeddings for tweet classification. Specifically, we obtain new state-of-the-art results in irony detection and sentiment analysis despite our neural network is simpler than previous proposals.

1 Introduction

Tweets are short messages shared on Twitter, one of the most popular social networking services with 326 million monthly active users word wide (Twitter, 2018). Tweets often use specialized language such as abbreviations (e.g., *TBH: To be honest*), hashtags (e.g., *#NBAFinals*), emoticons and emojis. The Oxford Dictionary defines an emoticon as “a facial expression such as a smile or frown, formed by various combinations of keyboard characters” (e.g., “:)”, “:-(”), and an emoji as “a small digital image or icon used to express an idea or emotion” (e.g., 😀, 👏🏼, 😷). While the number of emoticons is relatively small, the Unicode Standard includes over 2,800 emojis.

Emojis are interesting because they succinctly encode meaning that otherwise would require more than one word to convey (e.g., *grinning face*, *clapping hands* and *face with medical mask* for the emojis above). Additionally, emojis have become popular in social media. 5 billion emojis are sent daily on Facebook (Burge, 2018). While only 6% of the top-100 Facebook headlines used emojis in 2015, 52% did so in 2017 (Boland, 2017). Over 14% of tweets and 50% of Instagram posts contain at least one emoji (Cruse, 2015; Moon, 2015).

	Irony?
I just love being ignored😊|#not 😒	Yes
Love it when my mans on a cleaning spree.. Saves me doing it 👌🏼😘	No

	Sentiment
@Paul_OConnor187 hi we going to see ted 2 at the Odeon cinemas at Glasgow on Wednesday 😊	Positive
Serato DJ isn’t compatible with Windows 10 yet 😞 ...got to spin on my old laptop Saturday.	Negative

Table 1: Sample tweets with their irony and sentiment judgements. Note that the emojis help to determine irony usage and the author’s sentiment.

Irony detection and sentiment analysis in tweets are two popular tasks. Sentiment analysis has received substantially more attention than irony detection. Irony, however, is a major error source in sentiment analysis (0.71 F1 overall but 0.29 F1 with ironic tweets (Hee et al., 2018)), and natural language understanding in general does not generalize well with ironic texts (Liu et al., 2012; Maynard and Greenwood, 2014).

In this paper, we tackle both irony and sentiment analysis in tweets—two classification tasks. In particular, we focus on modeling emojis. Consider the examples in Table 1. Understanding the emojis is critical to making irony and sentiment judgements. In the first example, the contrast between the emojis helps determining that irony is present (the hashtag *#not* also helps). In the second tweet, the *OK hand sign* and *face blowing a kiss* emojis help reinforcing that the author is praising somebody and not being ironic. Similarly, the smiling and sad emojis in the last two examples are a clear

Proceedings of NAACL-HLT 2019, pages 2096–2101
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

sign of the author's sentiment towards the movie *Ted 2* and the incompatibility issue.

The main contributions of this paper are twofold. First, we present a simple strategy to model emojis: replace them with their textual description. Second, we show that this strategy outperforms previous methods and yields a new state-of-the-art in two tweet classification tasks: irony detection and sentiment analysis.

2 Related Work

Irony is closely related to sarcasm. The Oxford Dictionary defines irony as "The expression of one's meaning by using language that normally signifies the opposite, typically for humorous or emphatic effect", and sarcasm as "The use of irony to mock or convey contempt." Given these definitions, it is not surprising that many researchers do not distinguish between them (Maynard and Greenwood, 2014). The top-3 systems to detect irony are built with neural networks and pretrained word embeddings. Baziotis et al. (2018) build an ensemble of two stacks of BiLSTMs (word and character level) with attention. Wu et al. (2018) propose a BiLSTM and a multitask learning framework (hashtag, irony presence and irony type prediction), and complement the input text with sentiment features extracted from lexicons. Vu et al. (2018) propose a multilayer perceptron taking as input an embedding for the input text (average of word embeddings) as well as manually crafted lexical, syntactic, semantic and polarity features. Our strategy to incorporate emojis outperforms all of them (Table 3).

Sentiment analysis in tweets has been studied for years (Nakov et al., 2013). At its core, it is the task of classifying a tweet into expressing positive, neutral or negative sentiment (Rosenthal et al., 2017). Initial systems were primarily based on sentiment lexicons and manually extracted features, but the state of the art uses neural networks and word embeddings. Baziotis et al. (2017) propose a stack of two BiLSTMs at the word level and do not use any lexicons. Cliche (2017) presents a CNN and BiLSTM ensemble and experiment with three pretrained embeddings. Rouvier (2017) also presents a CNN and BiLSTM ensemble but incorporates manually defined features (e.g., word presence in emotion lexicons, all-caps). The strategy presented here to incorporate emojis outperforms all these systems (Table 4).

Within natural language processing and social media, emojis have received considerable attention. Barbieri et al. (2016) train emoji embeddings with word2vec and discover that the closest words are sound (e.g., ☕: coffee, roasters, caffeine, latte). Eisner et al. (2016) propose a complementary approach to train emoji embeddings (Section 3). Emojis have also been used as labels for distant supervision to improve tweet classification (Felbo et al., 2017). The strategy presented here to incorporate emojis is simpler and more effective than previous ones, does not require additional pretraining or domain specific corpora, and can be used with any neural architecture that takes text as input without any modifications. Simply put, we replace emojis with their textual descriptions and leverage existing pretrained word embeddings.

3 Strategies to Incorporate Emojis

Neural networks that take as input text usually transform the input tokens into pretrained embeddings. When the input text are tweets, it is common to use embeddings pretrained with large collections of tweets as opposed to general purpose text (Li et al., 2017; Pennington et al., 2014).

Emojis as Regular Tokens. The simplest option to incorporate emojis into a neural network is to consider them as any other token in the input text (Barbieri et al., 2016). This strategy relies on having seen enough instances of each emoji in the texts with which embeddings were pretrained—otherwise the embeddings will not capture the semantics of emoji tokens properly.

Emoji Embeddings. Another strategy is to use separate embeddings for emojis. Eisner et al. (2016) pretrain emoji embeddings using positive and negative (randomly sampled) emoji descriptions. Descriptions are transformed into a vector by adding the corresponding word2vec embeddings (Mikolov et al., 2013). Emoji embeddings are tuned quickly because only a positive and a negative description per emoji are considered.

We refer to this strategy as EMJ-EMBED.

Our Strategy: Emoji Descriptions. Our strategy is simple: replace emojis with their textual descriptions. Effectively, this eliminates all emojis in the input and incorporates a rather detailed description—several tokens—of the emojis (see examples in Table 2). Our rationale is as follows. First, lists of emojis and their textual descriptions

Emoji	Description
😂	Face with tears of joy
😘	Face blowing a kiss
😄	Grinning face with smiling eyes
😌	Relieved face
😝	Squinting face with tongue
😥	Sad but relieved face
😠	Angry face
😭	Loudly crying face
😓	Downcast face with sweat
😰	Anxious face with sweat

Table 2: Emojis and their textual description.

are readily available.[1] Second, while emojis are common (Section 1), words are more common. Thus, it is reasonable to expect word embeddings to capture the meaning of words better than emoji embeddings capture the meaning of emojis. Consider the last two examples in Table 2, 😓 and 😰. These emojis are relatively uncommon, and pretrained emoji embeddings do not leverage the fact that both of them are *faces* with *sweat*. Using the textual descriptions bypasses both issues.

Finally, this strategy is straightforward, fast to implement and run, and can be used regardless of the neural network architecture. Indeed, it could be considered a preprocessing step.

We refer to this strategy as EMJ-DESC.

4 Experiments and Results

We experiment with two tweet classification tasks: irony detection and sentiment analysis. We use standard corpora and compare with previous work using the same set up (i.e., we train and test with exactly the same instances they did).

4.1 Experimental Setup

Corpora. For irony detection, we use the corpus released by Hee et al. (2018). It includes two tasks: binary (Task A: yes or no) and 4-way multiclass irony detection (Task B: verbal irony realized through polarity contrast, other verbal irony, situational irony or non-irony). The corpus consists of 3,000 tweets (yes: 2396, no: 604; verbal irony with polarity contrast: 1,728, other verbal irony: 267, situational irony: 401, non-irony: 604). Here are some examples: *I love waking up with migraines #not* 😣 (verbal, polarity contrast), *I cared for 8 seconds, then I got distracted.* 😂 (other verbal), *I wonder what Professor Iaukea has to say about the new Disney Princess...?* 😒 (situational), and *Is Obamacare Slowing Health Care Spending? #NOT* (non-irony).

For sentiment analysis, we use the corpus released by Rosenthal et al. (2017), which has 62,617 tweets (positive: 22,277, neutral: 28,528, negative: 8,982). Table 1 shows examples of positive and negative sentiment, and here is an example of neutral sentiment: *I'm switching to T-Mobile tomorrow and I'm getting a new number.*

Evaluation Metrics. We follow the metrics used by previous work. Regarding irony detection, we report accuracy and macro-average F1 (all labels weighted equal regardless of frequency). Regarding sentiment analysis, we report accuracy, average recall and F1. Following previous work, we calculate accuracy and average recall using all labels (positive, negative and neutral) but F1 using only positive and negative instances.

Preprocessing. We preprocess the input text following standard steps. Specifically, we tokenize with the NLTK's TweetTokenizer (Bird, 2006), lowercase all text, and use regular expressions to remove stop words, numbers, urls, consecutive repeated words and Twitter users (i.e., tokens whose first character is '@'). We also expand hashtags (e.g., *#PickANewSong*: *Pick a new song*) with ekphrasis (Baziotis et al., 2017).

Regarding emojis, we either (a) do nothing special and use pretrained emoji embeddings (EMJ-EMBED strategy), or (b) replace emojis with their textual description and use pretrained word embeddings for the words in their descriptions (EMJ-DESC strategy).

Let us consider the following tweet: "@Paul_OConnor187 hi we going to see ted 2 at the Odeon cinemas at Glasgow on Wednesday 😊". After preprocessing, we transform it into "hi we going see ted odeon cinemas glasgow wednesday 😊" or "hi we going see ted odeon cinemas glasgow wednesday smiling face" (EMJ-EMBED and EMJ-DESC strategies respectively).

Neural Network Architecture. We experiment with a stack of two BiLSTMs (Dyer et al., 2015) with attention (Zhou et al., 2016) to generate distributed representations of the input, and a softmax layer as the output layer. This architecture is simpler than previous proposals, but as we shall see,

outperforms previous work when coupled with our strategy to incorporate embeddings. Regarding word embeddings, we use the ones trained by Baziotis et al. (2018) using word2vec (Mikolov et al., 2013) and 550 million tweets. Regarding emoji embeddings, we use emoji2vec (Eisner et al., 2016). Note that EMJ-EMBED uses both word and emoji embeddings whereas EMJ-DESC only uses word embeddings.

4.2 Results

Irony Detection. Table 3 presents the results for irony detection. EMJ-EMBED obtains virtually the same results than the state of the art, although the neural architecture is much simpler (Section 2). EMJ-DESC, however, obtains the best results to date: (Task A: 0.80 vs. 0.78 F1, Task B: 0.55 vs. 0.53 F1). These results show that replacing embeddings with their textual descriptions and using the corresponding word embeddings is more effective than using emoji embeddings. As discussed earlier, there is a large amount of emojis (over 2,800), and some of them are infrequent. Many have, however, words in common in their descriptions thus leveraging the descriptions is beneficial.

Sentiment Analysis. Table 4 presents results for sentiment analysis. The standard evaluation metric in this task is average recall (Rosenthal et al., 2017), but we also provide accuracy and F1. Both EMJ-EMBED and EMJ-DESC outperform the state of the art despite we experiment with a simpler neural architecture. Indeed, EMJ-DESC outperforms previous work by a substantial margin (+0.047, +6.9% avg. recall). The reason for these results is the same than for irony detection: modeling emojis is key for tweet classification and our strategies to incorporate emojis are better suited than the ones used by previous work, which primarily treat them as any other token.

5 Conclusions

We have presented a strategy to incorporate emojis into any neural network: replace them with their textual descriptions. This strategy does not require any additional pretraining or component in the network. Instead, it leverages pretrained word embeddings, which are readily available and pretrained using massive amounts of text (Mikolov et al., 2013; Pennington et al., 2014).

Experimental results show that our strategy is more effective than previous ones (either consider emojis as regular tokens or use specialized emoji embeddings). Indeed, we obtain new state-of-the-art results in two tweet classification tasks: irony detection and sentiment analysis. We hypothesize that this is due to two reasons. First, while emojis are common, the words in their descriptions are more common. Thus, there is more data to pretrain word embeddings than emoji embeddings. Simply put, there is more proper English texts available than social media text with emojis. Second, emoji descriptions have many words in common (Table

2), thus many emojis benefit from a single word embedding (e.g., the textual descriptions of 😌 and 😥 share the words *face* and *relieved*).

Abstract

There exist biases in individual's language use; the same word (*e.g.*, *cool*) is used for expressing different meanings (*e.g.*, *temperature range*) or different words (*e.g.*, *cloudy*, *hazy*) are used for describing the same meaning. In this study, we propose a method of modeling such personal biases in word meanings (hereafter, *semantic variations*) with personalized word embeddings obtained by solving a task on subjective text while regarding words used by different individuals as different words. To prevent personalized word embeddings from being contaminated by other irrelevant biases, we solve a task of identifying a review-target (objective output) from a given review. To stabilize the training of this extreme multi-class classification, we perform a multi-task learning with metadata identification. Experimental results with reviews retrieved from RateBeer confirmed that the obtained personalized word embeddings improved the accuracy of sentiment analysis as well as the target task. Analysis of the obtained personalized word embeddings revealed trends in semantic variations related to frequent and adjective words.

1 Introduction

When we verbalize what we have sensed, there exist inevitable personal biases in word meanings (hereafter, (*personal*) *semantic variations*). For example, when we say "this pizza is greasy," how greasy can vary widely among individuals. When we see the same beer, we may use different words (*e.g.*, *red*, *amber*) to refer its color. The semantic variations will thereby cause problems not only in communicating with each other, but also in building natural language processing (NLP) systems.

Several studies have attempted to personalize models to improve the performance on NLP tasks such as sentiment analysis (Gao et al., 2013) and dialogue systems (Li et al., 2016; Zhang et al., 2018). All of these studies, however, tried to estimate *subjective* output from *subjective* input (*e.g.*, estimating sentiment scores given by reviewers). These personalized models are thereby affected by not only semantic variations in subjective input but also *annotation bias* (deviation of outputs given by the annotators) and *selection bias* (deviation of outputs caused by the deviation of input) (§ 2). This makes it difficult to understand the pure impact of the personal semantic variations.

In this study, aiming at understanding semantic variations and their impact on NLP tasks, we propose a method for modeling personal semantic variations with personalized word embeddings obtained through the review-target identification task. This task estimates the review-target (*objective* output) from a given review (*subjective* input) (§ 3), and is free from *annotation bias* since output labels are given a priori. Also, *selection bias* can be suppressed by using a dataset in which the same reviewer evaluates the same target only once, so as not to learn the deviation of output labels caused by the choice of inputs. To stabilize the training of this extreme multi-class classification, we apply multi-task learning (MTL) with metadata estimation of the review-target to effectively learn a reliable model (personalized word embeddings).

We validate our hypothesis that words related to the five senses have large semantic variations. We first confirm the impact of personalized word embeddings in the review-target identification using a review dataset obtained from RateBeer, and next evaluate their usefulness in sentiment analysis (§ 4.2). Analysis of the obtained personalized word embeddings on three metrics (frequency, dissemination and polysemy) reveals trends on which words have large semantic variations (§ 4.3).

The contributions of this paper are as follows:

- We established a method to obtain personal semantic variations via multi-task learning on a task with objective outputs (§ 3).
- We categorized personal biases in NLP (§ 2).

Proceedings of NAACL-HLT 2019, pages 2102–2108
Minneapolis, Minnesota, June 2 - June 7, 2019.

- We confirmed the usefulness of personalized word embeddings in review-target identification and sentiment analysis tasks (§ 4.2).
- We revealed trends in personal semantic variations (§ 4.3).

2 Related Work

As discussed in § 1, biases considered by personalization in NLP tasks have three facets: (1) *semantic variation* in task inputs (biases in how people use words; our target) (2) *annotation bias* of output labels (biases in how annotators label) and (3) *selection bias* of output labels (biases in how people choose perspectives (*e.g.,* review-targets) that directly affects outputs (*e.g.,* polarity labels)).

Existing studies have modeled (2) and (3) with or without (1) for NLP tasks such as sentiment analysis (Li et al., 2011; Gao et al., 2013; Tang et al., 2015a,b; Chen et al., 2016), machine translation (Mirkin and Meunier, 2015; Michel and Neubig, 2018; Wuebker et al., 2018), and dialogue systems (Li et al., 2016; Zhang et al., 2018). However, it is difficult to untangle the different facets of personal biases, there is no study aiming to analyze solely personal semantic variations. Meanwhile, word embeddings induced for a simple NLP task such as sentiment classification conveys less information, which are not suitable for analyzing semantic variations.

Computational linguists have utilized word embeddings to capture semantic variations of words caused by diachronic (Hamilton et al., 2016; Szymanski, 2017; Rosenfeld and Erk, 2018; Jaidka et al., 2018), geographic (Bamman et al., 2014; Garimella et al., 2016) or domain (Tredici and Fernández, 2017) differences. In these studies, they have mainly discussed relationships between semantic variations of words and their frequency, dissemination (the number of users), or polysemy of the words. Hamilton et al. (2016) report that the meanings of more frequent words are more stable over time, and the meanings of polysemous words are likely to change over time since polysemous words appear in diverse contexts (Winter et al., 2014; Bréal, 1897). Tredici and Fernández (2017) report that the meanings of words used by more people are more stable. In this study, we analyze the personal semantic variations by inducing personalized word embeddings, mainly focusing on how frequent, disseminated or polysemous words are biased, following these studies.

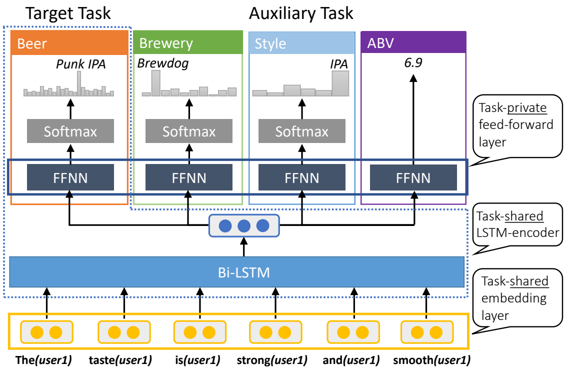

Figure 1: The overview of our model.

3 Personalized Word Embeddings

This section describes our neural network-based model (Figure 1) designed for inducing personalized word embeddings via review-target identification. This model estimates the review-target from a given review.

Model Overview: The whole process is as follows. First, a given review, represented as a sequence of words, is transformed to a sequence of their word embeddings via an embedding layer. Here, our model regards words written by different reviewers as different words for personalization. Next, we apply bi-directional long-short term memory (Bi-LSTM) (Gers et al., 1999) to the sequence of word embeddings and use the concatenation of outputs from the forward and backward LSTMs as a review representation. Finally, a feed-forward layer computes an output probability distribution from the encoded representation of the review.

Multi-task Learning (MTL): The extremely large number of labels (review-targets) makes it difficult to stably train the target identification model. To mitigate this, we jointly train auxiliary tasks that estimate the metadata of the review-target along with the target task. This approach assumes that understanding metadata contributes the performance of the target identification. Concretely, our MTL model contains a task-shared embedding layer, a task-shared LSTM-encoder, and task-private feed-forward layers similarly to (Dong et al., 2015; Luong et al., 2016). In our experiments, these task-private layers consist of three layers for classification and one layer for regression (Figure 1). In the classification tasks, the model computes log probability over target labels as the output and cross-entropy is used as the loss function. In the regression task, the output is the metadata itself represented as a scalar value and squared error is used as the loss function.

Here, multi-task learning raises a new problem. In auxiliary tasks, since the same reviewer can select the same label multiple times, the personalized word embeddings trained through the multi-task learning may implicitly include the *selection bias* of the output labels depending on the reviewers. Therefore, to exclude those irrelevant biases from the personalized embeddings, we introduce personalized bias terms to feed-forward layers of each task. These bias terms are fixed to the prior distributions of outputs in the training set depending on reviewers so that they absorb selection biases instead of personalized word embeddings.

4 Experiments

We first evaluate the effect of personalization in the target identification task. Next, to confirm the usefulness of the obtained personalized embeddings, we exploit them to solve a sentiment analysis task for extrinsic evaluation. Finally, we analyze the degree and tendencies of semantic variations captured by the obtained personalized word embeddings.

4.1 Settings

Data For training and intrinsic evaluation, we use a huge review dataset about beers constructed from RateBeer[1] (McAuley and Leskovec, 2013). It contains 2,924,163 reviews about 110,369 types of beers with various metadata (*e.g.,* brewery name, style, rating, etc.) written by 29,265 reviewers. From this dataset, we extracted 527,157 reviews about 83,049 types of beers written by the top-100 reviewers who wrote the most reviews, to guarantee enough data size per reviewer. After that, we randomly divided these reviews into training (421,725), development (52,716), and test sets (52,716) in the ratio of 8:1:1. We refer to this dataset as **RateBeer dataset**.

Tasks Our target task takes a beer review and estimates the target beer reviewed in it. Regarding the metadata estimated in multi-task learning (MTL), we chose **style** with 89 types and **brewery** with 6,208 types for classification tasks and **alcohol by volume (ABV)** for a regression task. Note that these metadata are objective and our MTL is free from annotation bias.

# Layers of Bi-LSTM	1
Dimensions of LSTM output	200
Dimensions of word embeddings	200
Dropout rate	0.5
Mini-batch size	400
Initial learning rate	0.005
Vocabulary size (w/o personalization)	23,556
Vocabulary size (w/ personalization)	469,346

Table 1: Hyperparameters of our model.

In the sentiment analysis task, we estimate the **ratings** of given reviews annotated by the reviewers. The ratings are integers and range from 1 to 20. Here, we solve this task as a regression task since it is natural to treat the fine-grained rating as continuous values.

Models and Hyperparameters In the review-target and its metadata identification tasks, we compare our model described in § 3 with five models with different settings.[2] Their differences are, (1) whether the model is trained through MTL, (2) whether personalization is applied to the embeddings, and (3) whether personalization is applied to the bias term in the output layers. When MTL is not employed, multiple models are independently trained by tasks without sharing layers.

Table 1 shows major hyperparameters. We initialize the embedding layer by pretrained skip-gram embeddings (Mikolov et al., 2013) induced from the training set of RateBeer dataset. The vocabulary is defined by all the words that appeared more than or equal to 10 times in the training set, and the top-100 reviewers have used at least once. For optimization, we train the models up to 100 epochs with Adam (Kingma and Ba, 2015) and select the one at the epoch with the best results on the development set.[3]

In the sentiment analysis task for extrinsic evaluation of the obtained personalized word embeddings, we train another set of models with the same architecture and hyperparameters as the review-target identification models in Figure 1 except that they have only one feed-forward layer for the target regression task. The embedding layers of the models are kept fixed after initialized by the word embeddings extracted from the corresponding review-target identification models with the same settings of personalization and MTL.

✓	✓	✓	**1.377**
baseline			2.903

Table 3: Results on the sentiment analysis: embedding layers are kept fixed to those of the corresponding models in Table 2.

4.2 Results

Table 2 shows the accuracies on the three classification tasks (product, style, and brewery) and RMSE on the regression task (ABV) through the test sets. We can see two insights from the results: (1) In the target task, the model adopted all the methods outperformed others, (2) In the auxiliary tasks, MTL and personalization had no effect.

As for the first one, since the identification of the review-target requires both detailed understandings of all the related metadata and capturing biases of word meanings, our proposed method considering both elements achieved the best performance as a natural consequence. The second one is not surprising since the metadata estimated in the auxiliary tasks are weakly related to each other. Thus multi-task learning and personalization did not contribute to the improvement of these auxiliary tasks.

Finally, Table 3 shows the results of the sentiment analysis task for extrinsic evaluation. Similarly to the review-target identification, the model with both MTL and personalization performed the best. The personalization of output bias term also slightly improved RMSE. These results confirm that the personalized word embeddings trained through our methods successfully learned task-independent personal semantic variations. In other words, they were helpful even for solving tasks other than the review-target identification.

4.3 Analysis

In this section, we analyze the personalized word embeddings extracted from the best model with MTL and personalization to confirm what kind of personal biases exist in each word. Here, we target on only the words used by more than or equal to 30% of the reviewers excluding stopwords to remove the influences of low frequent words.

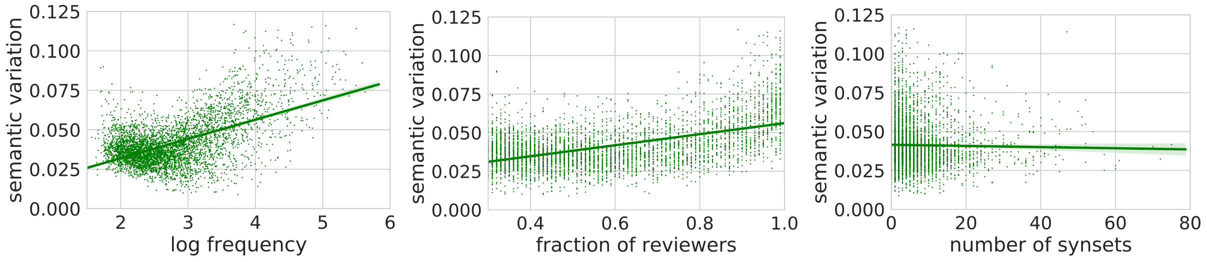
We first define the **personal semantic variations** of word w, to determine how the representations of the word are different by individuals, as:

$$\frac{1}{|\mathrm{U}(w_i)|}\sum_{u_j \in \mathrm{U}(w_i)} \left(1-\cos(\boldsymbol{e}_{w_i}^{u_j}, \bar{\boldsymbol{e}}_{w_i})\right) \tag{1}$$

where $\mathrm{U}(w_i)$ is the set of the reviewers who used the word w_i in the training set, $\boldsymbol{e}_{w_i}^{u_j}$ is the word embedding of w_i personalized to reviewer u_j, and $\bar{\boldsymbol{e}}_{w_i}$ is the average of $\boldsymbol{e}_{w_i}^{u_j}$ for $u_j \in \mathrm{U}(w_i)$.

Here, we focus on the three factors, **frequency**, **dissemination**, and **polysemy** which have been studied on semantic variations caused by diachronic, geographical or domain differences of text (see § 2). Figure 2 shows the semantic variations of words against the degree of the three metrics. The x-axes correspond to (a) log frequency of the word, (b) the ratio of the reviewers who used the word, and (c) the number of synsets found in WordNet (Miller, 1995) ver. 3.0, respectively.

Interestingly, in contrast to the results reported in previous studies (Hamilton et al., 2016; Tredici and Fernández, 2017), personal semantic variations correlate highly with frequency and dissemination, and poorly with polysemy in our results. This tendency can be explained as follows: In the dataset used in our experiments, words related to five senses such as “*mild*,” “*dry*” and “*soapy*” frequently appear and their usages depend on the feelings and experiences of each individual. Therefore, these words show high semantic variations. Regarding polysemy, although the semantic variations acquired through our method might change the degree or nuance of the word sense, they do not change its synset. This is because those words are still used only in highly skewed contexts related to beer where word senses and their meanings do not significantly fluctuate.



(a) log-frequency (b) dissemination (c) polysemy

Figure 2: Personal semantic variations: The Pearson coefficient correlations are (a) **0.55**, (b) **0.51**, (c) -0.02, respectively. The trendlines show 95% confidence intervals from bootstrapped kernel regressions.

top-50
surprisingly, **nice**, quite, **light**, **pleasant**, actually, though, buttery, **grassy**, really, **bready**, **dusty**, **fruity**, **decent**, **mild**, rather, little, **toffee**, **earthy**, **woody**, **subtle**, **nutty**, **strange**, even, still, **dry**, **tasty**, maybe, **medium**, bit, **soapy**, **interesting**, somewhat, malt, **pretty**, brewery, character, **solid**, lovely, **floral**, **herbal**, **grainy**, **big**, yet, nose, fruit, fairly, aroma, **good**, almost, **metallic**
bottom-50
lasted, primary, system, **secondary**, **personal**, test, acquired, ii, **greater**, standout, roof, england, flow, scored, purchase, partly, colorado, spare, rocks, ounce, se, jug, source, shipping, fullness, denmark, center, **diminished**, greatly, met, spirits, burns, comments, **surrounded**, scores, expectations, carmel, crew, die, **annual**, laces, reading, consumed, handpump, **disappeared**, suits, husks, duck, rise, meal, hall

Table 4: Top-50 words with the largest (and smallest) semantic variations. Adjectives are boldfaced.

Table 4 shows the top-50 words with the largest (and smallest) semantic variations. As can be seen from the table, the top-50 words contain much more adjectives (58%) compared with the bottom-50 ones (16%), which are likely to be used to represent our feelings depending on the five senses.

To see more precisely what kind of words have large semantic variations, we manually classify the adjectives of the top-50 (and bottom-50) by the five senses. From the results, on the RateBeer dataset, there were more words representing each sense except hearing in the top-50 words compared with the bottom-50 ones.

Finally, we analyze the relationships between words beyond the analysis focusing on the single word. We visualized the obtained personalized word embeddings of the word "*mild*" and some closest words in the embedding space as an example in Figure 3. From the results, intersection of the clusters (*e.g.*, "*grainy*" and "*grassy*") means that the same meaning can be represented in different ways by individuals.

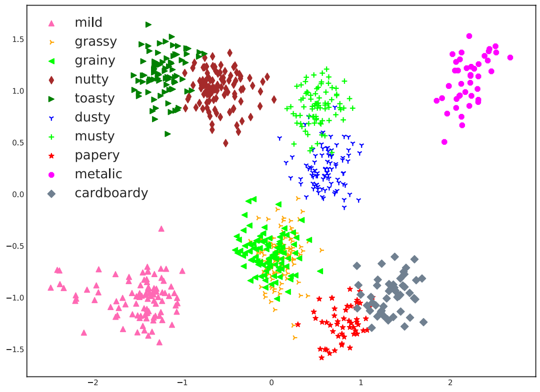


Figure 3: Two-dimensional visualization of the word "*mild*" with some closest words.

5 Conclusions

In this study, we proposed a method of modeling personal semantic variations with personalized word embeddings induced through the review-target identification task. The experimental results on the large-scale beer review dataset showed that personalized word embeddings obtained by multi-task learning with metadata identification improved the accuracy of sentiment analysis as well as the target task. Our analysis revealed that words related to the five senses and adjectives have large semantic variations.

We plan to analyze relationships between semantic variations and user factors of writers who used the target words such as age and gender. We will develop a generic method of inducing personalized word embeddings for any subjective text.

Abstract

In the context of fake news, bias, and propaganda, we study two important but relatively under-explored problems: (*i*) *trustworthiness estimation* (on a 3-point scale) and (*ii*) *political ideology detection* (left/right bias on a 7-point scale) of entire news outlets, as opposed to evaluating individual articles. In particular, we propose a multi-task ordinal regression framework that models the two problems jointly. This is motivated by the observation that hyper-partisanship is often linked to low trustworthiness, e.g., appealing to emotions rather than sticking to the facts, while center media tend to be generally more impartial and trustworthy. We further use several auxiliary tasks, modeling centrality, hyper-partisanship, as well as left-vs.-right bias on a coarse-grained scale. The evaluation results show sizable performance gains by the joint models over models that target the problems in isolation.

1 Introduction

Recent years have seen the rise of social media, which has enabled people to virtually share information with a large number of users without regulation or quality control. On the bright side, this has given an opportunity for anyone to become a content creator, and has also enabled a much faster information dissemination. However, it has also opened the door for malicious users to spread disinformation and misinformation much faster, enabling them to easily reach audience at a scale that was never possible before. In some cases, this involved building sophisticated profiles for individuals based on a combination of psychological characteristics, meta-data, demographics, and location, and then micro-targeting them with personalized "fake news" with the aim of achieving some political or financial gains (Lazer et al., 2018; Vosoughi et al., 2018).

A number of fact-checking initiatives have been launched so far, both manual and automatic, but the whole enterprise remains in a state of crisis: by the time a claim is finally fact-checked, it could have reached millions of users, and the harm caused could hardly be undone. An arguably more promising direction is to focus on fact-checking entire news outlets, which can be done in advance. Then, we could fact-check the news before they were even written: by checking how trustworthy the outlets that published them are. Knowing the reliability of a medium is important not only when fact-checking a claim (Popat et al., 2017; Nguyen et al., 2018), but also when solving article-level tasks such as "fake news" and click-bait detection (Brill, 2001; Finberg et al., 2002; Hardalov et al., 2016; Karadzhov et al., 2017; De Sarkar et al., 2018; Pan et al., 2018; Pérez-Rosas et al., 2018)

Political ideology (or left/right bias) is a related characteristic, e.g., extreme left/right media tend to be propagandistic, while center media are more factual, and thus generally more trustworthy. This connection can be clearly seen in Figure 1.

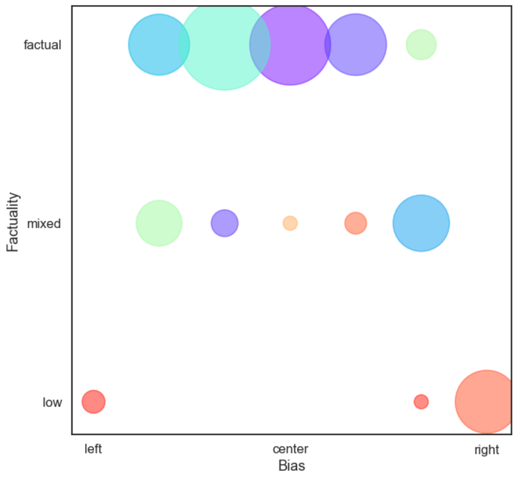

Figure 1: Correlation between bias and factuality for the news outlets in the Media Bias/Fact Check website.

Proceedings of NAACL-HLT 2019, pages 2109–2116
Minneapolis, Minnesota, June 2 - June 7, 2019.

Despite the connection between factuality and bias, previous research has addressed them as independent tasks, even when the underlying dataset had annotations for both (Baly et al., 2018). In contrast, here we solve them jointly. Our contributions can be summarized as follows:

- We study an under-explored but arguably important problem: predicting the factuality of reporting of news media. Moreover, unlike previous work, we do this jointly with the task of predicting political bias.
- As factuality and bias are naturally defined on an ordinal scale (factuality: from *low* to *high*, and bias: from *extreme-left* to *extreme-right*), we address them as ordinal regression. Using multi-task ordinal regression is novel for these tasks, and it is also an under-explored direction in machine learning in general.
- We design a variety of auxiliary subtasks from the bias labels: modeling centrality, hyper-partisanship, as well as left-vs.-right bias on a coarse-grained scale.

2 Related Work

Factuality of Reporting Previous work has modeled the factuality of reporting at the medium level by checking the general stance of the target medium with respect to known manually fact-checked claims, without access to gold labels about the overall medium-level factuality of reporting (Mukherjee and Weikum, 2015; Popat et al., 2016, 2017, 2018).

The trustworthiness of Web sources has also been studied from a Data Analytics perspective, e.g., Dong et al. (2015) proposed that a trustworthy source is one that contains very few false claims. In social media, there has been research targeting the user, e.g., finding malicious users (Mihaylov and Nakov, 2016; Mihaylova et al., 2018; Mihaylov et al., 2018), *sockpuppets* (Maity et al., 2017), *Internet water army* (Chen et al., 2013), and *seminar users* (Darwish et al., 2017).

Unlike the above work, here we study source reliability as a task in its own right, using manual gold annotations specific for the task and assigned by independent fact-checking journalists. Moreover, we address the problem as one of ordinal regression on a three-point scale, and we solve it jointly with political ideology prediction in a multi-task learning setup, using several auxiliary tasks.

Predicting Political Ideology In previous work, political ideology, also known as media bias, was used as a feature for "fake news" detection (Horne et al., 2018a). It has also been the target of classification, e.g., Horne et al. (2018b) predicted whether an article is biased (*political* or *bias*) vs. unbiased. Similarly, Potthast et al. (2018) classified the bias in a target article as (*i*) left vs. right vs. mainstream, or as (*ii*) hyper-partisan vs. mainstream. Left-vs-right bias classification at the article level was also explored by Kulkarni et al. (2018), who modeled both the textual and the URL contents of the target article. There has been also work targeting bias at the phrase or the sentence level (Iyyer et al., 2014), focusing on political speeches (Sim et al., 2013) or legislative documents (Gerrish and Blei, 2011), or targeting users in Twitter (Preoţiuc-Pietro et al., 2017). Another line of related work focuses on propaganda, which can be seen as a form of extreme bias (Rashkin et al., 2017; Barrón-Cedeño et al., 2019a,b). See also a recent position paper (Pitoura et al., 2018) and an overview paper on bias on the Web (Baeza-Yates, 2018). Unlike the above work, here we focus on predicting the political ideology of news media outlets.

In our previous work (Baly et al., 2018), we did target the political bias of entire news outlets, as opposed to working at the article level (we also modeled factuality of reporting, but as a separate task without trying multi-task learning). In addition to the text of the articles published by the target news medium, we used features extracted from its corresponding Wikipedia page and Twitter profile, as well as analysis of its URL structure and traffic information about it from Alexa rank. In the present work, we use a similar set of features, but we treat the problem as one of ordinal regression. Moreover, we model the political ideology and the factuality of reporting jointly in a multi-task learning setup, using several auxiliary tasks.

Multitask Ordinal Regression *Ordinal regression* is well-studied and is commonly used for text classification on an ordinal scale, e.g., for sentiment analysis on a 5-point scale (He et al., 2016; Rosenthal et al., 2017a). However, *multi-task ordinal regression* remains an understudied problem.

Yu et al. (2006) proposed a Bayesian framework for collaborative ordinal regression, and demonstrated that modeling multiple ordinal regression tasks outperforms single-task models.

Walecki et al. (2016) were interested in jointly predicting facial action units and their intensity level. They argued that, due to the high number of classes, modeling these tasks independently would be inefficient. Thus, they proposed the *copula ordinal regression* model for multi-task learning and demonstrated that it can outperform various single-task setups. We use this model in our experiments below.

Balikas et al. (2017) used multi-task ordinal regression for the task of fine-grained sentiment analysis. In particular, they introduced an auxiliary coarse-grained task on a 3-point scale, and demonstrated that it can improve the results for sentiment analysis on the original 5-point scale. Inspired by this, below we experiment with different granularity for political bias; however, we explore a larger space of possible auxiliary tasks.

3 Method

Copula Ordinal Regression We use the *Copula Ordinal Regression* (COR) model, which was originally proposed by Walecki et al. (2016) to estimate the intensities of facial action units (AUs). The model uses copula functions and conditional random fields (CRFs) to approximates the learning of the joint probability distribution function (PDF) of the facial AUs (random variables), using the bivariate joint distributions capturing dependencies between AU pairs. It was motivated by the fact that (*i*) many facial AUs co-exist with different levels of intensity, (*ii*) some AUs co-occur more often than others, and (*iii*) some AUs depend on the intensity of other units.

We can draw an analogy between modeling facial AUs and modeling news media, where each medium expresses a particular bias (political ideology) and can also be associated with a particular level of factuality. Therefore, bias and factuality can be analogous to the facial AUs in (Walecki et al., 2016), and represent two aspects of news reporting, each being modeled on a multi-point ordinal scale. In particular, we model bias on a 7-point scale (*extreme-left*, *left*, *center-left*, *center*, *center-right*, *right*, and *extreme-right*), and factuality on a 3-point scale (*low*, *mixed*, and *high*).

In our case, we train the COR model to predict the joint PDF between political bias and factuality of reporting. This could potentially work well given the inherent inter-dependency between the two tasks as we have seen on Figure 1.

Auxiliary Tasks We use a variety of auxiliary tasks, derived from the bias labels. This includes converting the 7-point scale to (*i*) 5-point and 3-point scales, similarly to (Balikas et al., 2017), and to (*ii*) a 2-point scale in two ways to model extreme partisanship, and centrality. Here is the list of the auxiliary tasks we use with precise definition of the label mappings:

- **Bias5-way:** Predict bias on a 5-pt scale; 1:*extreme-left*, 2:*left*, 3:{*center-left, center, center-right*}, 4:*right*, and 5:*extreme-right*.
- **Bias3-way:** Predict bias on a 3-pt scale; 1:{*extreme-left, left*}, 2:{*center-left, center, center-right*}, and 3:{*right, extreme-right*}.
- **Bias-extreme:** Predict extreme vs. non-extreme partisanship on a 2-pt scale; 1:{*extreme-left, extreme-right*}, 2:{*left, center-left, center, center-right, right*}.
- **Bias-center:** Predict center vs. non-center political ideology on a 2-pt scale, ignoring polarity: 1:{*extreme-left, left, right, extreme-right*}, 2:{*center-left, center, center-right*}.

Features We used the features from (Baly et al., 2018)[1]. We gathered a sample of articles from the target medium, and we calculated features such as POS tags, linguistic cues, sentiment scores, complexity, morality, as well as embeddings. We also used the Wikipedia page of the medium (if any) to generate document embedding. Then, we collected metadata from the medium's Twitter account (if any), e.g., whether is is verified, number of followers, whether the URL in the Twitter page matches the one of the medium. Finally, we added Web-based features that (*i*) model the orthographic structure of the medium's URL address, and (*ii*) analyze the Web-traffic information about the medium's website, as found in Alexa rank.[2]

4 Experiments and Evaluation

Data We used the MBFC dataset (Baly et al., 2018) that has 1,066 news media manually annotated for factuality (3-pt scale: *high*, *mixed*, *low*) and political bias (7-pt scale: from *extreme-left* to *extreme-right*). This dataset was annotated by volunteers using a detailed methodology[3] that is designed to guarantee annotation objectivity.

Table 1: Examples of media and their labels for bias and factuality of reporting derived from MBFC.

Furthermore, readers can provide their own feedback on existing annotations, and in case of a large discrepancy, annotation is adjusted after a thorough review. Therefore, we believe the annotation quality is good enough to experiment with. We noticed that 117 media had *low* factuality because they publish *satire* and *pseudo-science*, neither of which has a political perspective. Since we are interested in modeling the relation between factuality and bias, we excluded those websites, thus ending up with 949 news media. Some examples from this dataset are shown in Table 1 with both factuality and bias labels, in addition to their corresponding Twitter handles and Wikipedia pages. Overall, 64% of the media in our dataset have Wikipedia pages, and 65% have Twitter accounts. Table 2 further provides detailed statistics about the label distribution in the MBFC dataset.

Factuality		Bias	
Low	198	Extreme-Left	23
Mixed	282	Left	151
High	469	Center-Left	200
		Center	139
		Center-Right	105
		Right	164
		Extreme-Right	167

Table 2: Label distribution (counts) in the MBFC dataset, which we used in our experiments.

Experimental Setup We used the implementation[4] of the Copula Ordinal Regression (COR) model as described in (Walecki et al., 2016). In our experiments, we used 5-fold cross-validation, where for each fold we split the training dataset into a training part and a validation part, and we used the latter to fine-tune the model's hyper-parameters, optimizing for Mean Absolute Error (MAE). MAE is an appropriate evaluation measure given the ordinal nature of the tasks. These hyper-parameters include the copula function (*Gumbel* vs. *Frank*), the marginal distribution (*normal* vs. *sigmoid*), the number of training iterations, the optimizer (*gradient descent*, *BFGS*), and the connection density of the CRFs. We report both MAE and MAE^M, which is a variant of MAE that is more robust to class imbalance. See (Baccianella et al., 2009; Rosenthal et al., 2017b) for more details about MAE^M vs. MAE. We compare the results to two baselines: (*i*) majority class, and (*ii*) single-task ordinal regression.

Results and Discussion Table 3 shows the evaluation results for the COR model when trained to jointly model the main task (*shown in the columns*) using combinations of auxiliary tasks (*shown in the rows*). We can see that the single-task ordinal regression model performs much better than the majority class baseline based on both evaluation measures. We can further see that the performance on the main task improves when jointly modeling several auxiliary tasks. This improvement depends on the auxiliary tasks in use.

For factuality prediction, it turns out that the combination of *bias-center+bias-extreme* yields the best overall MAE of 0.481. This makes sense and aligns well with the intuition that knowing whether a medium is centric or hyper-partisan is important to predict the factuality of its reporting. For instance, a news medium without a political ideology tends to be more trustworthy compared to an extremely biased one, regardless of their polarity (left or right), as we should expect based on the data distribution shown in Figure 1 above.

For bias prediction (at a 7-point left-to-right scale), a joint model that uses political bias at different levels of granularity (5-point and 3-point) as auxiliary tasks yields the best overall MAE of 1.479. This means that jointly modeling bias with the same information at coarser levels of granularity, i.e., adding 3-point and 5-point as auxiliary tasks, reduces the number of gross mistakes.

+bias5-way+bias3-way	0.493	0.541	1.479 *(**1.475**)*	1.637 *(**1.623**)*
+bias-center+bias-extreme	**0.481**	**0.529**	1.563 *(1.526)*	1.714 *(1.672)*
+bias5-way+bias3-way+bias-center+bias-extreme	0.485	0.537	1.513 *(1.504)*	1.665 *(1.677)*

Table 3: Evaluating the copula ordinal regression model trained to jointly model the main task (*shown in the columns*) and different auxiliary tasks (*shown in the rows*). The results in parentheses correspond to the case when factuality is added as an additional auxiliary task (only applicable when the main task is bias prediction).

E.g., predicting *extreme-left* instead of *extreme-right*, since the model is encouraged by the auxiliary tasks to learn the correct polarity, regardless of its intensity. We can see that *factuality* is not very useful as an auxiliary task by itself (MAE=1.584 and MAE^M=1.695). In other words, a medium with low factuality could be extremely biased to either the right or to the left. Therefore, relying on *factuality* alone to predict bias might introduce severe errors, e.g., confusing extreme-left with extreme-right, thus leading to higher MAE scores. This can be remedied by adding *factuality* to the mix of other auxiliary tasks to model the main task (7-point bias prediction). The results of these experiments, shown in parentheses in Table 3, indicate that adding *factuality* to any combination of auxiliary tasks consistently yields lower MAE scores. In particular, modeling the combination of *factuality+bias5-way+bias3-way* yields the best results (MAE=1.475 and MAE^M=1.623). This result indicates that *factuality* provides complementary information that can help predict bias.

We ran a two-tailed t-test for statistical significance, which is suitable for an evaluation measure such as MAE, to confirm the improvements that were introduced by the multi-task setup. We found that the best models (shown in bold in Table 3) outperformed both the corresponding majority class baselines with a p-value ≤ 0.001, and the corresponding single-task ordinal regression baselines with a p-value ≤ 0.02.

Finally, we compared the above results to our previous work (Baly et al., 2018) by independently training a Support Vector Machine (SVM) classifier for each task, using the same features. The resulting MAE was 0.450 for factuality and 1.184 for bias prediction, which is slightly better then our results (yet, very comparable for factuality). However, our goal here is to emphasize the advantages of modeling the two tasks jointly.

5 Conclusion and Future Work

We have presented a multi-task ordinal regression framework for jointly predicting trustworthiness and political ideology of news media sources, using several auxiliary tasks, e.g., based on a coarser-grained scales or modeling extreme partisanship. Overall, we have observed sizable performance gains in terms of reduced MAE by the multi-task ordinal regression models over single-task models for each of the two individual tasks.

In future work, we want to try more auxiliary tasks, and to experiment with other languages. We further plan to go beyond *left vs. right*, which is not universal and can exhibit regional specificity (Tavits and Letki, 2009), and to model other kinds of biases, e.g., *eurosceptic vs. europhile*, *nationalist* vs. *globalist*, *islamist vs. secular*, etc.

Acknowledgments

This research is part of the Tanbih project,[5] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL) and the Qatar Computing Research Institute (QCRI), HBKU.

Joint Detection and Location of English Puns

Yanyan Zou and **Wei Lu**
StatNLP Research Group
Singapore University of Technology and Design

Abstract

A pun is a form of wordplay for an intended humorous or rhetorical effect, where a word suggests two or more meanings by exploiting polysemy (*homographic pun*) or phonological similarity to another word (*heterographic pun*). This paper presents an approach that addresses pun detection and pun location jointly from a sequence labeling perspective. We employ a new tagging scheme such that the model is capable of performing such a joint task, where useful structural information can be properly captured. We show that our proposed model is effective in handling both homographic and heterographic puns. Empirical results on the benchmark datasets demonstrate that our approach can achieve new state-of-the-art results.

1 Introduction

There exists a class of language construction known as *pun* in natural language texts and utterances, where a certain word or other lexical items are used to exploit two or more separate meanings. It has been shown that understanding of puns is an important research question with various real-world applications, such as human-computer interaction (Morkes et al., 1999; Hempelmann, 2008) and machine translation (Schröter, 2005). Recently, many researchers show their interests in studying puns, like detecting pun sentences (Vadehra, 2017), locating puns in the text (Cai et al., 2018), interpreting pun sentences (Sevgili et al., 2017) and generating sentences containing puns (Ritchie, 2005; Hong and Ong, 2009; Yu et al., 2018). A pun is a wordplay in which a certain word suggests two or more meanings by exploiting polysemy, homonymy, or phonological similarity to another sign, for an intended humorous or rhetorical effect. Puns can be generally categorized into two groups, namely heterographic puns (where the pun and its latent target are phonologically similar) and homographic puns (where the two meanings of the pun reflect its two distinct senses) (Miller et al., 2017). Consider the following two examples:

(1) When the church bought gas for their annual barbecue, proceeds went from the sacred to the *propane*.

(2) Some diets cause a *gut* reaction.

The first punning joke exploits the sound similarity between the word "*propane*" and the latent target "profane", which can be categorized into the group of heterographic puns. Another categorization of English puns is homographic pun, exemplified by the second instance leveraging distinct senses of the word "*gut*".

Pun detection is the task of detecting whether there is a pun residing in the given text. The goal of pun location is to find the exact word appearing in the text that implies more than one meanings. Most previous work addresses such two tasks separately and develop separate systems (Pramanick and Das, 2017; Sevgili et al., 2017). Typically, a system for pun detection is built to make a binary prediction on whether a sentence contains a pun or not, where all instances (with or without puns) are taken into account during training. For the task of pun location, a separate system is used to make a single prediction as to which word in the given sentence in the text that trigger more than one semantic interpretations of the text, where the training data involves only sentences that contain a pun. Therefore, if one is interested in solving both problems at the same time, a pipeline approach that performs pun detection followed by pun location can be used.

Compared to the pipeline methods, joint learning has been shown effective (Katiyar and Cardie, 2016; Peng et al., 2018) since it is able to re-

Proceedings of NAACL-HLT 2019, pages 2117–2123

duce error propagation and allows information exchange between tasks which is potentially beneficial to all the tasks. In this work, we demonstrate that the detection and location of puns can be jointly addressed by a single model. The pun detection and location tasks can be combined as a sequence labeling problem, which allows us to jointly detect and locate a pun in a sentence by assigning each word a tag. Since each context contains a maximum of one pun (Miller et al., 2017), we design a novel tagging scheme to capture this structural constraint. Statistics on the corpora also show that a pun tends to appear in the second half of a context. To capture such a structural property, we also incorporate word position knowledge into our structured prediction model. Experiments on the benchmark datasets show that detection and location tasks can reinforce each other, leading to new state-of-the-art performance on these two tasks. To the best of our knowledge, this is the first work that performs joint detection and location of English puns by using a sequence labeling approach.[1]

2 Approach

2.1 Problem Definition

We first design a simple tagging scheme consisting of two tags $\{\mathsf{N}, \mathsf{P}\}$:

- N tag means the current word is not a pun.
- P tag means the current word is a pun.

If the tag sequence of a sentence contains a P tag, then the text contains a pun and the word corresponding to P is the pun.

The contexts have the characteristic that each context contains a maximum of one pun (Miller et al., 2017). In other words, there exists only one pun if the given sentence is detected as the one containing a pun. Otherwise, there is no pun residing in the text. To capture this interesting property, we propose a new tagging scheme consisting of three tags, namely $\{\mathsf{B}, \mathsf{P}, \mathsf{A}\}$.

- B tag indicates that the current word appears before the pun in the given context.
- P tag highlights the current word is a pun.
- A tag indicates that the current word appears after the pun.

We empirically show that the BPA scheme can guarantee the context property that there exists a maximum of one pun residing in the text.

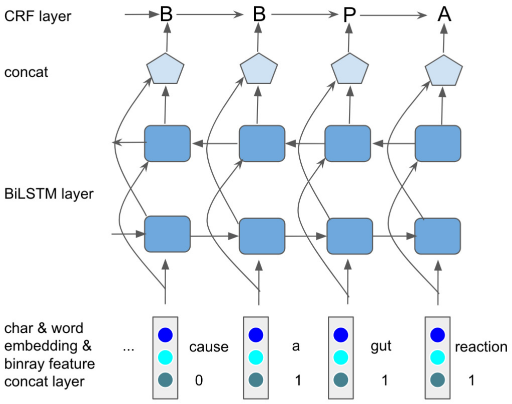

Figure 1: Model architecture

Given a context from the training set, we will be able to generate its corresponding gold tag sequence using a deterministic procedure. Under the two schemes, if a sentence does not contain any puns, all words will be tagged with N or B, respectively. Exemplified by the second sentence "*Some diets cause a gut reaction*," the pun is given as "*gut*." Thus, under the BPA scheme, it should be tagged with P, while the words before it are assigned with the tag B and words after it are with A, as illustrated in Figure 1. Likewise, the NP scheme tags the word "*gut*" with P, while other words are tagged with N. Therefore, we can combine the pun detection and location tasks into one problem which can be solved by the sequence labeling approach.

2.2 Model

Neural models have shown their effectiveness on sequence labeling tasks (Chiu and Nichols, 2016; Ma and Hovy, 2016; Liu et al., 2018). In this work, we adopt the bidirectional Long Short Term Memory (BiLSTM) (Graves and Schmidhuber, 2005) networks on top of the Conditional Random Fields (Lafferty et al., 2001) (CRF) architecture to make labeling decisions, which is one of the classical models for sequence labeling. Our model architecture is illustrated in Figure 1 with a running example. Given a context/sentence $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ where n is the length of the context, we generate the corresponding tag sequence $\mathbf{y} = (y_1, y_2, \ldots, y_n)$ based on our designed tagging schemes and the original annotations for pun detection and location provided by the corpora. Our model is then trained on pairs of $(\mathbf{x}, \mathbf{y})$.

Input. The contexts in the pun corpus hold the property that each pun contains exactly one content word, which can be either a noun, a verb, an

---

[1] Our code is publicly available at `https://github.com/zoezou2015/PunLocation`.

adjective, or an adverb. To capture this characteristic, we consider lexical features at the character level. Similar to the work of (Liu et al., 2018), the character embeddings are trained by the character-level LSTM networks on the unannotated input sequences. Nonlinear transformations are then applied to the character embeddings by highway networks (Srivastava et al., 2015), which map the character-level features into different semantic spaces.

We also observe that a pun tends to appear at the end of a sentence. Specifically, based on the statistics, we found that sentences with a pun that locate at the second half of the text account for around 88% and 92% in homographic and heterographic datasets, respectively. We thus introduce a binary feature that indicates if a word is located at the first or the second half of an input sentence to capture such positional information. A binary indicator can be mapped to a vector representation using a randomly initialized embedding table (He et al., 2017; Wang and Lu, 2018). In this work, we directly adopt the value of the binary indicator as part of the input.

The concatenation of the transformed character embeddings, the pre-trained word embeddings (Pennington et al., 2014), and the position indicators are taken as input of our model[2].

Tagging. The input is then fed into a BiLSTM network, which will be able to capture contextual information. For a training instance $(\mathbf{x}, \mathbf{y})$, we suppose the output by the word-level BiLSTM is $\mathbf{Z} = (\mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_n)$. The CRF layer is adopted to capture label dependencies and make final tagging decisions at each position, which has been included in many state-of-the-art sequence labeling models (Ma and Hovy, 2016; Liu et al., 2018). The conditional probability is defined as:

$$P(\mathbf{y}|\mathbf{x}) = \frac{\prod_{i=1}^{n} \exp\left(W_{y_{i-1},y_i}\mathbf{z}_i + b_{y_{i-1},y_i}\right)}{\sum_{\mathbf{y}' \in \mathbf{Y}} \prod_{i=1}^{n} \exp\left(W_{y'_{i-1},y'_i}\mathbf{z}_i + b_{y'_{i-1},y'_i}\right)}$$

where $\mathbf{Y}$ is a set of all possible label sequences consisting of tags from $\{\mathsf{N}, \mathsf{P}\}$ (or $\{\mathsf{B}, \mathsf{P}, \mathsf{A}\}$), W_{y_{i-1},y_i} and b_{y_{i-1},y_i} are weight and bias parameters corresponding to the label pair (y_{i-1}, y_i). During training, we minimize the negative log-likelihood summed over all training instances:

$$\mathcal{L} = -\sum_i \log P(\mathbf{y}_i|\mathbf{x}_i)$$

where $(\mathbf{x}_i, \mathbf{y}_i)$ refers to the i-th instance in the training set. During testing, we aim to find the optimal label sequence for a new input $\mathbf{x}$:

$$\mathbf{y}^* = \arg\max_{\mathbf{y} \in \mathbf{Y}} P(\mathbf{y}|\mathbf{x})$$

This search process can be done efficiently using the Viterbi algorithm.

3 Experiments

3.1 Datasets and Settings

We evaluate our model on two benchmark datasets (Miller et al., 2017). The homographic dataset contains 2,250 contexts, 1,607 of which contain a pun. The heterographic dataset consists of 1,780 contexts with 1,271 containing a pun. We notice there is no standard splitting information provided for both datasets. Thus we apply 10-fold cross validation. To make direct comparisons with prior studies, following (Cai et al., 2018), we accumulated the predictions for all ten folds and calculate the scores in the end.

For each fold, we randomly select 10% of the instances from the training set for development. Word embeddings are initialized with the 100-dimensional Glove (Pennington et al., 2014). The dimension of character embeddings is 30 and they are randomly initialized, which can be fine tuned during training. The pre-trained word embeddings are not updated during training. The dimensions of hidden vectors for both char-level and word-level LSTM units are set to 300. We adopt stochastic gradient descent (SGD) (Bottou, 1991) with a learning rate of 0.015.

For the pun detection task, if the predicted tag sequence contains at least one P tag, we regard the output (i.e., the prediction of our pun detection model) for this task as true, otherwise false. For the pun location task, a predicted pun is regarded as correct if and only if it is labeled as the gold pun in the dataset. As to pun location, to make fair comparisons with prior studies, we only consider the instances that are labeled as the ones containing a pun. We report precision, recall and F_1 score in Table 1. A list of prior works that did not employ joint learning are also shown in the first block of Table 1.

3.2 Results

We also implemented a baseline model based on conditional random fields (CRF), where features like POS tags produced by the Stanford POS tagger (Toutanova et al., 2003), n-grams, label tran-

---

[2] The word sense has also been shown helpful for the location of a homographic pun (Cai et al., 2018). However, such information may not always be helpful for the location of heterographic puns. We thus exclude such knowledge.

sitions, word suffixes and relative position to the end of the text are considered. We can see that our model with the BPA tagging scheme yields new state-of-the-art F_1 scores on pun detection and competitive results on pun location, compared to baselines that do not adopt joint learning in the first block. For location on heterographic puns, our model's performance is slightly lower than the system of (Vechtomova, 2017), which is a rule-based locator. Compared to CRF, we can see that our model, either with the NP or the BPA scheme, yields significantly higher recall on both detection and location tasks, while the precisions are relatively close. This demonstrates the effectiveness of BiLSTM, which learns the contextual features of given texts – such information appears to be helpful in recalling more puns.

Compared to the NP scheme, the BPA tagging scheme is able to yield better performance on these two tasks. After studying outputs from these two approaches, we found that one leading source of error for the NP approach is that there exist more than one words in a single instance that are assigned with the P tag. However, according to the description of pun in (Miller et al., 2017), each context contains a maximum of one pun. Thus, such a useful structural constraint is not well captured by the simple approach based on the NP tagging scheme. On the other hand, by applying the BPA tagging scheme, such a constraint is properly captured in the model. As a result, the results for such a approach are significantly better than the approach based on the NP tagging scheme, as we can observe from the table. Under the same experimental setup, we also attempted to exclude word position features. Results are given by BPA-p. It is expected that the performance of pun location drops, since such position features are able to capture the interesting property that a pun tends to appear in the second half of a sentence. While such knowledge is helpful for the location task, interestingly, a model without position knowledge yields improved performance on the pun detection task. One possible reason is that detecting whether a sentence contains a pun is not concerned with such word position information.

Additionally, we conduct experiments over sentences containing a pun only, namely 1,607 and 1,271 instances from homographic and heterographic pun corpora separately. It can be regarded as a "pipeline" method where the classifier for pun detection is regarded as perfect.[3] Following the prior work of (Cai et al., 2018), we apply 10-fold cross validation. Since we are given that all input sentences contain a pun, we only report accumulated results on pun location, denoted as Pipeline in Table 1. Compared with our approaches, the performance of such an approach drops significantly. On the other hand, such a fact demonstrates that the two task, detection and location of puns, can reinforce each other. These figures demonstrate the effectiveness of our sequence labeling method to detect and locate English puns in a joint manner.

3.3 Error Analysis

We studied the outputs from our system and make some error analysis. We found the errors can be broadly categorized into several types, and we elaborate them here. 1) Low word coverage: since the corpora are relatively small, there exist many unseen words in the test set. Learning the representations of such unseen words is challeng-

---

[3] Under a pipeline setting, the first step is to detect if a sentence contains a pun. Then another algorithm is called to locate the exact pun word residing in the sentence if such a sentence is detected as the one containing a pun. In our setting, we assume the detection phase is perfect. In other words, all sentences containing a pun are exactly retrieved.

ing, which affects the model's performance. Such errors contribute around 40% of the total errors made by our system. 2) Detection errors: we found many errors are due to the model's inability to make correct pun detection. Such inability harms both pun detection and pun location. Although our approach based on the BPA tagging scheme yields relatively higher scores on the detection task, we still found that 40% of the incorrectly predicted instances fall into this group. 3) Short sentences: we found it was challenging for our model to make correct predictions when the given text is short. Consider the example "*Superglue! Tom rejoined,*" here the word *rejoined* is the corresponding pun. However, it would be challenging to figure out the pun with such limited contextual information.

4 Related Work

Most existing systems address pun detection and location separately. Pedersen (2017) applied word sense knowledge to conduct pun detection. Indurthi and Oota (2017) trained a bidirectional RNN classifier for detecting homographic puns. Next, a knowledge-based approach is adopted to find the exact pun. Such a system is not applicable to heterographic puns. Doogan et al. (2017) applied Google n-gram and word2vec to make decisions. The phonetic distance via the CMU Pronouncing Dictionary is computed to detect heterographic puns. Pramanick and Das (2017) used the hidden Markov model and a cyclic dependency network with rich features to detect and locate puns. Mikhalkova and Karyakin (2017) used a supervised approach to pun detection and a weakly supervised approach to pun location based on the position within the context and part of speech features. Vechtomova (2017) proposed a rule-based system for pun location that scores candidate words according to eleven simple heuristics. Two systems are developed to conduct detection and location separately in the system known as UWAV (Vadehra, 2017). The pun detector combines predictions from three classifiers. The pun locator considers word2vec similarity between every pair of words in the context and position to pinpoint the pun. The state-of-the-art system for homographic pun location is a neural method (Cai et al., 2018), where the word senses are incorporated into a bidirectional LSTM model. This method only supports the pun location task on homographic puns. Another line of research efforts related to this work is sequence labeling, such as POS tagging, chunking, word segmentation and NER. The neural methods have shown their effectiveness in this task, such as BiLSTM-CNN (Chiu and Nichols, 2016), GRNN (Xu and Sun, 2016), LSTM-CRF (Lample et al., 2016), LSTM-CNN-CRF (Ma and Hovy, 2016), LM-LSTM-CRF (Liu et al., 2018).

In this work, we combine pun detection and location tasks as a single sequence labeling problem. Inspired by the work of (Liu et al., 2018), we also adopt a LSTM-CRF with character embeddings to make labeling decisions.

5 Conclusion

In this paper, we propose to perform pun detection and location tasks in a joint manner from a sequence labeling perspective. We observe that each text in our corpora contains a maximum of one pun. Hence, we design a novel tagging scheme to incorporate such a constraint. Such a scheme guarantees that there is a maximum of one word that will be tagged as a pun during the testing phase. We also found the interesting structural property such as the fact that most puns tend to appear at the second half of the sentences can be helpful for such a task, but was not explored in previous works. Furthermore, unlike many previous approaches, our approach, though simple, is generally applicable to both heterographic and homographic puns. Empirical results on the benchmark datasets prove the effectiveness of the proposed approach that the two tasks of pun detection and location can be addressed by a single model from a sequence labeling perspective.

Future research includes the investigations on how to make use of richer semantic and linguistic information for detection and location of puns. Research on puns for other languages such as Chinese is still under-explored, which could also be an interesting direction for our future studies.

Abstract

We explore the challenge of action prediction from textual descriptions of scenes, a testbed to approximate whether text inference can be used to predict upcoming actions. As a case of study, we consider the world of the Harry Potter fantasy novels and inferring what spell will be cast next given a fragment of a story. Spells act as keywords that abstract actions (e.g. 'Alohomora' to open a door) and denote a response to the environment. This idea is used to automatically build HPAC, a corpus containing 82 836 samples and 85 actions. We then evaluate different baselines. Among the tested models, an LSTM-based approach obtains the best performance for frequent actions and large scene descriptions, but approaches such as logistic regression behave well on infrequent actions.

1 Introduction

Natural language processing (NLP) has achieved significant advances in reading comprehension tasks (Chen et al., 2016; Salant and Berant, 2017). These are partially due to embedding methods (Mikolov et al., 2013; Devlin et al., 2018) and neural networks (Rosenblatt, 1958; Hochreiter and Schmidhuber, 1997; Vaswani et al., 2017), but also to the availability of new resources and challenges. For instance, in cloze-form tasks (Hermann et al., 2015; Bajgar et al., 2016), the goal is to predict the missing word given a short context. Weston et al. (2015) presented baBI, a set of proxy tasks for reading comprenhension. In the SQuAD corpus (Rajpurkar et al., 2016), the aim is to answer questions given a Wikipedia passage. Kocisky et al. (2018) introduce NarrativeQA, where answering the questions requires to process entire stories. In a related line, Fremann et al. (2017) use fictional crime scene investigation data, from the CSI series, to define a task where the models try to answer the question: 'who committed the crime?'.

In an alternative line of work, script induction (Schank and Abelson, 1977) has been also a useful approach to evaluate inference and semantic capabilities of NLP systems. Here, a model processes a document to infer new sequences that reflect events that are statistically probable (e.g. go to a restaurant, be seated, check the menu, ...). For example, Chambers and Jurafsky (2008) introduce narrative event chains, a representation of structured knowledge of a set of events occurring around a protagonist. They then propose a method to learn statistical scripts, and also introduce two different evaluation strategies. With a related aim, Pichotta and Mooney (2014) propose a multi-event representation of statistical scripts to be able to consider multiple entities. These same authors (Pichotta and Mooney, 2016) have also studied the abilities of recurrent neural networks for learning scripts, generating upcoming events given a raw sequence of tokens, using BLEU (Papineni et al., 2002) for evaluation.

This paper explores instead a new task: action prediction from natural language descriptions of scenes. The challenge is addressed as follows: given a natural language input sequence describing the scene, such as a piece of a story coming from a transcript, the goal is to infer which action is most likely to happen next.

Contribution We introduce a fictional-domain English corpus set in the world of Harry Potter novels. The domain is motivated by the existence of a variety of spells in these literary books, associated with keywords that can be seen as unambiguous markers for actions that potentially relate to the previous context. This is used to automatically create a natural language corpus coming from hundreds of users, with different styles, interests and writing skills. We then train a number of standard baselines to predict upcoming actions, a task that

Proceedings of NAACL-HLT 2019, pages 2124–2130
Minneapolis, Minnesota, June 2 - June 7, 2019.

requires to be aware of the context. In particular, we test a number of generic models, from a simple logistic regression to neural models. Experiments shed some light about their strengths and weaknesses and how these are related to the frequency of each action, the existence of other semantically related actions and the length of the input story.

2 HPAC: The Harry Potter's Action prediction Corpus

To build an action prediction corpus, we need to: (1) consider the set of actions, and (2) collect data where these occur. Data should come from different users, to approximate a real natural language task. Also, it needs to be annotated, determining that a piece of text ends up triggering an action. These tasks are however time consuming, as they require annotators to read vast amounts of large texts. In this context, machine comprehension resources usually establish a compromise between their complexity and the costs of building them (Hermann et al., 2015; Kocisky et al., 2018).

2.1 Domain motivation

We rely on an intuitive idea that uses transcripts from the Harry Potter world to build up a corpus for textual action prediction. The domain has a set of desirable properties to evaluate reading comprehension systems, which we now review.

Harry Potter novels define a variety of spells. These are keywords cast by witches and wizards to achieve purposes, such as turning on a light ('Lumos'), unlocking a door ('Alohomora') or killing ('Avada Kedavra'). They abstract complex and non-ambiguous actions. Their use also makes it possible to build an automatic and self-annotated corpus for action prediction. The moment a spell occurs in a text represents a response to the environment, and hence, it can be used to label the preceding text fragment as a scene description that ends up triggering that action. Table 1 illustrates it with some examples from the original books.

This makes it possible to consider texts from the magic world of Harry Potter as the domain for the action prediction corpus, and the spells as the set of eligible actions.[1] Determining the length of the preceding context, namely *snippet*, that has to be considered as the scene description is however not trivial. This paper considers experiments (§4) using snippets with the 32, 64, 96 and 128 previous tokens to an action. We provide the needed scripts to rebuild the corpus using arbitrary lengths.[2]

2.2 Data crawling

The number of occurrences of spells in the original Harry Potter books is small (432 occurrences), which makes it difficult to train and test a machine learning model. However, the amount of available fan fiction for this saga allows to create a large corpus. For HPAC, we used fan fiction (and *only* fan fiction texts) from `https://www.fanfiction.net/book/Harry-Potter/` and a version of the crawler by Milli and Bamman (2016).[3] We collected Harry Potter stories written in English and marked with the status 'completed'. From these we extracted a total of 82 836 spell occurrences, that we used to obtain the scene descriptions. Table 2 details the statistics of the corpus (see also Appendix A). Note that similar to Twitter corpora, fan fiction stories can be deleted over time by users or admins, causing losses in the dataset.[4]

Preprocessing We tokenized the samples with (Manning et al., 2014) and merged the occurrences of multi-word spells into a single token.

3 Models

This work addresses the task as a classification problem, and in particular as a sequence to label classification problem. For this reason, we rely on standard models used for this type of task: multinomial logistic regression, a multi-layered perceptron, convolutional neural networks and long short-term memory networks. We outline the essentials of each of these models, but will treat them as black boxes. In a related line, Kaushik and Lipton (2018) discuss the need of providing rigorous baselines that help better understand the improvement coming from future and complex models, and also the need of not demanding architectural novelty when introducing new datasets.

Although not done in this work, an alternative (but also natural) way to address the task is as a

---

[1] Note that the corpus is built in an automatic way and some occurrences might not correspond to actions, but for example, to a description of the spell or even some false positive samples. Related to this, we have not censored the content of the stories, so some of them might contain adult content.

[2] `https://github.com/aghie/hpac`

[3] Due to the website's Terms of Service, the corpus cannot be directly released.

[4] They also can be modified, making it unfeasible to retrieve some of the samples.

Text fragment	**Action**
Ducking under Peeves, they ran for their lives, right to the end of the corridor where they slammed into a door - and it was locked. 'This is it!' Ron moaned, as they pushed helplessly at the door, 'We're done for! This is the end!' They could hear footsteps, Filch running as fast as he could toward Peeves's shouts. 'Oh, move over', Hermione snarled. She grabbed Harry's wand, tapped the lock, and whispered, '**Alohomora**'.	Unlock the door
And then, without warning, Harry's scar exploded with pain. It was agony such as he had never felt in all his life; his wand slipped from his fingers as he put his hands over his face; his knees buckled; he was on the ground and he could see nothing at all; his head was about to split open. From far away, above his head, he heard a high, cold voice say, 'Kill the spare.' A swishing noise and a second voice, which screeched the words to the night: '**Avada Kedavra**'	Kill a target
Harry felt himself being pushed hither and thither by people whose faces he could not see. Then he heard Ron yell with pain. 'What happened?' said Hermione anxiously, stopping so abruptly that Harry walked into her. 'Ron, where are you? Oh, this is stupid' - '**Lumos**'	Turn on a light

Table 1: Examples from the Harry Potter books showing how spells map to reactions to the environment.

Statistics	**Training**	**Dev**	**Test**
#Actions	85	83	84
#Samples	66 274	8 279	8 283
#Tokens (s=32)	2 111 180	263 573	263 937
#Unique tokens (s=32)	33 067	13 075	13 207
#Tokens (s=128)	8 329 531	1 040 705	1 041 027
#Unique tokens (s=128)	60 379	25 146	25 285

Table 2: Corpus statistics: s is the length of the snippet.

special case of language modelling, where the output vocabulary is restricted to the size of the 'action' vocabulary. Also, note that the performance for this task is not expected to achieve a perfect accuracy, as there may be situations where more than one action is reasonable, and also because writers tell a story playing with elements such as surprise or uncertainty.

The source code for the models can be found in the GitHub repository mentioned above.

Notation $w_{1:n}$ denotes a sequence of words $w_1, ..., w_n$ that represents the scene, with $w_i \in V$. $F_\theta(\cdot)$ is a function parametrized by θ. The task is cast as $F : V^n \rightarrow A$, where A is the set of actions.

3.1 Machine learning models

The input sentence $w_{1:n}$ is encoded as a one-hot vector, $\mathbf{v}$ (total occurrence weighting scheme).

Multinomial Logistic Regression Let $\text{MLR}_\theta(\mathbf{v})$ be an abstraction of a multinomial logistic regression parametrized by θ, the output for an input $\mathbf{v}$ is computed as the $\arg\max_{a \in A} P(y = a|\mathbf{v})$, where $P(y = a|\mathbf{v})$ is a $softmax$ function, i.e, $P(y = a|\mathbf{v}) = \frac{e^{W_a \cdot \mathbf{v}}}{\sum_{a'}^{A} e^{W_{a'} \cdot \mathbf{v}}}$.

MultiLayer Perceptron We use one hidden layer with a rectifier activation function ($relu(x)$=$max(0, x)$). The output is computed as $\text{MLP}_\theta(\mathbf{v})$= $softmax(W_2 \cdot relu(W \cdot \mathbf{v} + \mathbf{b}) + \mathbf{b_2})$.

3.2 Sequential models

The input sequence is represented as a sequence of word embeddings, $\mathbf{w}_{1:n}$, where $\mathbf{w}_i$ is a concatenation of an internal embedding learned during the training process for the word w_i, and a pretrained embedding extracted from GloVe (Pennington et al., 2014)[5], that is further fine-tuned.

Long short-term memory network (Hochreiter and Schmidhuber, 1997): The output for an element $\mathbf{w}_i$ also depends on the output of $\mathbf{w}_{i-1}$. The $\text{LSTM}_\theta(\mathbf{w}_{1:n})$[6] takes as input a sequence of word embeddings and produces a sequence of hidden outputs, $\mathbf{h}_{1:n}$ ($\mathbf{h}_i$ size set to 128). The last output of the LSTM_θ, $\mathbf{h}_n$, is fed to a MLP_θ.

Convolutional Neural Network (LeCun et al., 1995; Kim, 2014). It captures local properties over continuous slices of text by applying a convolution layer made of different filters. We use a wide convolution, with a window slice size of length 3 and 250 different filters. The convolutional layer uses a $relu$ as the activation function. The output is fed to a max pooling layer, whose output vector is passed again as input to a MLP_θ.

4 Experiments

Setup All MLP_θ's have 128 input neurons and 1 hidden layer. We trained up to 15 epochs using mini-batches (size=16), Adam (lr=0.001) (Kingma and Ba, 2015) and early stopping.

Table 3 shows the macro and weighted F-scores for the models considering different snippet sizes.[7]

---

[5] `http://nlp.stanford.edu/data/glove.6B.zip`

[6] n is set to be equal to the length of the snippet.

[7] As we have addressed the task as a classification problem, we will use precision, recall and F-score as the evaluation metrics.

To diminish the impact of random seeds and local minima in neural networks, results are averaged across 5 runs.[8] 'Base' is a majority-class model that maps everything to 'Avada Kedavra', the most common action in the training set. This helps test whether the models predict above chance performance. When using short snippets (size=32), disparate models such as our MLR, MLP and LSTMs achieve a similar performance. As the snippet size is increased, the LSTM-based approach shows a clear improvement on the weighted scores[9], something that happens only marginally for the rest. However, from Table 3 it is hard to find out what the approaches are actually learning to predict.

Snippet	Model	Macro			Weighted		
		P	R	F	P	R	F

	CNN	8.8	7.8	7.1	24.8	30.2	25.0

Table 3: Macro and weighted F-scores over 5 runs.

To shed some light, Table 4 shows their performance according to a ranking metric, recall at k. The results show that the LSTM-based approach is the top performing model, but the MLP obtains just slightly worse results. Recall at 1 is in both cases low, which suggests that the task is indeed complex and that using just LSTMs is not enough. It is also possible to observe that even if the models have difficulties to correctly predict the action as a first option, they develop certain sense of the scene and consider the right one among their top choices. Table 5 delves into this by splitting the performance of the model into infrequent and frequent actions (above the average, i.e. those that occur more than 98 times in the training set, a total of 20 actions). There is a clear gap between the performance on these two groups of actions, with a ∼50 points difference in recall at 5. Also, a simple logistic regression performs similar to the LSTM on the infrequent actions.

Snippet	Model	R@1	R@2	R@5	R@10
-	Base	11.5	-	-	-
32	MLR	31.4	43.7	60.3	73.5

	CNN	33.7	36.9	71.4	6.5	5.0	14.6

Table 5: Performance on *frequent* (those that occur above the average) and *infrequent* actions.

Error analysis[10] Some of the misclassifications made by the LSTM approach were semantically related actions and counter-actions. For example, 'Colloportus' (to close a door) was never predicted. The most common mis-classification (14 out of 41) was 'Alohomora' (to unlock a door), which was 5 times more frequent in the training corpus. Similarly, 'Nox' (to extinguish the light from a wand) was correctly predicted 6 times, meanwhile 36 mis-classifications corre-

---

[8] Some macro F-scores do not lie within the Precision and Recall due to this issue.

[9] For each label, we compute their average, weighted by the number of true instances for each label. The F-score might be not between precision and recall.

[10] Made over one of the runs from the LSTM-based approach and setting the snippet size to 128 tokens.

spond to 'Lumos' (to light a place using a wand), which was 6 times more frequent in the training set. Other less frequent spells that denote vision and guidance actions, such as 'Point me' (the wand acts a a compass pointing North) and 'Homenum revelio' (to revel a human presence) were also mainly misclassified as 'Lumos'. This is an indicator that the LSTM approach has difficulties to disambiguate among semantically related actions, especially if their occurrence was unbalanced in the training set. This issue is in line with the tendency observed for recall at k. Spells intended for much more specific purposes, according to the books, obtained a performance significantly higher than the average, e.g. F-score('Riddikulus')=63.54, F-score('Expecto Patronum')=55.49 and F-score('Obliviate')=47.45. As said before, the model is significantly biased towards frequent actions. For 79 out of 84 gold actions in the test set, we found that the samples tagged with such actions were mainly classified into one of the top 20 most frequent actions.

Human comparison We collected human annotations from 208 scenes involving frequent actions. The accuracy/F-macro/F-weighted was 39.20/30.00/40.90. The LSTM approach obtained 41.26/25.37/39.86. Overall, the LSTM approach obtained a similar performance, but the lower macro F-score by the LSTM could be an indicator that humans can distinguish within a wider spectrum of actions. As a side note, super-human performance it is not strange in other NLP tasks, such as sentiment analysis (Pang et al., 2002).

5 Conclusion

We explored action prediction from written stories. We first introduced a corpus set in the world of Harry Potter's literature. Spells in these novels act as keywords that abstract actions. This idea was used to label a collection of fan fiction. We then evaluated standard NLP approaches, from logistic regression to sequential models such as LSTMs. The latter performed better in general, although vanilla models achieved a higher performance for actions that occurred a few times in the training set. An analysis over the output of the LSTM approach also revealed difficulties to discriminate among semantically related actions.

The challenge here proposed corresponded to a fictional domain. A future line of work we are interested in is to test whether the knowledge learned with this dataset could be transferred to real-word actions (i.e. real-domain setups), or if such transfer is not possible and a model needs to be trained from scratch.

Acknowlegments

This work has received support from the TELEPARES-UDC project (FFI2014-51978-C2-2-R) and the ANSWER-ASAP project (TIN2017-85160-C2-1-R) from MINECO, and from Xunta de Galicia (ED431B 2017/01), and from the European Research Council (ERC), under the European Union's Horizon 2020 research and innovation programme (FASTPARSE, grant agreement No 714150).

Abstract

Peer-review plays a critical role in the scientific writing and publication ecosystem. To assess the efficiency and efficacy of the reviewing process, one essential element is to understand and evaluate the reviews themselves. In this work, we study the content and structure of peer reviews under the argument mining framework, through automatically detecting (1) argumentative propositions put forward by reviewers, and (2) their types (e.g., evaluating the work or making suggestions for improvement). We first collect 14.2K reviews from major machine learning and natural language processing venues. 400 reviews are annotated with $10,386$ propositions and corresponding types of EVALUATION, REQUEST, FACT, REFERENCE, or QUOTE. We then train state-of-the-art proposition segmentation and classification models on the data to evaluate their utilities and identify new challenges for this new domain, motivating future directions for argument mining. Further experiments show that proposition usage varies across venues in amount, type, and topic.

Review #1 (*rating*: 5, *# sentences*: 11)
[Quality: This paper demonstrates that convolutional and relational neural networks fail to solve visual relation problems . . .]$_{\text{FACT}}$ [This points at important limitations of current neural network architectures where architectures depend mainly on rote memorization.]$_{\text{EVAL}}$ . . . [Significance: This work demonstrates failures of relational networks on relational tasks. . .]$_{\text{FACT}}$ [Pros: Important message about network limitations.]$_{\text{EVAL}}$ [Cons: Straightforward testing of network performance on specific visual relation tasks.]$_{\text{EVAL}}$ . . .
Review #2 (*rating*: 5, *# sentences*: 10)
[The authors present two autoregressive models . . .]$_{\text{FACT}}$. . . [In that context , this work can be viewed as applying deep autoregressive density estimators to policy gradient methods.]$_{\text{EVAL}}$. . . [At least one of those papers ought to be cited.]$_{\text{REQ}}$ [It also seems like a simple, obvious baseline is missing from their experiments . . .]$_{\text{EVAL}}$. . . [The method could even be made to capture dependencies between different actions by adding a latent probabilistic layer . . .]$_{\text{EVAL}}$. . .[A direct comparison against one of the related methods in the discussion section would help]$_{\text{REQ}}$. . .

Figure 1: Sample ICLR review excerpts. Propositions are annotated with types, such as FACT (fact), EVAL (evaluation), and REQ (request). Review #2 contains in-depth evaluation and actionable suggestion, thus is perceived to be of a higher quality.

1 Introduction

Peer review is a process where domain experts scrutinize the quality of research work in their field, and it is a cornerstone of scientific discovery (Hettich and Pazzani, 2006; Kelly et al., 2014; Price and Flach, 2017). In 2015 alone, approximately 63.4 million hours were spent on peer reviews (Kovanis et al., 2016). To maximize their benefit to the scientific community, it is crucial to understand and evaluate the construction and limitation of reviews themselves. However, minimal work has been done to analyze reviews' content and structure, let alone to evaluate their qualities.

As seen in Figure 1, peer reviews resemble arguments: they contain **argumentative propositions** (henceforth propositions) that convey reviewers' interpretation and evaluation of the research. Constructive reviews, e.g., review #2, often contain in-depth analysis as well as concrete suggestions. As a result, automatically identifying propositions and their types would be useful to understand the composition of peer reviews.

Therefore, we propose *an argument mining-based approach to understand the content and structure of peer reviews*. Argument mining studies the automatic detection of argumentative components and structure within discourse (Peldszus and Stede, 2013). Specifically, argument types (e.g. evidence and reasoning) and their arrangement are indicative of argument quality (Habernal and Gurevych, 2016; Wachsmuth et al., 2017). In this work, we focus on two specific tasks: (1) **proposition segmentation**—detecting elementary argumentative discourse units that are

Proceedings of NAACL-HLT 2019, pages 2131–2137
Minneapolis, Minnesota, June 2 - June 7, 2019.

propositions, and (2) **proposition classification**—labeling the propositions according to their types (e.g., evaluation vs. request).

Since there was no annotated dataset for peer reviews, as part of this study, we first collect 14.2K reviews from major machine learning (ML) and natural language processing (NLP) venues. We create a dataset, **AMPERE** (Argument Mining for PEer REviews), by annotating 400 reviews with $10,386$ propositions and labeling each proposition with the type of EVALUATION, REQUEST, FACT, REFERENCE, QUOTE, or NON-ARG.[1] Significant inter-annotator agreement is achieved for proposition segmentation (Cohen's $\kappa = 0.93$), with good consensus level for type annotation (Krippendorf's $\alpha_U = 0.61$).

We benchmark our new dataset with state-of-the-art and popular argument mining models to better understand the challenges posed in this new domain. We observe a significant drop of performance for proposition segmentation on AMPERE, mainly due to its different argument structure. For instance, 25% of the sentences contain more than one proposition, compared to that of 8% for essays (Stab and Gurevych, 2017), motivating new solutions for segmentation and classification.

We further investigate review structure difference across venues based on proposition usage, and uncover several patterns. For instance, ACL reviews tend to contain more propositions than those in ML venues, especially with more requests but fewer facts. We further find that reviews with extreme ratings, i.e., strong reject or accept, tend to be shorter and make much fewer requests. Moreover, we probe the salient words for different proposition types. For example, ACL reviewers ask for more "examples" when making requests, while ICLR reviews contain more evaluation of "network" and how models are "trained".

2 AMPERE Dataset

We collect review data from three sources: (1) `openreview.net`—an online peer reviewing platform for ICLR 2017, ICLR 2018, and UAI 2018 [2]; (2) reviews released for accepted papers at NeurIPS from 2013 to 2017; and (3) opted-in reviews for ACL 2017 from Kang et al. (2018).

EVALUATION: Subjective statements, often containing qualitative judgment. Ex: *"This paper shows nice results on a number of small tasks."*
REQUEST: Statements suggesting a course of action. Ex: *"The authors should compare with the following methods."*
FACT: Objective information of the paper or commonsense knowledge. Ex: *"Existing works on multi-task neural networks typically use hand-tuned weights..."*
REFERENCE: Citations and URLs. Ex: *"see MuseGAN (Dong et al), MidiNet (Yang et al), etc "*
QUOTE: Quotations from the paper. Ex: *"The author wrote 'where r is lower bound of feature norm'."*
NON-ARG: Non-argumentative statements. Ex: *"Aha, now I understand."*

Table 1: Proposition types and examples.

Dataset	#Doc	#Sent	#Prop
Comments (Park and Cardie, 2018)	731	3,994	4,931
Essays (Stab and Gurevych, 2017)	402	7,116	6,089
News (Al Khatib et al., 2016)	300	11,754	14,313
Web (Habernal and Gurevych, 2017)	340	3,899	1,882
AMPERE	400	8,030	10,386

Table 2: Statistics for AMPERE and some argument mining corpora, including # of annotated propositions.

In total, $14,202$ reviews are collected (ICLR: $4,057$; UAI: 718; ACL: 275; and NeurIPS: $9,152$). All venues except NeurIPS have paper rating scores attached to the reviews.

Annotation Process. For proposition segmentation, we adopt the concepts from Park et al. (2015) and instruct the annotators to identify elementary argumentative discourse units on sentence or sub-sentence level, based on their discourse functions and topics. They then classify the propositions into five types with an additional non-argument category, as explained in Table 1.

400 ICLR 2018 reviews are sampled for annotation, with similar distributions of length and rating to those of the full dataset. Two annotators who are fluent English speakers first label the 400 reviews with proposition segments and types, and a third annotator then resolves disagreements.

We calculate the inter-annotator agreement between the two annotators. A Cohen's κ of 0.93 is achieved for proposition segmentation, with each review treated as a BIO sequence. For classification, unitized Krippendorf's α_U (Krippendorff, 2004), which considers disagreements among segmentation, is calculated per review and then averaged over all samples, and the value is 0.61. Among the exactly matched proposition segments, we report a Cohen's κ of 0.64.

Statistics. Table 2 shows comparison between AMPERE and some other argument min-

---

ing datasets of different genres. We also show the number of propositions in each category in Table 3. The most frequent types are evaluation (38.3%) and fact (36.5%).

Eval	Req	Fact	Ref	Quot	Non-A	Total
3,982	1,911	3,786	207	161	339	10,386

Table 3: Number of propositions per type in AMPERE.

3 Experiments with Existing Models

We benchmark AMPERE with popular and state-of-the-art models for proposition segmentation and classification. Both tasks can be treated as sequence tagging problems with the setup similar to Schulz et al. (2018). For experiments, 320 reviews (7, 999 propositions) are used for training and 80 reviews (2, 387 propositions) are used for testing. Following Niculae et al. (2017), 5-fold cross validation on the training set is used for hyperparameter tuning. To improve the accuracy of tokenization, we manually replace mathematical formulas, variables, URL links, and formatted citation with special tokens such as `<EQN>`, `<VAR>`, `<URL>`, and `<CIT>`. Parameters, lexicons, and features used for the models are described in the supplementary material.

3.1 Task I: Proposition Segmentation

We consider three baselines. **FullSent**: treating each sentence as a proposition. **PDTB-conn**: further segmenting sentences when any discourse connective (collected from Penn Discourse Treebank (Prasad et al., 2007)) is observed. **RST-parser**: segmenting discourse units by the RST parser in Feng and Hirst (2014).

For learning-based methods, we start with Conditional Random Field (**CRF**) (Lafferty et al., 2001) with features proposed by Stab and Gurevych ((2017), Table 7), and **BiLSTM-CRF**, a bidirectional Long Short-Term Memory network (BiLSTM) connected to a CRF output layer and further enhanced with ELMo representation (Peters et al., 2018). We adopt the BIO scheme for sequential tagging (Ramshaw and Marcus, 1999), with O corresponding to Non-Arg. Finally, we consider **jointly modeling** segmentation and classification by appending the proposition types to BI tags, e.g., B-fact, with CRF (**CRF-joint**) and BiLSTM-CRF (**BiLSTM-CRF-joint**).

	Prec.	**Rec.**	**F1**
FullSent	73.68	56.00	63.64
PDTB-conn	51.11	49.71	50.40
RST-parser	30.28	43.00	35.54
CRF	66.53	52.92	58.95
BiLSTM-CRF	**82.25**	**79.96**	**81.09***
CRF-joint	74.99	63.33	68.67
BiLSTM-CRF-joint	81.12	78.42	79.75

Table 4: Proposition segmentation results. Result that is significantly better than all comparisons is marked with $*$ ($p < 10^{-6}$, McNemar test).

	Overall	Eval	Req	Fact	Ref	Quot
With Gold-Standard Segments						
Majority	40.75	57.90	–	–	–	–
PropLexicon	36.83	40.42	36.07	32.23	59.57	31.28
SVM	60.98	63.88	**69.02**	54.74	**69.47**	7.69
CNN	**66.56***	**69.02**	63.26	**66.17**	67.44	**52.94**
With Predicted Segments						
Majority	33.30	47.60	–	–	–	–
PropLexicon	23.21	22.45	23.97	23.73	35.96	16.67
SVM	51.46	54.05	48.16	52.77	52.27	4.71
CNN	55.48	57.75	53.71	55.19	48.78	33.33
CRF-joint	50.69	46.78	55.74	52.27	**55.77**	26.47
BiLSTM-CRF-joint	**62.64***	**62.36***	**67.31***	**61.86**	54.74	**37.36**

Table 5: Proposition classification F1 scores. Results that are significant better than other methods are marked with $*$ ($p < 10^{-6}$, McNemar test).

Table 4 shows that BiLSTM-CRF outperforms other methods in F1. More importantly, the performance on reviews is lower than those reached on existing datasets, e.g., an F1 of 86.7 is obtained by CRF for essays (Stab and Gurevych, 2017). This is mostly due to essays' better structure, with frequent use of discourse connectives.

3.2 Task II: Proposition Classification

With given proposition segments, predicted or gold-standard, we experiment with proposition-level models to label proposition types.

We utilize two baselines. **Majority** simply assigns the majority type in the training set. **PropLexicon** matches the following lexicons for different proposition types in order, and returns the first corresponding type with a match; if no lexicon is matched, the proposition is labeled as Non-Arg:

- Reference: `<URL>`, `<CIT>`
- Quote: “, ”, ’
- Request: *should, would be nice, why, please, would like to, need*
- Evaluation: *highly, very, unclear, clear, interesting, novel, well, important, similar, clearly, quite, good*
- Fact: *author, authors, propose, present, method, parameters, example, dataset, same, incorrect, correct*

For supervised models, we employ linear **SVM** with a squared hinge loss and group Lasso regularizer (Yuan and Lin, 2006). It is trained with the top 500 features selected from Table 9 in (Stab and Gurevych, 2017) by χ^2 test. We also train a convolutional neural network (**CNN**) proposed by Kim (2014), with the same setup and pre-trained word embeddings from word2vec (Mikolov et al., 2013). Finally, results by joint models of CRF and BiLSTM-CRF are also reported.

F1 scores for all propositions and each type are reported in Table 5. A prediction is correct when both segment and type are matched with the true labels. CNN performs better for types with significantly more training samples, i.e., evaluation and fact, indicating the effect of data size on neural model's performance. Joint models (CRF-joint and BiLSTM-CRF-joint) yield the best F1 scores for all categories when gold-standard segmentation is unavailable.

4 Proposition Analysis by Venues

Here we leverage the BiLSTM-CRF-joint model trained on the annotated AMPERE data to identify propositions and their types in unlabeled reviews from the four venues (ICLR, UAI, ACL, and NeurIPS), to understand the content and structure of peer reviews at a larger scale.

Proposition Usage by Venue and Rating. Figure 2 shows the average number of propositions per review, grouped by venue and rating. Scores in $1-10$ are scaled to $1-5$ by $\lceil x/2 \rceil$, with 1 as strong reject and 5 as strong accept. ACL and NeurIPS have significantly more propositions than ICLR and UAI. Ratings, which reflect a reviewer's judgment of paper quality, also affect proposition usage. We find that reviews with extreme ratings, i.e., 1 and 5, tend to have fewer propositions.

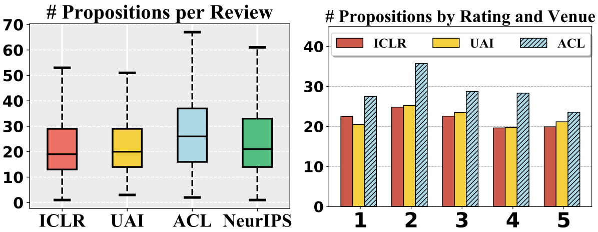

Figure 2: Proposition number in reviews. Differences among venues are all significant except UAI vs. ICLR and ACL vs. NeurIPS ($p < 10^{-6}$, unpaired t-test).

We further study the distribution of proposition type in each venue. As observed in Figure 3, ACL reviews contain more requests but fewer facts than other venues. Specifically, we find that 94.6% of ACL reviews have at least one REQUEST proposition, compared to 81.5% for ICLR and 84.7% for UAI. We also show proposition type distribution based on ratings in Figure 4. Reviews with the highest rating tend to use fewer evaluation and reference, while reviews with ratings of $3-4$ (borderline or weak accept) contain more requests. We further observe a sharp decrease of QUOTE usage in rating group 4, and a surge of NON-ARG for rating group 5, while FACT remains consistent across rating ranges.

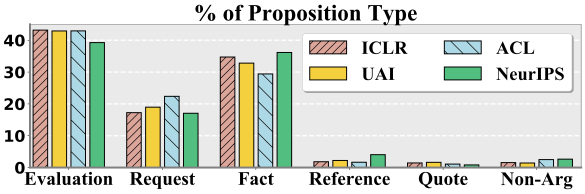

Figure 3: Distribution of proposition type per venue.

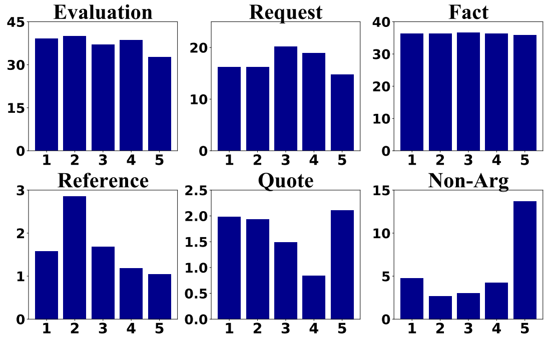

Figure 4: Distribution of proposition type per rating (in %) on AMPERE.

Proposition Structure. Argumentative structure, which is usually studied as support and attack relations, reveals how propositions are organized into coherent text. According to Park and Cardie (2018), 75% of support relations happen between adjacent propositions in user comments. We thus plot the proposition transition probability matrix in Figure 5, to show the argument structure in AMPERE. The high probabilities along the diagonal line imply that propositions of the same type are often constructed consecutively, with the exception of quote, which is more likely to be followed by evaluation.

Proposition Type and Content. We also probe the salient words used for each proposition type, and the difference of their usage across venues. For each venue, we utilize log-likelihood ratio test (Lin and Hovy, 2000) to identify the represen-

tative words in each proposition type compared to other types. Table 6 shows both the commonly used salient words across venues and the unique words with top frequencies for each venue ($\alpha = 0.001$, χ^2 test). For evaluation, all venues tend to focus on clarity and contribution, with ICLR discussing more about “network” and NeurIPS often mentioning equations. ACL reviews then frequently request for “examples”.

5 Related Work

There is a growing interest in understanding the content and assessing the quality of peer reviews. Authors’ feedback such as satisfaction and helpfulness have been adopted as quality indicators (Latu and Everett, 2000; Hart-Davidson et al., 2010; Xiong and Litman, 2011). Nonetheless, they suffer from author subjectivity and are often influenced by acceptance decisions (Weber et al., 2002). Evaluation by experts or editors proves to be more reliable and informative (van Rooyen et al., 1999), but requires substantial work and knowledge of the field. Shallow linguistic features, e.g., sentiment words, are studied in Bornmann et al. (2012) for analyzing languages in peer reviews. To the best of our knowledge, our work is the first to understand the content and structure of peer reviews via argument usage.

Our work is also in line with the growing body of research in argument mining (Teufel et al., 1999; Palau and Moens, 2009). Most of the work focuses on arguments in social media posts (Park and Cardie, 2014; Wei et al., 2016; Habernal and Gurevych, 2016), online debate portals or Oxford-style debates (Wachsmuth et al., 2017; Hua and Wang, 2017; Wang et al., 2017), and student essays (Persing and Ng, 2015; Ghosh et al., 2016). We study a new domain of peer reviews, and identify new challenges for existing models.

6 Conclusion

We study the content and structure of peer reviews under the argument mining framework. AMPERE, a new dataset of peer reviews, is collected and annotated with propositions and their types. We benchmark AMPERE with state-of-the-art argument mining models for proposition segmentation and classification. We leverage the classifiers to analyze the proposition usage in reviews across ML and NLP venues, showing interesting patterns in proposition types and content.

Abstract

We present a new dataset comprised of 210,532 tokens evenly drawn from 100 different English-language literary texts annotated for ACE entity categories (person, location, geo-political entity, facility, organization, and vehicle). These categories include non-named entities (such as "the boy", "the kitchen") and nested structure (such as [[the cook]'s sister]). In contrast to existing datasets built primarily on news (focused on geo-political entities and organizations), literary texts offer strikingly different distributions of entity categories, with much stronger emphasis on people and description of settings. We present empirical results demonstrating the performance of nested entity recognition models in this domain; training natively on in-domain literary data yields an improvement of over 20 absolute points in F-score (from 45.7 to 68.3), and mitigates a disparate impact in performance for male and female entities present in models trained on news data.

1 Introduction

Computational literary analysis works at the intersection of natural language processing and literary studies, drawing on the structured representation of text to answer literary questions about character (Underwood et al., 2018), objects (Tenen, 2018) and place (Evans and Wilkens, 2018).

Much of this work relies on the ability to extract entities accurately, including work focused on modeling (Bamman et al., 2014; Iyyer et al., 2016; Chaturvedi et al., 2017). And yet, with notable exceptions (Vala et al., 2015; Brooke et al., 2016), nearly all of this work tends to use NER models that have been trained on non-literary data, for the simple reason that labeled data exists for domains like news through standard datasets like ACE (Walker et al., 2006), CoNLL (Tjong Kim Sang and De Meulder, 2003) and OntoNotes (Hovy et al., 2006)—and even historical non-fiction (DeLozier et al., 2016; Rayson et al., 2017)—but not for literary texts.

This is naturally problematic for several reasons: models trained on out-of-domain data surely degrade in performance when applied to a very different domain, and especially for NER, as Augenstein et al. (2017) has shown; and without in-domain *test* data, it is difficult to directly estimate the severity of this degradation. At the same time, literary texts also demand slightly different representations of entities. While classic NER models typically presume a flat entity structure (Finkel and Manning, 2009), relevant characters and places (and other entities) in literature need not be flat, and need not be named: *The cook's sister ate lunch* contains two `PER` entities ([The cook] and [The cook's sister]).

We present in this work a new dataset of entity annotations for a wide sample of 210,532 tokens from 100 literary texts to help address these issues and help advance computational work on literature. These annotations follow the guidelines set forth by the ACE 2005 entity tagging task (LDC, 2005) in labeling all nominal entities (named and common alike), including those with nested structure. In evaluating the stylistic difference between the texts in ACE 2005 (primarily news) and the literary texts in our new dataset, we find considerably more attention dedicated to people and settings in literature; this attention directly translates into substantially improved accuracies for those classes when models are trained on them. The dataset is freely available for download under a Creative Commons ShareAlike 4.0 license at `https://github.com/dbamman/litbank`.

Proceedings of NAACL-HLT 2019, pages 2138–2144
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Corpus

We draw our corpus from the public-domain texts on Project Gutenberg, selecting individual works of fiction (both novels and short stories) that include a mix of high literary style (e.g., Edith Wharton's *Age of Innocence*, James Joyce's *Ulysses*) and popular pulp fiction (e.g., H. Rider Haggard's *King Solomon's Mines*, Horatio Alger's *Ragged Dick*). All texts are published before 1923 (the current threshold for public domain in the United States), with the majority falling between 1852 and 1911.

From each text, we select approximately the first 2,000 words as a sample, yielding a total dataset of 210,532 tokens.

3 Annotation

We adopt the ACE 2005 guidelines for entity annotation, focusing on the subset of people (`PER`), natural locations (`LOC`), built facilities (`FAC`), geo-political entities (`GPE`), organizations (`ORG`) and vehicles (`VEH`).[1] While traditional named entity recognition presumes a flat structure in which entity labels cannot be embedded within each other, we allow for nested structure, as in the following (from Jane Austen's *Emma*):

$$\ldots \overbrace{\text{the elder brother of } \overbrace{\overbrace{\text{Isabella}}^{\texttt{PER}} \text{'s husband}}^{\texttt{PER}}}^{\texttt{PER}}$$

This nested structure is in fact quite common in our data, with entities that contain at least one level of nesting accounting for 13.8% of the annotations—86.2% contain no nesting (as in *Isabella* above), 12.5% contain one level (*Isabella's husband*), 1.2% contain two (*the elder brother of Isabella's husband*), and 0.1% contain three. The dataset contains a total of 13,912 entity annotations.

3.1 Entity types

We generally follow the ACE annotation guidelines for each of the entity classes and restrict our annotations to proper and common noun phrases (i.e., excluding pronouns or WH-question words); table 1 illustrates examples for each class.

PER. By person we describe a single person indicated by a proper name (Tom Saywer) or common entity (the boy); or set of people, such as *her daughters* and *the Ashburnhams*.

FAC. ACE guidelines define a facility as a "functional, primarily man-made structure" designed for human habitation (buildings, museums), storage (barns, parking garages), transportation infrastructure (streets, highways), and maintained outdoor spaces (gardens) (LDC, 2005). We adopt the ACE threshold for taggability here as well, and rooms and closets within a house as the smallest possible facility.

GPE. Geo-political entities are single units that contain a population, government, physical location, and political boundaries (LDC, 2005). In literary data, this includes not only cities that have known geographical locations within the real world (London, New York), or nations (England, the United States), but also both named and common imagined entities as well (the town, the village).

LOC. Locations describe entities with physicality but without political entities. In our dataset, this includes named regions without political organization (New England, the South) and planets (Mars). The most common class, however, are geologically designated areas describing natural settings, such as the sea, the river, the country, the valley, the woods, and the forest.

VEH. Literary texts include a number of vehicles defined as "a physical device primarily designed to move an object from one location to another" (LDC, 2005); ships, trains, and carriages dominate since nearly all texts were written before the rise of automobiles.

ORG. Organizations are defined by the criterion of formal association and are relatively rare in literary data, comprising the least frequently occurring entity class. The most frequent organizations include the army and the Church (as an administrative entity, distinct from the church as a facility with a physical location).

3.2 Figurative language

Literary language in particular presents several unique challenges to entity annotation, including metaphor, personification and metonymy.

---

[1] We exclude the ACE category of weapons (`WEA`), since that class is rarely attested in our data.

Entity type	Count	Examples
PER	9,383	my mother, Jarndyce, the doctor, a fool, his companion
FAC	2,154	the house, the room, the garden, the drawing-room, the library
LOC	1,170	the sea, the river, the country, the woods, the forest
GPE	878	London, England, the town, New York, the village
VEH	197	the ship, the car, the train, the boat, the carriage
ORG	130	the army, the Order of Elks, the Church, Blodgett College

Table 1: Entity classes annotated in literary data.

Metaphor. For non-figurative texts, predicative structures like *John is a doctor* nearly always entail the two comparands to be identical in their entity type (here, *John* and *a doctor* are both `PER`). Literary texts, however, are awash in figurative metaphor, such as "the young man was not really a poet; but surely he was a poem" (Chesterton, *The Man Who Was Thursday*). In such cases where the metaphor takes a predicative structure of *x is y*, we annotate only those phrases whose type describes an entity class (in this case, labeling *a poet* as a `PER`, but not *a poem*).

Personification. Several works, such as London's *The Call of the Wild* and Sewell's *Black Beauty*, feature personified animals as main characters, with dialogue and evident cognition. We expand the criteria for `PER` to include such characters who engage in dialogue or have reported internal monologue, regardless of their human status (this includes depicted non-human life forms in science fiction, such as aliens and robots, as well).

Metonymy. Metonymy is a rhetorical device of describing one aspect of a concept by a closely related one (such as the *White House* to refer to the organization of government it houses). We see many examples of metonymy in literature, such as the following:

> 'Them men would eat and drink if we was all in our graves,' said the indignant cook, who indeed had a real grievance; and the outraged sentiment of *the kitchen* was avenged by a bad and hasty dinner." (Oliphant, Miss Marjoribanks)

Following ACE, we annotate such examples by annotating the evoked entity class; in this case, annotating *the kitchen* as a `PER` (describing a set of cooks who feel outrage) rather than as a `FAC`.

3.3 Annotation process

Two co-authors annotated all 100 texts with a single pass between them after an initial phase of discussions about the annotation process, difficulties encountered and formalizing annotation decisions specific to literary texts. At the end of annotating, the inter-annotator agreement was calculated by double-annotating the same five texts and measuring the F1 score. We find that agreement rate to be high (86.0 F), likely due to the existence of thorough previous guidelines in ACE that both annotators were able to reference during the process of annotation.[2]

4 Comparison with ACE

We can compare the properties of this dataset to those of the ACE 2005 annotated data. To enable an apples-to-apples comparison, we filter the ACE data to exclude entity labels for tokens that are marked with a mention type of pronoun (`PRO`) or WH-question (`WHQ`) and remove all weapon (`WEA`) labels; we consider only the subsets for broadcast conversation (bc), broadcast news (bn), newswire (nw) and weblog (wl), as in past work (Lu and Roth, 2015; Muis and Lu, 2017; Ju et al., 2018).

Figure 2 plots the difference in entity label distributions between the ACE 2005 data and our literary data: literature has a proportionally higher ratio of person and facility mentions, and much lower mentions for GPEs and organizations.

4.1 Prediction

To understand how this different distribution of entity types impacts the performance of models trained on these different sources, we evaluate the performance of a state-of-the-art model for nested

---

[2] Note we report F-score since we are measuring the agreement rates between annotators not only in their choice of labels (for which a categorical chance-corrected measure like Cohen's κ would be appropriate), but also the *spans* in text to which they apply.

Train → Test	Precision	Recall	F
ACE → ACE	75.3 [72.7–77.9]	63.3 [60.5–66.1]	68.8 [66.2–71.2]
ACE → Literature	57.8 [54.2–61.5]	37.7 [35.1–40.6]	45.7 [42.8–48.6]
Literature → Literature	75.1 [72.1–77.8]	62.6 [59.7–65.4]	68.3 [65.5–70.8]

Table 2: Performance on nested entity recognition using the layered BiLSTM-CRF of Ju et al. (2018) with different training → test combinations. All metrics are reported with 95% bootstrap confidence intervals.

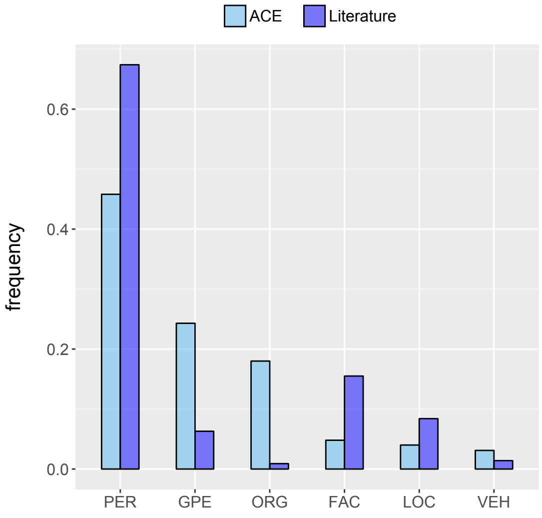

Figure 1: Distribution of entity types

entity recognition (Ju et al., 2018). We create training, development and test splits on the 100 literary books by stratifying at the document level, with 80 books in training, 10 books in development and 10 books in test.

To preprocess ACE, we tokenize and split sentences using the Stanford tokenizer (Manning et al., 2014), and create training, development and test partitions again stratified by document, so that sentences from the same document do not appear in both train and test. As above, we adapt the ACE annotations to our format by removing pronoun (`PRO`) and WH-question (`WHQ`) annotations and remove all weapon (`WEA`) labels, and consider only the subsets for broadcast conversation, broadcast news, newswire and weblogs. We present results with 95% confidence intervals using the bootstrap.

When trained on ACE and tested on ACE, the layered bidirectional LSTM-CRF of Ju et al. (2018) achieves an F-score of 68.8. When that same model (trained on ACE) is evaluated on our literature data, performance drops precipitously (23 absolute points in F-score). This alone—that cross-domain performance can be so strikingly worse—is a significant result, providing the first estimate of how performance degrades across these domains for this task.

However, when we train an identically parameterized model on the training partition of the literary data and evaluate it on the literary test partition, performance naturally improves substantially to an F-score of 68.3. As table 2 shows, performance improves dramatically for nearly all entity classes; the classes with the most statistically significant improvement are `PER` and `FAC`—both of which improve by 20 absolute points.

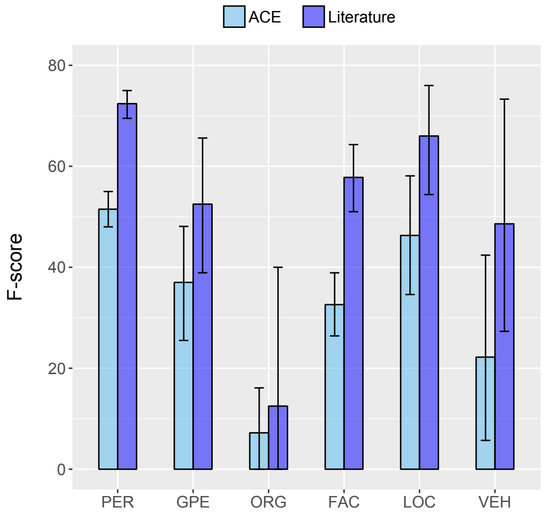

Figure 2: F-scores with 95% bootstrap confidence intervals by entity type when evaluating on literature test data with different training sources.

4.2 Analysis

To better understand the ways in which a model trained on ACE data differs in its predictions from an identically parameterized model trained on literary data, we used the two models described above to generate predictions for nested entities in a random sample of 1,000 full-text books from Project Gutenberg not in our training, development or test data (a total of 78M tokens). We then analyzed a simple difference in frequencies between the predictions of the two models on that same data; for a given entity e (e.g., *the boy*) and category t (e.g., `PER`), we calculate the frequency f as the number of times e was tagged by each model as t, and measure the difference:

$$f_{LIT}(e,t) - f_{ACE}(e,t)$$

The ten terms with the strongest positive difference in frequencies for the `PER` class—those phrases that are found significantly more often in a model trained on literary data than a model trained on ACE—are *Mrs., Miss, Lady, Aunt, Sir, Captain, no one, Mr, Madame* and *nobody*, suggesting a potential gender bias in the predictions; indeed, while ACE 2005 contains 47 instances of *Mr.*, it contains no mentions of *Mrs.* or honorific *Miss* (and only three instances of *Ms.*). While other work has demonstrated the gender bias present in word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017; Zhao et al., 2019) and in such NLP tasks as coreference resolution (Rudinger et al., 2018; Zhao et al., 2018), sentiment analysis (Kiritchenko and Mohammad, 2018), and speech recognition (Tatman, 2017), we can investigate the same phenomenon here: does a model trained on ACE result in a disparate impact in its performance recognizing men and women entities in text?

To answer this question, we annotate the gender for all `PER` entities in the literary test data (a total of 969 entities) and measure the recall of each model as a function of the gender of the true entity (measuring, for example, how many women in the gold literary data each model was able to identify, and how many men).

Training	Women	Men	Diff	p
ACE	38.0	49.6	−11.6	0.0009
Literature	69.3	68.2	1.1	0.7459

Table 3: Recall on literary test data by the gender of `PER` entity for models trained on ACE and literary data.

Table 4 lists these results: while a model trained on literary data recognizes male and female entities at roughly equal rates, ACE data shows a strong disparate performance, with female entities recognized at a rate over 11 points worse than male entities. This difference is significant at $p < 0.001$ under a permutation test (randomly shuffling the gender labels assigned to entities to generate a non-parametric null distribution, with 100,000 permutations).

If we remove the obvious entities from the gold data that begin with *Mrs.* and *Miss* (the honorifics that are rarely attested in ACE) along with those that begin with *Mr.*, we still see a sizable disparity in performance, suggesting that this result is more pervasive than the simple absence of those honorifics from the training data.

Training	Women	Men	Diff	p
ACE	40.4	48.3	−7.9	0.0358
Literature	63.7	67.1	−3.4	0.3542

Table 4: Recall on literary test data by the gender of `PER` entity for models trained on ACE and literary data, excluding all gold entities beginning with *Mrs.*, *Miss* and *Mr.*

5 Conclusion

We present in this work a new dataset of nested entity annotations for literature; such data allows us to measure the performance of existing NER systems when evaluated on literary data, train new models optimized for literature as a domain, and explore the stylistic differences in entity attention that help define literature as a genre. In addition to helping advance the state-of-the-art in NLP for literary texts, we provide this dataset to advance modeling for entity recognition generally; as Søgaard (2013) argues, the robustness of performance improvements for methods in NLP is best estimated by performance across a range of domains; we would expect a robust model that shows improvement on news entities in ACE and proteins in GENIA to show improvements on recognizing characters and settings in literature as well.

All data is freely available for public use under a Creative Commons Sharealike license and is available at: `https://github.com/dbamman/litbank`; code to support this work can be found at: `https://github.com/dbamman/NAACL2019-literary-entities`.

Abstract

Abuse on the Internet represents a significant societal problem of our time. Previous research on automated abusive language detection in Twitter has shown that community-based profiling of users is a promising technique for this task. However, existing approaches only capture shallow properties of online communities by modeling follower–following relationships. In contrast, working with graph convolutional networks (GCNs), we present the first approach that captures not only the structure of online communities but also the linguistic behavior of the users within them. We show that such a heterogeneous graph-structured modeling of communities significantly advances the current state of the art in abusive language detection.

1 Introduction

Matthew Zook (2012) carried out an interesting study showing that the racist tweets posted in response to President Obama's re-election were not distributed uniformly across the United States but instead formed clusters. This phenomenon is known as *homophily*: i.e., people, both in real life and online, tend to cluster with those who appear similar to themselves. To model homophily, recent research in abusive language detection on Twitter (Mishra et al., 2018a) incorporates embeddings for *authors* (i.e., users who have composed tweets) that encode the structure of their surrounding communities. The embeddings (called *author profiles*) are generated by applying a node embedding framework to an undirected unlabeled community graph where nodes denote the authors and edges the follower–following relationships amongst them on Twitter. However, these profiles do not capture the linguistic behavior of the authors and their communities and do not convey whether their tweets tend to be abusive or not.

In contrast, we represent the community of authors as a heterogeneous graph consisting of two types of nodes, authors and their tweets, rather than a homogeneous community graph of authors only. The primary advantage of such heterogeneous representations is that they enable us to model both community structure as well as the linguistic behavior of authors in these communities. To generate richer author profiles, we then propose a semi-supervised learning approach based on graph convolutional networks (GCNs) applied to the heterogeneous graph representation. To the best of our knowledge, our work is the first to use GCNs to model online communities in social media. We demonstrate that our methods provide significant improvements over existing techniques.

2 Related work

Supervised learning for abusive language detection was first explored by Spertus (1997) who extracted rule-based features to train their classifier. Subsequently, manually-engineered lexical–syntactic features formed the crux of most approaches to the task (Yin et al., 2009; Warner and Hirschberg, 2012). Djuric et al. (2015) showed that dense comment representations generated using *paragraph2vec* outperform bag-of-words features. Several works have since utilized (deep) neural architectures to achieve impressive results on a variety of abuse-annotated datasets (Nobata et al., 2016; Pavlopoulos et al., 2017a). Recently, the research focus has shifted towards extraction of features that capture behavioral and social traits of users. Pavlopoulos et al. (2017b) showed that including randomly-initialized user embeddings improved the performance of their RNN methods. Qian et al. (2018) employed LSTMs to generate inter and intra-user representations based on tweets, but they did not leverage community information.

Minneapolis, Minnesota, June 2 - June 7, 2019.

3 Dataset

Following previous work (Mishra et al., 2018a), we experiment with a subset of the Twitter dataset compiled by Waseem and Hovy (2016). Waseem and Hovy released a list of $16,907$ tweet IDs along with their corresponding annotations,[1] labeling each tweet as *racist*, *sexist* or *neither (clean)*. Recently, Mishra et al. (2018a) could only retrieve $16,202$ of these tweets since some of them are no longer available. This is the dataset we use in our experiments. $1,939$ (12%) of $16,202$ tweets are *racist*, $3,148$ (19.4%) are *sexist*, and the remaining $11,115$ (68.6%) are *clean*. The tweets have been authored by a total of $1,875$ unique users. Tweets in the *racist* class come from 5 of the users, while those in the *sexist* class come from 527 of them.

4 Approach

4.1 Representing online communities

We create two different graphs: the first one is identical to the community graph of Mishra et al. (2018a) (referred to as the *community* graph). It contains $1,875$ nodes representing each of the authors in the dataset. Two authors/nodes are connected by a single undirected edge if either one follows the other on Twitter. There are 453 *solitary authors* in the graph who are neither followed by nor follow any other author in the dataset. This graph is homogeneous, i.e., it has nodes (and hence edges) of a single type only.

Our second graph is an extended version of the first (referred to as the *extended* graph) that additionally contains nodes representing the tweets of the authors. Specifically, in addition to the $1,875$ author nodes, the graph contains $16,202$ tweet nodes. Each tweet node is connected to a single author node, denoting that the tweet is elicited from that particular author. This graph is no longer homogeneous since it contains nodes and edges of two different types.

4.2 Generating author profiles

We first describe the approach of Mishra et al. (2018a) that learns author embeddings using *node2vec* (Grover and Leskovec, 2016); this serves as our baseline. We then move on to our semi-supervised approach based on graph convolutional networks (Kipf and Welling, 2017).

Node2vec. *Node2vec* extends the *word2vec* skip-gram model (Mikolov et al., 2013) to graphs in order to create low-dimensional embeddings for nodes based on their position and neighborhood. Specifically, for a given graph with nodes $V = \{v_1, v_2, \ldots, v_n\}$, *node2vec* aims to maximize the following log probability:

$$\sum_{v \in V} \log \mathrm{P}\left(N_s(v) \mid v\right)$$

where $N_s(v)$ denotes the neighbor set of node v generated using neighbor sampling strategy s. The framework utilizes two different strategies for sampling neighbor sets of nodes: Depth-First Sampling (DFS) and Breadth-First Sampling (BFS). The former captures the structural role of nodes, while the latter captures the local neighborhood around them. Two hyper-parameters control the overall contribution of each of these strategies. Following Mishra et al. (2018a), we initialize these parameters to their default value of 1 and set the embedding size and number of iterations to 200 and 25 respectively. Since *node2vec* cannot produce embeddings for nodes without edges, we map the *solitary authors* to a single zero embedding as done by Mishra et al.

Graph convolutional networks. We propose an approach for learning author profiles using GCNs applied to the *extended* graph. In contrast to *node2vec*, our method allows us to additionally propagate information with respect to whether tweets composed by authors and their communities are abusive or not. Specifically, as labels are available for a subset of nodes in our graph (i.e., the tweet nodes), we frame the task as a graph-based semi-supervised learning problem, allowing the model to distribute gradient information from the supervised loss on the labeled tweet nodes. This, in turn, allows us to create profiles for authors that not only capture the structural traits of their surrounding community but also their own linguistic behavior based on the types of tweets that they have composed.

We consider a graph $G = (V, E)$, where V is the set of nodes ($|V| = n$) and E is the set of edges. A denotes the adjacency matrix of G. We assume that A is symmetric ($A_{ij} = A_{ji}$), and that all nodes in G have self loops ($A_{ii} = 1$). The significance of these assumptions is explained in Kipf and Welling (2017). Let D be the diagonal degree matrix defined as $D_{ii} = \sum_j A_{ij}$, and $F \in \mathbb{R}^{n \times m}$

---

[1] `https://github.com/ZeerakW/hatespeech/`

be the input feature matrix that holds feature vectors of length m for the nodes in G. We can now recursively define the computation that takes place at the i^{th} *convolutional layer* of a k-layer GCN as:

$$O^{(i)} = \sigma\,(\,\widetilde{A}\,O^{(i-1)}\,W^{(i)}\,)$$

with the computation at the first layer being:

$$O^{(1)} = \sigma\,(\,\widetilde{A}\,F\,W^{(1)}\,)$$

Here, σ denotes an activation function; $\widetilde{A} = D^{-\frac{1}{2}}A\,D^{-\frac{1}{2}}$ is the normalized adjacency matrix; $W^{(i)} \in \mathbb{R}^{d_{i-1}\times d_i}$ is the weight matrix of the i^{th} convolutional layer; $O^{(i-1)} \in \mathbb{R}^{n\times d_{i-1}}$ represents the output from the preceding convolutional layer, where d_i is the number of hidden units in the i^{th} layer (note that $d_0 = m$, i.e., the length of the input feature vectors).

In our experiments, we apply a 2-layer GCN to the *extended* graph.[2] Specifically, our GCN performs the following computation, yielding a softmax distribution over the 3 classes in the dataset for each of the nodes:

$$O = softmax\,(\,\widetilde{A}\ ReLU\,(\,\widetilde{A}\,F\,W^{(1)}\,)\,W^{(2)})$$

We set the input feature vectors in F to be the binary bag-of-words representations of the nodes (following Kipf and Welling 2017); for author nodes, these representations are constructed over the entire set of their respective tweets. Note that F is row-normalized prior to being fed to the GCN. We set the number of hidden units in the first convolutional layer to 200 in order to extract 200-dimensional embeddings for author nodes so that they are directly comparable with those from *node2vec* . The number of hidden units in the second convolutional layer is set to 3 for the output $O \in \mathbb{R}^{n\times 3}$ of the GCN to be a softmax distribution over the 3 classes in the data.

The GCN is trained by minimizing the cross-entropy loss with respect to the labeled nodes of the graph. Once the model is trained, we extract 200-dimensional embeddings $E = \widetilde{A}\,F\,W^{(1)}$ from the first layer (i.e., the layer's output without activation). This contains embeddings for author nodes as well as tweet nodes. For our experiments on author profiles, we make use of the former.

4.3 Classification methods

We experiment with five different supervised classification methods for tweets in the dataset. The first three (LR, LR+AUTH, LR+EXTD) serve as our baselines,[3] and the last two with GCNs[4] are the methods we propose.

LR. This method is adopted from Waseem and Hovy (2016) wherein they train a logistic regression classifier on character n-grams (up to 4-grams) of the tweets. Character n-grams have been shown to be highly effective for abuse detection due to their robustness to spelling variations.

LR + AUTH. This is the state of the art method (Mishra et al., 2018a) for the dataset we are using. For each tweet, the profile of its author (generated by *node2vec* from the *community* graph) is appended onto the tweet's character n-gram representation for training the LR classifier as above.

LR + EXTD. This method is identical to LR + AUTH, except that we now run *node2vec* on the *extended* graph to generate author profiles. Intuitively, since *node2vec* treats both author and tweet nodes as the same and does not take into account the labels of tweets, the author profiles generated should exhibit the same properties as those generated from the *community* graph.

GCN. Here, we simply assign a label to each tweet based on the highest score from the softmax distribution provided by our GCN model for the (tweet) nodes of the *extended* graph.

LR + GCN. Identical to LR + EXTD, except that we replace the author profiles from *node2vec* with those extracted by our GCN approach.

5 Experiments and results

5.1 Experimental setup

We run every method 10 times with random initializations and stratified train–test splits. Specifically, in each run, the dataset is split into a randomly-sampled train set (90%) and test set (10%) with identical distributions of the 3 classes in each. In methods involving our GCN, a small part of the train set is held out as validation data to prevent over-fitting using *early-stopping* regularization. When training the GCN, we only have

---

[2] Stacking more layers does not improve results on the validation set further.

Table 1: The baselines (LR, LR + AUTH/EXTD) vs. our GCN approaches (†) on the racism and sexism classes. *Overall* shows the macro-averaged metrics computed over the 3 classes: *sexism*, *racism*, and *clean*.

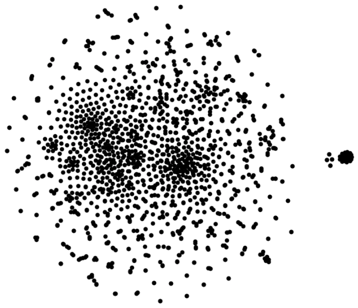
labeled tweet nodes for those tweets in the *extended* graph that are part of the train set. Our GCN is trained using the parameters from the original paper (Kipf and Welling, 2017): *Glorot* initialization (Glorot and Bengio, 2010), ADAM optimizer (Kingma and Ba, 2015) with a learning rate of 0.01, *dropout* regularization (Srivastava et al., 2014) rate of 0.5, 200 training epochs with an early-stopping patience of 10 epochs.

5.2 Results and analysis

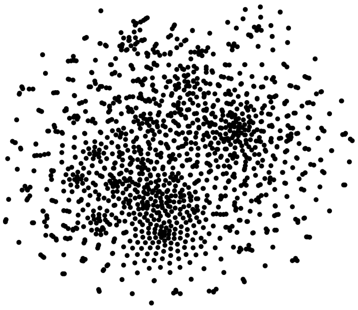
In Table 1, we report the mean precision, recall, and F_1 on the *racism* and *sexism* classes over the 10 runs. We further report the mean macro-averaged precision, recall, and F_1 for each method ('Overall') to investigate their overall performance on the data. LR + GCN significantly ($p < 0.05$ on paired t-test) outperforms all other methods. The author profiles from *node2vec* only capture the structural and community information of the authors; however, those from the GCN also take into account the (abusive) nature of the tweets composed by the authors. As a result, tweets like "*#MKR #mkr2015 Who is gonna win the peoples choice?*" that are misclassified as sexist by LR + AUTH (because their author is surrounded by others producing sexist tweets) are correctly classified as clean by LR + GCN.

GCN on its own achieves a high performance, particularly on the *sexism* class where its performance is typical of a community-based profiling approach, i.e., high recall at the expense of precision. However, on the *racism* class, its recall is hindered by the same factor that Mishra et al. (2018a) highlighted for their *node2vec*-only method, i.e., that racist tweets come from 5 unique authors only who have also contributed sexist or clean tweets. The racist activity of these authors is therefore eclipsed, leading to misclassifications of their tweets. LR + GCN alleviates this problem by incorporating character n-gram representations of the tweets, hence not relying solely on the linguistic behavior of their authors.

Figure 1 shows the t-SNE (van der Maaten and Hinton, 2008) visualizations of *node2vec* author profiles from the *community* and *extended* graphs. Both visualizations show that some authors belong to densely-connected communities while others are part of more sparse ones. The results from LR + AUTH and LR + EXTD have insignificant differences, further confirming that their author profiles have similar properties. In essence, *node2vec* is unable to gain anything more from the *extended* graph than what it does from the *community* graph.



(a) Author profiles from the *community* graph



(b) Author profiles from the *extended* graph

Figure 1: Visualizations of the *node2vec* author profiles from the *community* and *extended* graphs.

Figure 2 shows a t-SNE visualization of the author profiles generated using our GCN approach. Red dots denote the authors who are abusive (sexist or racist) according to our model (i.e., as per

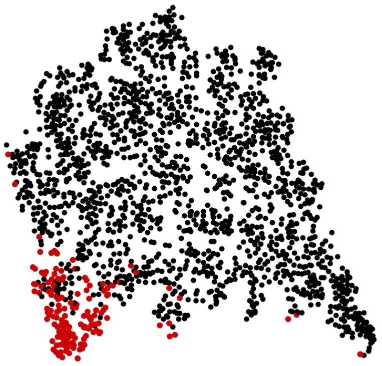


Figure 2: Visualization of the author profiles extracted from our GCN. Red dots represent the authors who are deemed abusive (racist or sexist) by the GCN.

the softmax outputs for the author nodes).[5] The red dots are mostly clustered in a small portion of the visualization, which corroborates the notion of homophily amongst abusive authors.

Despite the addition of improved author profiles, several abusive tweets remain misclassified. As per our analysis, many of these tend to contain URLs to abusive content but not the content itself, e.g., "*@MENTION: Logic in the world of Islam http://t.co/6nALv2HPc3*" and "*@MENTION Yes. http://t.co/ixbt0uc7HN*". Since Twitter shortens all URLs into a standard format, there is no indication of what they refer to. One possible way to address this limitation could be to append the content of the URL to the tweet; however this can lead to misclassifications in cases where the tweet is disagreeing with the URL. Another factor in misclassifications is the deliberate obfuscation of words and phrases by authors in order to evade detection, e.g., "*Kat, a massive c*nt. The biggest ever on #mkr #cuntandandre*". Mishra et al. (2018b) demonstrate in their work that character-based word composition models can be useful in dealing with this aspect.

6 Conclusions

In this paper, we built on the work of Mishra et al. (2018a) that introduces community-based profiling of authors for abusive language detection. We proposed an approach based on graph convolutional networks to show that author profiles that directly capture the linguistic behavior of authors along with the structural traits of their community significantly advance the current state of the art.

On the Importance of Distinguishing Word Meaning Representations: A Case Study on Reverse Dictionary Mapping

Mohammad Taher Pilehvar
Tehran Institute for Advanced Studies (TeIAS), Tehran, Iran
DTAL, University of Cambridge, Cambridge, UK
`mp792@cam.ac.uk`

Abstract

Meaning conflation deficiency is one of the main limiting factors of word representations which, given their widespread use at the core of many NLP systems, can lead to inaccurate semantic understanding of the input text and inevitably hamper the performance. Sense representations target this problem. However, their potential impact has rarely been investigated in downstream NLP applications. Through a set of experiments on a state-of-the-art reverse dictionary system based on neural networks, we show that a simple adjustment aimed at addressing the meaning conflation deficiency can lead to substantial improvements.

1 Meaning Conflation Deficiency

Words are often the most fine-grained meaning bearing components of NLP systems. As a standard practise, particularly for neural models, the input text is treated as a sequence of words and each word in the sequence is represent with a dense distributional representation (word embedding). Importantly, this setting ignores the fact that a word can be polysemous, i.e., it can take multiple (possibly unrelated) meanings. Representing a word with all its possible meanings as a single point (vector) in the embedding space, the so-called meaning conflation deficiency (Camacho-Collados and Pilehvar, 2018), can hinder system's semantic effectiveness.

To address this deficiency, many techniques have been put forward over the past few years, the most prominent of which is sense representation or multi-prototype embedding (Schütze, 1998; Reisinger and Mooney, 2010). However, as a general trend, these representations are usually evaluated either on generic benchmarks, such as word similarity, or on sense-centered tasks such as Word Sense Disambiguation, leaving their potential impact on downstream word-based systems unknown. In this paper, we provide an analysis to highlight the importance of addressing the meaning conflation deficiency. Specifically, we show how distinguishing different meanings of a word can facilitate a more accurate semantic understanding of a state-of-the-art reverse dictionary system, reflected by substantial improvements in recall and generalisation power.

2 Reverse Dictionary

Reverse dictionary, conceptual dictionary, or concept lookup is the task of returning a word given its description or definition (Brown and McNeill, 1966; Zock and Bilac, 2004). For example, given "a crystal of snow", the system has to return the word *snowflake*. The task is closely related to the "tip of the tongue" problem where an individual recalls some general features about a word but cannot retrieve that from memory. Therefore, a reverse dictionary system can be particularly useful to writers and translators when they cannot recall a word in time or are unsure how to express an idea they want to convey.

2.1 Evaluation framework

Our experiments are based on the reverse dictionary model of Hill et al. (2016) which leverages a standard neural architecture in order to map dictionary definitions to representations of the words defined by those definitions. Specifically, they proposed two neural architectures for mapping the definition of word t to its word embedding $\mathbf{e}_t$. Let $\mathcal{D}_t$ be the sequence of words in t's definition, i.e., $\mathcal{D}_t = \{w_1, w_2, \ldots, w_n\}$, with their corresponding embeddings $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n\}$. The two models differ in the way they process $\mathcal{D}_t$. In the bag-of-words (**BoW**) model, $\mathcal{D}_t$ is taken as a bag

Proceedings of NAACL-HLT 2019, pages 2151–2156
Minneapolis, Minnesota, June 2 - June 7, 2019.

of words, i.e., the representation of the definition is encoded by adding the word embeddings of all its content words, i.e., $\sum_{i=1}^{n} \mathbf{v}_i$. The model learns, using a fully-connected layer, a matrix for transforming the encoded representation to the target word's embedding $\mathbf{e}_t$. The BoW model is not sensitive to the order of words in $\mathcal{D}_t$. This might be crucial for an accurate semantic understanding. The Recurrent Neural Network (**RNN**) model alleviates this issue by encoding the input sequence using an LSTM architecture (Hochreiter and Schmidhuber, 1997). Similarly to the BoW model, a dense layer maps the encoded representation to the target word's embedding.

In both cases, the goal is to map a given definition to the corresponding target word's embedding $\mathbf{e}_t$, computed using Word2vec (Mikolov et al., 2013) and independently from the training of the main model. Two cost functions were tested: (1) the **cosine** distance between the estimated point in the target space ($\hat{\mathbf{e}}_t$) and $\mathbf{e}_t$, and (2) the **rank** loss which contrast the choice of $\mathbf{e}_t$ with a random choice for a randomly-selected word from the vocabulary other than t.

The reverse dictionary system takes advantage of a standard architecture which has proven effective in various NLP tasks. However, similarly to many other word-based models, the system ignores that the same word can have multiple (potentially unrelated) meanings. In fact, it tries to map multiple definitions, with different semantics, to the same point in the target space. For instance, the three semantically unrelated definitions of *crane*: "lifts and moves heavy objects", "large long-necked wading bird", and "a small constellation in the southern hemisphere" will have similar semantic interpretation by the system. This word-level meaning conflation can hamper the ability of the system in learning an accurate mapping function. In what follows in this paper, we will illustrate how a simple sense level distinction can facilitate a more accurate semantic understanding for the reverse dictionary system, hence leading to significant performance improvements.

2.2 Sense Integration

Let t be an ambiguous word with three meanings; hence, three distinct definitions $\mathcal{D}_{t_1}$, $\mathcal{D}_{t_2}$, and $\mathcal{D}_{t_3}$. The original model of Hill et al. (2016) maps all these definitions to $\mathbf{e}_t$. We mitigate the meaning conflation deficiency through a sense-specific mapping function that obtains distinct interpretations for individual definition, hence mapping them to different points in the target space: $\mathbf{s}_{t_1}$, $\mathbf{s}_{t_2}$, and $\mathbf{s}_{t_3}$. Specifically, in our experiments we leveraged DeConf (Pilehvar and Collier, 2016). DeConf is a WordNet-based sense representation technique which receives a set of pre-trained word embeddings and generates embeddings for individual word senses in the same semantic space, hence generating a combined space of words and word senses.

DeConf performs a set of random walks on WordNet's semantic network and extracts for each sense a set of *sense biasing* words $\mathcal{B}_{\mathbf{s}}$. A sense biasing word for the i^{th} meaning of a target word t is a semantically related word to that specific sense of the word ($\mathbf{s}_{t_i}$). For each word sense in WordNet we obtain the corresponding $\mathcal{B}_{\mathbf{s}}$. Then, the embedding for a specific word sense $\mathbf{s}$ is computed as:

$$\mathbf{s} = ||\, \mathbf{e}_w + \alpha \sum_{b \in \mathcal{B}_{\mathbf{s}}} \exp(-\delta_i)\, \mathbf{e}_b||, \qquad (1)$$

where δ is a decay parameter and $\mathbf{e}_w$ is the embedding of corresponding lemma of sense $\mathbf{s}$. In our experiments, as for word embeddings we used the 300-dimensional Word2vec embeddings, trained on the Google News corpus.[1] The same set was used as input to DeConf. As a result of this process, around 207K additional word senses were introduced in the space for the 155K unique words in WordNet 3.0.

2.2.1 Supersenses

It is widely acknowledged that sense distinctions in WordNet inventory are too fine-grained for most NLP applications (Hovy et al., 2013). For instance, for the noun *star*, WordNet 3.0 lists eight senses, among which two *celestial body* senses (as an "astronomical object" and that "visible, as a point of light, from the Earth"), and three *person* senses ("skillful person", "lead actor", and "performing artist"). This fine level of sense distinction is often more than that required by the target downstream application (Rüd et al., 2011; Severyn et al., 2013; Flekova and Gurevych, 2016). In our experiments, we used WordNet's lexicographer files (lexnames[2]) in order to reduce sense granularity. Created by the curators of WordNet

during its development, these files organize WordNet synsets into 45 groups (such as food, animal, event, and emotion) according to their syntactic and logical properties. These groupings are usually referred to as *supersenses*. Using supersenses, the *celestial* and *person* meanings of *star* are grouped into two main groups. A supersense embedding e_{ss} in our experiments is simply computed as a normalized average (centroid) of its contained sense embeddings, i.e., $e_{ss} = ||\sum_{s \in ss} e_s||$. This reduces the average number of senses for polysemous words in WordNet from 2.9 to 1.8.

3 Experiments

We carried out evaluations on the three reverse dictionary datasets created by Hill et al. (2016): WordNet definitions and "single-sentence descriptions" written for a set of frequent words (*concept mapping*). They proposed two different versions of the WordNet dataset: *WN-seen*, in which a test instance is already observed during training, and *WN-unseen*, in which test instances are excluded from the training data. The former dataset is targeted at evaluating the ability of the system to recall a previously encoded information.

We experimented with three variants of the reverse dictionary system: the original word-based model and the two proposed sense-based variants, based on WordNet senses and supersenses.[3]

Table 1 reports accuracy performance for four different configurations of the system (BoW and RNN definition composition and cosine and ranking loss; cf. Section 2.1) on the three datasets. In the last row, we also report results for the unsupervised baseline of Hill et al. (2016) which adds the embedding of words in the input definition and finds the nearest embedding in the target space.

Results reported in the Table clearly highlight that addressing the meaning conflation deficiency in the system has led to significant performance improvements (word vs. sense and supersense settings). This is observed consistently across all the three datasets and for both sense-based models. The better semantic understanding of the system is reflected by its better recall of seen test instances (WN-seen) and better generalisation to unseen and out-of-domain data (WN-unseen and concept mapping). The absolute top-10 accuracy improvements of the ranking-BoW supersense model over the best corresponding word-based configurations are: 14.4% (WN-seen), 15% (WN-unseen), and 7% (concept mapping).

Among the two proposed systems, supersenses prove to be more effective, suggesting that the fine-grained sense distinctions in WordNet might not be necessary for an accurate reverse dic-

---

[3] The experiments are based on the implementation available at `https://github.com/fh295/DefGen2`.

tionary mapping, corroborating previous findings (Flekova and Gurevych, 2016). Our results are also in line with the findings of Hill et al. (2016) that the reverse dictionary system performs best with the bag-of-words (BoW) input encoding and the ranking loss. One of the fundamental differences between the two input encodings lies in their sensitiveness to order: RNNs are sensitive to the order of words in a given sequence whereas permuting words in the sequence does not alter BoW's encoding. Hill et al. (2016) suggested that it is often possible to retrieve a concept even if the words in its corresponding definition are shuffled. This can partly explain the strikingly good relative performance of the BoW model.

4 Analysis

During our analysis of system outputs, we observed many examples in which the word-based model was unable to retrieve an ambiguous word since the definition was referring to one of its less frequent meanings. For instance, the word *dressing* might refer to different concepts such as "getting dressed" or "savory dressing for salads". Having a conflated understanding of *dressing*, the word-based model was unable to retrieve the salad meaning.

dressing *savory dressings for salads; basically of two kinds: either the thin french or vinaigrette type or the creamy mayonnaise type*

word: mayonnaise, marinade, sauce
sense: *dressing*, mayonnaise, mayo
baseline: or, either, type

Other similar examples include infrequent senses of *party*, defined as "an organization to gain political power", and *partition*, defined as "a vertical structure that divides or separates". In both cases, the sense-based model improves the original word-based one, in which the system is unable to retrieve the intended word. Numerous such examples were observed during our analysis of the results, highlighting the important limitation of word-based models for their inherent bias towards more frequent usages.

Moreover, as a side benefit, sense embeddings provide parts of speech distinction, unlike common pre-trained word embeddings which conflate all parts of speech to a single token. For instance, the word-based model is unable to recall the nominal *bear* because it has a conflated understanding of the word which includes all its senses, particularly the dominant verb meaning.[4]

bear *massive plantigrade carnivorous or omnivorous mammals with long shaggy coats and strong claws*

word: critter, rabbit, squirrel, wolf
sense: *bear*, mustelid, bruin
baseline: carnivorous, omnivorous.

The same applies to the "open land" meaning of *common*, which is a less frequent (nominal) meaning of the word which is usually used as an adjective for concepts such as "ordinary" or "usual".

common *a piece of open land for recreational use in an urban area*

word: park, plaza, entryway, courtway
sense: park, green, *common*
baseline: for, area, in, recreational

Additionally, word embeddings are insensitive to fine-grained semantic distinctions, such as antonymy, due to their construction nature. However, the sense representations used in our experiments (DeConf) were constructed by exploiting the knowledge encoded in WordNet. Hence, they benefit from the rich semantic and ontological knowledge provided by the resource (such as relation types). Some of the improvements can be attributed to this property of sense embeddings.

unanticipated *not anticipated*

word: unavoidable, inevitable, plausible
sense: unforeseen, *unanticipated*, unpredicted
baseline: not, anticipated, expected

However, there are cases in which the word-based model provided more accurate results. For instance:

service *work done by one person or group that benefits another*

word: *service*, caring
sense: organisation, dependant, programme

Our analysis showed that most of these errors were due to fine-grained sense distinctions in WordNet or obscure meanings. For instance, one of the senses[5] of *organisation* is semantically re-

---

[4] In our analysis, we found that improvements are mostly due to addressing semantic conflation rather than ambiguities in parts of speech.

[5] The 6th sense of *organisation* in WordNet 3.0, defined as "the activity or result of distributing or disposing persons or things properly or methodically".

lated (also close in WordNet's graph) to the meaning of *service* in the example. This would suggest the need for more accurate sense representations and highlight the fact that the fine-granularity of senses should be better adjusted to the underlying task. Moreover, it corroborates our finding that the coarse-grained supersenses are more suitable in the task of reverse dictionary mapping. We leave the experiments with other sense representation techniques to future work.

5 Related work

Sense representations address the meaning conflation deficiency of their word-based counterparts by computing distinct representations for individual meanings of words, usually referred to as word senses. Sense distinctions might be given by an external sense inventory, such as WordNet (Fellbaum, 1998). An inventory-based sense representation technique exploits the knowledge encoded in the resource to construct representations (Rothe and Schütze, 2015; Jauhar et al., 2015; Pilehvar and Collier, 2016). Alternatively, senses can be automatically induced in an unsupervised manner by analyzing the diversity of contexts in which a word appears (Schütze, 1998; Reisinger and Mooney, 2010; Huang et al., 2012; Neelakantan et al., 2014; Guo et al., 2014; Šuster et al., 2016).

Regardless of how senses are obtained, the integration of sense representations into NLP systems is not a straightforward process. Hence, they have often been evaluated on artificial tasks such as word similarity. This is also due to lack of suitable evaluation benchmarks for sense representation techniques. Pilehvar and Camacho-Collados (2019) recently proposed a dataset, The Word-in-Context (WiC), which provides a challenging, yet reliable, benchmark for the purpose.

Few attempts have been made at the integration of sense representation into downstream applications. Li and Jurafsky (2015) experimented with unsupervised sense representations in tasks such as part-of-speech tagging and named entity recognition, with mixed results. Also related to our work are the proposals of Flekova and Gurevych (2016) and Pilehvar et al. (2017) to disambiguate the input text and replace word embeddings with sense embeddings for the intended senses. Our results for supersenses corroborates the findings of Pilehvar et al. (2017) who found reducing fine-granularity of senses beneficial to some settings.

A more recent branch of research investigates the construction of dynamic word embeddings that can adapt according to the context in which they appear (Peters et al., 2018; Devlin et al., 2018). One of the objectives of this research has been to bypass the integration difficulties of sense representations into downstream models. These so-called contextualised word embeddings can easily be replaced with conventional static word embeddings in neural-based NLP systems. This integration has proven beneficial to a wide range of NLP applications. Pilehvar and Camacho-Collados (2019) carried out an analysis on the sense distinguishing capability of contextualised embeddings, showing that, despite their successful application to downstream applications, these embeddings are not very powerful in capturing distinct meanings of words.

6 Conclusions

We provided an analysis on the impact of addressing the meaning conflation deficiency of word embeddings on the performance of a downstream NLP application, i.e., reverse dictionary mapping. Through a set of experiments we showed that a simple migration from words to senses can significantly improve the ability of the system in semantic understanding, leading to consistent performance boost. In future work, we plan to evaluate sense integration in other NLP applications, such as Machine Translation, in the light of (Liu et al., 2018), and question answering.

Factorising AMR generation through syntax

Kris Cao and **Stephen Clark**

Abstract

Generating from Abstract Meaning Representation (AMR) is an underspecified problem, as many syntactic decisions are not constrained by the semantic graph. To explicitly account for this underspecification, we break down generating from AMR into two steps: first generate a syntactic structure, and then generate the surface form. We show that decomposing the generation process this way leads to state-of-the-art single model performance generating from AMR without additional unlabelled data. We also demonstrate that we can generate meaning-preserving syntactic paraphrases of the same AMR graph, as judged by humans.

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic annotation framework which abstracts away from the surface form of text to capture the core 'who did what to whom' structure. As a result, generating from AMR is underspecified (see Figure 1 for an example). Single-step approaches to AMR generation (Flanigan et al., 2016; Konstas et al., 2017; Song et al., 2016, 2017) therefore have to decide the syntax and surface form of the AMR realisation in one go. We instead explicitly try and capture this syntactic variation and factor the generation process through a syntactic representation (Walker et al., 2001; Dušek and Jurcicek, 2016; Gardent and Perez-Beltrachini, 2017; Currey and Heafield, 2018).

First, we generate a delexicalised constituency structure from the AMR graph using a syntax model. Then, we fill out the constituency structure with the semantic content in the AMR graph using a lexicalisation model to generate the final surface form. Breaking down the AMR generation process this way provides us with several advantages: we disentangle the variance caused by the choice of syntax from that caused by the choice of words. We can therefore realise the same AMR graph with a variety of syntactic structures by sampling from the syntax model, and deterministically decoding using the lexicalisation model. We hypothesise that this generates better paraphrases of the reference realisation than sampling from a single-step model.

We linearise both the AMR graphs (Konstas et al., 2017) and constituency trees (Vinyals et al., 2015b) to allow us to use sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) for the syntax and lexicalisation models. Further, as the AMR dataset is relatively small, we have issues with data sparsity causing poor parameter estimation for rarely seen words. We deal with this by anonymizing named entities, and including a *copy mechanism* (Vinyals et al., 2015a; See et al., 2017; Song et al., 2018) into our decoder, which allows open-vocabulary token generation.

We show that factorising the generation process in this way leads to improvements in AMR generation, setting a new state of the art for single-model AMR generation performance training only on labelled data. We also verify our diverse generation hypothesis with a human annotation study.

2 Data

Abstract Meaning Reprentation Abstract Meaning Representation is a semantic annotation formalism which represents the meaning of an English utterance as a rooted directed acyclic graph. Nodes in the graph represent entities, events, properties and states mentioned in the text, while leaves of the graph label the nodes with concepts (which do not have to be aligned to spans in the text). Re-entrant nodes correspond to coreferent entities. Edges in the graph represent

Figure 1: An example AMR graph, with variable names and verb senses, followed by the input to our system after preprocessing, and finally two sample realisations different in syntax.

relations between entities in the text. See Figure 1 for an example of an AMR graph, together with sample realisations.

Konstas et al. (2017) outline a set of preprocessing procedures for AMR graphs to both render them suitable for sequence-to-sequence learning and to ameliorate data sparsity; we follow the same pipeline. We train our models on the two most recent AMR releases. LDC2017T10 has roughly 36k training sentences, while LDC2015E86 is about half this size. Both share dev and test sets, facilitating comparison.

Constituency syntax While there are many syntactic annotation formalisms, we use delexicalised Penn treebank-style constituency trees to represent syntax. Constituency trees have the advantage of a well-defined linearization order compared to dependency trees. Further, constituency trees may be easier to realise, as they effectively correspond to a bracketing of the surface form.

Unfortunately, AMR annotated data does not come with syntactic annotation. We therefore parse the training and dev splits of both corpora with the Stanford parser (Manning et al., 2014) to provide silver-standard reference parse trees. We then delexicalise the parse trees by trimming the trees of the surface words; after this stage, the leaves of the tree are the preterminal POS tags. After this, we linearise the delexicalised constituency trees with depth-first traversal, following Vinyals et al. (2015b).

3 Model implementation and training

3.1 Model details

We wish to estimate $P(Y, Z|X)$, the joint probability of a parse Y and surface form Z given an AMR graph X. We model this in two parts, using the chain rule to decompose the joint distribution. The first model, which we call the syntax model, approximates $P(Y|X)$, the probability of a particular syntactic structure for a meaning representation. The second is $P(Z|X, Y)$, the lexicalisation model. This calculates the probability of a surface realisation given a parse tree and an AMR graph. We implement both as recurrent sequence-to-sequence models.

As we are able to linearise both the AMR graph and the parse tree, we use LSTMs (Hochreiter and Schmidhuber, 1997) both as the encoder and the decoder of our seq2seq models. Given an input sequence $X_1, \ldots, X_n$, which can either be an AMR graph or a parse tree, we first embed the tokens to obtain a dense vector representation of each token $x_1, \ldots, x_n$. Then we feed this into a stacked bidirectional LSTM encoder to obtain contextualised representations of each input token c_i. As far as possible, we share parameters between our two models. Concretely, this means that the syntax model uses the same AMR and parse embeddings, and AMR encoder, as the lexicalisation model. We find that this speeds up model inference, as we only have to encode the AMR sequence once for both models. Further, it regularises the joint model by reducing the number of parameters.

In our decoder, we use the dot-product formulation of attention (Luong et al., 2015): the attention potentials a_i at timestep t are given by

$$a_i = h_{t-1}^T W_{att} c_i$$

where h_{t-1} is the decoder hidden state at the previous timestep, and c_i is the context representation at position i given by the encoder. The attention weight w_i is then given by a softmax over the attention potentials, and the overall context representation s_t is given by $\sum w_i c_i$. The syntax model only attends over the input AMR graph; the linearisation model attends over both the input AMR and syntax tree independently, and the resulting context representation s_t is given by the concatenation of the AMR context representation and the syntax tree context representation (Libovický and Helcl, 2017).

We use s_t to augment the input to the LSTM: $\widetilde{y}_t = W_{in} \tanh([y_t; s_t])$. Then the LSTM hidden and cell state are updated according to the LSTM equations: $h_t, c_t = LSTM(h_{t-1}, c_{t-1}, \widetilde{y}_t)$. Finally, we again concatenate s_t to h_t before calculating the logits over the distribution of tokens:

$$\widetilde{h}_t = \tanh(W_{out}[h_t; s_t]) \quad (1)$$

$$p(y_t|y_{<t}) = \mathrm{softmax}(W\widetilde{h}_t) \quad (2)$$

For the syntax model, we further constrain the decoder to only produce valid parse trees; as we build the parse tree left-to-right according to a depth-first traversal, the permissible actions at any stage are to open a new constituent, produce a terminal (i.e. a POS tag), or close the currently open constituent. We implement this constraint by setting the logits of all impermissible actions to negative infinity before taking the softmax. We find that this improves both training speed and final model performance, as we imbue the decoder with an intrinsic bias towards producing well-formed parse trees.

3.2 Generation with a copy mechanism

Despite the preprocessing procedures referred to in Section 2, we found that the lexicalisation model still had trouble with out-of-vocabulary words, due to the small size of the training corpus. This led to poor vocabulary coverage on the unseen test portions of the dataset. On closer inspection, many out-of-vocabulary words in the dev split are open-class nouns and verbs, which correspond to concept nodes in the AMR graph. We therefore incorporate a copy mechanism (Vinyals et al., 2015a; See et al., 2017) into our lexicalisation model to make use of these alignments.

We implement this by decomposing the word generation probability into a weighted sum of two terms. One is the vocabulary generation term. This models the probability of generating the next token from the model vocabulary, and is calculated in the same way as the base model. The other is a copy term, which calculates the probability of generating the next token by copying a token from the input. This uses the attention distribution over the input tokens calculated in the decoder to decide which input token to copy. The weighting between these two terms is calculated as a function of the current decoder input token, the decoder hidden state, and the AMR and parse context vectors. To sum up, the per-word generation probability in the decoder is given by

$$p(y_t|y_{<t}) = (1-\theta_t)p_{lex}(y_t|y_{<t}) + \theta_t \sum_{i:X_i=y_t} w_i \quad (3)$$

where $p_{lex}(y_t|y_{<t})$ is as in Equation 2 and w_i is the attention weight on the input token X_i. θ is the weighting between the generation term and the copy term: this is implemented as a 2-layer MLP.

3.3 Model training procedures

The AMR training corpus, together with the automatically derived parse trees, give us aligned triples of AMR graph, parse tree and realisation. We train our model to minimise the sum of the parse negative log-likelihood from the syntax model and the text negative log-likelihood from the lexicalisation model. We use the ADAM optimizer (Kingma and Ba, 2015) with batch size 40 for 200 epochs. We evaluate model BLEU score on the dev set during training, and whenever this did not increase after 5 epochs, we multiplied the learning rate by 0.8. We select the model with the highest dev BLEU score during training as our final model.

We apply layer normalization (Ba et al., 2016) to all matrix multiplications inside our network, including in the LSTM cell, and drop out all non-recurrent connections with probability 0.5 (Srivastava et al., 2014). We also drop out recurrent connections in both encoder and decoder LSTMs with probability 0.3, tying the mask across timesteps as suggested by Gal and Ghahramani (2016). All model hidden states are size 500, and token embeddings are size 300. Word embeddings are initialised with pretrained `word2vec` embeddings (Mikolov et al., 2013). We replace words with count 1 in the training corpus with the UNK token with probability 0.5, and replace POS tags in the parse tree and AMR concepts with the UNK token with probability 0.1 regardless of count.

Decoding from our model During test time, we would like to estimate

$$\arg\max_Z \sum_Y P(Z, Y|X) \quad (4)$$

the most likely text realisation of an AMR, marginalising out over the possible parses. To do this, we heuristically find the n best parses $Y_1, \ldots, Y_n$ from the syntax model, generate a realisation Z_i for each parse Y_i, and take the highest scoring parse-realisation pair as the model output.

We use beam search with width 2 for both steps, removing complete hypotheses from the active beam and appending them to a k-best list. We terminate search after a predetermined number of steps, or if there are no active beam items left. After termination, if $k > n$, we return the top n items of the k-best list; otherwise we return additional

Model	Unlabelled F1	Labelled F1
Text-to-parse	87.5	85.8
AMR-to-parse	60.4	54.8
Unconditional	38.5	31.7

Model	# good realisations
Syntax-aware model	1.52
Baseline s2s	1.19

Table 2: Average number of acceptable realisations out of 3. The difference is significant with $p < 0.001$.

items from the beam. In our experiments, we find that considering realisations of the 2 best parses (i.e. setting $n = 2$ above) gives the highest BLEU score on the dev set.

4 Experiment 1: AMR and syntax

We first investigate how much information AMR contains about possible syntactic realisations. We train two seq2seq models of the above architecture to predict the delexicalised constituency tree of an example given either the AMR graph or the text. We then evaluate both models on labelled and unlabelled F1 score on the dev split of the corpus. As neither model is guaranteed to produce trees with the right number of terminals, we first run an insert/delete aligner between the predicted and reference terminals (i.e. POS tags) before calculating span F1s. We also report the results of running our aligner on the most probable parse tree as estimated by an unconditional LSTM as a baseline both to control for our aligner and also to see how much extra signal is in the AMR graph. The results in Table 1 show that predicting a syntactic structure from an AMR graph is a much harder task than predicting from the text, but there is information in the AMR graph to improve over a blind baseline.

5 Experiment 2: Generating natural language from AMR

Table 3 shows the results of our model on the AMR generation task. We evaluate using BLEU score (Papineni et al., 2002) against the reference realisations. As a baseline, we train a straight AMR-to-text model with the same architecture as above to control for the extra regularisation in our model compared to previous work. Our results show that adding syntax into the model dramatically boosts performance, resulting in state-of-the-art single model performance on both datasets without using external training data.

Model	Dev BLEU	Test BLEU
Trained on LDC2017T10		
Our model	**26.1**	**26.8**
Our model + oracle parse	57.5	-
Baseline s2s + copy	23.7	23.5
Beck et al. (2018)	-	23.3

Song et al. (2018)	-	33.0
Konstas et al. (2017)	33.1	33.8
Pourdamghani et al. (2016)	27.2	26.9
Song et al. (2017)	25.2	25.6

Table 3: BLEU results for generation.

As an oracle experiment, we also generate from the realisation model conditioned on the ground truth parse. The outstanding result here – BLEU scores in the 50s – demonstrates that being able to predict the gold reference parse tree is a bottleneck in the performance of our model. However, given the inherent difficulty of predicting a single syntax realisation (cf. Section 4), we suspect that there is an intrinsic limit to how well generating from an AMR graph can replicate the reference realisation.

We further note that we do not use models tailored to graph-structured data or character-level features as in Song et al. (2018); Beck et al. (2018), or additional unlabelled data to perform semi-supervised learning (Konstas et al., 2017). We believe that we can improve our results even further if we use these techniques.

6 Experiment 3: Generating varied realisations

Our model explicitly disentangles variation caused by syntax choice from that caused by lexical choice. This means that we can generate diverse realisations of the same AMR graph by sampling from the syntax model and deterministically decoding from the realisation model. We hypothesise that this procedure generates more meaning-preserving realisations than just sampling from a straight AMR-to-text model, which can result in incoherent output (Cao and Clark, 2017).

We selected the first 50 AMR graphs in the dev set on linearised length between 15 and 40 with coherent reference realisations and generated 5 different realisations with our joint model and our baseline model. For our joint model, we first sampled 3 parse structures from the syntax model with temperature 0.3. This means we divide the per-timestep logits of the syntax decoder by 0.3; this serves to sharpen the outputs of the syntax model and constrains the sampling process to produce relatively high-probability syntactic structures for the given AMR. Then, we realised each parse deterministically with the lexicalisation model. For the baseline model, we sample 3 realisations from the decoder with the same temperature. This gave us 100 examples in total.

We then crowdsourced acceptability judgments for each example from 100 annotators: we showed the reference realisation of an AMR graph, together with model realisations, and asked each annotator to mark all the grammatical realisations which have the same meaning as the reference realisation. Each annotator was presented 30 examples selected randomly. Our results in Table 2 show that the joint model can generate more meaning-preserving realisations compared to a syntax-agnostic baseline. This shows the utility of separating out syntactic and lexical variation: we model explicitly meaning-preserving invariances, and can therefore generate better paraphrases.

7 Conclusions and further work

We present an AMR generation model that factors the generation process through a syntactic decision, and show that this leads to improved AMR generation performance. In addition, we show that separating the syntactic decisions from the lexicalisation decisions allows the model to generate higher quality paraphrases of a given AMR graph.

In future work, we would like to integrate a semantic parser into our model (Yin et al., 2018). Annotating data with AMR is expensive, and existing AMR treebanks are small. By integrating a component which parses into AMR into our model, we can do semi-supervised learning on plentiful unannotated natural language sentences, and improve our AMR generation performance even further. In addition, we would be able to generate text-to-text paraphrases by parsing into AMR first and then carrying out the paraphrase generation procedure described in this paper (Iyyer et al., 2018). This opens up scope for data augmentation for downstream NLP tasks, such as machine translation.

Abstract

We present a resource for the task of FrameNet semantic frame disambiguation of over 5,000 word-sentence pairs from the Wikipedia corpus. The annotations were collected using a novel crowdsourcing approach with multiple workers per sentence to capture *inter-annotator disagreement*. In contrast to the typical approach of attributing the best single frame to each word, we provide a list of frames with disagreement-based scores that express the confidence with which each frame applies to the word. This is based on the idea that inter-annotator disagreement is at least partly caused by ambiguity that is inherent to the text and frames. We have found many examples where the semantics of individual frames overlap sufficiently to make them acceptable alternatives for interpreting a sentence. We have argued that ignoring this ambiguity creates an overly arbitrary target for training and evaluating natural language processing systems - if humans cannot agree, why would we expect the correct answer from a machine to be any different? To process this data we also utilized an expanded lemma-set provided by the Framester system, which merges FN with WordNet to enhance coverage. Our dataset includes annotations of 1,000 sentence-word pairs whose lemmas are not part of FN. Finally we present metrics for evaluating frame disambiguation systems that account for ambiguity.

1 Introduction

Crowdsourcing has been a popular method to collect corpora for a variety of natural language processing tasks (Snow et al., 2008), although one of its downsides is the crowd's lack of domain knowledge that is helpful in solving some tasks. *Semantic frame disambiguation* is an example of a complex natural language processing task that is usually performed by linguistic experts, subjected to strict annotation guidelines and quality control (Baker, 2012). The theory of frame semantics (J Fillmore, 1982) defines a *frame* as an abstract representation of a word sense, describing a type of entity, relation, or event, together with the associated *roles* implied by the frame. The FrameNet (FN) corpus (Baker et al., 1998) is a collection of semantic frames, together with a corpus of documents annotated with these frames. Similarly to word-sense disambiguation, *frame disambiguation* is the task of obtaining the correct frame for each word, since many words have multiple possible meanings.

Using domain experts for frame disambiguation is expensive and time consuming, resulting in small corpora for this task that do not scale well for modern machine learning methods – FN version 1.7, the latest one at the time of writing, contains only about 10,000 sentences annotated with frames. Furthermore, only using one expert to perform the annotation makes it difficult to capture any diversity of perspectives.

There have been a number of small-scale attempts at using crowdsourcing for frame disambiguation in sentences, showing that the crowd has comparable performance to the FN domain experts (Hong and Baker, 2011), and that the crowd can be used to correct wrong examples that have been collected automatically (Pavlick et al., 2015). Crowd performance can be improved by combining frame role identification with disambiguation (Fossati et al., 2013), or by asking crowd workers to give each other feedback and then letting them change their answer (Chang et al., 2015). Crowdsourcing has also been useful to identify the ambiguity in frame disambiguation (Jurgens, 2013).

Previously, we have shown (Dumitrache et al., 2018a) that while the crowd and FN expert mostly agree over frame disambiguation, disagreement cases are often caused by ambiguity, such as vague or overlapping frame definitions, or incomplete

Proceedings of NAACL-HLT 2019, pages 2164–2170
Minneapolis, Minnesota, June 2 - June 7, 2019.

information in the sentence. Because of these issues with the input data, the approach of selecting one single correct frame for every word, and ignoring alternative interpretations, often results in arbitrary, incomplete ground truth corpora. In order to aggregate annotated data while preserving disagreement, we use the CrowdTruth method[1] (Aroyo and Welty, 2014), which encourages using multiple crowd annotators to perform the same work, and processes the disagreement between them to signal low quality workers, sentences, and frames.

This paper presents a crowdsourced FN frame disambiguation corpus of 5,042 sentence-word pairs (which has since grown to over 9,000 since the submission of this paper). More than 1,000 of these are lexical units (LUs) not part of FN. To our knowledge, it is the largest corpus of this type outside of FN. In addition, we applied the CrowdTruth method, in which each sentence and lexical item is accompanied by *a list of multiple frames* with scores that express the confidence with which each frame applies to the word. This allows us to demonstrate that ambiguity is a prominent feature of frame disambiguation, with many cases where more than one possible frame can apply to the same word. Finally, we present an evaluation of several frame disambiguation models using evaluation metrics that leverage the multiple answers and their confidence scores, and show that even a model that always predicts the top crowd answer will not always have the best performance.

2 Corpus Collection & Analysis

2.1 Data Preprocessing

Our corpus consists of 5,042 candidate word-sentence pairs from Wikipedia (which has since grown to over 9,000 since the submission of this paper) and a candidate list of frames for the word, with 742 unique frames and 1,705 unique lexical units (LUs). The sentences have been randomly selected, based on these criteria:

- The candidate word has *no more than 25 candidate frames*, to not overwhelm the annotators.
- The part of speech of the word is a *verb*.
- The *distribution of candidate frames was optimized for maximum diversity* using a greedy approach.

To gather the candidate frames for each word, we gathered the candidate frames associated with the LU from FN1.7. Next we completed the candidate list using Framester (Gangemi et al., 2016), which maps FN semantic frames to synonym sets from WordNet (Miller, 1995). The sentences were processed with tokenization, sentence splitting, lemmatization and part-of-speech tagging. Then each word with a frame attached to it was matched with all of its possible synonym sets from WordNet, while making sure that the part-of-speech constraint of the synonym set is fulfilled. Using the WordNet mapping, we constructed the list of additional candidate frames for each word. Framester disambiguation used release 1.5 of FN, and some frames changed names in version 1.7, so we manually mapped these frames from FS to their latest version. Framester disambiguation was also used to collect a subset of our corpus consisting of 1,000 sentence-word pairs with LUs that are not part of the FN corpus. For simplicity, we refer to the sentence-word pairs as sentences in the rest of the paper.

2.2 Crowdsourcing Setup

We ran the task on Amazon Mechanical Turk, where the workers were asked to select *all frames* that fit the sense of the highlighted word in a sentence from the multiple choice candidate list, or that none of the frames is correct. We used 15 workers/sentence that were paid \$0.05 for each judgment, and a total cost of \$1.35 per sentence (after factoring in the additional AMT costs).[2]

To aggregate the results of the crowd while also capturing inter-annotator disagreement, we use the CrowdTruth metrics[3] (Dumitrache et al., 2018b), replicating the setup from our previous work (Dumitrache et al., 2018a). The choice of frames of one worker over one sentence are aggregated into a *worker vector* – a binary vector with $n + 1$ components, where n is the number of frames shown together with the sentence, where the decision to pick each of the frames (or none) corresponds to a component in the vector. The vectors are used to calculate quality scores for workers, sentences

7	The dance includes bending and **straightening** of the knee giving it a touch of Cuban motion.	0.24	*reshaping* (0.495), *arranging* (0.356), *body movement* (0.298), *cause motion* (0.249)

Table 1: Example sentences with disagreement over the frame annotations (candidate word in bold).

and frames. Although we make all quality scores available as part of the corpus, in this paper we focus on:

- **frame-sentence score** (FSS)**:** the degree with which a frame matches the sense of the word in the sentence. It is the ratio of workers that picked the frame to all the workers that read the sentence, weighted by the worker quality. A high FSS means the frame is clearly expressed in a sentence.
- **sentence quality** (SQS)**:** the overall worker agreement over one sentence. It is the average cosine similarity over all worker vectors for one sentence, weighted by the worker quality and frame quality. A high SQS indicates a clear sentence.

The aggregated crowdsourcing results and the FN 1.5 to 1.7 mapping table are available online.[4]

2.3 Ambiguity in the Corpus

An analysis of the corpus found many examples of inter-annotator disagreement, of which a few examples are shown in Table 1. For 720 sentences, a majority of the workers picked at least 2 frames (examples 1-3 in Table 1). And for 1,514 sentences, no one frame has been picked by a majority of the workers (examples 4-7 in Table 1). Disagreement is also more prominent in the sentences where the LU is not a part of FN (Figure 1).

The disagreement comes from a variety of causes: a parent-child relation between the frames (*statement* and *communication* in #3), an overlap in the definition of the frames (*accomplishment* and *successful action* in #2), the meaning of the word is expressed by a composition of frames (in #7, "straightening of the knee" is a combination of *reshaping* the form of the knee, *arranging* the knee in the right position, and *body movement*), and combinations of all of these reasons (in #4, "slices" is a combination of *part piece* and *cause harm*, and the other frames are their children). More example sentences for each type of disagreement are available in the appendix. The sentences themselves are not difficult to understand, and it can be argued that all of them have one frame that applies the best for the word. The goal of this corpus is to show that next to this best frame for the word, there are other frames that apply to a lesser degree, or capture a different part of the meaning. When evaluating a model for frame disambiguation, it seems unfair to penalize misclassifications of frames that still apply to the word, but with less clarity, in the same way we would penalize a frame that captures a wrong meaning. Also, we argue that models should take into account that annotators do not agree over some examples, and treat them differently than clear expressions of frames. Disagreement can also be caused by worker mistakes (in #6, *dimension* refers to the size of the object, not the act of measuring the size). While we try to mitigate for this by weighing confidence scores with the worker quality, the mistakes still appear in the corpus. This type of disagreement could be useful in future work to identify examples that workers need to be trained on.

3 Evaluating Frame Disambiguation

3.1 Systems Tested

As an example usage of our corpus, we used it to evaluate these frame disambiguation models:

---

[4] `https://github.com/CrowdTruth/FrameDisambiguation`

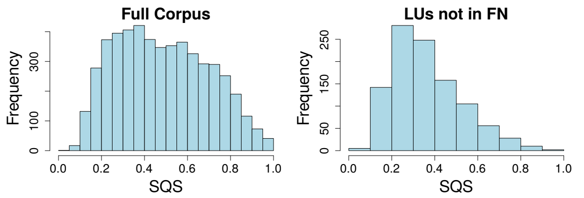

Figure 1: Histogram of SQS values - the quality scores in sentences where the LU is not in FN skew lower.

1. **OS:** The Open-Sesame (Swayamdipta et al., 2017) classifier, pre-trained on the FN corpus (release 1.7). Given a word-sentence pair, OS uses a BiLSTM model with a softmax final layer to predict a single frame for the word. If the LU is not in FN, it cannot make a prediction.
2. **OS+:** We modified the OS classifier to perform multi-label classification. To calculate the confidence score for candidate frame f, we removed the softmax layer and passed the output of the BiLSTM model $\nu(f)$ through the following transformation: $c(f) = [1 + tanh\,\nu(f)]/2$. This gave a score $c(f) \in [0, 1]$ expressing the confidence that frame f is expressed in the sentence.
3. **FS:** Framester includes a tool for rule-based multi-class multi-label frame disambiguation (Gangemi et al., 2016). While for the dataset pre-processing (Sec. 2) we considered the frames for all synsets a word is part of, FS performs an additional word-sense disambiguation step to return a more precise list of frames. We used the tool with *profile T* as it was shown to have the overall better performance. FS can only predict FN frames from the 1.5 release, which is missing 202 frames from version 1.7.

While OS+ produces confidence scores, the other methods produce binary labels for each frame-sentence pair. These models do not have state-of-the-art performance (Hermann et al., 2014; FitzGerald et al., 2015), we picked them because they were accessible and allowed testing on a novel corpus. Finally, we evaluate the quality of the **TC** corpus, containing only the top frame picked by the crowd for every sentence. This test shows what is the best possible performance over our corpus that can be expected from a system such as OS that selects a single frame per sentence.

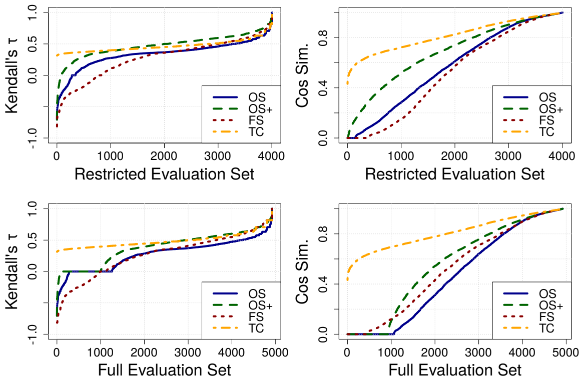

Figure 2: Baselines evaluation results.

	Eval. Metric	OS	OS+	FS	TC
R-Set	Kendall's τ AUC	0.339	**0.477**	0.279	0.466
	Kendall's τ w-avg	0.362	**0.497**	0.3	0.48
	Cos Sim AUC	0.57	**0.685**	0.518	0.818
	Cos Sim w-avg	0.608	**0.717**	0.545	0.854
F-Set	Kendall's τ AUC	0.269	**0.379**	0.253	0.491
	Kendall's τ w-avg	0.307	**0.421**	0.284	0.501
	Cos Sim AUC	0.453	**0.544**	0.511	0.810
	Cos Sim w-avg	0.515	**0.607**	0.539	0.849

Table 2: Aggregated evaluation results.

3.2 Evaluation Metrics & Results

Instead of traditional evaluation metrics that require binary labels, we propose an evaluation methodology that is able to consider multiple candidate frames for each sentence and their quality scores. We use **Kendall's** τ list ranking coefficient (Kendall, 1938) and **cosine similarity** to calculate the distance between the list of frames produced by the crowd labeled with the FSS, and the frames predicted by the baselines in each sentence. Whereas Kendall's τ only accounts for the ranking of the FSS for each frame, cosine similarity uses the actual FSS values in the calculation of the similarity. Both metrics compute a score per sentence (Kendall's $\tau \in [-1, 1]$, and cosine similarity $\in [0, 1]$). Using these metrics, we produce two aggregate statistics over our test corpus: (1) the area-under-curve (AUC) for each metric, normalized by the corpus size, and (2) the SQS-weighted average of each metric ($w - avg$), which also accounts for the ambiguity of the sentence as expressed by the SQS. We evaluate on two versions of the corpus: (1) the restricted set (R-Set) of 4,000 sentences with LUs from the FN corpus, and (2) the full set (F-Set) of 5,042 sentences.

The results (Figure 2 & Table 2) show that OS+ performs best out of all the models, even taking into account sentences with LUs not in FN for which OS+ cannot disambiguate. FS performs the worst out of all models on R-SET, because it cannot find newly added frames from the latest FN release, but improves on the F-SET (FS can find candidate frames for LUs not in FN). The scores on the F-SET were lower for all baselines, suggesting that sentences with LUs not in FN are more difficult to classify – this could be because FN is missing frames that can express the full meaning of these LUs. TC has a good performance, but is far from being unbeatable – when measuring Kendall's τ over the R-SET, OS+ performs better than TC.

4 Conclusions

We described a FrameNet frame disambiguation resource of 5,042 sentence-word pairs, and 1,000 LUs that are new to FN – the largest corpus of this type outside of FN. Since the submission of this paper, the corpus has grown to over 9,000 sentence-word pairs. We also provide confidence scores for each candidate frame that are based on inter-worker disagreement. We made a case for this kind of disagreement reflecting genuine cases of ambiguity in FrameNet frames, caused by: child-parent relations between frames, frames with overlapping definitions, or compositions of frames making up the meaning of a word. The evaluation method we proposed uses the scores for multiple frames, and is thus able to differentiate between frames that still apply to the word, but with less clarity, and frames that capture the wrong meaning. Our goal was to build a resource that recognizes different levels of ambiguity in the expression of the frames in the text, and allows a more fair evaluation of performance of frame disambiguation systems.

Acknowledgments

We would like to thank Luigi Asprino, Valentina Presutti and Aldo Gangemi for their assistance with using the Framester corpus, as well as their advice in better understanding the task of frame disambiguation. We would also like to thank the anonymous crowd workers for their contributions to our crowdsourcing tasks.

Abstract

Several datasets have recently been constructed to expose brittleness in models trained on existing benchmarks. While model performance on these *challenge datasets* is significantly lower compared to the original benchmark, it is unclear what particular weaknesses they reveal. For example, a challenge dataset may be difficult because it targets phenomena that current models cannot capture, or because it simply exploits blind spots in a model's specific training set. We introduce *inoculation by fine-tuning*, a new analysis method for studying challenge datasets by exposing models (the metaphorical patient) to a small amount of data from the challenge dataset (a metaphorical pathogen) and assessing how well they can adapt. We apply our method to analyze the NLI "stress tests" (Naik et al., 2018) and the Adversarial SQuAD dataset (Jia and Liang, 2017). We show that after slight exposure, some of these datasets are no longer challenging, while others remain difficult. Our results indicate that failures on challenge datasets may lead to very different conclusions about models, training datasets, and the challenge datasets themselves.

1 Introduction

NLP research progresses through the construction of dataset-benchmarks and the development of systems whose performance on them can be fairly compared. A recent pattern involves *challenges* to benchmarks:[1] manipulations to input data that result in severe degradation of system performance, but not human performance. These challenges have been used as evidence that current systems are brittle (Belinkov and Bisk, 2018; Mudrakarta et al., 2018; Zhao et al., 2018; Glockner et al., 2018; Ebrahimi et al., 2018; Ribeiro et al., 2018, *inter alia*). For instance, Naik et al. (2018) generated natural language inference challenge data by applying simple textual transformations to existing examples from MultiNLI (Williams et al., 2018) and SNLI (Bowman et al., 2015). Similarly, Jia and Liang (2017) built an adversarial evaluation dataset for reading comprehension based on SQuAD (Rajpurkar et al., 2016).

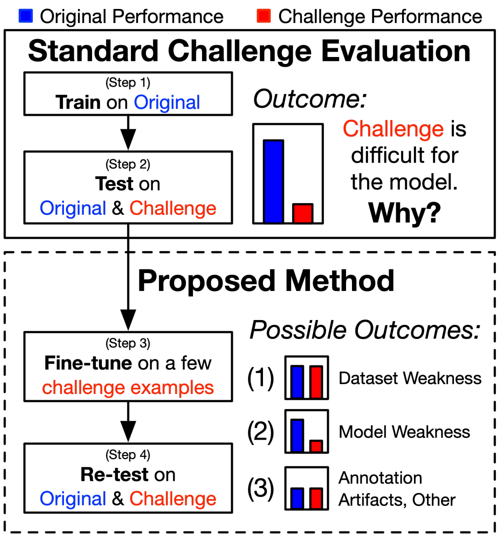

Figure 1: An illustration of the standard challenge evaluation procedure (e.g., Jia and Liang, 2017) and our proposed analysis method. "Original" refers to the a standard dataset (e.g., SQuAD) and "Challenge" refers to the challenge dataset (e.g., Adversarial SQuAD). Outcomes are discussed in Section 2.

What should we conclude when a system fails on a challenge dataset? In some cases, a challenge might exploit blind spots in the design of the *original* dataset (*dataset weakness*). In others, the challenge might expose an inherent inability of a particular model family to handle certain natural language phenomena (*model weakness*). These are, of course, not mutually exclusive.

We introduce **inoculation by fine-tuning**, a

---

[1] Often referred to as "adversarial datasets" or "attacks".

Proceedings of NAACL-HLT 2019, pages 2171–2179
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

new method for analyzing the effects of challenge datasets (Figure 1).[2] Given a model trained on the original dataset, we expose it to a small number of examples from the challenge dataset, allowing learning to continue. To the extent that the weakness lies with the original dataset, then the inoculated model will perform well on both the original and challenge held-out data (Outcome 1 in Figure 1). If the weakness lies with the model, then inoculation will prove ineffective and the model's performance will remain unchanged (Outcome 2).

Inoculation can also decrease a model's performance on the original dataset (Outcome 3). This case is not as clear as the first two, and could result from systematic differences between the original and challenge datasets, due to, e.g., predictive artifacts in either dataset (Gururangan et al., 2018).

We apply our method to analyze six challenge datasets: the *word overlap*, *negation*, *spelling errors*, *length mismatch* and *numerical reasoning* NLI challenge datasets proposed by Naik et al. (2018), as well as the Adversarial SQuAD reading comprehension challenge dataset (Jia and Liang, 2017). We analyze NLI datasets with the ESIM (Chen et al., 2017) and the decomposable attention (Parikh et al., 2016) models, and reading comprehension with the BiDAF (Seo et al., 2017) and the QANet (Yu et al., 2018) models.

By fine-tuning on, in some cases, as few as 100 examples, both NLI models are able to recover almost the entire performance gap on both the *word overlap* and *negation* challenge datasets (Outcome 1). In contrast, both models struggle to adapt to the *spelling error* and *length mismatch* challenge datasets (Outcome 2). On the *numerical reasoning* challenge dataset, both models close all of the gap using a small number of samples, but at the expense of performance on the original dataset (Outcome 3). For Adversarial SQuAD, BiDAF closes 60% of the gap with minimal fine-tuning, but suffers a 7% decrease in original test set performance (Outcome 3). QANet shows similar trends.

Our proposed analysis is broadly applicable, easy to perform, and task-agnostic. By gaining a better understanding of how challenge datasets stress models, we can better tease apart limitations of datasets and limitations of models.

2 Inoculation by Fine-Tuning

Our method assumes access to an original dataset divided into training and test portions, as well as a challenge dataset, divided into a (small) training set[3] and a test set. After training on the original (training) data, we measure system performance on both test sets. We assume the usual observation—a generalization gap with considerably lower performance on the challenge test set.

We then proceed to fine-tune the model on the challenge training data, i.e., continuing to train the pre-trained model on the new data until development performance on the original development set has not improved for five epochs.[4] Finally, we measure performance of the inoculated model on both the original and challenge test sets. Three clear outcomes of interest are:[5]

Outcome 1 The gap closes, i.e., the inoculated system retains its (high) performance on the original test set and performs as well (or nearly so) on the challenge test set. This case suggests that the challenge dataset did not reveal a weakness in the model family. Instead, the challenge has likely revealed a lack of diversity in the original dataset.

Outcome 2 Performance on both test sets is unchanged. This indicates that the challenge dataset has revealed a fundamental weakness of the model; it is unable to adapt to the challenge data distribution, even with some exposure.

Outcome 3 Inoculation damages performance on the original test set (regardless of improvement on the challenge test set). The main difference between Outcome 3 and Outcomes 1 and 2 is that here, by fine-tuning, the model is shifting towards a challenge distribution that somehow contradicts the original distribution. This could result from, e.g., a different label distribution between both datasets, or annotation artifacts that exist in one dataset but not in the other (see Sections 3.2, 3.3).

3 Not all Challenge Datasets are Alike

To demonstrate the utility of our method, we apply it to analyze the NLI stress tests (Naik et al.,

---

[2] *Inoculation* evokes the idea that treatable diseases have different implications (for society and for the patient) than untreatable ones. We differentiate the abstract process of inoculation from our way of executing it (fine-tuning) since it is easy to imagine alternative ways to inoculate a model.

[3] The exact amount of challenge data used for fine-tuning might affect our conclusions, so we consider different sizes of the "vaccine" in our experiments.

[4] The use of the original development set is meant to both prevent us from using more challenge data and verify that the learner does not completely forget the original dataset.

[5] The outcome may also lie between these extremes, necessitating deeper analysis.

Category	Premise	Hypothesis
Word Overlap	Possibly no other country has had such a turbulent history.	The country's history has been turbulent **and true is true**.
Negation	Possibly no other country has had such a turbulent history.	The country's history has been turbulent **and false is not true**.
Spelling Errors	Fix the engine, Dave Hanson, he called.	Hanson received **ordets** not to fix **teh** engine.
Length Mismatch	Possibly no other country has had such a turbulent history **and true is true and true is true and true is true and true is true and true is true**.	The countrys history has been turbulent.
Numerical Reasoning	**Tim has 350 pounds of cement in 100, 50, and 25 pound bags.**	**Tim has less than 750 pounds of cement in 100, 50, and 25 pound bags.**

Table 1: Examples from each of the NLI challenge datasets analyzed, a subset of a broader suite of NLI stress tests proposed by Naik et al. (2018). Boldface denotes perturbations to original MultiNLI examples. Figure contents reproduced from Naik et al. (2018).

Article: Super Bowl 50
Paragraph: *Peyton Manning became the first quarterback ever to lead two different teams to multiple Super Bowls. He is also the oldest quarterback ever to play in a Super Bowl at age 39. The past record was held by John Elway, who led the Broncos to victory in Super Bowl XXXIII at age 38 and is currently Denver's Executive Vice President of Football Operations and General Manager. Quarterback Jeff Dean had jersey number 37 in Champ Bowl XXXIV.*
Question: *What is the name of the quarterback who was 38 in Super Bowl XXXIII?*

Figure 2: An example from the Adversarial SQuAD dataset, with the distractor sentence in blue. Figure reproduced from Jia and Liang (2017).

2018) and the Adversarial SQuAD dataset (Jia and Liang, 2017). We fine-tune models on a varying number of examples from the challenge dataset training split in order to study whether our method is sensitive to the level of exposure.[6] Our results demonstrate that different challenge datasets lead to different outcomes. We release code for reproducing our results.[7]

3.1 Datasets

We briefly describe the analyzed datasets, but refer readers to the original publications for details.

NLI Stress Tests Naik et al. (2018) proposed six automatically-constructed "stress tests", each focusing on a different weakness of NLI systems. We analyze five of these stress tests (Table 1).[8]

The **word overlap** challenge dataset is designed to exploit models' sensitivity to high lexical overlap in the premise and hypothesis by appending the tautology *"and true is true"* to the hypothesis. The **negation** challenge dataset is based on the observation that negation words (e.g., *"no"*, *"not"*) cause the model to classify neutral or entailed statements as contradiction. In this dataset, the tautology *"and false is not true"* is appended to the hypothesis sentence. The **spelling errors** challenge dataset is designed to evaluate model robustness to noisy data in the form of misspellings. The **length mismatch** challenge dataset is designed to exploit models' inability to handle examples with much longer premises than hypotheses. In this dataset, the tautology *"and true is true"* is appended five times to the end of the premise. Lastly, the **numerical reasoning** challenge dataset is designed to test models' ability to perform algebraic calculations, by introducing premise-hypothesis pairs containing numerical expressions.

We analyze these challenge datasets using two models, both trained on the MultiNLI dataset:[9] the ESIM model (Chen et al., 2017) and the decomposable attention model (DA; Parikh et al., 2016).

To better address the spelling errors challenge dataset, we also train a character-sensitive version of the ESIM model. We concatenate the word representations with the 50-dimensional hidden states

---

[6] See Appendix A for experimental process details.

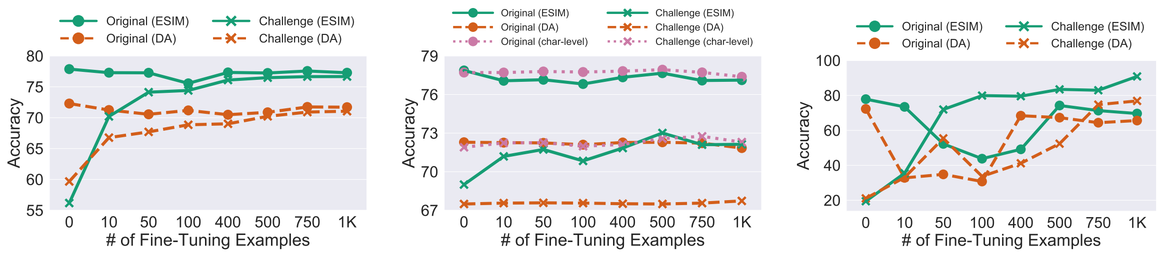
[7] `http://nelsonliu.me/papers/inoculation-by-finetuning`

[8] The remaining challenge dataset—**antonym**—is briefly discussed in Section 3.3.

[9] MultiNLI has domain-matched and mismatched development data, so we train separate "matched" and "mismatched" models that each use the corresponding development set for learning rate scheduling and early stopping. We observe similar results in both cases, so we focus on the models trained on "matched" data. See Appendix B for mismatched results.

Outcome 1 **Outcome 2** **Outcome 3**

(a) Word Overlap **(c) Spelling Errors** **(e) Numerical Reasoning**



(b) Negation **(d) Length Mismatch** **(f) Adversarial SQuAD**

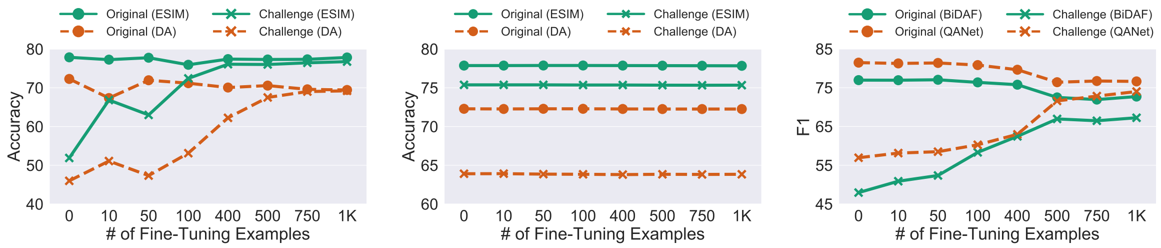


Figure 3: Inoculation by fine-tuning results. (a–e): NLI accuracy for the ESIM and decomposable attention (DA) models. (f): Reading comprehension F_1 scores for the BiDAF and QANet models.
Fine-tuning on a small number of word overlap (a) and negation (b) examples erases the performance gap (Outcome 1). Fine-tuning does not yield significant improvement on spelling errors (c) and length mismatch (d), but does not degrade original performance either (Outcome 2). Fine-tuning on numerical reasoning (e) closes the gap entirely, but also reduces performance on the original dataset (Outcome 3). On Adversarial SQuAD (f), around 60% of the performance gap is closed after fine-tuning, though performance on the original dataset decreases (Outcome 3). On each challenge dataset, we observe similar trends between different models.

produced by running each token through a character bidirectional GRU (Cho et al., 2014).

Adversarial SQuAD Jia and Liang (2017) created a challenge dataset for reading comprehension by appending automatically-generated distractor sentences to SQuAD passages. The appended distractor sentences are crafted to look similar to the question while not contradicting the correct answer or misleading humans (Figure 2). The authors released model-independent Adversarial SQuAD examples, which we analyze. For our analysis, we use the BiDAF model (Seo et al., 2017) and the QANet model (Yu et al., 2018).

3.2 Results

We refer to difference between a model's pre-inoculation performance on the original test set and the challenge test set as the *performance gap*.

NLI Stress Tests Figure 3 presents NLI accuracy for the ESIM and DA models on the word overlap, negation, spelling errors, length mismatch and numerical reasoning challenge datasets after fine-tuning on a varying number of challenge examples.

For the word overlap and negation challenge datasets, both ESIM and DA quickly close the performance gap when fine-tuning (Outcome 1). For instance, on both of the aforementioned challenge datasets, ESIM requires only 100 examples to close over 90% of the performance gap while maintaining high performance on the original dataset. Since these performance gaps are closed after seeing a few challenge dataset examples (< 0.03% of the original MultiNLI training dataset), these challenges are likely difficult because they exploit easily-recoverable gaps in the models' training dataset rather than highlighting their inability to capture semantic phenomena.

In contrast, on spelling errors and length mismatch, fine-tuning does not allow either model to close a substantial portion of the performance gap, while performance on the original dataset is unaffected (Outcome 2).[10] Interestingly, the character-aware ESIM model trained on spelling errors shows a similar trend, suggesting that the this challenge set is highlighting a weakness of ESIM that goes beyond the word representation.

On numerical reasoning, the entire gap is closed by fine-tuning ESIM on 100 examples, or DA on 750 examples. However, both models' original dataset performance substantially decreases (Outcome 3; see discussion in Section 3.3).

Adversarial SQuAD Figure 3(f) shows BiDAF and QANet results after fine-tuning on a varying number of challenge samples.

Fine-tuning BiDAF on only 400 challenge examples closes more than 60% of the performance gap, but also results in substantial performance loss on the original SQuAD development set; fine-tuning QANet yields the same trend (Outcome 3). In this case, the model likely takes advantage of the fact that the adversarial distractor sentence is always concatenated to the end of the paragraph.[11]

3.3 Discussion

Explaining the Numerical Reasoning Results The relative ease with which the ESIM model overcomes the numerical reasoning challenge seems to contradict the findings of Naik et al. (2018), who observed that "*the model is unable to perform reasoning involving numbers or quantifiers . . .*". Indeed, it seems unlikely that a model will learn to perform algebraic numerical reasoning based on as few as 50 NLI examples.

However, a closer look at this dataset provides a potential explanation for this finding. The dataset was constructed such that a simple 3-rule baseline is able to surpass 80% on the task (see Appendix C). For instance, 35% of the dataset examples contain the phrase "more than" or "less than" in their hypothesis, and 95% of these have the label "neutral". As a result, learning a handful of these rules is sufficient for achieving high performance on this challenge dataset.

This observation highlights a key property of Outcome 3: challenge datasets that are easily recoverable by our method, at the expense of performance on the original dataset, are likely not testing the full breadth of a linguistic phenomenon but rather a specific aspect of it.

Limitations of Our Method Our inoculation method assumes a somewhat balanced label distribution in the challenge dataset training portion. If a challenge dataset is highly skewed to a specific label, fine-tuning will result in simply learning to predict the majority label; such a model would achieve high performance on the challenge dataset and low performance on the original dataset (Outcome 3). For such datasets, the result of our method is not very informative.[12] Nonetheless, as in the numerical reasoning case discussed above, this lack of diversity signals a somewhat limited phenomenon captured by the challenge dataset.

4 Conclusion

We presented a method for studying *why* challenge datasets are difficult for models. Our method fine-tunes models on a small number of challenge dataset examples. This analysis yields insights into models, their training datasets, and the challenge datasets themselves. We applied our method to analyze the challenge datasets of Naik et al. (2018) and Jia and Liang (2017). Our results indicate that some of these challenge datasets break models by exploiting blind spots in their training data, while others may challenge more fundamental weaknesses of model families.

Acknowledgments

We thank Aakanksha Naik and Abhilasha Ravichander for generating NLI stress test examples from the MultiNLI training split, and Robin Jia for answering questions about the Adversarial SQuAD dataset. We also thank the members of the Noah's ARK group at the University of Washington, the researchers at the Allen Institute for Artificial Intelligence, and the anonymous reviewers for their valuable feedback. NL is supported by a Washington Research Foundation Fellowship and a Barry M. Goldwater Scholarship. This work was supported in part by a hardware gift from NVIDIA Corporation.

---

[10] The length mismatch dataset is not particularly challenging for the ESIM model: its untuned performance on the challenge set is only 2.5% lower than its original performance. Nonetheless, this gap remains fixed even after fine-tuning

[11] Indeed, Jia and Liang (2017) show that models trained on Adversarial SQuAD are able to overcome the adversary by simply learning to ignore the last sentence of the passage.

[12] For instance, the *antonym* challenge dataset of Naik et al. (2018), in which all examples are labeled "contradiction".

Appendices

A Experimental Setup Details

Generating challenge training sets When varying the size of the challenge dataset train split used for fine-tuning, we subsample inclusively. For example, the dataset used for fine-tuning on 5 examples is a subset of the dataset used for fine-tuning on 100 examples, which is a subset of the dataset used for fine-tuning on 1000 examples.

The *word overlap*, *negation*, *spelling errors* and *length mismatch* NLI challenge datasets, as well as Adversarial SQuAD, include splits for training and evaluation. To generate the datasets used for fine-tuning, we subsample 1000 random examples from each of the challenge dataset train splits.[13] The evaluation splits are used as-is.

The *numerical reasoning* NLI challenge dataset is unsplit. As a result, we generate the datasets used for fine-tuning by subsampling 1000 random examples from the entirety of the challenge dataset, and use the remaining examples for evaluation.

Experimental details To train the ESIM model of Chen et al. (2017), the decomposable attention model of Parikh et al. (2016), the BiDAF model of Seo et al. (2017), and the QANet model of Yu et al. (2018), we use the implementations in AllenNLP (Gardner et al., 2018). The models are trained with the same hyperparameters as described in their respective papers.

For each training dataset size, we tune the learning rate on the *original* development set accuracy; the learning rate is halved whenever validation performance (F_1 for SQuAD, accuracy for NLI) does not improve, and we employ early stopping with a patience of 5. This ensures that we are not implicitly using additional challenge dataset examples. For each model and amount of challenge dataset examples used for fine-tuning, the reported challenge dataset performance is the performance of the learning rate configuration that yields the best challenge dataset performance. We leave all other hyperparameters (such as the batch size and choice of optimizer) unchanged from the model's original training procedure.

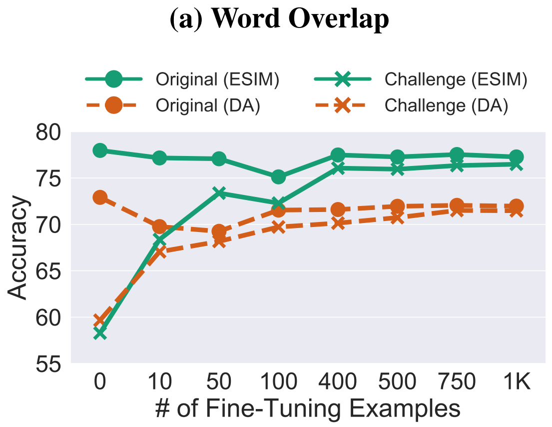
For the Adversarial SQuAD experiments, we experiment with learning rates of 0.00001, 0.0001, 0.001 and 0.01. For the NLI stress test experiments, we experiment with learning rates of 0.000001, 0.00001, 0.0001, 0.0004, 0.001, and 0.01.

We use AllenNLP to run our fine-tuning experiments.

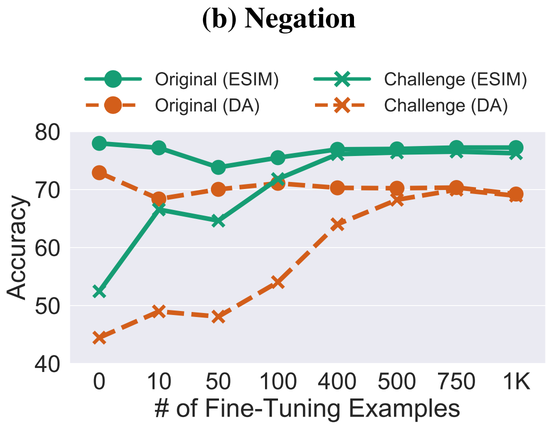
---

[13] For Adversarial SQuAD, we subsample from distinct passages.

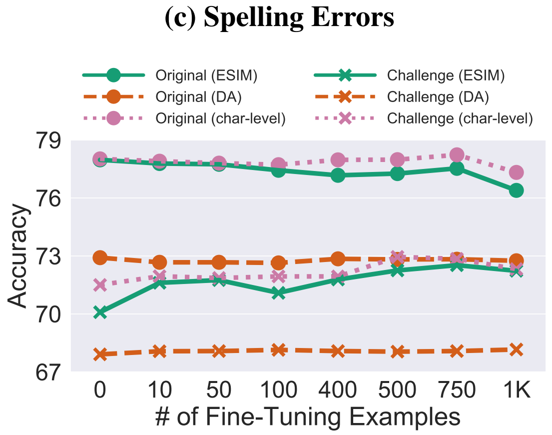
B MultiNLI Mismatched Stress Test Results



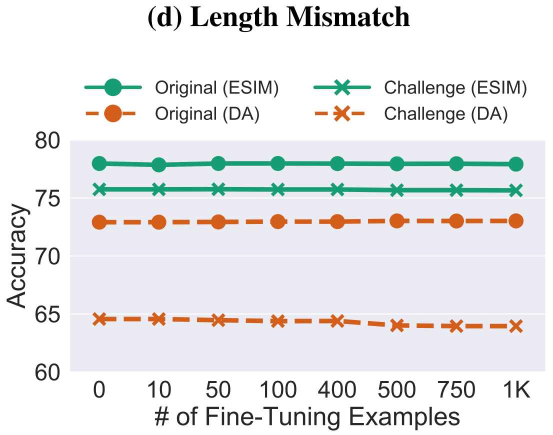
(a) Performance of the ESIM and DA models after fine-tuning on a variable number of word overlap challenge dataset examples generated from the MultiNLI mismatched development set.



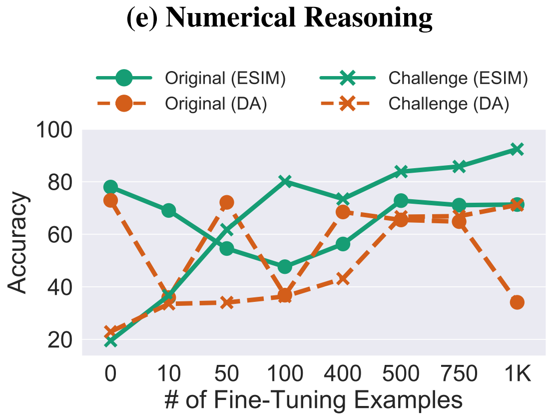
(b) Performance of the ESIM and DA models after fine-tuning on a variable number of negation challenge dataset examples generated from the MultiNLI mismatched development set.



(c) Performance of the ESIM (with and without an additional character-level component) and DA models after fine-tuning on a variable number of spelling error challenge dataset examples generated from the MultiNLI mismatched development set.



(d) Performance of the ESIM and DA models after fine-tuning on a variable number of length mismatch challenge dataset examples generated from the MultiNLI mismatched development set.



(e) Performance of the ESIM and DA models (where the mismatched development set was used during training to control learning rate scheduling and early stopping) after fine-tuning on a variable number of numerical reasoning challenge dataset examples.

C Three Simple Rules for the Numerical Reasoning Dataset

The numerical reasoning dataset of Naik et al. (2018) has 7,596 examples in total, with 2,532 in each of the “entailment”, “neutral”, and “contradiction” categories. With only three rules, we can correctly classify around 82% of the examples.

1,235 examples (out of the 7,596 in total) can be correctly labeled as contradiction with the rule: “more than” or “less than” do not appear in the premise or the hypothesis.

2,664 examples (out of the 6,361 examples left to be considered) contain “more than” or “less than” in the hypothesis. Of these 2,664 examples, 2,532 have the label “neutral”, 66 have the label “entailment”, and 66 have the label “contradiction”. So, if the hypothesis contains “more than” or “less than”, we predict “neutral”. This rule leads us to correctly classify 2,532 examples and incorrectly classify 132 examples.

Finally, we have 3,697 examples to be considered. All 3,697 of these examples have “more than” or “less than” in the premise. 2,466 of these examples are labeled “entailment”, while 1,231 are labeled “contradicion”. By assigning the label “entailment” to examples that contain “more than” or “less than” in their premise, we correctly classify 2,446 examples and incorrectly classify 1,231 examples.

In total, these three rules result in correct predictions on 6,233 examples out of 7,596 (82.05%).

A Capsule Network-based Embedding Model for Knowledge Graph Completion and Search Personalization

Abstract

In this paper, we introduce an embedding model, named CapsE, exploring a capsule network to model relationship triples *(subject, relation, object)*. Our CapsE represents each triple as a 3-column matrix where each column vector represents the embedding of an element in the triple. This 3-column matrix is then fed to a convolution layer where multiple filters are operated to generate different feature maps. These feature maps are reconstructed into corresponding capsules which are then routed to another capsule to produce a continuous vector. The length of this vector is used to measure the plausibility score of the triple. Our proposed CapsE obtains better performance than previous state-of-the-art embedding models for knowledge graph completion on two benchmark datasets WN18RR and FB15k-237, and outperforms strong search personalization baselines on SEARCH17.

1 Introduction

Knowledge graphs (KGs) containing relationship triples *(subject, relation, object)*, denoted as *(s, r, o)*, are the useful resources for many NLP and especially information retrieval applications such as semantic search and question answering (Wang et al., 2017). However, large knowledge graphs, even containing billions of triples, are still incomplete, i.e., missing a lot of valid triples (West et al., 2014). Therefore, much research efforts have focused on the knowledge graph completion task which aims to predict missing triples in KGs, i.e., predicting whether a triple not in KGs is likely to be valid or not (Bordes et al., 2011, 2013; Socher et al., 2013). To this end, many embedding models have been proposed to learn vector representations for entities (i.e., *subject*/head entity and *object*/tail entity) and relations in KGs, and obtained state-of-the-art results as summarized by Nickel et al. (2016a) and Nguyen (2017). These embedding models score triples *(s, r, o)*, such that valid triples have higher plausibility scores than invalid ones (Bordes et al., 2011, 2013; Socher et al., 2013). For example, in the context of KGs, the score for *(Melbourne, cityOf, Australia)* is higher than the score for *(Melbourne, cityOf, United Kingdom)*.

Triple modeling is applied not only to the KG completion, but also for other tasks which can be formulated as a triple-based prediction problem. An example is in search personalization, one would aim to tailor search results to each specific user based on the user's personal interests and preferences (Teevan et al., 2005, 2009; Bennett et al., 2012; Harvey et al., 2013; Vu et al., 2015, 2017). Here the triples can be formulated as *(submitted query, user profile, returned document)* and used to re-rank documents returned to a user given an input query, by employing an existing KG embedding method such as TransE (Bordes et al., 2013), as proposed by Vu et al. (2017). Previous studies have shown the effectiveness of modeling triple for either KG completion or search personalization. However, there has been no single study investigating the performance on both tasks.

Conventional embedding models, such as TransE (Bordes et al., 2013), DISTMULT (Yang et al., 2015) and ComplEx (Trouillon et al., 2016), use addition, subtraction or simple multiplication operators, thus only capture the linear relationships between entities. Recent research has raised interest in applying deep neural networks to triple-based prediction problems. For example, Nguyen et al. (2018) proposed ConvKB—a convolutional neural network (CNN)-based model for KG completion and achieved state-of-the-art results. Most of KG embedding models are constructed to modeling entries at the same dimension of the given triple, where presumably each dimension captures some relation-specific attribute of entities. To the

Proceedings of NAACL-HLT 2019, pages 2180–2189
Minneapolis, Minnesota, June 2 - June 7, 2019.

best of our knowledge, however, none of the existing models has a "deep" architecture for modeling the entries in a triple at the same dimension.

Sabour et al. (2017) introduced capsule networks (CapsNet) that employ capsules (i.e., *each capsule is a group of neurons*) to capture entities in images and then uses a routing process to specify connections from capsules in a layer to those in the next layer. Hence CapsNet could encode the intrinsic spatial relationship between a part and a whole constituting viewpoint invariant knowledge that automatically generalizes to novel viewpoints. Each capsule accounts for capturing variations of an object or object part in the image, which can be efficiently visualized. Our high-level hypothesis is that embedding entries at the same dimension of the triple also have these variations, although it is not straightforward to be visually examined.

To that end, we introduce CapsE to explore a novel application of CapsNet on triple-based data for two problems: KG completion and search personalization. Different from the traditional modeling design of CapsNet where capsules are constructed by splitting feature maps, we use capsules to model the entries at the same dimension in the entity and relation embeddings. In our CapsE, $\boldsymbol{v}_s$, $\boldsymbol{v}_r$ and $\boldsymbol{v}_o$ are unique k-dimensional embeddings of s, r and o, respectively. The embedding triple $[\boldsymbol{v}_s, \boldsymbol{v}_r, \boldsymbol{v}_o]$ of *(s, r, o)* is fed to the convolution layer where multiple filters of the same 1×3 shape are repeatedly operated over every row of the matrix to produce k-dimensional feature maps. Entries at the same dimension from all feature maps are then encapsulated into a capsule. Thus, *each capsule can encode many characteristics in the embedding triple to represent the entries at the corresponding dimension*. These capsules are then routed to another capsule which outputs a continuous vector whose length is used as a score for the triple. Finally, this score is used to predict whether the triple *(s, r, o)* is valid or not.

In summary, our main contributions from this paper are as follows:

• We propose an embedding model CapsE using the capsule network (Sabour et al., 2017) for modeling relationship triples. To our best of knowledge, our work is the first consideration of exploring the capsule network to knowledge graph completion and search personalization.

• We evaluate our CapsE for knowledge graph completion on two benchmark datasets WN18RR (Dettmers et al., 2018) and FB15k-237 (Toutanova and Chen, 2015). CapsE obtains the best mean rank on WN18RR and the highest mean reciprocal rank and highest Hits@10 on FB15k-237.

• We restate the prospective strategy of expanding the triple embedding models to improve the ranking quality of the search personalization systems. We adapt our model to search personalization and evaluate on SEARCH17 (Vu et al., 2017) – a dataset of the web search query logs. Experimental results show that our CapsE achieves the new state-of-the-art results with significant improvements over strong baselines.

2 The proposed CapsE

Let $\mathcal{G}$ be a collection of valid factual triples in the form of *(subject, relation, object)* denoted as *(s, r, o)*. Embedding models aim to define a *score function* giving a score for each triple, such that valid triples receive higher scores than invalid triples.

We denote $\boldsymbol{v}_s$, $\boldsymbol{v}_r$ and $\boldsymbol{v}_o$ as the k-dimensional embeddings of s, r and o, respectively. In our proposed CapsE, we follow Nguyen et al. (2018) to view each embedding triple $[\boldsymbol{v}_s, \boldsymbol{v}_r, \boldsymbol{v}_o]$ as a matrix $\boldsymbol{A} = [\boldsymbol{v}_s, \boldsymbol{v}_r, \boldsymbol{v}_o] \in \mathbb{R}^{k \times 3}$, and denote $\boldsymbol{A}_{i,:} \in \mathbb{R}^{1 \times 3}$ as the i-th row of $\boldsymbol{A}$. We use a filter $\boldsymbol{\omega} \in \mathbb{R}^{1 \times 3}$ operated on the convolution layer. This filter $\boldsymbol{\omega}$ is repeatedly operated over every row of $\boldsymbol{A}$ to generate a feature map $\mathbf{q} = [\mathsf{q}_1, \mathsf{q}_2, ..., \mathsf{q}_k] \in \mathbb{R}^k$, in which $\mathsf{q}_i = g\left(\boldsymbol{\omega} \cdot \boldsymbol{A}_{i,:} + b\right)$ where $\cdot$ denotes a dot product, $b \in \mathbb{R}$ is a bias term and g is a non-linear activation function such as ReLU. Our model uses multiple filters $\in \mathbb{R}^{1 \times 3}$ to generate feature maps. We denote $\boldsymbol{\Omega}$ as the set of filters and $\mathsf{N} = \mid \boldsymbol{\Omega} \mid$ as the number of filters, thus we have N k-dimensional feature maps, for which each feature map can capture one single characteristic among entries at the same dimension.

We build our CapsE with two single capsule layers for a simplified architecture. In the first layer, we construct k capsules, wherein entries at the same dimension from all feature maps are encapsulated into a corresponding capsule. Therefore, each capsule can capture many characteristics among the entries at the corresponding dimension in the embedding triple. These characteristics are generalized into one capsule in the second layer which produces a vector output whose length is used as the score for the triple.

The first capsule layer consists of k capsules, for which each capsule $i \in \{1, 2, ..., k\}$ has a vector

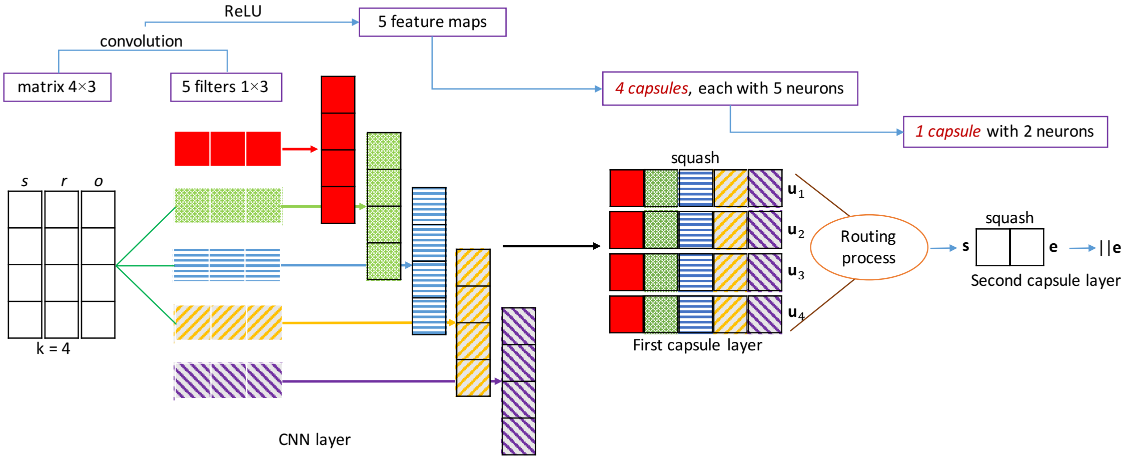

Figure 1: An example illustration of our CapsE with $k = 4$, $\mathsf{N} = 5$, and $d = 2$.

output $\mathbf{u}_i \in \mathbb{R}^{\mathsf{N}\times 1}$. Vector outputs $\mathbf{u}_i$ are multiplied by weight matrices $\mathbf{W}_i \in \mathbb{R}^{d\times\mathsf{N}}$ to produce vectors $\hat{\mathbf{u}}_i \in \mathbb{R}^{d\times 1}$ which are summed to produce a vector input $\mathbf{s} \in \mathbb{R}^{d\times 1}$ to the capsule in the second layer. The capsule then performs the non-linear squashing function to produce a vector output $\mathbf{e} \in \mathbb{R}^{d\times 1}$:

$$\mathbf{e} = \mathsf{squash}\left(\mathbf{s}\right) \quad ; \quad \mathbf{s} = \sum_i c_i \hat{\mathbf{u}}_i \quad ; \quad \hat{\mathbf{u}}_i = \mathbf{W}_i \mathbf{u}_i$$

where $\mathsf{squash}\left(\mathbf{s}\right) = \frac{\|\mathbf{s}\|^2}{1+\|\mathbf{s}\|^2}\frac{\mathbf{s}}{\|\mathbf{s}\|}$, and c_i are coupling coefficients determined by the routing process as presented in Algorithm 1. Because there is one capsule in the second layer, we make only one difference in the routing process proposed by Sabour et al. (2017), for which we apply the softmax in a direction from all capsules in the previous layer to each of capsules in the next layer.[1]

```
for all capsule $i \in$ the first layer do
    $b_i \leftarrow 0$
for iteration = 1, 2, ..., $m$ do
    $\mathbf{c} \leftarrow \mathsf{softmax}\left(\mathbf{b}\right)$
    $\mathbf{s} \leftarrow \sum_i c_i \hat{\mathbf{u}}_i$
    $\mathbf{e} = \mathsf{squash}\left(\mathbf{s}\right)$
    for all capsule $i \in$ the first layer do
        $b_i \leftarrow b_i + \hat{\mathbf{u}}_i \cdot \mathbf{e}$
```

Algorithm 1: The routing process is extended from Sabour et al. (2017).

We illustrate our proposed model in Figure 1 where embedding size: $k = 4$, the number of filters: $\mathsf{N} = 5$, the number of neurons within the capsules in the first layer is equal to N, and the number of neurons within the capsule in the second layer: $d = 2$. The length of the vector output $\mathbf{e}$ is used as the score for the input triple.

Formally, we define the score function f for the triple (s, r, o) as follows:

$$f\left(s, r, o\right) = \|\mathsf{capsnet}\left(g\left(\left[\boldsymbol{v}_s, \boldsymbol{v}_r, \boldsymbol{v}_o\right] * \boldsymbol{\Omega}\right)\right)\|$$

where the set of filters $\boldsymbol{\Omega}$ is shared parameters in the convolution layer; $*$ denotes a convolution operator; and capsnet denotes a capsule network operator. We use the Adam optimizer (Kingma and Ba, 2014) to train CapsE by minimizing the loss function (Trouillon et al., 2016; Nguyen et al., 2018) as follows:

$$\mathcal{L} = \sum_{(s,r,o)\in\{\mathcal{G}\cup\mathcal{G}'\}} \log\left(1 + \exp\left(-t_{(s,r,o)} \cdot f\left(s, r, o\right)\right)\right)$$

$$\text{in which, } t_{(s,r,o)} = \begin{cases} 1 \text{ for } (s, r, o) \in \mathcal{G} \\ -1 \text{ for } (s, r, o) \in \mathcal{G}' \end{cases}$$

here $\mathcal{G}$ and $\mathcal{G}'$ are collections of valid and invalid triples, respectively. $\mathcal{G}'$ is generated by corrupting valid triples in $\mathcal{G}$.

3 Knowledge graph completion evaluation

In the knowledge graph completion task (Bordes et al., 2013), the goal is to predict a missing entity given a relation and another entity, i.e, inferring a head entity s given (r, o) or inferring a tail entity o given (s, r). The results are calculated based on ranking the scores produced by the score function f on test triples.

---

[1] The softmax in the original routing process proposed by Sabour et al. (2017) is applied in another direction from each of capsules in the previous layer to all capsules in the next layer.

3.1 Experimental setup

Datasets: We use two recent benchmark datasets WN18RR (Dettmers et al., 2018) and FB15k-237 (Toutanova and Chen, 2015). These two datasets are created to avoid reversible relation problems, thus the prediction task becomes more realistic and hence more challenging (Toutanova and Chen, 2015). Table 1 presents the statistics of WN18RR and FB15k-237.

Dataset	#E	#R	#Triples in train/valid/test		
WN18RR	40,943	11	86,835	3,034	3,134
FB15k-237	14,541	237	272,115	17,535	20,466

Table 1: Statistics of the experimental datasets. #E is the number of entities. #R is the number of relations.

Evaluation protocol: Following Bordes et al. (2013), for each valid test triple (s, r, o), we replace either s or o by each of all other entities to create a set of corrupted triples. We use the "Filtered" setting protocol (Bordes et al., 2013), i.e., not taking any corrupted triples that appear in the KG into accounts. We rank the valid test triple and corrupted triples in descending order of their scores. We employ evaluation metrics: mean rank (MR), mean reciprocal rank (MRR) and Hits@10 (i.e., the proportion of the valid test triples ranking in top 10 predictions). Lower MR, higher MRR or higher Hits@10 indicate better performance. Final scores on the test set are reported for the model obtaining the highest Hits@10 on the validation set.

Training protocol: We use the common Bernoulli strategy (Wang et al., 2014; Lin et al., 2015b) when sampling invalid triples. For WN18RR, Pinter and Eisenstein (2018)[2] found a strong evidence to support the necessity of a WordNet-related semantic setup, in which they averaged pre-trained word embeddings for word surface forms within the WordNet to create synset embeddings, and then used these synset embeddings to initialize entity embeddings for training their TransE association model. We follow this evidence in using the pre-trained 100-dimensional Glove word embeddings (Pennington et al., 2014) to train a TransE model on WN18RR.

We employ the TransE and ConvKB implementations provided by Nguyen et al. (2016b) and Nguyen et al. (2018). For ConvKB, we use a new process of training up to 100 epochs and monitor the Hits@10 score after every 10 training epochs to choose optimal hyper-parameters with the Adam initial learning rate in $\{1e^{-5}, 5e^{-5}, 1e^{-4}\}$ and the number of filters N in $\{50, 100, 200, 400\}$. We obtain the highest Hits@10 scores on the validation set when using N= 400 and the initial learning rate $5e^{-5}$ on WN18RR; and N= 100 and the initial learning rate $1e^{-5}$ on FB15k-237.

Like in ConvKB, we use the same pre-trained entity and relation embeddings produced by TransE to initialize entity and relation embeddings in our CapsE for both WN18RR and FB15k-237 ($k = 100$). We set the batch size to 128, the number of neurons within the capsule in the second capsule layer to 10 ($d = 10$), and the number of iterations in the routing algorithm m in $\{1, 3, 5, 7\}$. We run CapsE up to 50 epochs and monitor the Hits@10 score after each 10 training epochs to choose optimal hyper-parameters. The highest Hits@10 scores for our CapsE on the validation set are obtained when using $m = 1$, $\mathsf{N} = 400$ and the initial learning rate at $1e^{-5}$ on WN18RR; and $m = 1$, $\mathsf{N} = 50$ and the initial learning rate at $1e^{-4}$ on FB15k-237.

3.2 Main experimental results

Table 2 compares the experimental results of our CapsE with previous state-of-the-art published results, using the same evaluation protocol. Our CapsE performs better than its closely related CNN-based model ConvKB on both experimental datasets (except Hits@10 on WN18RR and MR on FB15k-237), especially on FB15k-237 where our CapsE gains significant improvements of $0.523 - 0.418 = 0.105$ in MRR (which is about 25.1% relative improvement), and $59.3\% - 53.2\% = 6.1\%$ absolute improvement in Hits@10. Table 2 also shows that our CapsE obtains the best MR score on WN18RR and the highest MRR and Hits@10 scores on FB15k-237.

Following Bordes et al. (2013), for each relation r in FB15k-237, we calculate the averaged number η_s of head entities per tail entity and the averaged number η_o of tail entities per head entity. If η_s <1.5 and η_o <1.5, r is categorized one-to-one (1-1). If η_s <1.5 and η_o ≥1.5, r is categorized one-to-many (1-M). If η_s ≥1.5 and η_o <1.5, r is

---

[2] Pinter and Eisenstein (2018) considered WN18RR and evaluated their M3GM model only for 7 relations as they employed the inverse rule model (Dettmers et al., 2018) for 4 remaining symmetric relations. Regarding a fair comparison to other models, we use the M3GM implementation released by Pinter and Eisenstein (2018) to re-train and re-evaluate the M3GM model for all 11 relations. We thank Pinter and Eisenstein (2018) for their assistance running their code.

Method	**WN18RR**			**FB15k-237**		
	MR	MRR	H@10	MR	MRR	H@10
DISTMULT (Yang et al., 2015)	5110	0.425	49.1	254	0.241	41.9

KBGAN (Cai and Wang, 2018)	–	0.213	48.1	–	0.278	45.8
M3GM (Pinter and Eisenstein, 2018)	1864	0.311	53.3	–	–	–
TransE (Bordes et al., 2013)	743*	0.245*	56.0*	347	0.294	46.5
ConvKB (Nguyen et al., 2018)	763*	0.253*	**56.7***	254*	0.418*	53.2*
Our **CapsE**	**719**	0.415	56.0	303	**0.523**	**59.3**

Table 2: Experimental results on the WN18RR and FB15k-237 test sets. Hits@10 (H@10) is reported in %. Results of DISTMULT, ComplEx and ConvE are taken from Dettmers et al. (2018). Results of TransE on FB15k-237 are taken from Nguyen et al. (2018). Our CapsE Hits@1 scores are 33.7% on WN18RR and 48.9% on FB15k-237. Formulas of MRR and Hits@1 show a strong correlation, so using Hits@1 does not really reveal any additional information for this task. The best score is in bold, while the second best score is in underline. $\star$ denotes *our new results* for TransE and ConvKB, which are better than those published by Nguyen et al. (2018).

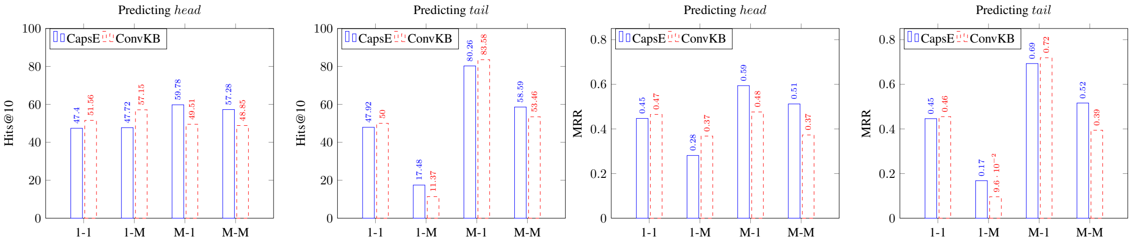

Figure 2: Hits@10 (in %) and MRR on the FB15k-237 test set w.r.t each relation category.

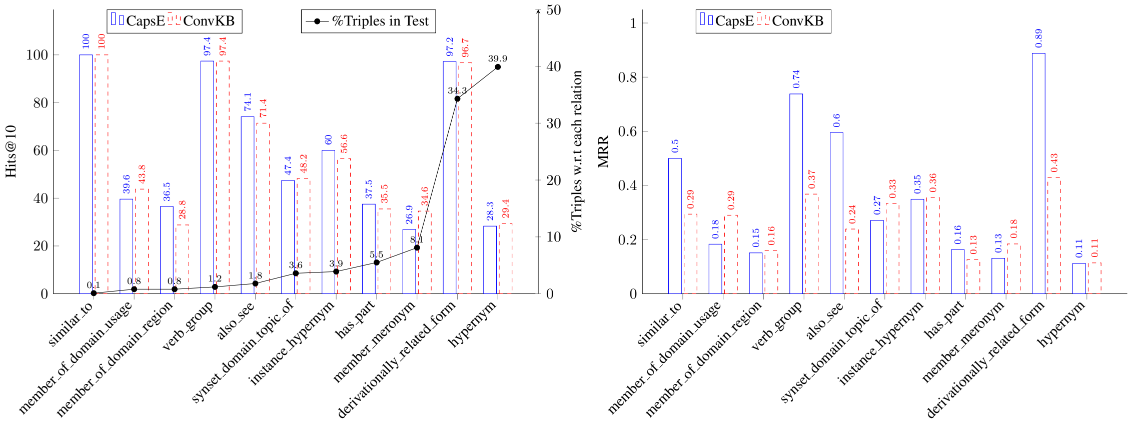

Figure 3: Hits@10 and MRR on the WN18RR test set w.r.t each relation. The right y-axis is the percentage of triples corresponding to relations.

categorized many-to-one (M-1). If $\eta_s \geq 1.5$ and $\eta_o \geq 1.5$, r is categorized many-to-many (M-M). As a result, 17, 26, 81 and 113 relations are labelled 1-1, 1-M, M-1 and M-M, respectively. And 0.9%, 6.3%, 20.5% and 72.3% of the test triples in FB15k-237 contain 1-1, 1-M, M-1 and M-M relations, respectively.

Figure 2 shows the Hits@10 and MRR results for predicting head and tail entities w.r.t each relation category on FB15k-237. CapsE works better than ConvKB in predicting entities on the "side M" of triples (e.g., predicting *head* entities in M-1 and M-M; and predicting *tail* entities in 1-M and M-M), while ConvKB performs better than CapsE in predicting entities on the "side 1" of triples (i.e., predicting *head* entities in 1-1 and 1-M; and predicting *tail* entities in 1-1 and M-1).

Figure 3 shows the Hits@10 and MRR scores w.r.t each relation on WN18RR. $also\_see$, $similar\_to$, $verb\_group$ and $derivationally\_related\_form$ are symmetric relations which can be considered as M-M relations. Our CapsE also performs better than ConvKB on these 4 M-M relations. Thus, results

m	10	20	30	40	50
1	**48.37**	**52.60**	**53.14**	**53.33**	**53.21**
3	47.78	52.34	52.93	52.99	52.86
5	47.03	52.25	45.80	45.99	45.76
7	40.46	45.36	45.79	45.85	45.93

Table 3: Hits@10 on the WN18RR validation set with $\mathsf{N} = 50$ and the initial learning rate at $1e^{-5}$ w.r.t each number of iterations in the routing algorithm m and each 10 training epochs.

shown in Figures 2 and 3 are consistent. These also imply that our CapsE would be a potential candidate for applications which contain many M-M relations such as search personalization.

We see that the length and orientation of each capsule in the first layer can also help to model the important entries in the corresponding dimension, thus CapsE can work well on the "side M" of triples where entities often appear less frequently than others appearing in the "side 1" of triples. Additionally, existing models such as DISTMULT, ComplEx and ConvE can perform well for entities with high frequency, but may not for rare entities with low frequency. These are reasons why our CapsE can be considered as the best one on FB15k-237 and it outperforms most existing models on WN18RR.

Effects of routing iterations: We study how the number of routing iterations affect the performance. Table 3 shows the Hits@10 scores on the WN18RR validation set for a comparison w.r.t each number value of the routing iterations and epochs with the number of filters $\mathsf{N} = 50$ and the Adam initial learning rate at $1e^{-5}$. We see that the best performance for each setup over each 10 epochs is obtained by setting the number m of routing iterations to 1. This indicates the opposite side for knowledge graphs compared to images. In the image classification task, setting the number m of iterations in the routing process higher than 1 helps to capture the relative positions of entities in an image (e.g., eyes, nose and mouth) properly. In contrast, this property from images may be only right for the 1-1 relations, but not for the 1-M, M-1 and M-M relations in the KGs because of the high variant of each relation type (e.g., symmetric relations) among different entities.

4 Search personalization application

Given a *user*, a submitted *query* and the *documents* returned by a search system for that query, our approach is to re-rank the returned documents so that the more relevant documents should be ranked higher. Following Vu et al. (2017), we represent the relationship between the submitted query, the user and the returned document as a *(s, r, o)*-like triple *(query, user, document)*. The triple captures how much interest a user puts on a document given a query. Thus, we can evaluate the effectiveness of our CapsE for the search personalization task.

4.1 Experimental setup

Dataset: We use the SEARCH17 dataset (Vu et al., 2017) of query logs of 106 users collected by a large-scale web search engine. A log entity consists of a user identifier, a query, top-10 ranked documents returned by the search engine and clicked documents along with the user's dwell time. Vu et al. (2017) constructed short-term (session-based) user profiles and used the profiles to personalize the returned results. They then employed the SAT criteria (Fox et al., 2005) to identify whether a returned document is relevant from the query logs as either a clicked document with a dwell time of at least 30 seconds or the last clicked document in a search session (i.e., a SAT click). After that, they assigned a $relevant$ label to a returned document if it is a SAT click and also assigned $irrelevant$ labels to the remaining top-10 documents. The rank position of the $relevant$ labeled documents is used as the ground truth to evaluate the search performance before and after re-ranking.

The dataset was uniformly split into the training, validation and test sets. This split is for the purpose of using historical data in the training set to predict new data in the test set (Vu et al., 2017). The training, validation and test sets consist of 5,658, 1,184 and 1,210 relevant (i.e., valid) triples; and 40,239, 7,882 and 8,540 irrelevant (i.e., invalid) triples, respectively.

Evaluation protocol: Our CapsE is used to re-rank the original list of documents returned by a search engine as follows: (i) We train our model and employ the trained model to calculate the score for each (s, r, o) triple. (ii) We then sort the scores in the descending order to obtain a new ranked list. To evaluate the performance of our proposed model, we use two standard evaluation metrics: mean reciprocal rank (MRR) and Hits@1.[3] For each metric, the higher value indi-

---

[3] We re-rank the list of top-10 documents returned by the

cates better ranking performance.

We compare CapsE with the following baselines using the same experimental setup: (**1**) SE: The original rank is returned by the search engine. (**2**) CI (Teevan et al., 2011): This baseline uses a personalized navigation method based on previously clicking returned documents. (**3**) SP (Bennett et al., 2012; Vu et al., 2015): A search personalization method makes use of the session-based user profiles. (**4**) Following Vu et al. (2017), we use TransE as a strong baseline model for the search personalization task. Previous work shows that the well-known embedding model TransE, despite its simplicity, obtains very competitive results for the knowledge graph completion (Lin et al., 2015a; Nickel et al., 2016b; Trouillon et al., 2016; Nguyen et al., 2016a, 2018). (**5**) The CNN-based model ConvKB is the most closely related model to our CapsE.

Embedding initialization: We follow Vu et al. (2017) to initialize user profile, query and document embeddings for the baselines TransE and ConvKB, and our CapsE.

We train a LDA topic model (Blei et al., 2003) with 200 topics only on the *relevant* documents (i.e., SAT clicks) extracted from the query logs. We then use the trained LDA model to infer the probability distribution over topics for every returned document. We use the topic proportion vector of each document as its document embedding (i.e. $k = 200$). In particular, the z^{th} element ($z = 1, 2, ..., k$) of the vector embedding for document d is: $\boldsymbol{v}_{d,z} = \mathrm{P}(z \mid d)$ where $\mathrm{P}(z \mid d)$ is the probability of the topic z given the document d.

We also represent each query by a probability distribution vector over topics. Let $\mathcal{D}_q = \{d_1, d_2, ..., d_n\}$ be the set of top n ranked documents returned for a query q (here, $n = 10$). The z^{th} element of the vector embedding for query q is defined as in (Vu et al., 2017): $\boldsymbol{v}_{q,z} = \sum_{i=1}^{n} \lambda_i \mathrm{P}(z \mid d_i)$, where $\lambda_i = \frac{\delta^{i-1}}{\sum_{j=1}^{n} \delta^{j-1}}$ is the exponential decay function of i which is the rank of d_i in D_q. And δ is the decay hyper-parameter ($0 < \delta < 1$). Following Vu et al. (2017), we use $\delta = 0.8$. Note that if we learn query and document embeddings during training, the models will overfit to the data and will not work for new queries and documents. Thus, after the initialization process, we fix (i.e., not updating) query and document embeddings during training for TransE, ConvKB and CapsE.

In addition, as mentioned by Bennett et al. (2012), the more recently clicked document expresses more about the user current search interest. Hence, we make use of the user clicked documents in the training set with the temporal weighting scheme proposed by Vu et al. (2015) to initialize user profile embeddings for the three embedding models.

Hyper-parameter tuning: For our CapsE model, we set batch size to 128, and also the number of neurons within the capsule in the second capsule layer to 10 ($d = 10$). The number of iterations in the routing algorithm is set to 1 ($m = 1$). For the training model, we use the Adam optimizer with the initial learning rate $\in \{5e^{-6}, 1e^{-5}, 5e^{-5}, 1e^{-4}, 5e^{-4}\}$. We also use ReLU as the activation function g. We select the number of filters $\mathsf{N} \in \{50, 100, 200, 400, 500\}$. We run the model up to 200 epochs and perform a grid search to choose optimal hyper-parameters on the validation set. We monitor the MRR score after each training epoch and obtain the highest MRR score on the validation set when using $\mathsf{N} = 400$ and the initial learning rate at $5e^{-5}$.

We employ the TransE and ConvKB implementations provided by Nguyen et al. (2016b) and Nguyen et al. (2018) and then follow their training protocols to tune hyper-parameters for TransE and ConvKB, respectively. We also monitor the MRR score after each training epoch and attain the highest MRR score on the validation set when using margin = 5, l_1-norm and SGD learning rate at $5e^{-3}$ for TransE; and $\mathsf{N} = 500$ and the Adam initial learning rate at $5e^{-4}$ for ConvKB.

4.2 Main results

Table 4 presents the experimental results of the baselines and our model. Embedding models TranE, ConvKB and CapsE produce better ranking performances than traditional learning-to-rank search personalization models CI and SP. This indicates a prospective strategy of expanding the triple embedding models to improve the ranking quality of the search personalization systems. In particular, our MRR and Hits@1 scores are higher than those of TransE (with relative improvements of 14.5% and 22% over TransE, respectively). Specifically, our CapsE achieves the highest performances in both MRR and Hits@1 (our improvements over all five baselines are statistically

---

search engine, so Hits@10 scores are same for all models.

Method	**MRR**	**H@1**
SE [$\star$]	0.559	38.5
CI [$\star$]	0.597	41.6
SP [$\star$]	0.631	45.2
TransE [$\star$]	0.645	48.1
TransE (ours)	0.669	50.9
ConvKB	$0.750_{+12.1\%}$	$59.9_{+17.7\%}$
Our CapsE	$\mathbf{0.766}_{+14.5\%}$	$\mathbf{62.1}_{+22.0\%}$

Table 4: Experimental results on the test set. [$\star$] denotes the results reported in (Vu et al., 2017). Hits@1 (H@1) is reported in %. In information retrieval, Hits@1 is also referred to as P@1. The subscripts denote the relative improvement over our TransE results.

significant with $p < 0.05$ using the *paired t-test*).

To illustrate our training progress, we plot performances of CapsE on the validation set over epochs in Figure 4. We observe that the performance is improved with the increase in the number of filters since capsules can encode more useful properties for a large embedding size.

5 Related work

Other transition-based models extend TransE to additionally use projection vectors or matrices to translate embeddings of s and o into the vector space of r, such as: TransH (Wang et al., 2014), TransR (Lin et al., 2015b), TransD (Ji et al., 2015) and STransE (Nguyen et al., 2016b). Furthermore, DISTMULT (Yang et al., 2015) and ComplEx (Trouillon et al., 2016) use a tri-linear dot product to compute the score for each triple. Moreover, ConvKB (Nguyen et al., 2018) applies convolutional neural network, in which feature maps are concatenated into a single feature vector which is then computed with a weight vector via a dot product to produce the score for the input triple. ConvKB is the most closely related model to our CapsE. See an overview of embedding models for KG completion in (Nguyen, 2017).

For search tasks, unlike classical methods, personalized search systems utilize the historical interactions between the user and the search system, such as submitted queries and clicked documents to tailor returned results to the need of that user (Teevan et al., 2005, 2009). That historical information can be used to build the *user profile*, which is crucial to an effective search personalization system. Widely used approaches consist of two separated steps: (1) building the user profile from the interactions between the user and the search system; and then (2) learning a ranking function to *re-rank* the search results using the user profile (Bennett et al., 2012; White et al., 2013; Harvey et al., 2013; Vu et al., 2015). The general goal is to re-rank the documents returned by the search system in such a way that the more relevant documents are ranked higher. In this case, apart from the user profile, dozens of other features have been proposed as the input of a learning-to-rank algorithm (Bennett et al., 2012; White et al., 2013). Alternatively, Vu et al. (2017) modeled the potential *user*-oriented relationship between the submitted query and the returned document by applying TransE to reward higher scores for more relevant documents (e.g., clicked documents). They achieved better performances than the standard ranker as well as competitive search personalization baselines (Teevan et al., 2011; Bennett et al., 2012; Vu et al., 2015).

6 Conclusion

We propose CapsE—a novel embedding model using the capsule network to model relationship triples for knowledge graph completion and search personalization. Experimental results show that our CapsE outperforms other state-of-the-art models on two benchmark datasets WN18RR and FB15k-237 for the knowledge graph completion. We then show the effectiveness of our CapsE for the search personalization, in which CapsE outperforms the competitive baselines on the dataset SEARCH17 of the web search query logs. In addition, our CapsE is capable to effectively model many-to-many relationships. Our code is available at: https://github.com/daiquocnguyen/CapsE.

Abstract

For many structured learning tasks, the data annotation process is complex and costly. Existing annotation schemes usually aim at acquiring *completely* annotated structures, under the common perception that *partial* structures are of low quality and could hurt the learning process. This paper questions this common perception, motivated by the fact that structures consist of *interdependent* sets of variables. Thus, given a fixed budget, partly annotating each structure may provide the same level of supervision, while allowing for more structures to be annotated. We provide an information theoretic formulation for this perspective and use it, in the context of three diverse structured learning tasks, to show that learning from partial structures can *sometimes* outperform learning from complete ones. Our findings may provide important insights into structured data annotation schemes and could support progress in learning protocols for structured tasks.

1 Introduction

Many machine learning tasks require structured outputs, and the goal is to assign values to a set of variables coherently. Specifically, the variables in a structure need to satisfy some global properties required by the task. An important implication is that once some variables are determined, the values taken by other variables are constrained. For instance, in the temporal relation extraction problem in Fig. 1a, if *met* happened before *leaving* and *leaving* happened on *Thursday*, then we know that *met* must either be before *Thursday* ("met (1)") or has to happen on *Thursday*, too ("met (2)") (Ning et al., 2018a). Similarly, in the semantic frame of the predicate *gave* (Kingsbury and Palmer, 2002) in Fig. 1b, if *the boy* is ARG0 (short for argument 0), then it rules out the possibility of *a frog* or *to the girl* taking the same role. Figure 1c further shows an example of part-labeling of images (Choi et al., 2018); given the position of FOREHEAD and LEFT_EYE of the cat in the picture, we roughly know that its NECK should be somewhere in the red solid box, while the blue dashed box is likely to be wrong.

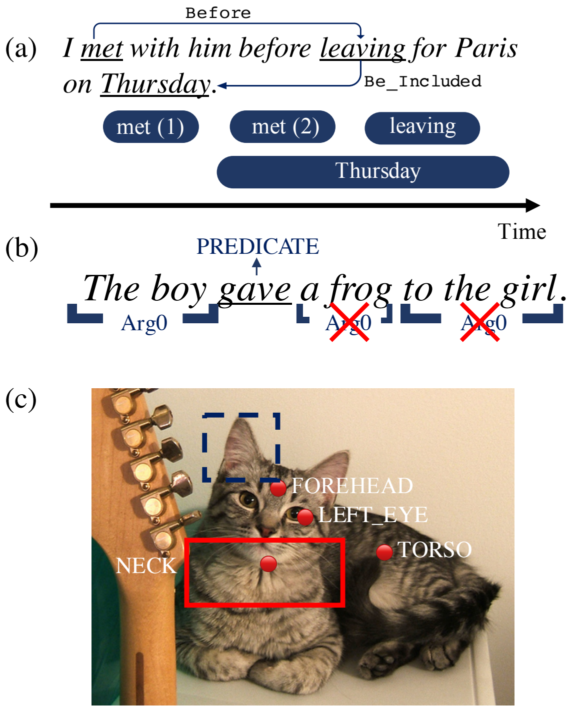

Figure 1: Due to the inherent structural constraints of each task, individual instances therein put restrictions on others. (a) The temporal relation between *met* and *Thursday* has to be BEFORE ("met (1)") or BE_INCLUDED ("met (2)"). (b) The argument roles of *a frog* and *to the girl* cannot be ARG0 anymore. (c) Given the position of the cat's FOREHEAD and LEFT_EYE, a rough estimate of its NECK can be the red solid box rather than the blue dashed box.

Data annotation for these structured tasks is complex and costly, thus requiring one to make the most of a given budget. This issue has been

Proceedings of NAACL-HLT 2019, pages 2190–2200
Minneapolis, Minnesota, June 2 - June 7, 2019.

investigated for decades from the perspective of active learning for classification tasks (Angluin, 1988; Atlas et al., 1990; Lewis and Gale, 1994) and for structured tasks (Roth and Small, 2006a,b, 2008; Hu et al., 2019). While active learning aims at selecting the next structure to label, we try to investigate, from a different perspective, whether we should annotate each structure completely or partially. Conventional annotation schemes typically require *complete* structures, under the common perception that partial annotation could adversely affect the performance of the learning algorithm. But note that partial annotations will allow for more structures to be annotated (see Fig. 2). Therefore, a fair comparison should be done while maintaining a fixed annotation budget, which was not done before. Moreover, even if partial annotation leads to comparable learning performance to conventional complete schemes, it provides more flexibility in data annotation.

Another potential benefit of partial annotation is that it imposes constraints on the remaining parts of a structure. As illustrated by Fig. 1, with partial annotations, we already have some knowledge about the unannotated parts. Therefore, further annotations of these variables may use the available budget less efficiently; this effect was first discussed in Ning et al. (2018c). Motivated by the observations in Figs. 1-2, we think it is important to study partialness systematically, before we hastily assume that *completeness* should always be favored in data collection.

To study whether the above benefits of partialness can offset its weakness for learning, **our first contribution** is the proposal of *early stopping partial annotation* (ESPA) scheme, which randomly picks up instances to label in the beginning, and stops before a structure is completed. We do not claim that ESPA should *always* be preferred; instead, it serves as an *alternative* to conventional, complete annotation schemes that we should keep in mind, because, as we show later, it can be comparable to (and sometimes even better than) complete annotation schemes. ESPA is straightforward to implement even in crowdsourcing; instances to annotate can be selected *offline* and distributed to crowdsourcers; this can be contrasted with the difficulties of implementing active learning protocols in these settings (Ambati et al., 2010; Laws et al., 2011). We think that ESPA is a good representative for a systematic study of partialness.

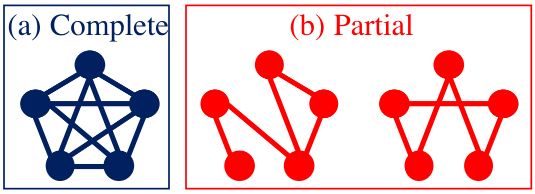

Figure 2: If we need training data for a graph labeling task (assuming the gold values for the nodes are given) and our annotation budget allows us to annotate, for instance, 10 edges in total, we could (a) completely annotate one graph (and then we run out of budget), or (b) partially annotate two graphs.

Our second contribution is the development of an information theoretic formulation to explain the benefit of ESPA (Sec. 2), which we further demonstrate via three structured learning tasks in Sec. 4: temporal relation (TempRel) extraction (UzZaman et al., 2013), semantic role classification (SRC),[1] and shallow parsing (Tjong Kim Sang and Buchholz, 2000). These tasks are chosen because they each represent a wide spectrum of structures that we will detail later. **As a byproduct**, we extend constraint-driven learning (CoDL) (Chang et al., 2007) to cope with partially annotated structures (Sec. 3); we call the algorithm *Structured Self-learning with Partial ANnotations* (SSPAN) to distinguish it from CoDL.[2]

We believe in the importance of work in this direction. *First, partialness is inevitable in practice*, either by mistake or by choice, so our theoretical analysis can provide unique insight into understanding partialness. *Second, it opens up opportunities for new annotation schemes.* Instead of considering partial annotations as a compromise, we can in fact annotate partial data *intentionally*, allowing us to design favorable guidelines and collect more important annotations at a cheaper price. Many recent datasets that were collected via crowdsourcing are already partial, and this paper provides some theoretical foundations for them. Furthermore, the setting described here addresses natural scenarios where only partial, indirect supervision is available, as in *Incidental Supervision*

---

[1] A subtask of semantic role labeling (SRL) (Palmer et al., 2010) that only classifies the role of an argument.

[2] There has been many works on learning from partial annotations, which we review in Sec. 3. SSPAN is only an experimental choice in demonstrating ESPA. Whether SSPAN is better than other algorithms is out of the scope here, and a better algorithm for ESPA will only strengthen the claims in this paper.

(Roth, 2017), and this paper begins to provide theoretical understanding for this paradigm, too. Further discussions can be found in Sec. 5.

It is important to clarify that we assume uniform cost over individual annotations (that is, all edges in Fig. 2 cost equally), often the default setting in crowdsourcing. We realize that the annotation difficulty can vary a lot in practice, sometimes incurring different costs. To address this issue, we randomly select instances to label so that on average, the cost is uniform. We agree that, even with this randomness, there could still be situations where the assumption does not hold, but we leave it for future studies, possibly in the context of active learning schemes.

2 ESPA: Early Stopping Partial Annotation

In this section, we study whether the effect demonstrated by the examples in Fig. 1 exists in general. First, we formally define *structure* and *annotation*.

Definition 1. *A structure of size* d *is a vector of random variables (RV)* $\mathbf{Y} = [Y_1, \ldots, Y_d] \in C(\mathcal{L}^d)$*, where* $\mathcal{L} = \{\ell_1, \ldots, \ell_{|\mathcal{L}|}\}$ *is the label set for each variable and* $C(\mathcal{L}^d) \subseteq \mathcal{L}^d$ *represents the constraints imposed by this type of structure.*

It is necessary to model a structure as a set of *random* variables because when it is not completely annotated, there is still uncertainty in the annotation assignment. To study partial annotations, we introduce the following:

Definition 2. *A* k*-step annotation* ($0 \le k \le d$) *is a vector of RVs* $\mathbf{A}_k = [A_{k,1}, \ldots, A_{k,d}] \in (\mathcal{L} \cup \sqcap)^d$ *where* $\sqcap$ *is a special character for null, such that*

$$\sum_{i=1}^{d} \mathbb{1}(A_{k,i} \neq \sqcap) = k, \qquad (1)$$

$$P(\mathbf{Y}|\mathbf{A}_k = \mathbf{a}_k) = P(\mathbf{Y}|Y_j = a_{k,j}, j \in \mathcal{J}), \quad (2)$$

where $\mathcal{J}$ *is the set of indices that* $a_{k,j} \neq \sqcap$.

Eq. (1) means that, in total, k variables are already annotated at step k. Obviously, $\mathbf{A}_0$ means that no variables are labeled, and $\mathbf{A}_d$ means that all variables in $\mathbf{Y}$ are determined. $\mathbf{A}_k$ is what we call a k-step ESPA, so hereafter we use k/d to represent annotation completeness. Eq. (2) assumes no annotation mistakes, so if the i-th variable is labeled, then Y_i must be the same as $A_{k,i}$.

To measure the theoretical benefit of $\mathbf{A}_k$, we propose the following quantity

$$I_k = \log |C(\mathcal{L}^d)| - E\left[\log f(\mathbf{a}_k)\right] \qquad (3)$$

for $k = 0, \ldots, d$, where $f(\mathbf{a}_k) = |\{\mathbf{y} \in C(\mathcal{L}^d) : \mathrm{P}(\mathbf{y}|\mathbf{a}_k) > 0\}|$ is the total number of structures in $C(\mathcal{L}^d)$ that are still valid given $\mathbf{A}_k = \mathbf{a}_k$. Since we assume that the labeled variables in $\mathbf{A}_k$ are selected uniformly randomly, $E[\cdot]$ is simply the average of $\log f(\mathbf{a}_k)$. When $k = 0$, $f(\mathbf{a}_k) \equiv C(\mathcal{L}^d)$ and $I_0 \equiv 0$; as k increases, I_k increases since the structure has more and more variables labeled; finally, when $k = d$, the structure is fully determined and $I_d \equiv \log |C(\mathcal{L}^d)|$. The first-order finite difference, $I_k - I_{k-1}$, is the benefit brought by annotating an additional variable at step k; if I_k is concave (i.e., a decaying $I_k - I_{k-1}$), the benefit from a new annotation attenuates, suggesting the potential benefit of the ESPA strategy.

In an extreme case where the structure is so strong that it requires all individual variables to share the same label, then labeling any variable is sufficient for determining the entire structure. Intuitively, we do not need to annotate more than one variable. Our I_k quantity can support this intuition: The structural constraint, $C(\mathcal{L}^d)$, contains only $|\mathcal{L}|$ elements: $\{[\ell_i, \ell_i, \ldots, \ell_i]\}_{i=1}^{|\mathcal{L}|}$, so $I_0 = 0$, and $I_1 = \cdots = I_d = \log |\mathcal{L}|$. Since I_k does not increase at all when $k >= 1$, we should adopt first-step annotation $\mathbf{A}_1$. Another extreme case is that of a trivial structure that has no constraints (i.e., $C(\mathcal{Y}^d) = \mathcal{Y}^d$). The annotation of all variables are independent and we gain no advantage from skipping any variables. This intuition can be supported by our I_k analysis as well: Since $I_k = k \log |\mathcal{L}|$, $\forall k = 0, 1, \ldots, d$, I_k is linear and all steps contribute equally to improving I_k by $\log |\mathcal{L}|$; therefore ESPA is not necessary.

Real-world structures are often not as trivial as the two extreme cases above, but I_k can still serve as a guideline to help determine whether it is beneficial to use ESPA. We next discuss three diverse types of structures and how to obtain I_k for them.

Example 1. *The ranking problem is an important machine learning task and often depends on pairwise comparisons, for which the label set is* $\mathcal{L} = \{<, >\}$. *For a ranking problem with* n *items, there are* $d = n(n-1)/2$ *pairwise comparisons in total. Its structure is a chain following the transitivity constraints, i.e., if* $A < B$ *and* $B < C$*, then* $A < C$.

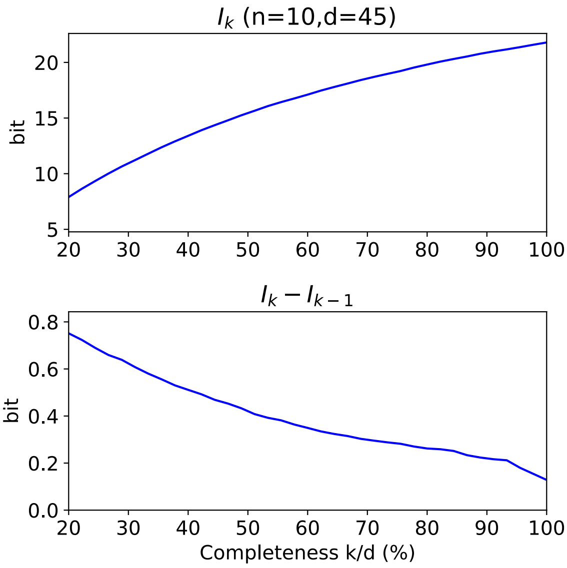

Figure 3: The mutual information between the chain structure and its k-step ESPA, I_k, is concave, suggesting possible benefit of using ESPA. In the simulation, there are $n = 10$ items in the chain and thus $d = 45$ pairs, k of which are labeled. The values of I_k's, as defined by Eq. (3), were obtained through averaging 1000 experiments. We use base-2 logarithm and the unit on y-axis is thus "bit".

A k-step ESPA $\mathbf{A}_k$ for a chain means that only k (out of d) pairs are compared and labeled, resulting in a directed acyclic graph (DAG). In this case, $f(\mathbf{a}_k)$ is actually counting the number of linear extensions of the DAG, which is known to be #P-complete (Brightwell and Winkler, 1991), so we do not have a closed-form solution to I_k. In practice, however, we can use the Kahn's algorithm and backtracking to simulate with a relatively small n, as shown by Fig. 3, where $n = 10$ and I_k was obtained through averaging 1000 random simulations. I_k is concave, as reflected by the downward shape of $I_k - I_{k-1}$. Therefore, new annotations are less and less efficient for the chain structure, suggesting the usage of ESPA.

Example 2. *The general assignment problem requires assigning d agents to d′ tasks such that the agent nodes and the task nodes form a bipartite graph (without loss of generality, assume d ≤ d′). That is, an agent can handle exactly one task, and each task can only be handled by at most one agent. Then from the agents' point of view, the label set for each of them is* $\mathcal{L} = \{1, 2, \ldots, d'\}$*, denoting the task assigned to the agent.*

A k-step ESPA $\mathbf{A}_k$ for this problem means that k agents are already assigned with tasks, and $f(\mathbf{a}_k)$ is to count the valid assignments of the remaining tasks to the remaining $d - k$ agents, to which we have closed-form solutions: $f(\mathbf{a}_k) = \frac{(d'-k)!}{(d'-d)!}, \forall \mathbf{a}_k$. According to Eq. (3), $I_k = \log \frac{d'!}{(d'-k)!}$ regardless of d or the distribution of $\mathbf{A}_k$, and is concave (Fig. 4 shows an example of it when $d = 4, d' = 10$).

Example 3. *Sequence tagging is an important NLP problem, where the tags of tokens are interdependent. Take chunking as an example. A basic scheme is for each token to choose from three labels, B(egin), I(nside), and O(utside), to represent text chunks in a sentence. That is,* $\mathcal{L} = \{B, I, O\}$*. Obviously, O cannot be immediately followed by I.*

Let d be the number of tokens in a sentence. A k-step ESPA $\mathbf{A}_k$ for chunking means that k tokens are already labeled by B/I/O, and $f(\mathbf{a}_k)$ counts the valid BIO sequences that do not violate those existing annotations. Again, as far as we know, there is no closed-form solution to $f(\mathbf{a}_k)$ and I_k, but in practice, we can use dynamic programming to obtain $f(\mathbf{a}_k)$ and then I_k using Eq. (3). We set $d = 10$ and show $I_k - I_{k-1}$ for this task in Fig. 4, where we observe the same effect we see in previous examples: The benefit provided by labeling a new token in the structure attenuates.

Interestingly, based on Fig. 4, we find that **the slope of $I_k - I_{k-1}$ may be a good measure of the "tightness" or "strength" of a structure**. When there is no structure at all, the curve is flat (black). The BIO structure is intuitively simple, and it indeed has the flattest slope among the three structured tasks (purple). When the structure is a chain, the level of uncertainty goes down rapidly with every single annotation (think of standard sorting algorithms); the constraint is intuitively strong and in Fig. 4, it indeed has a steep slope (blue).

Finally, we want to emphasize that the definition of I_k in Eq. (3) is in fact backed by information theory. When we do not have prior information about $\mathbf{Y}$, we can assume that $\mathbf{Y}$ follows a uniform distribution over $C(\mathcal{L}^d)$. Then, I_k is essentially the mutual information between structure $\mathbf{Y}$ and annotation $\mathbf{A}_k$, $I(\mathbf{Y}; \mathbf{A}_k)$:

$$\begin{aligned} I(\mathbf{Y}; \mathbf{A}_k) &= H(\mathbf{Y}) - H(\mathbf{Y}|\mathbf{A}_k) \\ &= \log |C(\mathcal{L}^d)| - E\left[H(\mathbf{Y}|\mathbf{A}_k = \mathbf{a}_k)\right] \\ &= \log |C(\mathcal{L}^d)| - E\left[\log f(\mathbf{a}_k)\right], \end{aligned}$$

where $H(\cdot)$ is the entropy function. This is an important discovery, since it points out a new way to view a structure and its annotations. It may be useful for studying active learning methods for structured tasks, and other annotation phenomena such as noisy annotations. The usage of mutual information also aligns well with the information bottleneck framework (Shamir et al., 2010; Shwartz-Ziv and Tishby, 2017; Yu and Principe, 2018), although a more recent paper challenges the interpretation of information bottleneck (Saxe et al., 2018).

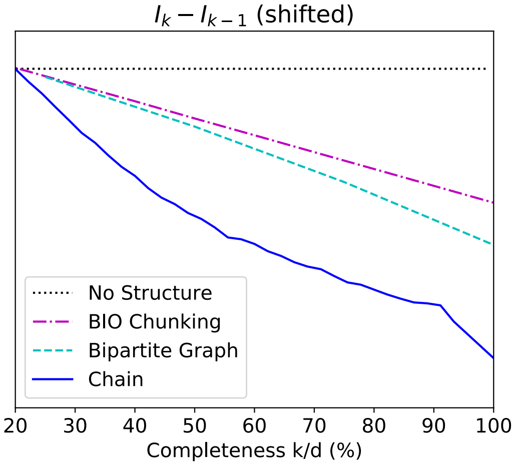

Figure 4: The $I_k - I_{k-1}$ curves from several different structures. The curves are shifted to almost the same starting point for better visualization, so the Y-Axis grid is not shown. The curve for "Chain" was obtained via simulations, and the other curves all have closed-form formulations.

3 Learning from Partial Structures

So far, we have been advocating the ESPA strategy to maximize the information we can get from a fixed budget. Since early stopping leads to partial annotations, one missing component before we can benefit from it is an approach to learning from partial structures. In this study, we assume the existence of a relatively small but complete dataset that can provide a good initialization for learning from a partial dataset, which is very similar to semi-supervised learning (SSL). SSL, in its most standard form, studies the combined usage of a labeled set $\mathcal{T} = \{(x_i, y_i)\}_i$ and an unlabeled set $\mathcal{U} = \{x_j\}_j$, where the x's are instances and y's are the corresponding labels. SSL gains information about $p(x)$ through $\mathcal{U}$, which may improve the estimation of $p(y|x)$. Specific algorithms range from self-training (Scudder, 1965; Yarowsky, 1995), co-training (Blum and Mitchell, 1998), generative models (Nigam et al., 2000), to transductive SVM (Joachims, 1999) etc., among which one of the most basic algorithms is Expectation-Maximization (EM) (Dempster et al., 1977). By treating them as hidden variables, EM "marginalizes" out the missing labels of $\mathcal{U}$ via expectation (i.e., soft EM) or maximization (i.e., hard EM). For structured ML tasks, soft and hard EMs turn into posterior regularization (PR) (Ganchev et al., 2010) and constraint-driven learning (CoDL) (Chang et al., 2007), respectively.

Unlike unlabeled data, the partially annotated structures caused by early stopping urge us to gain information not only about $p(x)$, but also from their labeled parts. There have been many existing work along this line (Tsuboi et al., 2008; Fernandes and Brefeld, 2011; Hovy and Hovy, 2012; Lou and Hamprecht, 2012), but in this paper, we decide to extend CoDL to cope with partial annotations due to two reasons. First, CoDL, which itself can be viewed as an extension of self-training to *structured* learning, is a wrapper algorithm having wide applications. Second, as its name suggests, CoDL learns from $\mathcal{U}$ by guidance of constraints, so partial annotations in $\mathcal{U}$ are technically easy to be added as extra equality constraints.

Algorithm 1 describes our *Structured Self-learning with Partial ANnotations* (SSPAN) algorithm that learns a model $\mathcal{H}$. The same as CoDL, SSPAN is a wrapper algorithm requiring two components: LEARN and INFERENCE. LEARN attempts to estimate the *local* decision function for each individual instance regardless of the *global* constraints, while INFERENCE takes those local decisions and performs a *global* inference. Lines 3-9 are the procedure of self-training, which iteratively completes the missing annotations in $\mathcal{P}$ and learns from both $\mathcal{T}$ and the completed version of $\mathcal{P}$ (i.e., $\tilde{\mathcal{P}}$).[3] Line 6 requires that the inference follows the structural constraints inherently in the task, turning the algorithm into CoDL; Line 7 enforces those partial annotations in $\mathbf{a}_i$, further turning it into SSPAN. In practice, INFERENCE can be realized by the Viterbi or beam search algorithm in sequence tagging, or more generally, by Integer Linear Programming (ILP)

---

[3] Line 9 can be interpreted in different ways, either as $\mathcal{T} \cup \tilde{\mathcal{P}}$ (adopted in this work) or as a weighted combination of LEARN($\mathcal{T}$) and LEARN($\tilde{\mathcal{P}}$) (adopted by (Chang et al., 2007)).

(Punyakanok et al., 2005); either way, the partial constraints of Line 7 can be easily incorporated.

Algorithm 1: Structured Self-learning with Partial Annotations (SSPAN)

```
   Input: $\mathcal{T} = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{N}, \mathcal{P} = \{(\mathbf{x}_i, \mathbf{a}_i)\}_{i=N+1}^{N+M}$
1  Initialize $\mathcal{H} = \text{LEARN}(\mathcal{T})$
2  while convergence criteria not satisfied do
3      $\tilde{\mathcal{P}} = \emptyset$
4      foreach $(\mathbf{x}_i, \mathbf{a}_i) \in \mathcal{P}$ do
5          $\hat{\mathbf{y}}_i$ = INFERENCE($\mathbf{x}_i; \mathcal{H}$), such that
6                  ◇ $\hat{\mathbf{y}}_i \in C(\mathcal{Y}^d)$
7                  ◇ $\hat{y}_{i,j} = a_{i,j}, \forall a_{i,j} \neq \sqcap$
8          $\tilde{\mathcal{P}} = \tilde{\mathcal{P}} \cup \{(\mathbf{x}_i, \hat{\mathbf{y}}_i)\}$
9      $\mathcal{H} = \text{LEARN}(\mathcal{T} + \tilde{\mathcal{P}})$
10 return $\mathcal{H}$
```

4 Experiment

In Sec. 2, we argued from an information theoretic view that ESPA is beneficial for structured tasks if we have a fixed annotation resource. We then proposed SSPAN in Sec. 3 to learn from the resulting partial structures. **However**, on one hand, there is still a gap between the I_k analysis and the actual system performance; on the other hand, whether the benefit can be realized in practice also depends on how effective the algorithm exploits partial annotations. Therefore, it remains to be seen how ESPA works in practice. Here we use three NLP tasks: temporal relation (TempRel) extraction, semantic role classification (SRC), and shallow parsing, analogous to the chain, assignment, and BIO structures, respectively.

For all tasks, we compare the following two schemes in Fig. 5, where we use graph structures for demonstration. Initially, we have a relatively small but complete dataset $\mathcal{T}_0$, an unannotated dataset $\mathcal{U}_0$, and some budget to annotate $\mathcal{U}_0$. The conventional scheme I, also our baseline here, is to annotate each structure completely before randomly picking up the next one. Due to the limited budget, some $\mathcal{U}_0$ remain untouched (denoted by $\mathcal{U}$). The proposed scheme II adopts ESPA so that all structures at hand are annotated but only partially. For fair comparisons, we use CoDL to incorporate $\mathcal{U}$ into scheme I as well. Finally, the systems trained on the dataset from I/II via CoDL/SSPAN are evaluated on unseen but complete testset $\mathcal{T}_{test}$. Note that because ESPA is a new annotation scheme, there exists no dataset collected this way. We use existing complete datasets and randomly throw out some annotations to mimic ESPA in the following. Due to the randomness in selecting which structures/instances to keep in scheme I/II, we repeat the whole process multiple times and report the mean F_1. The budget, defined as the total number of individual instances that can be annotated, ranges from 10% to 100% with a stepsize of 10%, where x% means x% of all instances in $\mathcal{U}_0$ can be annotated.

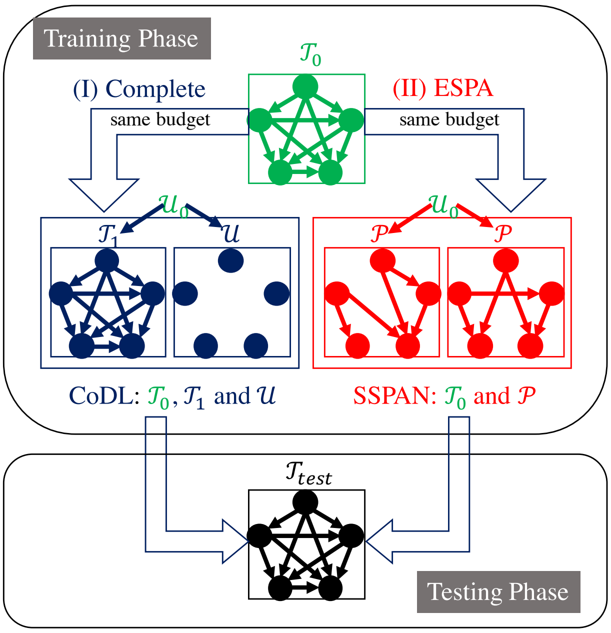

Figure 5: The two annotation schemes we compare in Sec. 4. $\mathcal{T}$, $\mathcal{P}$, and $\mathcal{U}$ denote complete, partial, and empty structures, respectively. Both schemes start with a complete and relatively small dataset and an unannotated dataset (green). (I) Conventional complete annotation scheme (blue). (II) The proposed ESPA scheme (red). Finally, they are tested on an unseen and complete dataset (black).

4.1 Temporal Relation Extraction

Temporal relations (TempRel) are a type of important relations representing the temporal ordering of events described by natural language text. That is to answer questions like which event happens earlier or later in time (see Fig. 1a). Since time is physically one-dimensional, if *A* is before *B* and *B* is also before *C*, then *A* must be before *C*. In practice, the label set for TempRels can be more complex, e.g., with labels such as SIMULTANEOUS and VAGUE, but the structure can still be represented by transitivity constraints (see Table 1 of (Ning et al., 2018a)), which can be viewed as an analogy of the chain structure in Example 1.

To avoid missing relations, annotators are required to exhaustively label every pair of events in a document (i.e., the complete annotation scheme), so it is necessary to study ESPA in this context. Here we adopt the MATRES dataset (Ning et al., 2018b) for its better inter-annotator agreement and relatively large size.

Specifically, we use 35 documents as $\mathcal{T}_0$ (the TimeBank-Dense section,[4] 147 documents as $\mathcal{U}_0$ (the TimeBank section minus those documents in $\mathcal{T}_0$), and the Platinum section (a benchmark testset of 20 documents with 1K TempRels) as $\mathcal{T}_{test}$. Note that both schemes I and II are mimicked by downsampling the original annotations in MATRES, where the budget is defined as the total number of TempRels that are kept. Following CogCompTime (Ning et al., 2018d), we choose the same features and sparse-averaged perceptron algorithm as the LEARN component and ILP as INFERENCE for SSPAN.

4.2 Semantic Role Classification (SRC)

Semantic role labeling (SRL) is to represent the semantic meanings of language and answer questions like *Who did What to Whom* and *When, Where, How* (Palmer et al., 2010). Semantic Role Classification (SRC) is a subtask of SRL, which assumes gold predicates and argument chunks and only classifies the semantic role of each argument. We use the Verb SRL dataset provided by the CoNLL-2005 shared task (Carreras and Màrquez, 2005), where the semantic roles include numbered arguments, e.g., ARG0 and ARG1, and argument modifiers, e.g., location (AM-LOC), temporal (AM-TMP), and manner (AM-MNR) (see PropBank (Kingsbury and Palmer, 2002)). The structural constraints for SRC is that each argument can be assigned to exactly one semantic role, and the same role cannot appear twice for a single verb, so SRC is an assignment problem as in Example 2.

Specifically, we use the Wall Street Journal (WSJ) part of Penn TreeBank III (Marcus et al., 1993). We randomly select 700 sentences from the Sec. 24 of WSJ, among which 100 sentences as $\mathcal{T}_0$ and 600 sentences as $\mathcal{U}_0$. Our $\mathcal{T}_{test}$ is 5700 sentences (about 40K arguments) from Secs. 00, 01, 23. The budget here is defined as the total number of the arguments. We adopt the SRL system in CogCompNLP (Khashabi et al., 2018) and uses the sparse averaged perceptron as LEARN and ILP as INFERENCE.

4.3 Shallow Parsing

Shallow parsing, also referred as *chunking*, is a fundamental NLP task to identify constituents in a sentence, such as noun phrases (NP), verb phrases (VP), and adjective phrases (ADJP), which can be viewed as extending the standard BIO structure in Example 3 with different chunk types: B-NP, I-NP, B-VP, I-VP, B-ADJP, I-ADJP, . . . , O.

We use the chunking dataset provided by the CoNLL-2000 shared task (Tjong Kim Sang and Buchholz, 2000). Specifically, we use 2K tokens' annotations as $\mathcal{T}_0$, 14K tokens as $\mathcal{U}_0$, and the benchmark testset (25K tokens) as $\mathcal{T}_{test}$. The budget here is defined as the total number of tokens' BIO labels. The algorithm we use here is the chunker provided in CogCompNLP, where the LEARN component is the sparse averaged perceptron and the INFERENCE is described in (Punyakanok and Roth, 2001).

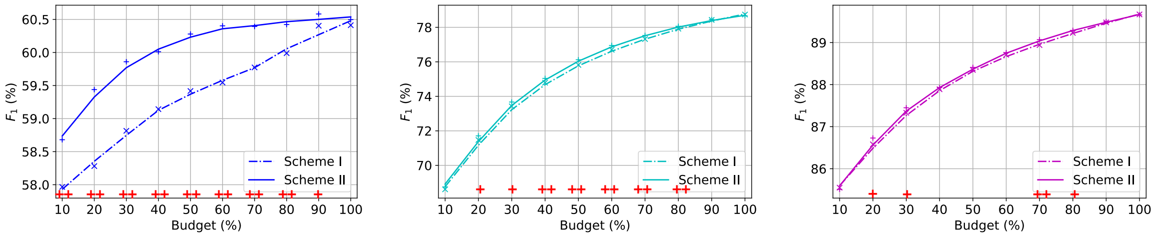
4.4 Results

We compare the F_1 performances of all three tasks in Fig. 6, averaged from 50 experiments with different randomizations. As the budget increases, the system F_1 increases for both schemes I and II in all three tasks, which confirms the capability of the proposed SSPAN framework to learn from partial structures. When the budget is 100% (i.e., the entire $\mathcal{U}_0$ is annotated), schemes I and II have negligible differences; when the budget is not large enough to cover the entire $\mathcal{U}_0$, scheme II is consistently better than I in all tasks, which follows our expectations based on the I_k analysis. The strict improvement for all budget ratios indicates that the observation is definitely not by chance.

Figure 7 further compares the improvement from I to II across tasks. When the budget goes down from 100%, the advantage of ESPA is more prominent; but when the budget is too low, the quality of $\tilde{\mathcal{P}}$ degrades and hurts the performance of SSPAN, leading to roughly hill-shaped curves in Fig. 7. We have also conjectured based on Fig. 4 that the structure strength goes up from BIO chunks, to bipartite graphs, and to chains; interestingly, the improvement brought by ESPA is consistent with this order.

---

[4] The original TimeBank-Dense section contains 36 documents, but in collecting MATRES, one of the documents was filtered out because it contained no TempRels between main-axis events.



(a) Temporal Relation Extraction (b) SRC (c) Shallow Parsing

Figure 6: Comparison of the baseline, complete annotation scheme and the proposed ESPA scheme (See I & II in Fig. 5) under three structured learning tasks (note the scale difference). Each F_1 value is the average of 50 experiments, and each curve is based on corresponding F_1 values smoothed by Savitzky-Golay filters. We can see that scheme II is consistently better than scheme I. Per the Wilcoxon rank-sum test, the significance levels at each given budget are shown on the x-axes, where $+$ and $++$ mean $p < 5\%$ and $p < 1\%$, respectively.

Admittedly, the improvement, albeit statistically significant, is small, but it does not diminish the contribution of this paper: Our goal is to remind people that the ESPA scheme (or more generally, partialness) is, at the least, comparable to (or sometimes even better than) complete annotation schemes. Also, the comparison here is in fact unfair to the partial scheme II, because we assume equal cost for both schemes, although it often costs less in a partial scheme as a large problem is decomposed into smaller parts. Therefore, the results shown here implies that the information theoretical benefit of partialness can possibly offset its disadvantages for learning.

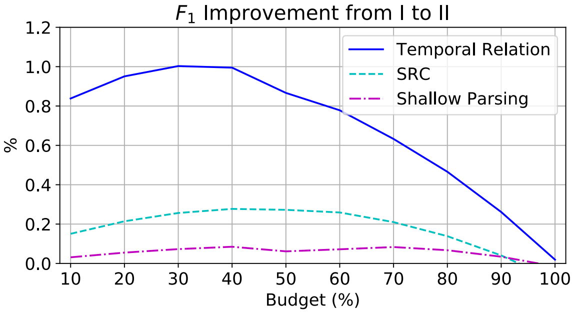


Figure 7: The improvement of F_1 brought by ESPA for each task in Fig. 6. Note that we conjectured earlier in Fig. 4 that the BIO structure is the weakest among the three, which is consistent with the fact that shallow parsing benefits the least from ESPA.

5 Dicussion and Conclusion

In this paper, we investigate a less studied, yet important question for structured learning: Given a limited annotation budget (either in time or money), which strategy is better, completely annotating each structure until the budget runs out, or annotating more structures at the cost of leaving some of them partially annotated? Neubig and Mori (2010) investigated this issue specifically in annotating word boundaries and pronunciations for Japanese. Instead of annotating full sentences, they proposed to annotate only some words in a sentence (i.e., partially) that can be chosen heuristically (e.g., skip those that we have seen or those low frequency words). Conceptually, Neubig and Mori (2010) is an active learning work, with the understanding that if the order of annotation is deliberately designed, better learning can be achieved. The current paper addresses the problem from a different angle: Even without active learning, can we still answer the question above?

The observation driving our questions is that when annotating a particular structure, the labels of the yet to be labeled variables may already be constrained by previous annotations and carry less information than those in a totally new structure. Therefore, we systematically study the ESPA scheme – stop annotating a given structure before it is completed and continue annotating another new structure.

An important notion is annotation *cost*. Throughout the paper we have an ideal assumption that the cost is linear in the total number of annotations, but in practice the case can be more complicated. First, the actual cost of each individual annotation may vary across different instances. We try to eliminate this issue by enforcing random selection of annotation instances, rather than allowing the annotators to select arbitrarily by themselves. This strategy may be useful in practice as well, to avoid people only annotating easy cases. Second, even if we only require labeling partial structures, it is likely that the annotator still needs to comprehend the entire structure, incurring additional cost (usually in terms of time). This issue, however, is not addressed in this paper.

Using this definition of cost, we provide a theoretical analysis for ESPA based on the mutual information between target structures and annotation processes. We show that for structures like chains, bipartite graphs, and BIO chunks, the information brought by an extra annotation attenuates as the annotation of the structure is more complete, suggesting to stop early and move to a new structure (although it still remains unclear when it is optimal to stop). This analysis is further supported by experiments on temporal relation extraction, semantic role classification, and shallow parsing, three tasks analogous to the three structures analyzed earlier, respectively. The ratio of the attenuation curve as in Fig. 4 is also shown to be an actionable metric to quantify the strength of a type of structure, which can be useful in various analysis, including judging whether ESPA is worthwhile for a particular task. For example, a more detailed I_k-based analysis for SRC shows that predicates with more arguments are stronger structures than those with fewer arguments; we have investigated ESPA on those with more than 6 arguments and indeed, observed much larger improvement in SRC. More details on this analysis are put in the appendix.

We think that the findings in this paper are very important. First, as far as we know, we are the first to propose the mutual information analysis that provides a unique view of structured annotation, that of the reduction in the uncertainty of a target of interest $\mathbf{Y}$ by another random variable/process. From this perspective, signals that have non-zero mutual information with $\mathbf{Y}$ can be viewed as "annotations". These can be partially labeled structures (studied here), partial labels (restricting the possible labels rather than determining a single one as in e.g., Hu et al. (2019), noisy labels (e.g., generated by crowdsourcing or heuristic rules) or, generally, other indirect supervision signals that are correlated with $\mathbf{Y}$. As we proposed, these can be studied within our mutual information framework as well. This paper thus provides a way to analyze the benefit of general *incidental supervision signals* (Roth, 2017)) and possibly even provides guidance in selecting good incidental supervision signals.

Second, the findings here open up opportunities for new annotation schemes for structured learning. In the past, partially annotated training data have been either a compromise when completeness is infeasible (e.g., when ranking entries in gigantic databases), or collected freely without human annotators (e.g., based on heuristic rules). If we intentionally ask human annotators for partial annotations, the annotation tasks can be more flexible and potentially, cost even less. This is because annotating complex structures typically require certain expertise, and smaller tasks are often easier (Fernandes and Brefeld, 2011). It is very likely that some complex annotation tasks require people to read dozens of pages of annotation guidelines, but once decomposed into smaller subtasks, even laymen can handle them. Annotation schemes driven by crowdsourced question-answering, known to provide only partial coverage are successful examples of this idea (He et al., 2015; Michael et al., 2017). Therefore, this paper is hopefully interesting to a broad audience.

Abstract

In Community-based Question Answering system(CQA), Answer Selection(AS) is a critical task, which focuses on finding a suitable answer within a list of candidate answers. For neural network models, the key issue is how to model the representations of QA text pairs and calculate the interactions between them. We propose a Sequential Attention with Keyword Mask model(SAKM) for CQA to imitate human reading behavior. Question and answer text regard each other as context within keyword-mask attention when encoding the representations, and repeat multiple times(hops) in a sequential style. So the QA pairs capture features and information from both question text and answer text, interacting and improving vector representations iteratively through hops. The flexibility of the model allows to extract meaningful keywords from the sentences and enhance diverse mutual information. We perform on answer selection tasks and multi-level answer ranking tasks. Experiment results demonstrate the superiority of our proposed model on community-based QA datasets.

1 Introduction

Answering selection(AS) is one of the most fundamental challenges in community-based question answering(CQA) services. Given a question and a list of candidate answers, its aim is to choose the most matching one to the question. During this process of matching questions and answer candidates, how to encode the question and answer(QA) into meaningful and semantic representations impacts on the results directly.

Earlier conventional statistic methods are normally based on feature engineering and resource toolkits. Though these methods are easy in implementation, they require extra efforts and handcrafted features(Heilman and Smith, 2010; Tymoshenko and Moschitti, 2015). Recently, with the development of neural network, deep learning based models attract much attention in various tasks(Krizhevsky et al., 2012; Sutskever et al., 2014). In question answering field, the convolutional neural networks(CNNs)(Yu et al., 2014; Hu et al., 2014; Severyn and Moschitti, 2015) and recurrent neural networks(RNNs)(Wang and Nyberg, 2015; Feng et al., 2015) are widely employed to convert the question and answer text into vectors and define a feed-forward multi-layer perceptron to compute the interactions between them. These models construct sentences in an end-to-end fashion with less manual involvement. To capture fine-grained features, on the one hand, some works are concerned with matching QA pairs relationship in a more complex and diverse way, e.g., CNTN(Qiu and Huang, 2015) and MV-LSTM(Wan et al., 2016). On the other hand, latent representation models aim to jointly learn lexical and semantic information from QA sentences and influence the vector generation directly, e.g., attention mechanism(Bahdanau et al., 2015).

Attention mechanism learns attention weights of each words pairs between QA sentences. Afterwards it can calculate the weighted sum of hidden states over all time steps(dos Santos et al., 2016). This approach has shown promising results, while challenges still exist. For example, questions and answers in CQA services are generally long sentences, as such it is still difficult to compress all information into a fixed-length vector. To solve this problem, Sha et al. (2018) proposes co-attention view which brings improvement, and Zhang et al. (2018) further proposes a two-step attention to build dynamic question vectors based on various answer words. These kinds of methods usually require more parameters to learn representations. More importantly, when computing attention weights, every words

Proceedings of NAACL-HLT 2019, pages 2201–2211
Minneapolis, Minnesota, June 2 - June 7, 2019.

in QA pairs are involved. This word-to-word pattern takes meaningless noise into consideration, such as informal language usage or text irrelevant to the question. To alleviate this problem, Chen et al. (2018) proposes a context-aligned model to align phrase in QA relying on overlapped words and Stanford Core NLP tools[1]. Inspired by co-attention, we extend it to sequential style to learn better representations and try to extract useful keywords with less parameters and resource toolkits.

In this work, we propose a Sequential Attention with Keyword Mask(SAKM) model for answer selection task. We encode sentences similar to human reading behavior. When generating the question, our model refers to the answer and combines the mutual information. It is the same processing for producing answer representations. So when encoding a question, answer text is used as context and vice versa. We term this co-attention view as one “hop”. Afterwards we repeat this process several times(hops) in a sequential style. As such QA pairs review each other recurrently to remind of mutual information and refine the sentence representations to be more precise across hops. Besides, the Keyword Mask modifies the attention mechanism such that the attention is computed over keywords instead of all words in the QA pair. So only keywords in the long context are extracted at each time step.

The contributions in this paper are three folders: 1) We extend attention mechanism to sequential structure, so the question and answer review each other recurrently to improve the sentence representations. 2) Different from standard soft attention, we propose sequential attention with keyword mask(SAKM) model. Besides, our model focuses on the significant words and filters other meaningless data. 3) We analyse the proposed SAKM model not only on classical answer selection tasks and but also multi-level answer ranking tasks. Experiment results show that our model tends to encode more rich semantic representations with less parameters.

2 Related Work

In Community-based Question Answering(CQA) services, since normally there exists a large number of question and answer pairs in repository, answer selection(AS) is a critical task, which focuses on finding a suitable answer within a list of candidate answers. As for traditional methods, feature engineering is a core work, but also a time-consuming and laborious task. BM25(Robertson et al., 1994) calculates relevance with item frequency, while language models(Ponte and Croft, 2017; Zhai and Lafferty, 2004) use the maximum likelihood of a word estimated from the question. Translation-based language models(Jeon et al., 2005; Xue et al., 2008) further improve. Considering the syntactic structure, some prior works(Heilman and Smith, 2010; Tymoshenko and Moschitti, 2015) convert the sentence into a tree structure by dependency parsing. Additionally, linguistics resources such as WordNet are utilized to enhance lexical features. Classification models like chain Conditional Random Fields have been used to match the questions and answers(Kiritchenko et al., 2014).

Recently, neural network based models have shown effectiveness in various fields, such as computer vision(Krizhevsky et al., 2012) and natural language processing(Kim, 2014). Different from aforementioned approaches, deep neural architectures(Hu et al., 2014; Wang and Nyberg, 2015) map each word into an embedding space, and compress the whole sentence into a low dimension vector. Then a similarity function is defined to calculate the interactions between QA pairs. Closer vectors in the embedding space represent much more relevant text.

To model fine-grained features, Qiu and Huang (2015) combines CNN with neural tensor network(NTN) to learn complex interactions between QA pairs. But NTN increases a lot of parameters and costs more runtime and memory. MV-LSTM proposed by Wan et al. (2016) uses bi-direction LSTM to generate a positional representation at each time step. Subsequently these representations from questions and answers are fed into a tensor layer. Shen et al. (2017) learns word representations in an embedding space by a translation matrix, and calculates relevance of each word pair in QA to compute a similarity matrix. Then CNN maps this matrix to a score scalar. Recently, (Tay et al., 2018b) applies the hyperbolic distance function to model the relationship between QA.

Other latent representation models construct interactions between QA when encoding sentences. More mutual information is extracted to learn a better latent representation. Miao et al. (2016) pro-

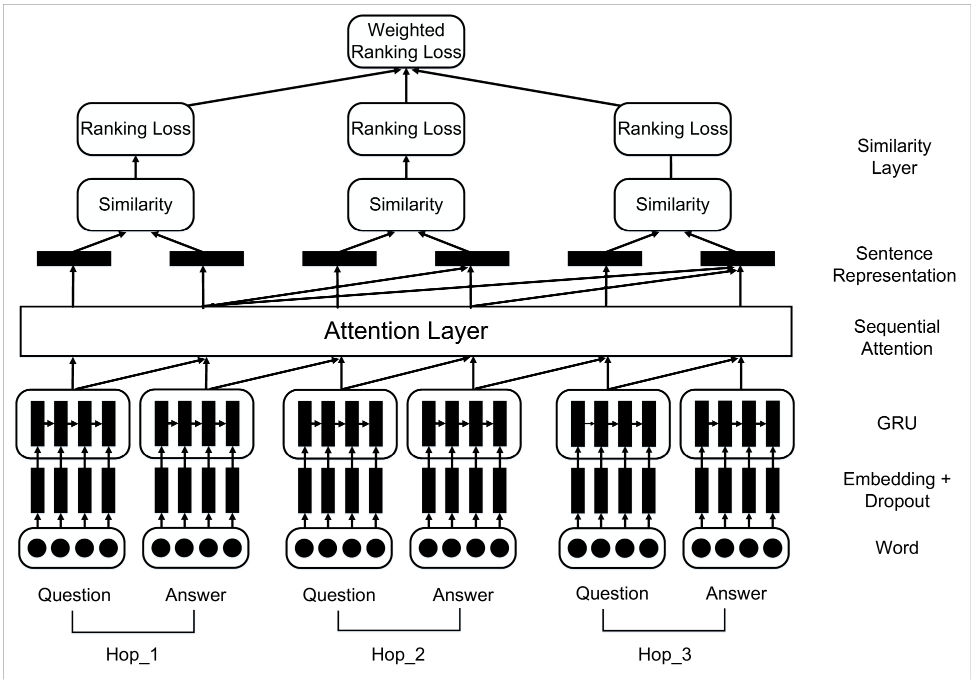

Figure 1: The architecture of 3 hops SAKM model. For simplification, we omit the lines in Sentence Representation Layer of Question part.

poses neural variational inference network. Wang et al. (2016) takes question context into consideration in RNN cell of answer network with gate mechanism. Yin et al. (2016) and dos Santos et al. (2016) propose attention-based CNN models to add attention weight matrix between a QA pair as a feature map. Additionally, Zhang et al. (2017) extends attention weight matrix to 3D tensor including more diverse information. Sha et al. (2018) proves co-attention view can significantly outperform the single attention. Further more, Zhang et al. (2018) constructs two-step attention to obtain question aware vectors based on various words in an answer sentence.

3 Sequential Attention with Keyword Mask Model

Given a question, which may contain one or more clauses, it can be denoted as $Q = (q_1, q_2, ..., q_n)$. Similarly, an answer can be denoted as $A = (a_1, a_2, ..., a_n)$. A^+ and A^- represent a positive answer and a negative answer, respectively. Fig. 1 describes the overall architecture of the proposed Sequential Attention with Keyword Mask(SAKM) model(in this figure, we use three hops as illustration). We extend our network in a sequential style. For each hop, a serial of stacked layers are constructed for the questions and the answers.

3.1 Embedding and Dropout

Firstly the questions and the answers need to be fed into the embedding layer and each word in sentences corresponds to an one-hot vector. Given a look-up table, each word is converted into an embedding space. The index of the low dimensional vector in the look-up table is the same as one-hot vector. We denote the embedding vectors of the QA pairs as $Q_{emb} = (x_1, x_2, ..., x_n) \in R^{d\times|Q|}$ and $A_{emb} = (y_1, y_2, ..., y_n) \in R^{d\times|A|}$, where d is the embedding size, $|Q|$ and $|A|$ denote the length of the question and answer respectively.

In order to mitigate the risk of overfitting, we employ dropout layer to randomly ignore different part of neurons in different hops during training. This process learns better representations of local regions and leads to better generalization during testing.

3.2 Sequential Attention

Gated Recurrent Unit(GRU) To encode a sentence into a single vector, we choose gated recurrent unit(Cho et al., 2014) and construct Q-GRU and A-GRU for the questions and answers, respectively. Given an input sentence $S = (s_1, s_2, ..., s_n) \in R^{d\times|S|}$, GRU handles each word recurrently and at time step t the operation is defined as follow:

$$\begin{aligned} r_t &= \sigma(W_r s_t + U_r h_{t-1} + b_r) \\ z_t &= \sigma(W_z s_t + U_z h_{t-1} + b_z) \\ h_t &= z_t \odot h_{t-1} + (1 - z_t) \odot \tilde{h}_t \end{aligned} \quad (1)$$

where

$$\tilde{h}_t = \tanh\left(W_h s_t + U_h(r_t \odot h_{t-1}) + b_h\right) \quad (2)$$

In the above equations, W_r, W_z, $W_h \in R^{m \times d}$ and U_r, U_z, $U_h \in R^{m \times m}$ are parameters in the neurons. m is the dimension size of the hidden states. b_r, b_z and $b_h \in R^m$ are bias. σ is sigmoid function and $\odot$ means element-wise product.

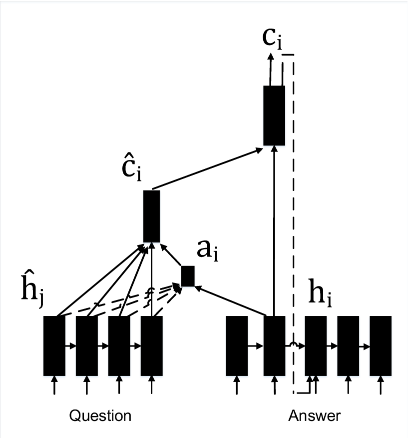

Figure 2: soft attention details.

Attention Mechanism During the GRU encoding process, an attention mechanism helps to combine context information with the current hidden states. For the standard soft attention mechanism(Bahdanau et al., 2015), as demonstrated in Fig. 2, the hidden state at time t computes attention weights with all of the context hidden states, and then obtains alignment scores after softmax operation. This mechanism takes all of the words in the context into consideration, while our model expects to extract some keywords to the current word and ignore other meaningless or noisy segments. The keyword mask relies on the attention weights and reserves top percent of words to account for alignment scores. It can be formulated as:

$$\begin{aligned} e_{ij} &= v^T \tanh(W_a[h_i; \hat{h}_j]) \\ e_{ij}^{mask} &= f_{mask\_top\_k}(e_{ij}, -inf) \\ a_{ij} &= \frac{\exp(e_{ij}^{mask})}{\sum_{k=1}^{|S|} \exp(e_{ik}^{mask})} \\ \hat{c}_i &= \sum_{j=1}^{|S|} a_{ij} \hat{h}_j \\ c_i &= \tanh(W_c[\hat{c}_i; h_i]) \end{aligned} \quad (3)$$

where $[;]$ is the operator of concatenation, and $f_{mask\_top\_k}$ denotes the function that the top percent of values are reserved while others are masked as value $-inf$. So these masked positions in a_{ij} become 0 after softmax operation, which represents no influence to the current hidden state h_i. Fig. 3 shows the details of this attention mechanism. We will discuss the keywords percentage in more detail in Section 5.2.

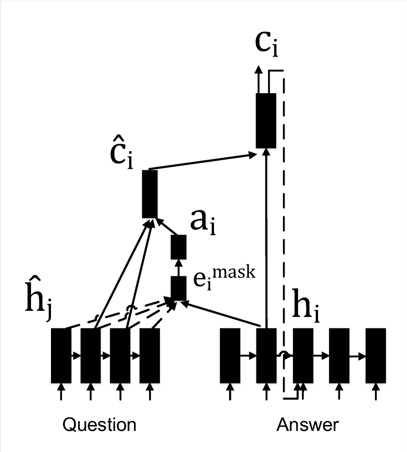

Figure 3: keyword-mask attention details.

After obtaining the representation of hidden neuron at time step t, we concat c_i with next word as input corresponding to the dotted line described in Fig. 3. When the whole sentence is processed, the final hidden output does not become representation directly because it loses much information about the beginning of the sentence. Instead, average operation over all hidden outputs is taken to produce the final representation.

Sequential Extension As shown in Fig. 1, A-GRU regards the question sentences as context to compute attention and representations. Likewise, Q-GRU reviews the answer contents to tune the representations. We extend this process in a sequential style to capture features and enhance information both from question text and answer text.

All of the parameters across hops are shared. For each hop, the vectors of QA pairs interact and improve. Compared to single direction attention or single hop attention, our model gets much more flexibility. It is capable of updating the representations towards the correct direction with the guide of a loss function and gradients across hops. We rename the Eq. 3 as $MaskAttention()$, as such the equations of the sequential extension is defined as:

$$\begin{aligned} Q^h &= MaskAttention(Q^h_{emb}, A^{h-1}) \\ A^h &= MaskAttention(A^h_{emb}, Q^h) \end{aligned} \quad (4)$$

where h is the current number of hop. The model iteratively updates the joint representations of the question and answer pair and obtains different outputs across hops.

Sentence Representation In the sentence representation layer, $Q^h_{representation}$ and $A^h_{representation}$ denote the final representation outputs of QA pairs at the hop h. Since Q^h and A^h only contain the information extracted at hop h, more meaningful content would be lost after more hops. But we expect to remember it from the beginning hops. To convey more information across hops, we do not simply take Q^h and A^h as the sentence representations. Instead, all of the previous outputs from $MaskAttention$ are involved. They can be calculated as:

$$\begin{aligned} Q^h_{representation} &= \frac{1}{h}\sum_{j=1}^{h} Q^h \\ A^h_{representation} &= \frac{1}{h}\sum_{j=1}^{h} A^h \end{aligned} \quad (5)$$

3.3 Similarity Calculation

Finally, we design a weighted loss strategy to compute the relevance and the loss value between QA pairs. For each hop, we have a pair of QA sentence representations and pass them through a similarity function described as:

$$s^h(Q,A) = \frac{{Q^h_{representation}}^T A^h_{representation}}{||Q^h_{representation}||_2 \cdot ||A^h_{representation}||_2} \quad (6)$$

where $s^h(Q,A)$ is the matching score between QA pairs at hop h. $||\cdot||_2$ means euclidean distance. As for the loss function during training, given a question, we use pair-wise margin-based ranking loss for a triple (Q, A^+, A^-). Thus the mathematical expression is:

$$\begin{aligned} L^h(Q, A^+, A^-) = \max(0, m - (s^h(Q, A^+) \\ -s^h(Q, A^-))) \end{aligned} \quad (7)$$

where m is the predefined margin.

Since we expect that vector representations generated from posterior hops are more precisely than the ones produced from prior hops, relatively small tolerance to the risk of matching incorrect QA pairs is accepted for posterior hops. Therefore, the loss values take increasing weights across hops. We denote r_h as loss weights. The objective loss function can be defined as:

$$L(Q, A^+, A^-) = \sum_{h=1}^{H} r_h L^h(Q, A^+, A^-) \quad (8)$$

4 Experimental Study

In this section, we test the proposed model on classical answer selection task and also multi-level answer ranking task to validate the model's effectiveness[2].

4.1 Answer Selection

Dataset & Implementation Details In this task, we use a community-based question answering dataset YahooCQA provided by Tay et al. (2017). It is an open-domain community forum, and the dataset contains 142,627 QA pairs. Sentences in YahooCQA are generally long and noisy. We follow the preprocessing in their work without extra process. Four negative answers are generated for a question using *Lucene*. Table 1 demonstrates the statistics of YahooCQA.

Dataset	YahooCQA	ZhihuCQA
# of Qns	50.1k / 6.2k / 6.2k	16k / 2k / 2k
# of Pairs	253k / 31.7k / 31.7k	80k / 10k / 10k

Table 1: Statistics of Datasets.

For our model, we tune the hidden size to 300, and the numbers of GRU layers for modeling questions and answers are both 1. Dropout is 0.5 and word embedding is pre-trained by skip-gram model. For the Sequential Extension layer, the number of hops is 3. For the Similarity Calculation, margin is 0.1 and weights for all hops are

---

[2] Our code is available at `https://github.com/sheep-for/question_answer_matching`

set as (0.2, 0.3, 0.5). Weights are set to constants because we promise to put more weight on later hops and keep reasonable tolerance for prior ones. Batch size is 20. All of the parameters are optimized by Back Propagation and Momentum.

Baselines We compare our model against several advanced deep neural network models. CNTN(Qiu and Huang, 2015), NTN-LSTM, HD-LSTM(Tay et al., 2017) and HyperQA(Tay et al., 2018b) are interaction focused methods, while AP-CNN, AP-BiLSTM(dos Santos et al., 2016), QRNN(Bradbury et al., 2017), CTRN(Tay et al., 2018a) and two-step attention(Zhang et al., 2018) are latent representation models. Additionally, we choose two traditional methods Random Guess and BM25(Robertson et al., 1994).

Evaluation Metrics For YahooCQA, we use Precision@1(P@1) and Mean Reciprocal Rank(MRR) to evaluate our model and the metrics are defined as:

$$\begin{aligned} P@1 &= \frac{1}{N}\sum_{i=1}^{N}\delta(r(A^{+})=1) \\ MRR &= \frac{1}{N}\sum_{i=1}^{N}\frac{1}{r(q_i)} \end{aligned} \tag{9}$$

where δ is indicator function, N is the number of all queries and $r(q_i)$ is the rank of the first correct answer to question q_i.

Model	**P@1**	MRR
Random Guess	20.0%	45.7%
BM25	22.5%	49.3%
CNN	41.3%	63.2%
LSTM	46.5%	66.9%
CNTN	46.5%	63.2%
NTN-LSTM	54.5%	73.1%
AP-CNN	56.0%	72.6%
AP-BiLSTM	56.8%	73.1%
QRNN	57.3%	73.6%
HD-LSTM	55.7%	73.5%
CTRN	60.1%	75.5%
Two-step attention	62.2%	77.4%
HyperQA	68.3%	80.1%
SA	66.0%	79.2%
SAKM	**69.3%**	**81.4%**

Table 2: Experiment results on YahooCQA. SA is the sequential attention baseline without keyword-mask operation. SAKM is our sequential attention with keyword mask model.

Experiment Results The results are shown in Table 2. Firstly, it is observed that deep neural network models outperform traditional models. Most latent representation models obtain better results than interaction focused models, indicating that earlier interactions when encoding sentences produces semantic vectors. Most importantly, the proposed SAKM model achieves best results on both P@1 and MRR. Our basic SA model outperforms two-step attention model by 3.8% in terms of P@1 and 1.8% in terms of MRR, which shows that our sequential extension structure is effective. Furthermore, our SAKM model outperforms HyperQA model by 1.0% in terms of P@1 and 1.3% in terms of MRR. Since HyperQA is an interaction focused model which adopts the hyperbolic distance function to model the relevance between QA. we can combine it with our SAKM to obtain better performance in further study. The experiment results agree with our intuition that extracting meaningful keywords in attention mechanism helps to generate more precise representations.

4.2 Multi-Level Answer Ranking

Relevant relationship in answer selection datasets is binary, only including relevance and irrelevance. However, in the real CQA applications, it is difficult to verify whether the answers are completely correct or not. This scenario has caused a challenge called multi-level answer ranking(Liu et al., 2018). These answers for one question are annotated as several levels corresponding to the thumb-up numbers.

Dataset & Implementation Details To test the proposed model in multi-level answer ranking task, we choose the dataset ZhihuCQA provided by Liu et al. (2018). Zhihu[3] is a popular and professional Chinese QA community platform with more than millions of users and QA pairs. Table 1 describes the statistics of ZhihuCQA. For each question, top five answers are selected and ranked by the thumb-up numbers. We replace margin based ranking loss with RankNet(Burges et al., 2005).

In this task, we use the jieba[4] toolkits for word segmentation and tune the hidden size to 200, and the numbers of GRU layers for modeling questions and answers are both 2. Other settings are the same as YahooCQA.

---

[3] `https://www.zhihu.com/`

[4] `https://github.com/fxsjy/jieba`

Baselines We compare our model against available advanced methods in (Liu et al., 2018). ARC-II learns hierarchical pattern based on ARC-I(Hu et al., 2014). Skip-Thoughts model(Kiros et al., 2015) trains an encoder-decoder model to construct sentence vectors. Attentive LSTM, ABCNN and Compare-Aggregate(Wang and Jiang, 2017) are attention-based models and Rewrite+Rank is based on generative adversarial network.

Evaluation Metrics In this task, since the labels for an answer are not binary, we choose normalized discounted cumulative gain(NDCG) and expected reciprocal rank(ERR) for evaluation. $(o_1, o_2, ..., o_M)$ denotes the predicted orders of answers to a question. NDCG is defined as:

$$\begin{aligned} NDCG &= \frac{DCG}{iDCG} \\ DCG &= \sum_{i=1}^{M} \frac{2^{o_i} - 1}{\log(1+i)} \end{aligned} \tag{10}$$

where $iDCG$ is the ideal DCG calculated from the correct orders $(l_1, l_2, ..., l_M)$. ERR is defined as:

$$\begin{aligned} ERR &= \sum_{r=1}^{M} \frac{R_r}{r} \prod_{i=1}^{r-1} (1 - R_i) \\ R_i &= \frac{2^{o_i} - 1}{2^{o_m}} \end{aligned} \tag{11}$$

where o_m is the maximum of degree values.

Model	**NDCG**	ERR
Random Guess	41.7%	30.3%
ARC-I	64.4%	56.4%
ARC-II	68.5%	58.8%
Skip-Thoughts	69.1%	60.1%
Attentive LSTM	71.4%	61.1%
ABCNN	72.5%	62.0%
Compare-Aggregate	74.8%	63.2%
Rewrite+Rank	77.2%	65.0%
SA	80.7%	68.2%
SAKM	**81.0%**	**68.4%**

Table 3: Experiment results on ZhihuCQA.

Experiment Results Table 3 reports the results on ZhihuCQA. Similar to YahooCQA, attention-based models perform better than other baselines. Our SA model outperforms Rewrite+Rank by 3.6% in terms of NDCG and 3.2% in terms of ERR. SAKM model achieves slightly improvement compared to SA version. Results show that on multi-level answer ranking task, our review mechanism allows question and answer interaction while encoding in a more fine-grain aspect and leads to better performance.

5 Discussion and Analysis

In this section, we divide our discussion into three parts, including the trade-off between information transmission and avoidance of overfitting, the relationship between sentence length and keyword percentage, the advantages of our SAKM model.

5.1 Trade-off between Information Transmission and Avoidance of Overfitting

Our model processes QA text in a sequential style. For the first hop, the original contents are fed as inputs. Afterwards, the representations are updated based on previous outputs across hops, thus it is significant to convey rich mutual information. Meanwhile, since the sentences are long and redundant, it is necessary to avoid overfitting.

Information Transmission across Hops In order to utilize context better, We propose sequential style to refine the sentence vectors through multiple hops. When calculating the sentence representations, we take the average over outputs of all time steps instead of selecting the final hidden state, and get the final sentence representations based on all hops. Additionally, in embedding layer we pretrain the word embeddings on the corpus using word2vec(Mikolov et al., 2013). To guide the vectors update in a correct direction based on gradients, the loss function is calculated over all hops, and puts more weight on later ones.

Avoidance of Overfitting There are some tricks to reduce the risk of overfitting. Our model extracts some keywords according to the attention weights, and applies dropout to ignore different neurons in different hops. Besides, the GRU layer is shallow and the number of hops is suitable.

5.2 Relationship between Sentence Length and Keyword Percentage

In the attention mechanism, we use $f_{mask\_top\_k}$ to reserve top percent of attention weights. In this part, we propose two strategies to explore the relationship between the sentence length and keyword percentage.

Fixed-Percentage: We set the number of keywords based on the statistics of the dataset. Firstly, we count the lengths of all questions and answers respectively, and then sort them in an ascending order. We choose the value of the third quartile as the number of keywords in a question, while the value of the first quartile as the number of keywords in an answer. This strategy allows us not to calculate percentage according to various lengths in the dataset. Our experiments empirically show that it works well.

Variable-Percentage: The second strategy is to compute the number of keywords for all sentences.

Question: Since the answers are produced based on question sequences, the question generally contains more meaningful information such as inquiry type, inquiry main verb, topic and so on. We empirically calculate the number of keywords k in a question of length x as follow:

$$k = \min(10 \ln x, x) \tag{12}$$

Answer: As for answers submitted by users in community forum, there exists redundant contents, typos errors, emoticon and other informal language usage. Inspired by TF-IDF algorithm, in our experiments, we propose a heuristics rule to calculate the number of keywords k. The length of an answer is denoted as x. For the first part, we compute the Total-Length(TL) term as follow:

$$TL(x) = x\lfloor \lg x \rfloor \tag{13}$$

where $\lfloor \cdot \rfloor$ is rounding down operation. TL value increases monotonously with length of sentence. For the second part, we compute the Inverse-Noise-Frequency(INF) term as follow:

$$INF(x) = \frac{1}{\lg 2x} \tag{14}$$

This term represents the percent of the meaningful words, which is an inverse proportion to noisy words. Finally, the number of keywords k can be obtained by multiplying these two terms.

$$k = \min(TL(x) \cdot INF(x), x) \tag{15}$$

5.3 Advantages of SAKM model

Simplicity: Our SAKM model is simple but outperforms on large CQA datasets. The network is shallow and all of the parameters across hops are shared. Our model is not complicated and has less parameters than other mentioned neural network models. Table 4 demonstrates the complexity analysis of some models.

Our model is an end-to-end neural network, and trained via back-propagation automatically. The SAKM model could be an universal way to learn sentence vectors effectively and integrated in other larger neural network models. It could be a useful tool in building neural architecture based representations for text sequences.

Model	**Complexity**	**Parameters**
AP-BiLSTM	$4(md + d^2) + 4d^2$	1.08M
NTN	$2dk + 2k + d^2k$	2.1M
CTRN	$3kdm + 2dh + h$	1.05M
Two-step	$6md + 10d^2 + 12d^2k$	1.31M
SAKM (Our)	$3(md + d^2) + 4d^2$	0.9M

Table 4: Complexity analysis on YahooCQA. m is embedding size, k is the filter width, d is the output dimension and h is the size of full-connected layer.

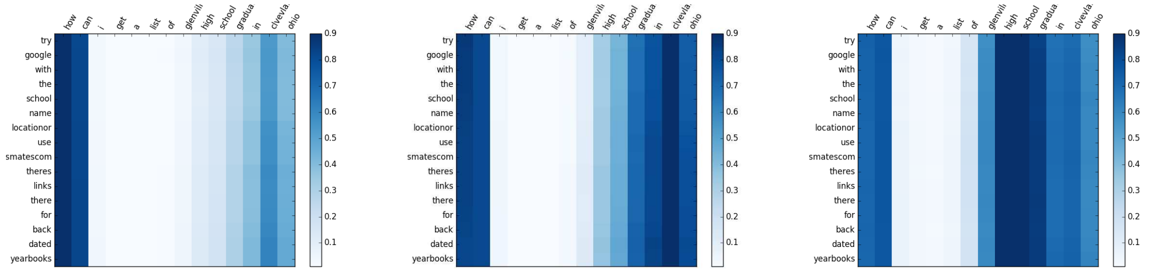
Convergency: As the sentence representations are tuned and improved across hops in one epoch, it costs less epochs for our model to converge. In our experiments, performance improve quickly in first ten epochs.

Effectiveness: The QA pairs capture features and information both from question text and answer text, iteratively updating and improving question and answer representations through hops.

At the test time, choosing the outputs of the last hop from sentence representation layer as sentence vectors can obtain better results on P@1 and MRR, demonstrating the effectiveness of improvement across hops. SAKM model outperforms SA model by more than 3% on P@1 and 2% on MRR. It proves that extracting keywords is significant and necessary. Besides, even if we choose the first hop of SA model, the gains are significant compared to two-way attention model. It means that our refinement procedure leads to better representations for all hops. Table 5 shows the details.

Representation	**P@1**	**MRR**
SA_hop_1	64.5%	78.2%
SA_hop_last	66.0%	79.2%
SA_concat_hops	65.7%	79.0%
SAKM_hop_1	68.7%	81.0%
SAKM_hop_last	**69.3%**	**81.4%**
SAKM_concat_hops	69.2%	81.3%

Table 5: Experiment results on YahooCQA using various representations. SAKM_hop_1 denotes that SAKM model tests with the sentence representations of the first hop.



(a) Visualization of SA at first hop (b) Visualization of SA at last hop (c) Visualization of SAKM at last hop

Figure 4: Attention Visualization.

Given a pair of QA as example. *Q: How can i get a list of glenville high school graduates in clvevland ohio. A: Try google with the school name locationor use classmatescom theres links there for back dated yearbooks.* Fig. 4 displays the heatmap of the attention weights. We can observe that compared to the first hop of SA model, the last hop puts more weights on phrase *glenville high school graduates in clvevland ohio*. Further more, the last hop of SAKM model focuses on keywords *how can, glenville high school graduates.* It shows that the inquiry type words and topic words achieve more attention. From this heatmap, it indicates that our SAKM model is reasonable and works well.

6 Conclusion

In this work, we propose a sequential attention with keyword mask model for CQA. Our model handles answer selection task similar to human reading behavior. The questions and answers review each other recurrently to improve the representations. This proposed attention mechanism focuses on some keywords and filters other meaningless data. We evaluate our model on two tasks, answering selection and multi-level answer ranking. The experiment results demonstrate that our model outperforms on CQA datasets and enhance mutual information between QA pairs effectively.

Simple Attention-Based Representation Learning for Ranking Short Social Media Posts

Peng Shi,[1] **Jinfeng Rao**,[2*] and **Jimmy Lin**[1]

`{peng.shi, jimmylin}@uwaterloo.ca`, `raojinfeng@fb.com`

Abstract

This paper explores the problem of ranking short social media posts with respect to user queries using neural networks. Instead of starting with a complex architecture, we proceed from the bottom up and examine the effectiveness of a simple, word-level Siamese architecture augmented with attention-based mechanisms for capturing semantic "soft" matches between query and post tokens. Extensive experiments on datasets from the TREC Microblog Tracks show that our simple models not only achieve better effectiveness than existing approaches that are far more complex or exploit a more diverse set of relevance signals, but are also much faster. Implementations of our **samCNN** (**S**imple **A**ttention-based **M**atching CNN) models are shared with the community to support future work.[1]

1 Introduction

Despite a large body of work on neural ranking models for "traditional" *ad hoc* retrieval over web pages and newswire documents (Huang et al., 2013; Shen et al., 2014; Guo et al., 2016; Xiong et al., 2017; Mitra et al., 2017; Pang et al., 2017; Dai et al., 2018; McDonald et al., 2018), there has been surprisingly little work (Rao et al., 2017) on applying neural networks to searching short social media posts such as tweets on Twitter. Rao et al. (2019) identified short document length, informality of language, and heterogeneous relevance signals as main challenges in relevance modeling, and proposed the first neural model specifically designed to handle these characteristics. Evaluation on a number of datasets from the TREC Microblog Tracks demonstrates state-of-the-art effectiveness as well as the necessity of different model components to capture a multitude of relevance signals.

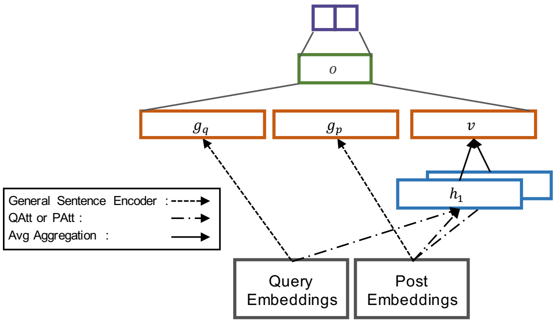

Figure 1: Our model architecture: a general sentence encoder is applied on query and post embeddings to generate $\mathbf{g}_q$ and $\mathbf{g}_p$; an attention encoder is applied on post embeddings to generate variable-length query-aware features $\mathbf{h}_i$. These features are further aggregated to yield $\mathbf{v}$, which feeds into the final prediction.

In this paper, we also examine the problem of modeling relevance for ranking short social media posts, but from a complementary perspective. As Weissenborn et al. (2017) notes, most systems are built in a *top-down* process: authors propose a complex architecture and then validate design decisions with ablation experiments. However, such experiments often lack comparisons to strong baselines, which raises the question as to whether model complexity is empirically justified. As an alternative, they advocate a *bottom-up* approach where architectural complexity is gradually increased. We adopt exactly such an approach, focused exclusively on word-level modeling. As shown in Figure 1, we examine variants of a simple, generic architecture that has emerged as "best practices" in the NLP community for tackling modeling problems on two input sequences: a Siamese CNN architecture for learning representations over both inputs (a query and a social media post in our case), followed by fully-connected layers that produce a final relevance prediction (Severyn and Moschitti, 2015; He et al., 2016; Rao

Proceedings of NAACL-HLT 2019, pages 2212–2217
Minneapolis, Minnesota, June 2 - June 7, 2019.

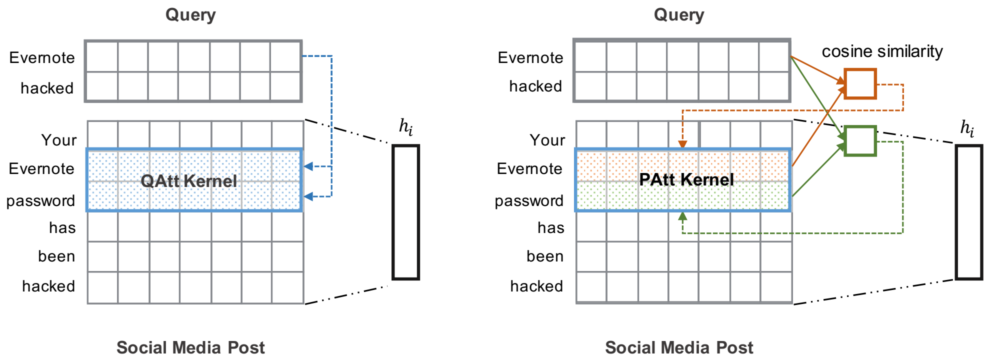

Figure 2: The Query-Aware Attention (QAtt) architecture on the left and the Position-Aware Attention (PAtt) architecture on the right. In both, we construct F convolutional kernels for *each* query token (here, one kernel for the query token ‘Evernote’ is visualized). In QAtt, the query token embedding is directly “injected” into the kernel via element-wise product (blue dotted arrows). In PAtt, cosine similarity between the query token and tokens in the post within the convolution window are used as attention weights in the kernel.

et al., 2016), which we refer to as a General Sentence Encoder in Section 2.1. Further adopting best practices, we incorporate query-aware convolutions with an average aggregation layer in the representation learning process.

Recently, a number of researchers (Conneau et al., 2017; Mohammed et al., 2018) have started to reexamine simple baselines and found them to be highly competitive with the state of the art, especially with proper tuning. For example, the InferSent approach (Conneau et al., 2017) uses a simple BiLSTM with max pooling that achieves quite impressive accuracy on several classification benchmarks. Our contribution is along similar lines, where we explore simple yet highly effective models for ranking social media posts, to gain insights into query–post relevance matching using standard neural architectures. Experiments with TREC Microblog datasets show that our best model not only achieves better effectiveness than existing approaches that leverage more signals, but also demonstrates 4× speedup in model training and inference compared to a recently-proposed neural model.

2 Model

Our model comprises a representation learning layer with convolutional encoders and another simple aggregation layer. These architectural components are described in detail below.

2.1 Representation Learning Layer

General Sentence Encoder: The general sentence encoder uses a standard convolutional layer with randomly initialized kernels to learn semantic representations for text. More formally, given query q and post p as sentence inputs, we first convert them to embedding matrices $\mathbf{Q}$ and $\mathbf{P}$ through an embedding lookup layer, where $\mathbf{Q} \in \mathbb{R}^{n \times d}$ and $\mathbf{P} \in \mathbb{R}^{m \times d}$, d is the dimension of embeddings, and n and m are the number of tokens in q and p, respectively. Then we apply a standard convolution operation with kernel window size k over the embedding matrix $\mathbf{Q}$ and $\mathbf{P}$. The convolution operation is parameterized by a weight term $\mathbf{W} \in \mathbb{R}^{F \times k \times d}$ and a bias term $b_w \in \mathbb{R}^F$, where F is the number of convolutional kernels. This generates semantic representation $\mathbf{O}_q \in \mathbb{R}^{n \times F}$ and $\mathbf{O}_p \in \mathbb{R}^{m \times F}$, on which max pooling and an MLP are applied to obtain query representation $\mathbf{g}_q \in \mathbb{R}^d$ and post representation $\mathbf{g}_p \in \mathbb{R}^d$.

The weakness of the kernels in the general sentence encoder is that they do not incorporate knowledge from the query when attempting to capture feature patterns from the post. Inspired by attention mechanisms (Bahdanau et al., 2014), we propose two novel approaches to incorporate query information when encoding the post representation, which we introduce below.

Query-Aware Attention Encoder (QAtt): In QAtt (Figure 2, left), for each query token, we construct a token-specific convolutional kernel to “inject” the query information. Unlike methods that apply attention mechanisms after the sentence representations are generated (Bahdanau et al., 2014; Seo et al., 2016), our approach aims to model the representation learning process jointly with an attention mechanism.

Formally, for each query token t_q, the QAtt kernel $\mathbf{W}_{\text{QAtt}}^{t_q}$ is composed as follows:

$$\mathbf{W}_{\text{QAtt}}^{t_q} = \mathbf{U} \otimes \mathbf{Q}_{t_q} \tag{1}$$

where $\mathbf{U} \in \mathbb{R}^{F \times k \times d}$ represents trainable parameters, $\mathbf{Q}_{t_q}$ is the embedding of token t_q with size $\mathbb{R}^d$ and $\mathbf{W}_{\text{QAtt}}^{t_q} \in \mathbb{R}^{F \times k \times d}$. The element-wise product $\otimes$ is applied between the token embedding $\mathbf{Q}_{t_q}$ and the last dimension of kernel weights $\mathbf{U}$. In other words, we create F convolutional kernels for *each* query token, where each kernel is "injected" with the embedding of that query token via element-wise product. Figure 2 (left) illustrates one kernel for the query token 'Evernote', where element-wise product is represented by blue dotted arrows. When a QAtt token-specific kernel is applied, a window slides across the post embeddings $\mathbf{P}$ and learns soft matches to each query token to generate query-aware representations.

On top of the QAtt kernels, we apply max-pooling and an MLP to produce a set of post representations $\{\mathbf{h}_i\}$, with each $\mathbf{h}_i \in \mathbb{R}^d$ standing for the representation learned from query token t_{q_i}.

Position-Aware Attention Encoder (PAtt): In the QAtt encoder, token-specific kernels learn soft matches to the query. However, they still ignore positional information when encoding the post semantics, which has been shown to be effective for sequence modeling (Gehring et al., 2017). To overcome this limitation, we propose an alternative attention encoder that captures positional information through interactions between query embeddings and post embeddings.

Given a query token t_q and the j-th position in post p, we compute the interaction scores by taking the cosine similarity between the word embeddings of token t_q and post tokens $t_{p_{j:j+k-1}}$ from position j to $j+k-1$:

$$S_j = [\cos(t_q, t_{p_j}); ...; \cos(t_q, t_{p_{j+k-1}})] \tag{2}$$

where $S_j \in \mathbb{R}^{k \times 1}$ and k is the width of the convolutional kernel we are learning. That is, for each token in the post within the window, we compute its cosine similarity with query token t_q. We then convert the similarity vector S_j into a matrix:

$$\hat{S}_j = S_j \cdot \mathbb{1}, \hat{S}_j \in \mathbb{R}^{k \times d} \tag{3}$$

where $\mathbb{1} \in \mathbb{R}^{1 \times d}$ with each element set to 1. Finally, the PAtt convolutional kernel for query token t_q at the j-th position is constructed as:

$$\mathbf{W}_{\text{PAtt}}^{t_q, j} = \mathbf{V} \otimes \hat{S}_j \tag{4}$$

where $\mathbf{V} \in \mathbb{R}^{F \times k \times d}$ represents the trainable parameters. The element-wise product $\otimes$ is applied between the attention weights $\hat{S}_j$ and the last two dimensions of kernel weights $\mathbf{V}$.

Conceptually, this operation can be thought as adding a soft attention weight (with values in the range of $[0, 1]$) to each convolutional kernel, where the weight is determined by the cosine similarity between the token from the post and a particular query token; since cosine similarity is a scalar, we fill in the value in all d dimensions of the kernel, where d is the size of the word embedding. This is illustrated in Figure 2 (right), where we show one kernel of width two for the query token 'Evernote'. The brown (green) arrows capture cosine similarity between the query token 'Evernote' and the first (second) token from the post in the window. These values then serve as weights in the kernels, shown as the hatched areas. Similar to QAtt, the PAtt encoder with max-pooling and an MLP generates a set of post representations $\{\mathbf{h}_i\}$, with each $\mathbf{h}_i$ standing for the representation learned from query token t_{q_i}.

It is worth noting that both the QAtt and PAtt encoders have no extra parameters over a general sentence encoder. However, incorporating the query-aware and position-aware information enables more effective representation learning, as our experiments show later. The QAtt and PAtt encoders can also be used as plug-in modules in any standard convolutional architecture to learn query-biased representations.

2.2 Aggregation Layer

After the representation layer, a set of vectors $\{\mathbf{g}_q, \mathbf{g}_p, \{\mathbf{h}_i\}\}$ is obtained. Because our model yields different numbers of $\mathbf{h}_i$ with queries of different lengths, further aggregation is needed to output a global feature $\mathbf{v}$. We directly average all vectors $\mathbf{v} = \frac{1}{N_q} \sum \mathbf{h_i}$ as the aggregated feature, where N_q is the length of the query.

2.3 Training

To obtain a final relevance score, the feature vectors $\mathbf{g}_q$, $\mathbf{g}_p$, and $\mathbf{v}$ are concatenated and fed into an MLP with ReLU activation for dimensionality reduction to obtain $\mathbf{o}$, followed by batch normalization and fully-connected layer and softmax to output the final prediction. The model is trained end-to-end with a Stochastic Gradient Decent optimizer using negative log-likelihood loss.

Year	2011	2012	2013	2014
# queries	49	60	60	55

Kernel number	250	Dropout ratio	0.5
Kernel size	2	Learning rate	0.03

Table 2: Hyperparameters for our models. GloVe (Pennington et al., 2014) embeddings are used and fine-tuned during training. Unknown words are initialized from a uniform distribution $[-k, k]$.

3 Experimental Setup

Datasets and Hyperparameters. Our models are evaluated on four tweet test collections from the TREC 2011–2014 Microblog (MB) Tracks (Ounis et al., 2011; Soboroff et al., 2012; Lin and Efron, 2013; Lin et al., 2014). Each dataset contains around 50–60 queries; detailed statistics are shown in Table 1. As with Rao et al. (2019), we evaluated our models in a reranking task, where the inputs are up to the top 1000 tweets retrieved from "bag of words" ranking using query likelihood (QL). We ran four-fold cross-validation split by year (i.e., train on three years' data, test on one year's data) and followed Rao et al. (2019) for sampling validation sets. For metrics, we used average precision (AP) and precision at rank 30 (P30). We conducted Fisher's two-sided, paired randomization tests (Smucker et al., 2007) to assess statistical significance at $p < 0.05$. The best model hyperparameters are shown in Table 2.

Baselines. On top of QL, RM3 (Abdul-Jaleel et al., 2004) provides strong non-neural results using pseudo-relevance feedback. We also compared against MP-HCNN (Rao et al., 2019), the first neural model that captures specific characteristics of social media posts, which improves over many previous neural models, e.g., K-NRM (Xiong et al., 2017) and DUET (Mitra et al., 2017), by a significant margin. To the best of our knowledge, Rao et al. (2019) is the most effective neural model to date. We compared against two variants of MP-HCNN; MP-HCNN+QL includes a linear interpolation with QL scores.

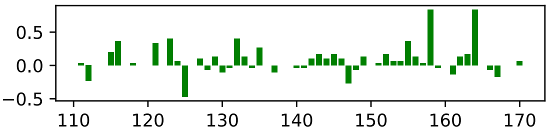

Figure 3: Per-query AP differences between PAtt and QL on TREC 2013 (queries 111–170).

4 Results and Discussion

Table 3 shows the effectiveness of all variants of our model, compared against previous results copied from Rao et al. (2019). Model 1 illustrates the effectiveness of the basic BiCNN model with a kernel window size of two; combining different window sizes (Kim, 2014) doesn't yield any improvements. It appears that this model performs worse than the QL baseline.

Comparing Model 2 to Model 1, we find that query-aware kernels contribute significant improvements, achieving effectiveness comparable to the QL baseline. With Model 3, which captures positional information with the position-aware encoder, we obtain competitive effectiveness compared to Model 8, the full MP-HCNN model that includes interpolation with QL. Note that Model 8 leverages additional signals, including URL information, character-level encodings, and external term features such as tf–idf. With Model 4, which interpolates the position-aware encoder with QL, we obtain state-of-the-art effectiveness.

Per-Query Analysis. In Figure 3, we show per-query AP differences between the PAtt model and the QL baseline on the TREC 2013 dataset. As we can see, PAtt improves on most of the queries. For the best-performing query 164 "*lindsey vonn sidelined*", we project the hidden states **o** into a low-dimensional space using t-SNE (Maaten and Hinton, 2008), shown in Figure 4. We observe that with the basic BiCNN model (left), relevant posts are scattered. With the addition of an attention mechanism (either QAtt in the middle or PAtt on the right), most of the relevant posts are clustered together and separated from the non-relevant posts. With PAtt, there appears to be tighter clustering and better separation of the relevant posts from the non-relevant posts, giving rise to a better ranking. We confirmed similar behavior in many queries, which illustrates the ability of our position-aware attention encoder to learn better query-biased representations compared to the other two models.

Table 3: Results of various models on the TREC Microblog Tracks datasets. Models 5–8 are copied from Rao et al. (2019); note that MP-HCNN exploits URL information (+URL). Models with +QL include interpolation with the QL baseline. BiCNN denotes our general sentence encoder architecture, with either query-aware attention (QAtt) or position-aware attention (PAtt). Superscripts and subscripts indicate the row indexes for which a metric difference is statistically significant at $p < 0.05$.

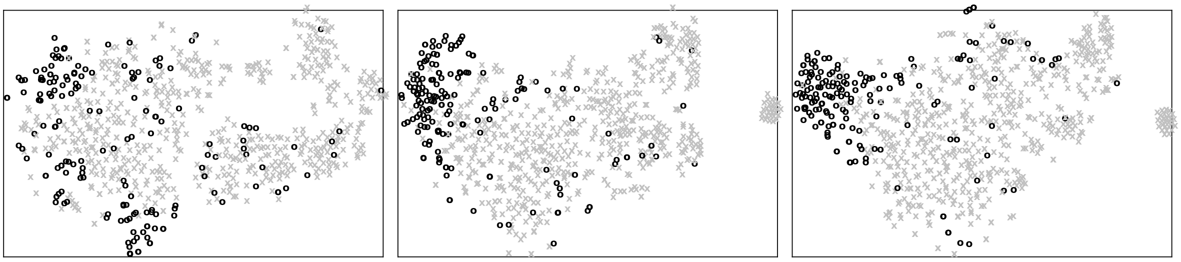

Figure 4: t-SNE visualizations of hidden states for the best-performing query 164 "*lindsey vonn sidelined*" from the BiCNN (left), QAtt (middle), and PAtt (right). Black circle (grey cross) represents relevant (non-relevant) post.

Match	Count
Oscars	28
snub	20
Affleck	25
Oscars snub	18
snub Affleck	15
Oscars Affleck	23
Oscars snub Affleck	13

Table 4: Matching patterns for the worst-performing query 127 "*Oscars snub Affleck*".

For the worst-performing query 125 "*Oscars snub Affleck*", the PAtt model lost 0.47 in AP and 0.11 in P30. To diagnose what went wrong, we sampled the top 30 posts ranked by the PAtt model and counted the number of posts that contain different combinations of the query terms in Table 4. The PAtt model indeed captures matching patterns, mostly on *Oscars* and *Affleck*. However, from the relevance judgments we see that *snub* is the dominant term in most relevant posts, while *Oscars* is often expressed implicitly. For example, QL assigns more weight to the term *snub* in the relevant post "*argo wins retributions for the snub of ben affleck*" because of the term's rarity; in contrast, the position-aware encoder places emphasis on the wrong query terms.

Model Performance. Finally, in terms of training and inference speed, we compared the PAtt model with MP-HCNN on a machine with a GeForce GTX 1080 GPU (batch size: 300). In addition to being more effective (as the above results show), PAtt is also approximately 4× faster.

5 Conclusions

In this paper, we proposed two novel attention-based convolutional encoders to incorporate query-aware and position-aware information with minimal additional model complexity. Results show that our model is simpler, faster, *and* more effective than previous neural models for searching social media posts.

AttentiveChecker: A Bi-Directional Attention Flow Mechanism for Fact Verification

T.Y.S.S.Santosh, Vishal G, Avirup Saha, Niloy Ganguly

Abstract

The recently released FEVER dataset provided benchmark results on a fact-checking task in which given a factual claim, the system must extract textual evidence (sets of sentences from Wikipedia pages) that support or refute the claim. In this paper, we present a completely task-agnostic pipelined system, AttentiveChecker, consisting of three homogeneous Bi-Directional Attention Flow (BIDAF) networks, which are multi-layer hierarchical networks that represent the context at different levels of granularity. We are the first to apply to this task a bi-directional attention flow mechanism to obtain a query-aware context representation without early summarization. AttentiveChecker can be used to perform document retrieval, sentence selection, and claim verification. Experiments on the FEVER dataset indicate that AttentiveChecker is able to achieve the state-of-the-art results on the FEVER test set.

1 Introduction

The rising influence of fake news poses a clear threat to ethical journalism and the future of democracy. In order to tackle the sheer volume of fake news produced, robust automatic techniques to counter it need to be developed. To that end, in order to facilitate researchers to develop algorithms, a number of fact checking datasets have been released in the recent past (Vlachos and Riedel, 2014), (Wang, 2017), (Ferreira and Vlachos, 2016), (Pérez-Rosas et al., 2017), the 2017 Fake News Challenge (Pomerleau and Rao, 2017) dataset, the dataset released against Triple Scoring Task at the WSDM Cup 2017 (Heindorf et al., 2017) etc.

However, none of these datasets provide manual annotation for sentence or phrase-level evidence. In this work, we experiment on the Fact Extraction and VERification (FEVER) dataset (Thorne et al., 2018a), which is one of the first which provides sentence-level annotations. (An Arabic corpus (Baly et al., 2018) has been recently released.) A shared task corresponding to the dataset was floated that required verification of an input claim with potential evidence in a large database of about 5 million Wikipedia documents, and also provided a standardized benchmark setting which enabled easy and fair comparison. Table 1 lists the dataset splits and sizes.

Split	Supports	Refutes	NotEnough Info
train	80,035	29,775	35,639
dev	3,333	3,333	3,333
test	3,333	3,333	3,333
reserved	6,666	6,666	6,666

Table 1: Statistics of claims in FEVER

Several attempts have been made to tackle the task defined by FEVER, the most notable ones being (Nie et al., 2018; Yoneda et al., 2018; Hanselowski et al., 2018) which secured the 1st, 2nd and 3rd place on this shared task respectively (Thorne et al., 2018b). Diverse methods were applied, mostly using task-specific features which allowed them to beat the baseline given by (Thorne et al., 2018a). In this paper, we propose a completely task-agnostic system, AttentiveChecker to tackle the FEVER task.

AttentiveChecker is a pipelined system consisting of three identical Bi-Directional Attention Flow (BIDAF) networks, which are multi-layer hierarchical networks that represent the context at different levels of granularity. We use a bi-directional attention flow mechanism where we allow the context vector at each step to flow to the next layers in the BIDAF model. This helps to obtain a query-aware context representation without

Proceedings of NAACL-HLT 2019, pages 2218–2222
Minneapolis, Minnesota, June 2 - June 7, 2019.

early summarization. This is different from previously used attention layers employed in (Sordoni et al., 2016), (Shen et al., 2017) where the query and context are summarized into a single feature vector. AttentiveChecker achieves a FEVER Score of 66.72 on the test set, which beats the 1st ranked system (Nie et al., 2018) by more than 2 points.

2 Task Definition

The task can be described as verifying a claim using evidence from Wikipedia. The system must label the claim as SUPPORTED or REFUTED based on the evidence from Wikipedia or NotEnoughInfo if there is not sufficient evidence to either support or refute it. The system must also extract textual evidence (a set of sentences from Wikipedia pages) that support or refute the claim. A prediction is said to be correct only if both (a). the label is correct and (b). the predicted evidence set (containing at most five sentences) covers the annotated evidence set. The accuracy in percentage of such predictions is called the FEVER score. The overall task can be compartmentalized into three distinct subtasks: (i). identifying relevant documents from Wikipedia (Document Retrieval), (ii). selecting sentences forming the evidence from the documents (Sentence Selection) and (iii). classifying the claim w.r.t. collected evidence (Claim Verification).

2.1 Document Retrieval

For this sub-task, we provide the first sentence of the document and the claim as the two input sequences to the BIDAF model which outputs the probability of selecting the current document as evidence. As the number of documents is huge, we first reduce the search space by performing keyword match with titles of Wikipedia pages i.e. the document is selected if there is an exact match between the title and a span of text in the input claim. We use our BIDAF model to rank the chosen documents in order of relevance. The top-k documents based on their score are shortlisted for the next level.

2.2 Sentence Selection

For this sub-task, we provide (i). each sentence of the documents in the evidence set and (ii). the claim as the two input sequences to the BIDAF model which outputs the probability of selecting the current sentence as an evidential sentence. Since the search space is already reduced by Document Retrieval, we can directly traverse all the sentences and compare them with the claim using the BIDAF model. We rank all the sentences in every document from the evidence set and choose the top-k sentences.

2.3 Claim Verification

For this sub-task, we provide (i) the claim, and (ii) all evidential sentences together with the corresponding document names (to address coreference issues) as the two input sequences to our BIDAF model. The BIDAF model outputs the scores for three labels, namely SUPPORTED, REFUTED and NotEnoughInfo. Then the claim is labelled as the one with the highest score. Note that in order to have fair comparison across methods, the FEVER challenge limits the sentences in the evidence to a maximum of five. Also in the test set of FEVER data, the number of sentences providing evidence is at most five.

3 The BIDAF Model

In this section, we will describe the architecture of the Bi-Directional Attention Flow (BIDAF) model which constitutes the basic building block of AttentiveChecker. In each stage of the pipeline, the BIDAF model takes two input sequences and outputs labels based on the particular sub-task being performed. Let X and Y denote two input word sequences of length m and n respectively. The BIDAF model consists of four layers: (i). the embedding layer takes raw text sequences X and Y as input and encodes them into suitable vector sequences $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$, (ii). the attention layer takes $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$ as input, computes the attention scores of each sequence w.r.t. the other, and outputs two attended sequences $\mathbf{C}$ and $\mathbf{D}$, (iii). the modeling layer takes $\mathbf{C}$ and $\mathbf{D}$ as input and outputs two fixed size vectors $\hat{C}$ and $\hat{D}$ which capture the semantic similarity between the two sequences, and (iv). the output layer takes $\hat{C}$ and $\hat{D}$ as input and provides the scores for the output labels. The layers are described below in detail.

Embedding Layer: In the embedding layer the input sequences are encoded at three levels of granularity viz. character, word and context. We obtain the character-level embedding of each word using Convolutional Neural Networks (CNN) as described in (Kim, 2014). For word level encoding, we use pre-trained word vectors, to obtain the word embedding of each word in the input sequences. Corresponding to each word, we output a vector concatenating the word level and character level encoding. Let $\mathbf{X}'$ denote the sequence of concatenated vectors for the input word sequence X. We use a Bi-directional Long Short-Term Memory Network (BiLSTM) on $\mathbf{X}'$, to model the temporal interactions between words within each sequence and thus obtain the contextual embedding :

$$\hat{\mathbf{A}} = \mathbf{BiLSTM}(\mathbf{X}') \in \mathbb{R}^{d_0 \times m}$$

where $\hat{\mathbf{A}}$ denotes the sequence of all output vectors of the BiLSTM. Similarly we get a sequence $\hat{\mathbf{B}} \in \mathbb{R}^{d_0 \times n}$ for the sequence Y. Note that the character-level embeddings obviate the need for task-specific embeddings or features (e.g. those used by (Nie et al., 2018) for claim verification), as character-level embeddings can encode a far more generalized set like numeric sequences, misspellings, emoticons or other languages.

Attention Layer: Intuitively, the attention layer give higher importance or weight to those parts of a sequence which overlap with parts of the other sequence. We compute attention for the two sequences $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$ with respect to each other. Here we compute attention in both directions: from first sequence to second sequence and vice versa. To achieve this we make use of a similarity matrix $\mathbf{S} \in \mathbb{R}^{m \times n}$ where $\mathbf{S_{ij}}$ indicates the similarity (or attention score) between the i^{th} word in the first sequence and the j^{th} word in the second sequence and is computed by applying a linear mapping after a single layer perceptron stage on the i^{th} column vector of the first sequence and the j^{th} column vector of the second sequence (Hermann et al., 2015).

$$\mathbf{S_{ij}} = \mathbf{W_1}^{\intercal}.\tanh(\mathbf{W_2}.[\hat{\mathbf{A}}_i : \hat{\mathbf{B}}_j] + \mathbf{b}) \in \mathbb{R}$$

where $\mathbf{W_1}$, $\mathbf{W_2}$ indicate trainable weight matrices, $\mathbf{b}$ indicates trainable bias matrix, $\hat{\mathbf{A}}_i$, $\hat{\mathbf{B}}_j$ indicate i^{th} column vector of $\hat{\mathbf{A}}$ and j^{th} column vector of $\hat{\mathbf{B}}$ respectively. : indicates vector concatenation. The context vector for the i^{th} word of the sequence $\hat{\mathbf{A}}$ w.r.t. the sequence $\hat{\mathbf{B}}$ is given by

$$\tilde{\mathbf{A}}_i = \sum_j \alpha_{ij} \hat{\mathbf{B}}_j \in \mathbb{R}^{d_0}$$

where $\alpha_{ij} = \text{softmax}_j(\mathbf{S_{ij}}) = \frac{\exp(\mathbf{S_{ij}})}{\sum_{j=1}^{n} \exp(\mathbf{S_{ij}})}$.

Finally we obtain the attention vector sequence for the sequence X as $\mathbf{C} \in \mathbb{R}^{d_1 \times m}$ by adding ReLU after applying single layer perceptron to the vector obtained by concatenating the i^{th} column vector of contextual embedding ($\hat{\mathbf{A}}$) and i^{th} column vector of context vectors ($\tilde{\mathbf{A}}$):

$$\mathbf{C}_i = \max(0, \mathbf{W}.[\hat{\mathbf{A}}_i : \tilde{\mathbf{A}}_i] + \mathbf{b}) \in \mathbb{R}^{d_1}$$

where $\mathbf{C}_i$, $\mathbf{W}$, $\mathbf{b}$ indicate i^{th} column vector of $\mathbf{C}$ corresponding to the i^{th} word of X, trainable weight matrix, trainable bias matrix, respectively; : indicates concatenation of vectors. Each column vector of $\mathbf{C}$ can be considered as the Y-aware representation of each word in the sequence X. The above computation is repeated to obtain the context vector $\tilde{\mathbf{B}}$ and subsequently the attention vector sequence $\mathbf{D} \in \mathbb{R}^{d_1 \times n}$ for Y.

Modeling Layer: We apply bi-directional LSTM to the obtained sequence $\mathbf{C}$ for X to obtain a new sequence $\tilde{\mathbf{C}}$

$$\tilde{\mathbf{C}} = \mathbf{BiLSTM}(\mathbf{C}) \in \mathbb{R}^{d_2 \times m}$$

and then take the concatenation of the final forward and backward outputs of the BiLSTM to obtain a fixed size vector representation $\hat{C} = \overleftarrow{\tilde{\mathbf{C}}}_1 : \overrightarrow{\tilde{\mathbf{C}}}_m \in \mathbb{R}^{2d_2}$ which captures the semantic interaction between the two sequences because of the attention applied in the previous layer. This is different from the embedding layer, which captures the interaction among words of one sequence independent of the other sequence. Similarly we get a sequence $\tilde{\mathbf{D}} \in \mathbb{R}^{d_2 \times n}$ and a vector $\hat{D} = \overleftarrow{\tilde{\mathbf{D}}}_1 : \overrightarrow{\tilde{\mathbf{D}}}_n \in \mathbb{R}^{2d_2}$ for Y.

Output Layer: To quantify the semantic similarity between the two sequences, we apply the inverse exponential of the Manhattan distance (M) as suggested in (Mueller and Thyagarajan, 2016) to the representations obtained from the modeling layer.

$$\mathbf{O} = M(\hat{C}, \hat{D}) = \exp(-||\hat{C} - \hat{D}||_1)$$

Then $\mathbf{O}$ is fed to a single layer perceptron, to obtain the required sub-task specific output. For document retrieval and sentence selection, we have one output neuron in the single layer perceptron which indicates the probability of selecting the current document or sentence as evidence, while for claim verification, we have three output neurons indicating the scores for three labels, namely SUPPORTED, REFUTED and NotEnoughInfo.

We note that although the output layer must necessarily be sub-task specific (since the objective of each subtask is different), however the difference in architecture is only in the number of output neurons.

4 Results

In this section we first present the results for the full system and then the ablation results for each stage of the pipeline.

Full Pipelined system: We evaluated our complete system with all components on the test set by setting k=5 for both document retrieval and sentence selection. We found that the accuracy values obtained by AttentiveChecker (a). with the requirement to provide correct sentences as evidence (FEVER Score) and (b). without the requirement to provide correct sentences as evidence (Label Accuracy) for the SUPPORTED/REFUTED labels are 66.72 and 69.98 respectively. Table 4 compares performance of AttentiveChecker with two baselines (i). the FEVER baseline given by (Thorne et al., 2018a) and (ii). NSMN (Nie et al., 2018). We observe that AttentiveChecker performs better than the baselines on the overall task.

Task	Metric	FEVER Baseline	NSMN	Our System
Full System	Label Acc.	50.91	68.16	69.98
Full System	FEVER Score	31.87	64.23	**66.72**

Table 2: Performance of AttentiveChecker on the test set vis-a-vis the baseline systems for k=5.

NSMN (Nie et al., 2018) is a homogeneous BiLSTM-based pipeline but still uses task-specific features as input for claim verification. The key difference in AttentiveChecker compared to NSMN is the attention layer which we claim to be a better way of matching corresponding parts of the two sequences than the sequence alignment which is done in the analogous 'alignment layer' of NSMN. This attention layer is the major reason behind our improvement over NSMN and justifies the name of our system.

We now present the ablation results for the individual pipeline stages.

Document Retrieval & Sentence Selection: Table 4 shows the performance of our document retrieval and sentence selection systems on the dev set for different values of k (no. of documents/sentences retrieved). We report the Oracle Accuracy which is the upper bound of the FEVER score assuming perfect downstream stages.

k	Oracle Acc. (Document Retrieval)	Oracle Acc. (Sentence Selection)
3	93.30	82.37
5	94.05	88.23
7	94.15	88.24

Table 3: Performance of the retrieval systems on the dev set for top-k retrieval using k = 3, k = 5, and k =7

Claim Verification: To understand how well AttentiveChecker performs in this sub-task, we performed an oracle evaluation on the dev set by providing a gold standard evidence set and achieved an accuracy of 90.63 (this has to be done with $k = 5$ as per requirement of the shared task). The ablation results are summarized in Table 4 for k=5 and compared with the baselines. We observe that AttentiveChecker performs better in most sub-tasks (except sentence selection where it falls marginally short) compared to the baselines.

Task	Metric	FEVER Baseline	NSMN	Our System
Doc. Retrieval	Oracle Acc.	70.20	92.42	94.05
Sent. Selection	Oracle Acc.	62.81	91.19*	88.23
Claim Verif.	Oracle Acc.	88.00	N/A	90.63

Table 4: Ablation results of pipeline stages on the dev set vis-a-vis the baseline systems for k=5.
*With Annealed Sampling. Score without it is 86.65.

5 Conclusion

We developed a homogeneous BIDAF model for all three FEVER subtasks achieving the state-of-the-art on the overall task. Our system is completely task-agnostic and can therefore be transferred to other similar tasks (e.g. exaggeration detection) if need be. For the first time in this task, we have used a query-aware bi-directional attention model that avoids early summarization. Although the improvement in the FEVER Score appears modest (2 points), it is still significant considering the hardness of the problem.

Abstract

Scholars in inter-disciplinary fields like the Digital Humanities are increasingly interested in semantic annotation of specialized corpora. Yet, under-resourced languages, imperfect or noisily structured data, and user-specific classification tasks make it difficult to meet their needs using off-the-shelf models. Manual annotation of large corpora from scratch, meanwhile, can be prohibitively expensive. Thus, we propose an active learning solution for named entity recognition, attempting to maximize a custom model's improvement per additional unit of manual annotation. Our system robustly handles any domain or user-defined label set and requires no external resources, enabling quality named entity recognition for Humanities corpora where such resources are not available. Evaluating on typologically disparate languages and datasets, we reduce required annotation by 20-60% and greatly outperform a competitive active learning baseline.

1 Introduction

Reaping the benefits of recent advances in Named Entity Recognition (NER) is challenging when dealing with under-resourced languages, niche domains, imperfect or noisily structured data, or user-specific classification tasks. Scholars in inter-disciplinary fields like the Digital Humanities (DH) are increasingly interested in semantic annotation of specialized corpora that invoke many of these challenges. Thus, such corpora cannot easily be annotated automatically with blackbox, off-the-shelf NER models. Manual annotation of large corpora from scratch, meanwhile, can be prohibitively costly. Successful DH initiatives like the Pelagios Commons (Simon et al., 2016), which collects geospatial data from historical sources, often require extensive funding, relying on considerable manual annotation (Simon et al., 2017).

To this end, we introduce the Humanities Entity Recognizer (HER),[1] a whitebox toolkit for build-your-own NER models, freely available for public use. HER robustly handles any domain and user-defined label set, guiding users through an active learning process whereby sentences are chosen for manual annotation that are maximally informative to the model. Informativeness is determined based on novel interpretations of the *uncertainty*, *representativeness*, and *diversity* criteria proposed by Shen et al. (2004). In contrast to literature emphasizing the disproportionate or exclusive importance of uncertainty (Shen et al., 2017; Zhu et al., 2008; Olsson, 2009), we observe significant improvements by integrating all three criteria.

In addition to a robust active learning based NER toolkit, we also contribute a novel evaluation framework. This *inclusive* framework considers the accuracy with which an entire corpus is annotated, regardless of which instances are annotated manually versus automatically, such that no instance is held out when the active learning algorithm considers candidates for annotation. The standard, *exclusive* evaluation framework, by contrast, only measures the accuracy of the final trained model's predictions on a held out test set. Thus, the inclusive framework is relevant to the user who wants to annotate a finite corpus as fast and as accurately as possible by any means necessary, whereas the exclusive framework is relevant to the user who wants to build an NER tool that can generalize well to other corpora.

We conduct extensive experiments comparing several combinations of active learning algorithms and NER model architectures in both frameworks across many typologically diverse languages and domains. The systematic differences between inclusive and exclusive results demonstrate that while deep NER model architectures

Minneapolis, Minnesota, June 2 - June 7, 2019.

(Lample et al., 2016) are highly preferable for tagging held out sentences, shallow models (Lafferty et al., 2001) perform better on sentences that could have been chosen for manual annotation but were not selected by the active learning algorithm. We argue for the importance of considering both frameworks when evaluating an active learning approach, as the intended application determines which framework is more relevant and thus, which model should be employed. Controlling for the NER model, HER's active learning sentence ranking component achieves significant improvement over a competitive baseline (Shen et al., 2017). Because HER does not reference the inference model during sentence ranking, this provides counter evidence to Lowell et al. (2018)'s hypothesis that *non-native* active learning is suboptimal.

2 Related Work

The best known NER systems among humanists are Stanford NER (Finkel et al., 2005), with pretrained models in several languages and an interface for building new models, and among researchers interested in NER for spatial research, the Edinburgh Geoparser (Grover et al., 2010), with fine grained NER for English. Erdmann et al. (2016) and Sprugnoli (2018), among others, have shown that such off-the-shelf models can be substantially improved on DH-relevant data. Work such as Smith and Crane (2001) and Simon et al. (2016) represent a large community mining such data for geospatial entities. Additional DH work on NER concerns the impact of input data structure and noisy optical character recognition (Van Hooland et al., 2013; Kettunen et al., 2017).

Low Resource NER Language agnostic NER is highly desirable, yet limited by the data available in the least resourced languages. Curran and Clark (2003) demonstrate that careful feature engineering can be typologically robust, though data hungry neural architectures have achieved state-of-the-art performance without feature engineering (Lample et al., 2016). To enable neural architectures in low resource environments, many approaches leverage external resources (Al-Rfou et al., 2015). Cotterell and Duh (2017), for instance, harvest silver annotations from structured Wikipedia data and build models for typologically diverse languages, though their approach is limited to specific domains and label sets. Lin and Lu (2018) adapt well-resourced NER systems to low resource target domains, given minimal annotation and word embeddings in domain. Several translation-based approaches leverage better resourced languages by inducing lexical information from multi-lingual resources (Bharadwaj et al., 2016; Nguyen and Chiang, 2017; Xie et al., 2018). In a slightly different vein, Shang et al. (2018) use dictionaries as distant supervision to resolve entity ambiguity. Unfortunately, external resources are not always publicly available. It is in fact impossible to replicate many of the above studies without a government contract and extensive knowledge of linguistic resources, limiting their applicability to many DH scenarios. Mayhew et al. (2017) suggest manually building bilingual dictionaries when no other translation resources are available to facilitate their method, though active learning provides a more direct means of improving NER quality.

Active Learning Active learning seeks to maximize the performance of a model while minimizing the manual annotation required to train it. Shen et al. (2004) define three broad criteria for determining which data will be most *informative* to the model if annotated: *uncertainty*, where instances which confuse the model are given priority; *diversity*, where instances that would expand the model's coverage are prioritized; and *representativeness*, prioritizing instances that best approximate the true distribution over all instances. Uncertainty-based approaches outperform other single-criterion approaches, though many works, primarily in Computer Vision, demonstrate that considering diversity reduces repetitive training examples and representativeness reduces outlier sampling (Roy and McCallum, 2001; Zhu et al., 2003; Settles and Craven, 2008; Zhu et al., 2008; Olsson, 2009; Gu et al., 2014; He et al., 2014; Yang et al., 2015; Wang et al., 2018b).

For active learning in NER, Shen et al. (2017) propose the uncertainty-based metric maximized normalized log-probability (MNLP). It prioritizes sentences based on the length normalized log probability of the model's predicted label sequence. To make neural active learning tractable, they shift workload to lighter convolutional neural networks (CNN) and update weights after each manual annotation batch instead of retraining from scratch. They demonstrate state-of-the-art performance with MNLP, though Lowell et al. (2018) show its improvement above random sampling to be less dramatic, as do our experiments. Low-

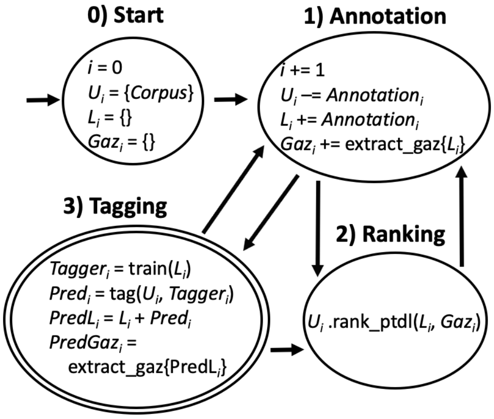

Figure 1: High level HER system architecture. Unlabeled sentences in U are manually labeled and moved to L, enabling iterative updates of gazetteers, the NER model, and the informativity ranking of sentences in U.

ell et al. (2018) compare calculating MNLP from the *native* inference model and from a *non-native* model with a separate architecture. They conclude that non-native models are ill-suited to active learning, which our findings using more robust informativeness criteria contradict.

3 The Humanities Entity Recognizer

As illustrated in Figure 1, HER consists of three components: (1) a human $User$ who provides an unlabeled corpus U at state 0 and annotates selected sentences in state 1, thus moving them from U to the labeled corpus L, (2) an active learning engine, $Ranker$, that ranks sentences from U in state 2 for $User$ to annotate based on how informative they might be to (3), the NER model, $Tagger$, to be trained on L in state 3.[2]

All states are linked by an interface that "white-boxes" the process. It advises $User$ on qualitative observations which might improve performance by manually interacting with $Ranker$, e.g., removing problematic gazetteer entries, or with $Tagger$, e.g., forcing it to sample some known minority labels. The contributions of the interface will not be reflected in our human-out-of-the-loop experiments on standard datasets, as these evaluate only the contributions of $Ranker$ and $Tagger$. Thus, reported performances should be considered a lower bound that can often be improved with minimal human intervention.

3.1 Ranking Sentences by Informativeness

At state 1 with i=0, $User$ is prompted to annotate randomly ordered sentences until 50-100 named entities are labeled. We use a 200-sentence seed for all experiments except that of Section 4.1, where an entity-sparse corpus requires a 300-sentence seed. Such a small seed, often annotated in less than 30 minutes, is sufficient to support $Ranker$'s *Pre-Tag DeLex* (PTDL) algorithm in state 2. PTDL uses only shallow, fast Conditional Random Fields (CRF) to avoid delaying manual annotation. As demonstrated on a sample corpus in Figure 2, PTDL involves four subtasks: *pre-tagging*, *delexicalized tagging*, *vocabulary weighting* and *sentence ranking*.

Pre-tagging We naively and greedily *pre-tag* U with binary entity–non-entity labels based on gazetteer matches. Hence, every n-gram in U matching a named entity from a gazetteer gets pre-tagged as such unless it overlaps with a longer named entity. State 2 cannot occur until the seed has been annotated, so Gaz will never be empty, as entities are automatically extracted into gazetteers after each annotation batch in state 1.

Delexicalized Tagging $U_{pre-tagged}$ is divided into U_{NE}, containing sentences with at least one pre-tagged named entity, and its complement, U_{noNE}. We train a *trusted* NER model (t) on L and two *biased* models (b_1 and b_2) on L plus random mutually exclusive halves of U_{NE}. b_1 and b_2 are biased in that they use non-gold data (U_{NE}) exhibiting an exaggerated density of named entities. Models are trained using only *delexicalized* features, which, unlike character n-grams for example, do not directly reference the focal word or its form. Many delexicalized features are context-based, like preceding and following words. Trained thus, models are less hampered by the class imbalance problem (Japkowicz, 2000), more likely to predict more named entities, and more capable of determining which Out Of Vocabulary (OOV) lexical items (in U but not L) make good named entity candidates.

Vocabulary Weighting After tagging U with delexicalized models, t, b_1, and b_2, OOVs are scored by weighted frequency. Weights are sums determined by which models tagged the OOV in an entity at least once. t contributes 1 to the sum and each biased model, $\frac{1}{2}$. OOVs not tagged by any model recieve a negligible positive weight, ϵ.

---

[2] In our experiments, we assume no previous annotation or pre-existing gazetteers at state 0, though, in practice, HER robustly leverages non-empty L_0 and/or Gaz_0 when available.

Figure 2: Step-by-step example outputs from ranking unlabeled sentences in a sample corpus with PTDL.

This motivates PTDL to target frequent OOVs after exhausting OOVs more likely to be named entities.

Sentence Ranking As shown in Figure 2, sentences in U are ranked by the sum of scores of unique OOVs therein, normalized by the word length of the sentence. OOVs occurring in higher ranked sentences do not count toward this sum.

While typical active learning strategies for NER rely on the inference model's output probabilities, these are noisy, especially given scarce annotation. Data-scarce models lexically memorize training instances, yielding high precision at the expense of recall. They struggle to model non-lexical features more subtly correlated with entity status but also more likely to occur on OOVs. Hence, data-scarce models know what they know but are somewhat equally perplexed by everything else (Li et al., 2008). For this reason, uncertainty-based active learners can suffer from problematically weak discriminative power in addition to redundant and outlier-prone sampling.

By forcing reliance on delexicalized features and biasing models toward recall, our three-criteria approach identifies frequent (representativeness) OOV words (diversity) that are plausible candidate members of named entities. These make for better indicators of where the model may fail (uncertainty) because named entities are minority labels in NER and minority labels are challenging.

3.2 Sentence Tagging Architectures

$User$ can stop iteratively annotating and re-ranking U at any time to train a $Tagger$ on L to perform the full NER task on U (state 3). L is combined with $Tagger$'s predictions on U ($Pred$) to form $PredL$, from which an imperfect gazetteer is extracted ($PredGaz$). $User$ must inspect these to determine if additional annotation is required. We explore three $Tagger$ architectures:

CRF For tagging with Okazaki (2007)'s feature-based CRF, $Tagger$ first trains preliminary models on L, cross-validating on folds of the random seed. Each model leverages a unique permutation drawn from a universal set of features. The best performing feature set is used to train the final model. Training and inference are fast, even with preliminary cross-validation. In the exclusive evaluation, CRF is the best tagger until about 40K tokens of training data are acquired. In the inclusive evaluation, CRF's tendency to overfit is rewarded, as it outperforms both deep models regardless of corpus size.

CNN-BiLSTM The near state-of-the-art architecture proposed by Shen et al. (2017) aims to reduce training with minimal harm to accuracy. It leverages CNNs—as opposed to slower recurrent networks—for character and word encoding, and a bidirectional long short-term memory network (BiLSTM) for tags. CNN-BiLSTM outperforms all other models in the exclusive evaluation for a stretch of the learning curve between about 40K tokens acquired and 125K. While faster than the other deep model considered here, training time is slower than the CRF and computationally costly.

BiLSTM-CRF The state-of-the-art BiLSTM-CRF architecture of (Lample et al., 2016) projects a sequence of word embeddings to a character level BiLSTM which in turn projects into a CRF at the tag level, with an additional hidden layer between the BiLSTM and CRF. In our experiments, BiLSTM-CRF surpasses CNN-BiLSTM performance once about 125K tokens are acquired.

3.3 HER in the Digital Humanities

HER was developed to benefit diverse DH projects. It is currently facilitating three such ventures.

The Herodotos Project (`u.osu.edu/herodotos`) aims at cataloguing ancient ethnogroups and their interactions (Boeten, 2015; de Naegel, 2015). HER is used to identify such groups in Classical Greek and Latin texts. Manually annotated data as well as a trained NER tagger are freely available from `github.com/alexerdmann/Herodotos-Project-Latin-NER-Tagger-Annotation`.

Artl@s `artlas.huma-num.fr` is a global database of art historical catalogs from the 19th and 20th centuries for the scholarly study of the diffusion and globalization of art. HER serves as a method for mining semi-structured texts characterized by noisy OCR and recurrent patterns of granular named entities.

Visualizing Medieval Places Wrisley (2017) concerns the study of recurrent places found within a mixed-genre corpus of digitized medieval French texts. NER has heretofore been challenged by sparsity from the unstandardized orthography. The related Open Medieval French project (`github.com/OpenMedFr`) benefits from HER's robust handling of sparsity, using the system to create open data regarding people and places referenced in medieval French texts.

4 Experiments

We now describe several experiments evaluating HER's performance on diverse corpora. When a standard test set is available, we perform inclusive evaluation on the combined train and dev sets and evaluate exclusively on test. Otherwise, we only evaluate inclusively. In both settings, we compare multiple combinations of ranking systems and taggers over a learning curve, reporting F1 exact match accuracy of identified entities. In all figures, line dashing (contiguous, dashed, or dotted) denotes inference model (CRF, BiLSTM-CRF, or CNN-BiLSTM), whereas line accents (stars, circles, triangles, or squares) denotes active learning method. Besides PTDL, we also consider a random active learning method (RAND), MNLP, and Erdmann et al. (2016)'s CAP algorithm. Like PTDL, CAP ranks sentences based on frequency weighted OOVs, but calculates weights based on capitalization patterns, prioritizing capitalized OOVs occurring in non-sentence initial position.

Quantity of training data is reported as percentage of the entire corpus for inclusive evaluations, and as tokens actively annotated (i.e., not counting the random seed sentences) for exclusive evaluations. For consistency, following seed annotation, we always fetch additional annotation batches at the following intervals, in tokens: 1K, 4K, 5K, 10K, 20K until we reach 100K total tokens, 50K until 300K total, 100K until 500K total, and 250K from there. For all experiments leveraging neural taggers, we use freely available pretrained embeddings (Grave et al., 2018), except for Latin, where we train fasttext (Bojanowski et al., 2017) embeddings on the Perseus (Smith et al., 2000) and Latin Library collections with default parameters (using pretrained embeddings yield small performance boosts that decrease with additional training data). We conclude this section with a direct comparison to the recently proposed active learning pipeline of Shen et al. (2017) and their MNLP ranking algorithm.

4.1 Consistency of Non-deterministic Results

Because the active learning pipeline involves taking a random seed and many of the experiments on larger corpora could not be averaged over several runs, we first measure performance variation as a function of ranking algorithm and quantity of annotation. Figure 3 displays our findings on a sample corpus of about 250K tokens[3] in five diverse, pre-1920 prose genres extracted from the FranText corpus (`www.frantext.fr`) and annotated for

---

[3] HER considers sentence boundaries to be tokens, as this helps users locate words, i.e., the line number will correspond to token number when rendered in CoNLL format.

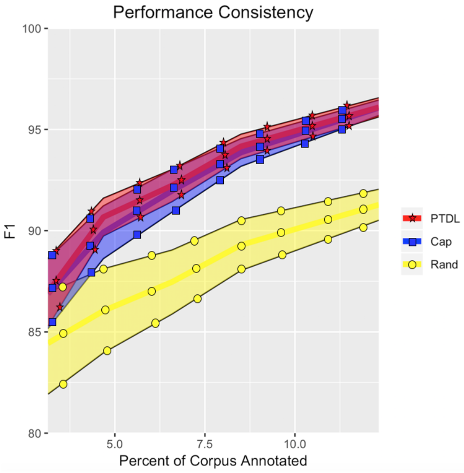

Figure 3: ±1 standard deviation bands around the mean performance of each sentence ranking algorithm using the CRF tagger over 100 inclusive evaluations on our FranText corpus.

geospatial entities. Our sample covers topics from gastronomy to travel, exhibiting inconsistent entity density characteristic of DH corpora.

Noise is much higher for the first few batches of annotation, particularly due to the low recall of data scarce models. Reluctant to generalize, they behave more like look-up tables extracted from the seed, exacerbating the effect of random seed variation. After about 20K tokens annotated or 10% of the corpus, performance becomes much more predictable. All algorithms start with about a 5 point spread for ±1 standard deviation, with means around 70 F, and all exhibit the diminishing variation trend, though RAND does less so. Unlike CAP and PTDL, subsequent annotation batches in RAND are not predictable from previous annotation batches. This results in a spread of 0.76 after annotating 12.33% of the corpus, whereas the other algorithms are close to 0.4.

While we only tested variation on one corpus, multiple runs on other corpora tended to reflect the same diminishing variation trends despite marked differences in entity granularity, density or corpus size. Switching to the exclusive evaluation only minimally increases variation. It was not feasible to rigorously test variation using neural taggers, though we note that they are somewhat more prone to seed related noise which does not diminish as rapidly as it does for CRF with more annotation.

In terms of performance, random annotation requires one to label between 23% and 31% of the corpus to achieve the performance of PTDL after labeling just 12%. For this corpus, PTDL reduces annotation time between 46% and 60%, requiring only 32K tokens from annotators instead of 60-80K. CAP's competitiveness with PTDL is not surprising given that French uses the capitalization standards it is designed to exploit. Both algorithms achieve 15% error reduction above RAND after the first post-seed annotation batch (left edge of Figure 3), increasing monotonically to 55% error reduction after the fifth batch (right edge).

4.2 Inclusive Versus Exclusive Evaluation

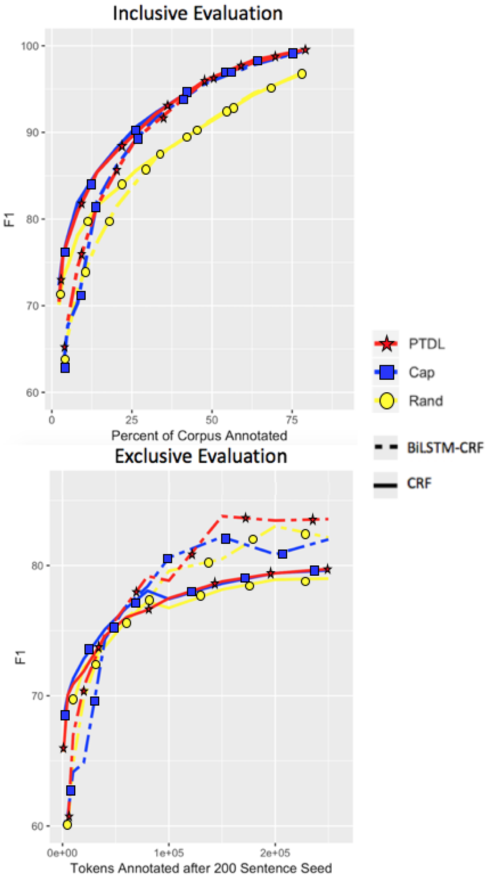

Figure 4: Comparing shallow and deep learning architectures on inclusive and exclusive evaluations with the CoNLL Spanish corpus.

Using the Spanish CoNLL corpus (Tjong Kim Sang and De Meulder, 2003) with canonical train, dev, test splits, we examine the relationship between evaluation framework, $Ranker$, and $Tagger$ in Figure 4.[4] For the inclusive framework, $Ranker$ selects sentences from train+dev for $Tagger$ to train on, and the performance is calculated over the combination of those se-

---

[4] Lample et al. (2016) achieve 85.75 F on the exclusive evaluation, slightly beating our best BiLSTM-CRF models which sacrifice some performance for speed, switching to Adam optimization limited to 5 epochs.

lected sentences (trivially all correct) and trained $Tagger$'s predictions on the rest of train+dev. By reporting results over a learning curve, this evaluation framework is meaningful to the user whose primary goal is to produce a finite annotated corpus as efficiently and accurately as possible, a frequent concern in DH. The standard exclusive framework also gives $Ranker$ access to train+dev sentences, but calculates accuracy from $Tagger$'s predictions on the held out test set. The exclusive framework is thus more meaningful for future users of $Tagger$ who need the tool to generalize to sentences outside of train+dev.

In the inclusive framework, regardless of corpus size, BiLSTM-CRFs do not surpass CRFs until the accuracy is so high that the distinction is negligible. Promoting overfitting by reducing dropout did not significantly affect this result. In the exclusive framework, BiLSTM-CRF surpasses CRF around 50K tokens annotated. This holds for all languages and corpora we investigate, suggesting quantity of data annotated is more predictive of exclusive performance trends, whereas proportion of the corpus annotated better predicts inclusive trends.

4.3 Typology, Granularity, and Corpus Size

We consider the effect of language typology, label scheme granularity, and corpus size on inclusive and exclusive evaluations of taggers and rankers.

4.3.1 Insights from German

We repeat our experiments from Section 4.2 on the German NER corpus, GermEval (Benikova et al., 2014), to determine how robust our findings are to a larger corpus with finer label granularity and different capitalization standards. Our results in Figure 5 confirm many of our previous findings, with BiLSTM-CRFs overtaking CRFs of the same ranker after 50K tokens annotated on the exclusive evaluation. Shallow CRFs again dominate inclusively, and again, exclusive performance is less predictable, though the contribution of PTDL is more obvious.

GermEval contains over 520K tokens to Spanish CoNLL's 321K, showing that deep models are not just slower to overtake shallow models in the inclusive evaluation, but they only asymptotically approach shallow performance.[5] Furthermore, the finer grained named entity distinctions in GermEval do not seem to affect our previous findings, but do cause BiLSTM-CRF to start slowly, as the model does not begin training until all possible labels manifest in the training set. While this is merely an effect of programming choices, it provides interesting insights. For instance, BiLSTM-CRF CAP models consistently start later than RAND which starts later than PTDL, meaning that PTDL is doing well on the diversity criteria, whereas CAP likely struggles because it relies on English-like capitalization standards. Since German capitalizes all nouns, CAP struggles here, having to search through many capitalized OOVs before finding named entities of each category. By not considering uncapitalized OOVs as named entity candidates, it can systematically avoid entire labels which do not take capitalization, such as dates. Thus, while PTDL performs robustly on the GermEval dataset, CAP is only weakly superior to RAND due to the weak correlation between entity status and capitalization.

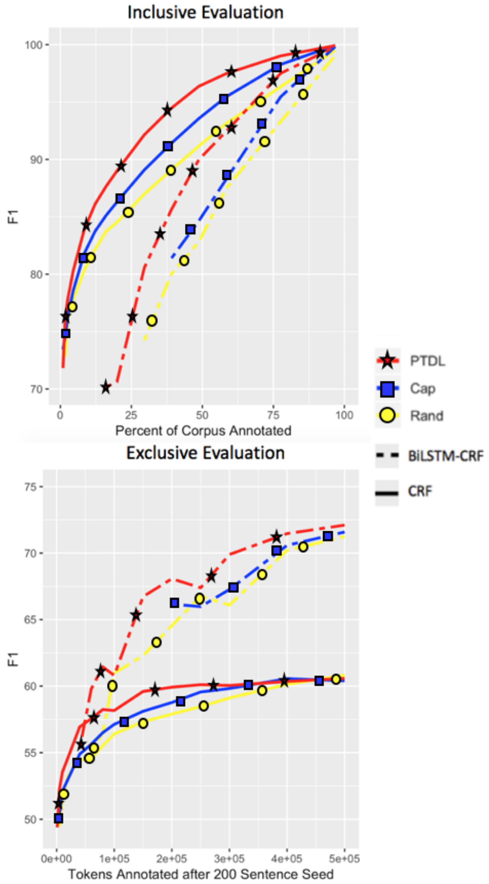

Figure 5: A comparison of shallow and deep learning architectures on inclusive and exclusive evaluations with the GermEval corpus.

---

[5] Our evaluation is equivalent to metric 3 from the shared task (Benikova et al., 2014), though our results are not comparable as we did not leverage nested labels.

4.3.2 Insights from Latin

Latin presents an opportunity to explore the impact of capitalization on ranking algorithms more thoroughly. Erdmann et al. (2016) selected their Latin corpus because English capitalization standards had been imposed during digitization, making CAP more likely to succeed. Figure 6 demonstrates that it even marginally outperforms PTDL on the corpus (left pane). However, capitalizing proper nouns is not a native attribute of Latin orthography and is not available in all digitized manuscripts, limiting the Latin texts in which CAP will succeed. The right pane in Figure 6 demonstrates this, as the same evaluation from the left pane is repeated on a lower cased version of the same corpus. The minuscule error reduction CAP achieves over RAND in this environment is due to its general preference for OOVs. Meanwhile, despite suffering from weaker named entity signals without capitalization, PTDL still manages to robustly identify what non-capitalization features are relevant, maintaining 25% error reduction over RAND. Finally, in German, where capitalization is a weak signal of entity status, PTDL is similarly better equipped to incorporate the weak signal, reducing error twice as much as CAP. Interestingly, PTDL performance in the lower cased Latin corpus almost exactly matches RAND performance on the capitalized version. This suggests the benefits of PTDL are comparable to the benefits of having English-like capitalization to mark entities.

4.3.3 Insights from Arabic

Unlike the other corpora, the news domain ANER Arabic corpus (Benajiba and Rosso, 2007) features rich templatic morphology, frequent lexical ambiguity, and an orthography lacking capitalization. Hence, not only will feature-based signals be more subtle, but the gazetteer-based pre-tagging component of PTDL will suffer from low precision, because Arabic is written in an abjad orthography where short vowels among other characters are seldom marked, making many words polysemous. Even so, PTDL significantly outperforms RAND, likely due to its ability to shift reliance to contextual features better suited for newswire, where formulaic expressions are often used to refer to certain entity types.

While PTDL compares well to RAND, it does not approach 100% accuracy after annotating 50% of the corpus as in Section 4.3.2. Besides ambiguity and lack of capitalization, this could be due to a typological bias in our "universal" feature set. Contiguous character n-grams, for example, will not capture non-concatenative subword phenomena. Going forward, we will investigate which feature sets were most useful as a function of language typology to identify gaps in our coverage.

4.4 Comparing to MNLP

Shen et al. (2017) and Lowell et al. (2018) evaluate the purely uncertainty-based MNLP active NER system on English corpora, reporting starkly different results. We address discrepancies and test the robustness of their findings by comparing MNLP to PTDL and RAND on the GermEval corpus. Results are displayed in Figure 8, with shaded regions corresponding to the range of performance over multiple runs. To compare fairly, we use the same CNN-BiLSTM tagger for all rankers and iteratively update weights instead of re-training from scratch after each annotation batch, as in Shen et al. (2017). We report results on our previously mentioned batch annotation schedule, though results were comparable using the batch schedule of Lowell et al. (2018). Shen et al. (2017) claim iterative updating does not affect accuracy significantly, though the best performing active CNN-BiLSTM in Figure 8 lags a few points behind the BiLSTM-CRF after 150K tokens annotated, with that gap reaching nearly 5 F when training on the whole corpus. Meanwhile, a CNN-BiLSTM trained from scratch on the whole corpus scores only 1 F less than the BiLSTM-CRF.

While Lowell et al. (2018) report improvement over RAND using MNLP when training on 0-10% of the corpus, we see little improvement after about 2%, and even then, PTDL greatly outperforms both. The relationship between the PTDL curves in the exclusive evaluation shows that CNN-BiLSTM is actually the optimal tagging architecture for a brief window, overtaking CRF around 30K tokens and staying in front of BiLSTM-CRF until about 125K tokens.

5 Conclusion and Future Work

We have presented the HER toolkit and its novel active learning algorithm, demonstrating robust handling of typological diversity, niche domains, and minority labels. The algorithm addresses the weak discriminative power of uncertainty-based models caused by class imbalance and precision bias. We also argued for the relevance of in-

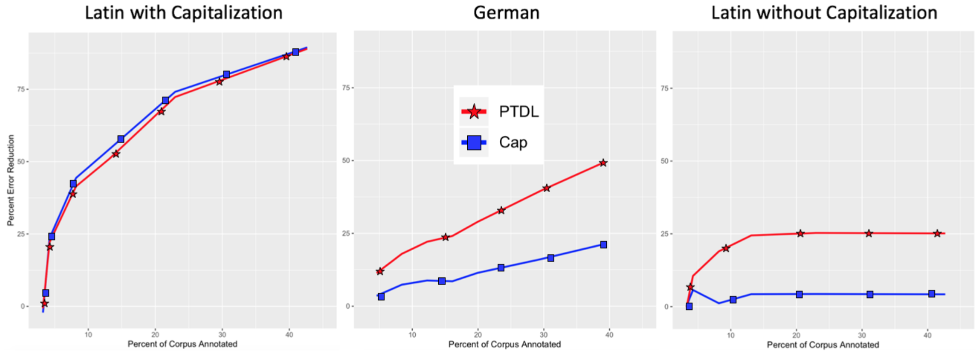

Figure 6: Percent error reduction over RAND in three corpora exhibiting typologically distinct capitalization standards. Corpora are presented in descending order of the correlation of capitalization with named entity status.

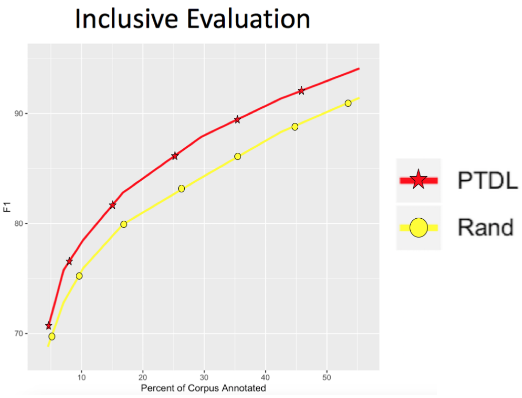

Figure 7: Effect of PTDL in the ANER Arabic corpus.

clusive evaluations, demonstrating that a shallow CRF tagger outperforms deep taggers on sentences which the active learner could have selected for training. The CRF's tendency to overfit is rewarded in this case, as the selected sentences are especially representative of the remaining sentences to be tagged. When tagging held out test sets, CRFs are only optimal until about 30K training tokens are acquired, then CNN-BiLSTMs are preferable until 125K tokens when BiLSTM-CRFs become the best high resourced tagger.

In future work, we will investigate sources of noise in performance to see if these are due to gaps in the model, idiosyncrasies of corpora, or both. Additionally, we will expand HER to model hierarchically nested entity labels. Named entities are often difficult to label deterministically, inviting a problematic level of subjectivity, which is of crucial interest in DH and should not be oversimplified. We will consider strategies such as Wang et al. (2018a)'s shift-reduced-based LSTM architecture or Sohrab and Miwa (2018)'s method of modeling the contexts of overlapping potential named entity spans with bidirectional LSTM's.

Abstract

Learning to hash via generative models has become a powerful paradigm for fast similarity search in documents retrieval. To get binary representation (i.e., hash codes), the discrete distribution prior (i.e., Bernoulli Distribution) is applied to train the variational autoencoder (VAE). However, the discrete stochastic layer is usually incompatible with the backpropagation in the training stage and thus causes a gradient flow problem. In this paper, we propose a method, Doc2hash, that solves the gradient flow problem of the discrete stochastic layer by using continuous relaxation on priors, and trains the generative model in an end-to-end manner to generate hash codes. In qualitative and quantitative experiments, we show the proposed model outperforms other state of the art methods.

1 Introduction

A popular theme for deep learning is that of representation learning, whose goal is to use existing data to learn a compact and meaningful representation when building classifiers or other predictors. Learning continuous representation has been achieving a great success in various NLP tasks, including text classification, word and sentence representation (Mikolov et al., 2013; Le and Mikolov, 2014), yet learning discrete representation is potentially more suitable for tasks we are interested in such as learning to hash.

Hashing serves as a fast solution for similarity search also called approximate nearest neighbor search. In document retrieval, semantic hashing is the strategy that turn the document into binary codes (hash codes) which capture semantic information. One can use a query (a document) to retrieve similar documents by calculating the hamming distances between their hash codes. Given the fast calculation process and the efficient storage property (one modern PC can execute millions of hamming distance computations in just a few milliseconds). This semantic hashing strategy is very attractive.

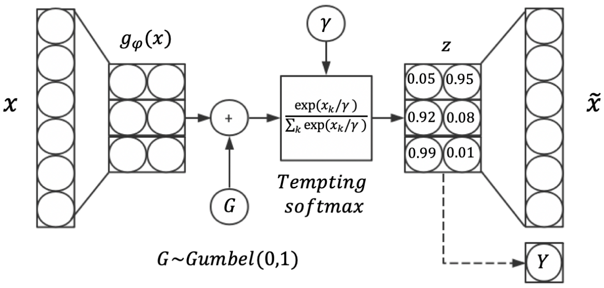

Figure 1: The end-to-end semantic hashing framework: Training the cycle $x \rightarrow z \rightarrow x$ to obtain the latent variables z. The one hot representation of discrete latent variables z has been relaxed to $\{(0.05, 0.95), (0.92, 0.08), (0.99, 0.01)\}$ by the tempting softmax. Hash codes $z_h = \{1, 0, 0\}$ is obtained via taking the $\arg\max$ of z. Y is the label/tag used in the supervised hashing

Inspired by the recent success of modeling latent variables via generative models in solving various NLP problems (van den Oord et al., 2017; Semeniuta et al., 2017; Bowman et al., 2015), Some approaches obtain binary codes of documents from a generative perspective via parameterizing models using neural networks and stochastic optimization using gradient-based techniques: (Chaidaroon and Fang, 2017) designed a two-stage training procedures to generate hash codes with variational autoencoder: (i) it first infers continuous representations of text through VAE with isotropic Gaussian distribution prior (ii) Obtain hash codes via binarizing the continuous representation of texts. Since the model parameters are not learned in an end-to-end manner, the two-stage training strategy may result in a suboptimal local optima. (Shen et al., 2018) replaced the Gaussian distribution prior with Bernoulli distribution prior so that the stochastic layer of the

Proceedings of NAACL-HLT 2019, pages 2235–2240
Minneapolis, Minnesota, June 2 - June 7, 2019.

VAE can directly produce binary codes in the latent space and train hash codes in an end-to-end manner. Unfortunately, the Bernoulli stochastic layer is non-differentiable. Although the Straight-Through (ST) estimator is adapted to propagate gradients where it skips the gradient of the stochastic layer during backpropagation (Bengio et al., 2013). The ST estimator is still a biased estimator which introduces high-variance biased gradients of objectives during the training.

In this paper, we propose a generative model with a categorical distribution prior for semantic hashing which learns binary codes of documents in an end-to-end manner. To train the generative model, instead of using the ST estimator, we use the Gumbel-Softmax trick to overcome the inability by applying the re-parameterization trick to discrete latent variables. There are two advantages: 1) a nice parameterization for a discrete (or categorical) distribution is given in terms of the Gumbel distribution (the Gumbel trick); and 2) although the corresponding function is non-continuous, it can be made continuous by applying using a continuous approximation that depends on a temperature parameter. Therefore, it produces low-variance biased gradients of the stochastic layer in the backpropagation. Our experiment shows our model achieves the state of the art performance on three standard datasets for semantic hashing.

2 Methodology

2.1 Discrete NVI Framework For Semantic Hashing

In this section, we introduce the neural variational inference (NVI) framework (Shen et al., 2018) with discrete latent variables for semantic hashing in detail. First, a generative model whose encoding distribution and decoding distribution are defined as $p(z|x), p(x|z)$. We approximate these two distributions by defining approximations $q_\phi(z|x)$, $p_\theta(x|z)$ and model them as the inference (encoding) network $g_\phi(x)$ and the generative network (decoding) $g_\theta(z)$. $x \in R^V$ is the bag of word representation of a document where V is vocabulary size. Specially, the weight schema of bag of words can be binary, TF, TFIDF. The inference network $g_\phi(x)$ produces latent variables z from x approximating the true posterior distribution $p(z|x)$ as $q_\phi(z|x)$. Then, the generative network $g_\theta(z)$ maps latent variable z back to x by approximating $p(z|x)$ as $p_\theta(x|z)$. We model the conditional probability over the word w_i as softmax:

$$p(x_i = w_i|z) = \frac{\exp(w_i g_\theta(z))}{\sum_V \exp(w_i g_\theta(z))} \quad (1)$$

where $w_i \in \{0,1\}^V$ is represented as an one-hot vector indicating the i-th word in the total vocabulary and the likelihood $p_\theta(x|z) = \prod_i p(x_i = w_i|z)$. Training the generative model that synthesizes the observed data x, we can obtain the meaningful latent variables z.

To learn discrete latent variables under the NVI framework for semantic hashing, we cast z to be the discrete random variables and assume a multivariate categorical prior on z: $p(z) \sim \mathbf{Cat}(\pi) = \prod_i^l I(z = k)\pi_{ik}$, where π_{ik} is the k-th class probability on i-th component of parameters π. In this way, the posterior distribution approximated by the encoding network is constrained in the form of $q_\phi(z|x) = \mathbf{Cat}(h)$, where $h = g_\phi(x)$ is the output of the encoding network.

2.2 Variational Low Bound of Discrete Latent Variable Training

To train the parameters θ, ϕ of the encoding network $q_\theta(z|x)$ and the decoding network $p_\phi(x|z)$, we maximize the variational low bound as same as in the VAE framework (Kingma and Welling, 2013):

$$L_{ELBO} = E_{z\sim q_\phi(z|x)}[\log \frac{q_\theta(x|z)p(z)}{q_\phi(z|x)}] \quad (2)$$

$$= E_{z\sim q_\phi(z|x)}[\log q_\theta(x|z)] - KL(q_\phi(z|x)||p(z)) \quad (3)$$

the first term is the reconstruction loss, which encourages the decoder network to learn the mapping from latent variables z to the original document x. The second term is Kullback-Leibler (KL) divergence $KL(q_\phi(z|x)||p(z))]$, which encourages the posterior distribution $q_\phi(z|x)$ to be close to the multivariate categorical prior $p(z)$. we can write the KL term in the following form:

$$KL(q_\phi(z|x)||p(z)) = \sum_i \sum_k g_\phi^{ik}(x) \log \frac{g_\phi^{ik}(x)}{\pi_{ik}} \quad (4)$$

2.3 Gradients of Discrete Stochastic Layer

To evaluate $E_{z\sim q_\phi(z|x)}$, the reparameterization trick is often employed to make the sampling process $z \sim q_\phi(z|x)$ compatible with backpropagation (Kingma and Welling, 2013). But sampling from a discrete distribution using reparameterization tricks still has problem during backpropagation. Due to the sampling from the stochastic layer usually incorporate hard threshold operators such as $\mathbf{sign(.)}$ and $\mathbf{arg\,max(.)}$ (Jang et al., 2016; Maddison et al., 2016), the stochastic layer becomes non-differentiable. In general, the solution to this issue is using the Straight-Through (ST) estimator where a biased path derivative estimator can be utilized even when z is not reparameterizable as shown in Figure 2. For example, NASH (Shen et al., 2018) passes the gradients through the Bernoulli stochastic layer using ST estimator. Specifically, they do:

$$\frac{dL}{d\phi} = \frac{dL}{dz}\frac{dz}{dg_\phi(x)}\frac{dg_\phi(x)}{d\phi} \approx \frac{dL}{dz}\frac{dg_\phi(x)}{d\phi} \quad (5)$$

where the ST estimator lets the gradients of the stochastic layer $\frac{dz}{dg_\phi(x)} \approx 1$. However, the ST estimator is backpropagating with respect to the sample-independent. It may cause discrepancies between the forward and backward pass, and thus lead to higher variance (Jang et al., 2016).

2.4 Continuous Relaxation of Discrete Stochastic Layer

As mention above, we want to learn discrete Latent variables (hash codes) by maximizing the variational low bound assuming a multivariate categorical prior. Supposed the output of the encoding network, $h = g_\phi(x)$, $h \in R^{l\times 2}$, represents the parameters of the multivariate categorical posterior $q(z|x)$. We can use reparameterization trick to draw samples of z from the categorical posterior using Gumbel distribution (Gumbel, 1954; Jang et al., 2016):

$$z_i = \arg\max_k (G_k + logh_i^k), k \in \{0, 1\} \quad (6)$$

G_1, G_2 is drawn i.i.d. from Gumbel (0, 1) = $\log(-\log(U(0, 1))$ where U is the uniform distribution. We further represent z_i as one-hot vector with 2 dimensions:

$$z_i = \text{OneHot}[\arg\max_k (G_k + logh_i^k)], k \in \{0, 1\} \quad (7)$$

discrete latent variables z can be seen as concatenation of l one-hot vectors.

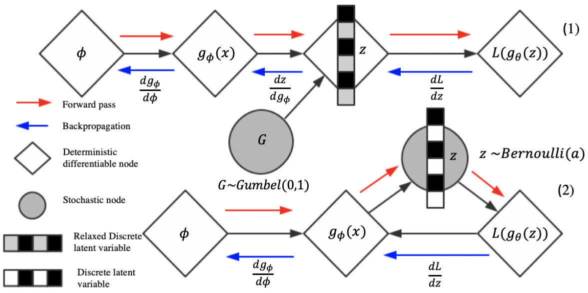

Figure 2: Gradients estimation in stochastic computation graphs (1) Gumbel-Softmax trick (2) The Straight-Through estimator, used for Bernoulli discrete variables, skips stochastic node by approximating $\frac{dz}{dg_\phi} \approx 1$

In the forward pass, we sample z from the stochastic discrete layer via Eq. 7. However, in backpropagation, we cannot pass gradient through the hard threshold operator, $\arg\max$, since it is non-differentiable. The derivative of $\arg\max$ is 0 everywhere except the boundary of state change, where it is undefined. To end this, instead of employing ST estimator to skip gradients, we use the tempting softmax as a continuous relaxation of the $\arg\max$ computation:

$$z_i = \frac{\exp((G_k + \log h_i^k)/\gamma)}{\sum_k \exp((G_k + \log h_i^k)/\gamma)}, k \in \{0, 1\} \quad (8)$$

This relaxation approximates the exactly discrete $\arg\max$ computation as temperature parameter $\gamma \rightarrow 0$ yet keeps the relative order of $(G_k + \log h_i^k)$. similar relaxation techniques have been introduced as the Gumbel-Softmax trick in (Jang et al., 2016; Maddison et al., 2016). Since Eq. 8 is differentiable, we can train the generative model in an end-to-end way via stochastic gradient descent to get the discrete latent variables (hash codes). The whole framework is summarized in the Figure 1 and the difference against the ST estimator is exemplified in the Figure 2.

2.5 Supervised Hashing

We extend our method to the supervised setting, where the mapping from latent variables z to the label y is learned, here parameterized by a two-layer multilayer perceptron (MLP) followed by a fully-connected softmax layer. To balance maximizing the variational lower bound and minimizing the discriminative loss, the following joint training objective is employed:

$$L = -L_{ELBO}(\theta, \phi, \boldsymbol{x}) + \alpha L_{dis}(\eta, \boldsymbol{z}, y) \quad (9)$$

where η refers to parameters of the MLP classifier and α controls the relative weight between the variational lower bound (L_{ELBO}) and the discriminative loss (L_{dis}). We assume a general multi-label classification setting where each document could have multiple labels/tags. $P(y_j|f(\boldsymbol{z};\eta))$ can be modeled by the logistic function defined as:

$$P(y_j|f(\boldsymbol{z},\eta)) = \frac{1}{1+\exp(-y_j^T \eta_j \boldsymbol{z})} \tag{10}$$

Table 2: Precision of the top 100 retrieved documents on Reuters dataset.

We evaluate the proposed method named Doc2hash in both supervised and unsupervised setting for semantic hashing. For unsupervised task, these baselines are selected: Locality Sensitive Hashing (LSH) (Datar et al., 2004), Stack Restricted Boltzmann Machines (Salakhutdinov and Hinton, 2009), Spectral Hashing (Weiss et al., 2009), Self taught Hashing (STH) (Zhang et al., 2010), Variational Deep Semantic Hashing (VDSH) (Chaidaroon and Fang, 2017), and the best variant of Neural Architecture for Generative Semantic Hashing (Shen et al., 2018) (NASH-DN). For the supervised task, we also compare the proposed method with kinds of baselines: Supervised Hashing with Kernels (KSH) (Liu et al., 2012), Semantic Hashing using Tags and Topic Modeling (SHTTM) (Wang et al., 2013), Supervised VDSH (VDSH-SP) and Supervised NASH (NASH-DN-S).

Table 3: Precision of the top 100 retrieved documents on RCV1 dataset.

We follow the same experimental protocol and setting used in (Shen et al., 2018; Chaidaroon and Fang, 2017). Three standard public datasets of documents are chosen for training and evaluation: Reuters (Lewis, 1997), TMC (Oza, 2010), and RCV1 (Lewis et al., 2004). We evaluate the proposed model by calculating the precision of top 100 retrieved documents based on hamming distance of their hash codes. The final precision score is then averaged over all test documents. To make comparable results with previous works, we experiment with latent variables size of 8, 32, 64 and 128.

3.2 Semantic Hashing Evaluation

In this section, we evaluate Doc2hash over various number of bits on the three datasets. In the unsupervised hashing, Doc2hash outperforms NASH-DN, the current state of the art model for semantic hashing, and other methods. The Table 1 shows the result of TMC dataset. Doc2hash shows its ability to assign the similar data (with the same label) to the hash codes of which hamming distances are small. The same trend and superiority of Doc2hash are also observed in both Reuters and RCV1 datasets as shown in Tables 2 and 3. Note that we do not compare with NASH-DN in RCV1 because NASH doesn't report any results on RCV1 dataset and doesn't release any code to reproduce their result. We compare the reminding methods with Doc2hash. Table 3 shows our approach improves the precision with significant margin compared with other models. We note that the retrieval results tend to drop when we set the length of hash codes to be 64 or larger, which also happens for some baselines. It is probably because of over-fitting. Compared with other methods, the proposed method is robust when the codes length increase. Our approach performs better than other methods in 64 and 128 bits setting, suggesting that Doc2hash can effectively generate hash codes to documents even with limited training data.

We also evaluate Doc2hash in the supervised hashing setting with the same datasets. We make use of the label/tag information during training. As shown in Tables 1, 2 and 3, Doc2hash yields better results than the other baseline models in different bits length.

3.3 Quantitative Analysis

In this section, we explore the reason why the proposed method outperforms the counterpart based on the ST estimator. We try to analyze the distribution of latent variables that trained with ST estimator (NASH) and Gumbel softmax relaxation (our method) respectively to quantitatively estimate the coding efficiency. To obtain efficient hash codes in the unsupervised setting, an expected pattern is that we get the same amount of 1 as well as 0. Because according to information theory, such a uniform distribution produces the maximum entropy in Bernoulli distribution. Motivated by this idea, we make a comparison between NASH and Doc2hash in the conditional probabilistic distribution of latent variables (i.e., $p(z|x)$). As we can see in Figure 4(a), the distribution of $p(z|x)$ in NASH is significantly asymmetric while the proposed method generates a well-balanced distribution (as Shown in Figure 4(b)). This comparison demonstrates that our approach is more close to the expected target in the probabilistic distribution of $p(z|x)$. Furthermore, we calculate the proportion of 1 in both methods. The proportion of NASH is 40%, while our method is 49%. Thus, it shows our approach is able to produce more efficient hash codes by using Gumbel softmax relaxation because it is very close to the up-bound of information theory for Bernoulli distribution. We demonstrate this point more clearly by showing the distribution of $g_\phi(x)$ in NASH. It is asymmetric because the peak value tilts to the left side. And quantization based on thresholding around the zero point implies that the hash codes produced by NASH contain more number of 0 than the number of 1.

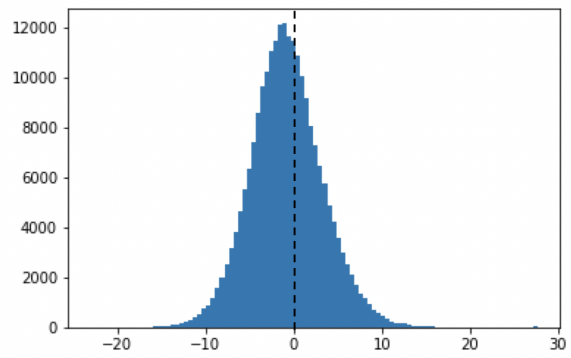

Figure 3: The distribution of $g_\phi(x)$ in NASH

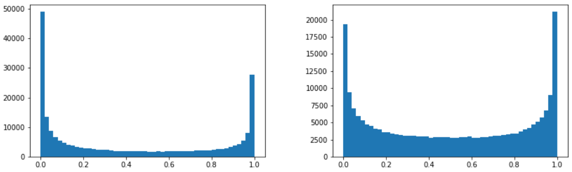

(a) (b)

Figure 4: the distribution of $p(z|x)$: (a) is the distribution of NASH. (b) is the distribution of Doc2hash

4 Conclusion

In this paper, we present a generative model with discrete latent variables to learn binary representation for semantic hashing. We show that compared with the Straight-Through estimator, the Gumbel-Softmax relaxation provides a better solution to learn hash codes and thus gains the state of the art performance in three different datasets. We also explore the reason why the proposed method produces more efficient hash codes compared with the counterpart based on the ST estimator.

Abstract

Generative Adversarial Networks (GANs) are a promising approach for text generation that, unlike traditional language models (LM), does not suffer from the problem of "exposure bias". However, A major hurdle for understanding the potential of GANs for text generation is the lack of a clear evaluation metric. In this work, we propose to approximate the distribution of text generated by a GAN, which permits evaluating them with traditional probability-based LM metrics. We apply our approximation procedure on several GAN-based models and show that they currently perform substantially worse than state-of-the-art LMs. Our evaluation procedure promotes better understanding of the relation between GANs and LMs, and can accelerate progress in GAN-based text generation.

1 Introduction

Neural networks have revolutionized the field of text generation, in machine translation (Sutskever et al., 2014; Neubig, 2017; Luong et al., 2015; Chen et al., 2018), summarization (See et al., 2017), image captioning (You et al., 2016) and many other applications (Goldberg, 2017).

Traditionally, text generation models are trained by going over a gold sequence of symbols (characters or words) from left-to-right, and maximizing the probability of the next symbol given the history, namely, a language modeling (LM) objective. A commonly discussed drawback of such LM-based text generation is *exposure bias* (Ranzato et al., 2015): during training, the model predicts the next token conditioned on the ground truth history, while at test time prediction is based on predicted tokens, causing a train-test mismatch. Models trained in this manner often struggle to overcome previous prediction errors.

Generative Adversarial Networks (Goodfellow et al., 2014) offer a solution for *exposure bias*. Originally introduced for images, GANs leverage a discriminator, which is trained to discriminate between real images and generated images via an adversarial loss. In such a framework, the generator is not directly exposed to the ground truth data, but instead learns to imitate it using global feedback from the discriminator. This has led to several attempts to use GANs for text generation, with a generator using either a recurrent neural network (RNN) (Yu et al., 2017; Guo et al., 2017; Press et al., 2017; Rajeswar et al., 2017), or a Convolutional Neural Network (CNN) (Gulrajani et al., 2017; Rajeswar et al., 2017).

However, evaluating GANs is more difficult than evaluating LMs. While in language modeling, evaluation is based on the log-probability of a model on held-out text, this cannot be straightforwardly extended to GAN-based text generation, because the generator outputs discrete tokens, rather than a probability distribution. Currently, there is no single evaluation metric for GAN-based text generation, and existing metrics that are based on n-gram overlap are known to lack robustness and have low correlation with semantic coherence (Semeniuta et al., 2018).

In this paper, we propose a method for evaluating GANs with standard probability-based evaluation metrics. We show that the expected prediction of a GAN generator can be viewed as a LM, and suggest a simple Monte-Carlo method for approximating it. The approximated probability distribution can then be evaluated with standard LM metrics such as perplexity or Bits Per Character (BPC).

To empirically establish our claim, we implement our evaluation on several RNN-based GANs: (Press et al., 2017; Yu et al., 2017; Guo et al., 2017). We find that all models have substantially lower BPC compared to state-of-the-art LMs. By directly comparing to LMs, we put in perspective the current performance of RNN-based GANs for

text generation. Our results are also in line with recent concurrent work by Caccia et al. (2018), who reached a similar conclusion by comparing the performance of textual GANs to that of LMs using metrics suggested for GAN evaluation.

Our code is available at: `http://github.com/GuyTevet/SeqGAN-eval` and `http://github.com/GuyTevet/rnn-gan-eval`.

2 Background

Following the success of GANs in image generation, several works applied the same idea to texts using convolutional neural networks (Gulrajani et al., 2017; Rajeswar et al., 2017), and later using RNNs (Press et al., 2017; Yu et al., 2017). RNNs enable generating variable-length sequences, conditioning each token on the tokens generated in previous time steps. We leverage this characteristic in our approximation model (§4.1).

A main challenge in applying GANs for text is that generating discrete symbols is a non-differentiable operation. One solution is to perform a continuous relaxation of the GAN output, which leads to generators that emit a nearly discrete continuous distribution (Press et al., 2017). This keeps the model differentiable and enables end-to-end training through the discriminator. Alternatively, SeqGAN (Yu et al., 2017) and LeakGAN (Guo et al., 2017) used policy gradient methods to overcome the differentiablity requirement. We apply our approximation to both model types.

3 Evaluating GANs and LMs

LM Evaluation. Text generation from LMs is commonly evaluated using probabilistic metrics. Specifically, given a test sequence of symbols $(t_1, \dots, t_n)$, and a LM q, the average cross-entropy over the entire test set is computed: $ACE = -\frac{1}{n}\sum_{i=1}^{n}\log_2 q(t_i \mid t_1 ... t_{i-1})$. For word-based models, the standard metric is perplexity: $PP = 2^{ACE}$, while for character-based models it is $BPC = ACE$ directly.

Intrinsic improvement in perplexity does not guarantee an improvement in an extrinsic downstream task that uses a language model. However, perplexity often correlates with extrinsic measures (Jurafsky and Martin, 2018), and is the de-facto metric for evaluating the quality of language models today.

GAN-based Text Generation Evaluation. By definition, a text GAN outputs a discrete sequence of symbols rather than a probability distribution. As a result, LM metrics cannot be applied to evaluate the generated text. Consequently, other metrics have been proposed:

- N-gram overlap: (Yu et al., 2017; Press et al., 2017): Inspired by BLEU (Papineni et al., 2002), this measures whether n-grams generated by the model appear in a held-out corpus. A major drawback is that this metric favors conservative models that always generate very common text (e.g., *"it is"*). To mitigate this, self-BLEU has been proposed (Lu et al., 2018) as an additional metric, where overlap is measured between two independently sampled texts from the model.
- LM score: The probability of generated text according to a pre-trained LM. This has the same problem of favoring conservative models.
- Zhao et al. (2017) suggested an indirect score by training a LM on GAN-generated text, and evaluating it using perplexity. The drawback in this setting is the coupling of the performance of the GAN with that of the proxy LM.
- Heusel et al. (2017) used Frechet InferSent Distance (FID) to compute the distance between distributions of features extracted from real and generated samples. However, this approach relies on a problematic assumption that features are normally distributed.
- Rajeswar et al. (2017) used a context-free grammar (CFG) to generate a reference corpus, and evaluated the model by the likelihood the CFG assigns to generated samples. However, simple CFGs do not fully capture the complexity of natural language.
- To overcome the drawbacks of each individual method, Semeniuta et al. (2018) proposed a unified measure based on multiple evaluation metrics (N-grams, BLEU variations, FID, LM score variations and human evaluation). Specifically, they argue that the different measures capture different desired properties of LMs, e.g., quality vs. diversity.
- Following Semeniuta et al. (2018), and in parallel to this work, Caccia et al. (2018) proposed a temperature sweep method that trades-off quality for diversity using a single parameter. Similar to our findings, they concluded that GANs perform worse than LMs on this metric.

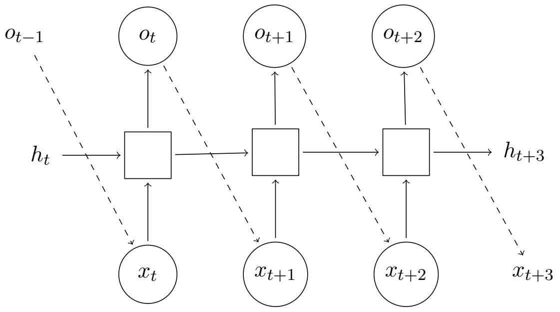

Figure 1: Generator recurrent connections. $\{h_t\}$ is the internal state sequence and $\{o_t\}$ is the generator prediction sequence (one-hot). During inference, the outputs $\{o_t\}$ are fed back as the input for the next time step (dashed lines). During LM approximation, the input $\{x_t\}$ is a sequence of one-hot vectors from the test set.

Algorithm 1 LM Evaluation of RNN-based GANs

```
Input: $G_t(\cdot)$: the generator function at time step $t$
       $(x_0, ..., x_t)$: previous gold tokens
       $x_{t+1}$: the gold next token (as ground truth)
       $f(\cdot,\cdot)$: a LM evaluation metric
       $N$: number of samples
for $n \leftarrow 1$ to $N$ do
    $g_{t,n} \longleftarrow$ sample from $G_t(x_0...x_t)$
$\tilde{G}_{t,N} = \frac{1}{N}\Sigma_{n=1}^{N} g_{t,n}$
return $f(\tilde{G}_{t,N}, x_{t+1})$
```

Overall, current evaluation methods cannot fully capture the performance of GAN-based text generation models. While reporting various scores as proposed by Semeniuta et al. (2018) is possible, it is preferable to have a single measure of progress when comparing different text generation models.

4 Proposed Method

We propose a method for approximating a distribution over tokens from a GAN, and then evaluate the model with standard LM metrics. We will describe our approach given an RNN-based LM, which is the most commonly-used architecture, but the approximation can be applied to other auto-regressive models (Vaswani et al., 2017).

4.1 Language Model Approximation

The inputs to an RNN at time step t, are the state vector h_t and the current input token x_t. The output token (one-hot) is denoted by o_t. In RNN-based GANs, the previous output token is used at inference time as the input x_t (Yu et al., 2017; Guo et al., 2017; Press et al., 2017; Rajeswar et al., 2017). In contrast, when evaluating with BPC or perplexity, the gold token x_t is given as input. Hence, LM-based evaluation neutralizes the problem of exposure bias addressed by GANs. Nevertheless, this allows us to compare the quality of text produced by GANs and LMs on an equal footing. Figure 1 illustrates the difference between inference time and during LM approximation.

We can therefore define the generator function at time step t as a function of the initial state h_0 and the past generated tokens $(x_0 \dots x_t)$, which we denote as $o_t = G_t(h_0, x_0...x_t)$ (x_0 is a start token). Given a past sequence $(x_0 \dots x_t)$, G_t is a stochastic function: the stochasticity of G_t can be gained either by using a noise vector as the initial state h_0 (Press et al., 2017), or by sampling from the GAN's internal distribution over possible output tokens (Yu et al., 2017; Guo et al., 2017). Since h_0 is constant or a noise vector that makes G_t stochastic, we can omit it to get $G_t(x_0 \dots x_t)$. In such a setup, the expected value $\mathbb{E}[G_t(x_0 \dots x_t)]$ is a distribution q over the next vocabulary token a_t:

$$q(a_t \mid a_0 \dots a_{t-1}) = \{\mathbb{E}[G_t(x_0 \dots x_t)]\}_{a_t}$$

To empirically approximate q, we can sample from it N i.i.d samples, and compute an approximation $\tilde{G}_{t,N} = \frac{1}{N}\Sigma_{n=1}^{N} g_{t,n}$, where $g_{t,n}$ is one sample from $G_t(x_0...x_t)$. Then, according to the strong law of large numbers:

$$\mathbb{E}[G_t(x_0 \dots x_t)] = \lim_{N \to \infty} \tilde{G}_{t,N} \tag{1}$$

Given this approximate LM distribution, we can evaluate a GAN using perplexity or BPC. We summarize the evaluation procedure in Algorithm 1.[1]

4.2 Approximation Bound

We provide a theoretical bound for choosing a number of samples N that results in a good approximation of $\tilde{G}_{t,N}$ to $\mathbb{E}[G_t]$.

Perplexity and BPC rely on the log-probability of the ground truth token. Since the ground truth token is unknown, we conservatively define the bad event B in which there exists $v \in V$ such that $|\{E[G_t]\}_v - \{\tilde{G}_{t,N}\}_v| > \gamma$, where V is the vocabulary. We can then bound the probability of B by some ϵ. We define the following notations:

1. The probability of a token a_t to be v is $p_v \overset{\Delta}{=} q(a_t = v | a_0 \dots a_{t-1}) = \{\mathbb{E}[G_t(x_0 \dots x_t)]\}_v$.
2. $\chi_{v,n} \overset{\Delta}{=} \{g_{t,n}\}_v$ is a random variable representing the binary value of the v'th index of

---

[1] Our evaluation algorithm is linear in the length of the test set and in the number of samples N.

$g_{t,n}$ which is a single sample of G_t. Note that the average of $\chi_{v,n}$ over N samples is $X_v \triangleq \frac{1}{N}\sum_{n=1}^{N}\chi_{v,n} = \left\{\frac{1}{N}\sum_{n=1}^{N} g_{t,n}\right\}_v = \{\tilde{G}_{t,N}\}_v$.

Using the above notation, we can re-define the probability of the bad event B with respect to the individual coordinates in the vectors:

$$\begin{aligned} Pr(B) &= Pr\left(\|\mathbb{E}[G_t] - \tilde{G}_{t,N}\|_\infty > \gamma\right) \\ &= Pr\left(\bigcup_{v\in V} |p_v - X_v| > \gamma\right) \overset{!}{<} \epsilon \end{aligned} \tag{2}$$

We note that $\chi_{v,n} \sim Bernoulli(p_v)$, and given that $\{\chi_{v,n}\}_{n=1}^{N}$ are i.i.d., we can apply the Chernoff-Hoeffding theorem (Chernoff et al., 1952; Hoeffding, 1963). According to the theorem, for every $v \in V$, $Pr(|X_v - p_v| > \gamma) < 2e^{-2N\gamma^2}$. Taking the union bound over V implies:

$$Pr(B) = Pr\left(\bigcup_{v\in V} |X_v - p_v| > \gamma\right) < 2|V|e^{-2N\gamma^2} < \epsilon \tag{3}$$

Hence, we get a lower bound on N:

$$N > \frac{1}{2\gamma^2}\ln\left(\frac{2|V|}{\epsilon}\right) \tag{4}$$

As a numerical example, choosing $\gamma = 10^{-3}$ and $\epsilon = 10^{-2}$, for a character-based LM over the text8 dataset, with $|V| = 27$, we get the bound: $N > 4.3 \cdot 10^6$. With the same γ and ϵ, a typical word-based LM with vocabulary size $|V| = 50,000$ would require $N > 8.1 \cdot 10^6$.

In practice, probability vectors of LMs tend to be sparse (Kim et al., 2016). Thus, we argue that we can use a much smaller N for a good approximation $\tilde{G}_{t,N}$. Since the sparsity of LMs is difficult to bound, as it differs between models, we suggest an empirical method for choosing N.

The approximation $\tilde{G}_{t,N}$ is a converging sequence, particularly over $\|\cdot\|_\infty$ (see Equation 1). Hence, we can empirically choose an N which satisfies $\|\tilde{G}_{t,N-\alpha} - \tilde{G}_{t,N}\|_\infty < \gamma', \quad \alpha \in \mathbb{N}$. In Section 5 we empirically measure $\|\tilde{G}_{t,N-\alpha} - \tilde{G}_{t,N}\|_\infty$ as a function of N to choose N. We choose a global N for a model, rather than for every t, by averaging over a subset of the evaluation set.

5 Evaluation

5.1 Models

We focus on character-based GANs as a test-case for our method. We evaluate two RNN-based GANs with different characteristics. As opposed to the original GAN model (Goodfellow et al., 2014), in which the generator is initialized with random noise, the GANs we evaluated both leverage gold standard text to initialize the generator, as detailed below.

Recurrent GAN (Press et al., 2017) is a continuous RNN-based generator which minimizes the improved WGAN loss (Gulrajani et al., 2017). To guide the generator, during training it is initialized with the first $i-1$ characters from the ground truth, starting the prediction in the ith character. Stochasticity is obtained by feeding the generator with a noise vector z as a hidden state. At each time step, the input to the RNN generator is the output distribution of the previous step.

SeqGAN (Yu et al., 2017) is a discrete RNN-based generator. To guide the generator, it is pretrained as a LM on ground truth text. Stochasticity is obtained by sampling tokens from an internal distribution function over the vocabulary. To overcome differentiation problem, it is trained using a policy gradient objective (Sutton et al., 2000).

We also evaluated **LeakGAN** (Guo et al., 2017), another discrete RNN-based generator, but since it is similar to SeqGAN and performed worse, we omit it for brevity.

5.2 Evaluation Settings

To compare to prior work in LM, we follow the common setup and train on the text8 dataset.[2] The dataset is derived from Wikipedia, and includes 26 English characters plus spaces. We use the standard 90/5/5 split to train/validation/test. Finally, we measure performance with BPC.

We tuned hyper-parameters on the validation set, including sequence length to generate at test time (7 for Press et al. (2017), 1000 for Yu et al. (2017)). We chose the number of samples N empirically for each model, as described in Section 4.2. We set α to 10, and the boundary to $\gamma' = 10^{-3}$ as a good trade-off between accuracy and run-time. Figure 2 plots the approximate error $\|\tilde{G}_{t,N-\alpha} - \tilde{G}_{t,N}\|_\infty$ as a function of N. For both models, $N > 1600$ satisfies this condition (red line in Figure 2). To be safe, we used $N = 2000$.

5.3 Results

Table 1 shows model performance on the test set.

Table 2: Random samples of 100 characters generated by each model.

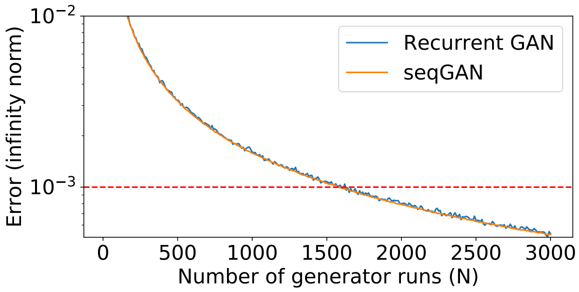

Figure 2: Approximate error $\|\tilde{G}_{t,N-\alpha} - \tilde{G}_{t,N}\|_\infty$ as a function of samples N. $\alpha = 10$, $\gamma' = 10^{-3}$.

Because SeqGAN models output a distribution over tokens at every time step, we can measure the true BPC and assess the quality of our approximation. Indeed, we observe that approximate BPC is only slightly higher than the true BPC.

GAN-based models perform worse than state-of-the-art LMs by a large margin. Moreover, in SeqGAN, the pre-trained LM performs better than the fully trained model with approximate BPC scores of 1.95 and 2.06, respectively, and the BPC deteriorates as adversarial training continues.

Finally, we note that generating sequences larger than 7 characters hurts the BPC of Press et al. (2017). It is difficult to assess the quality of generation with such short sequences.

In Table 2 we present a few randomly generated samples from each model. We indeed observe that adversarial training slightly reduces the quality of generated text for SeqGAN, and find that the quality of 100-character long sequences generated from Press et al. (2017) is low.

6 Conclusions

We propose an evaluation procedure for text GANs that is based on approximating the GAN output distribution and using standard LM metrics. We provide a bound for the number of samples required for the approximation and empirically show in practice as few as 2000 samples per time-step suffice. We evaluate character-based GAN models using our procedure, and show their performance is substantially lower than state-of-the-art LM. We hope our simple evaluation method leads to progress in GAN-based text generation by shedding light on the quality of such models.

Abstract

Text generation with generative adversarial networks (GANs) can be divided into the text-based and code-based categories according to the type of signals used for discrimination. In this work, we introduce a novel text-based approach called Soft-GAN to effectively exploit GAN setup for text generation. We demonstrate how autoencoders (AEs) can be used for providing a continuous representation of sentences, which we will refer to as soft-text. This soft representation will be used in GAN discrimination to synthesize similar soft-texts. We also propose hybrid latent code and text-based GAN (LATEXT-GAN) approaches with one or more discriminators, in which a combination of the latent code and the soft-text is used for GAN discriminations. We perform a number of subjective and objective experiments on two well-known datasets (SNLI and Image COCO) to validate our techniques. We discuss the results using several evaluation metrics and show that the proposed techniques outperform the traditional GAN-based text-generation methods.

1 Introduction

Text generation is an active research area and has many real-world applications, including, but not limited to, machine translation (Bahdanau et al., 2014), AI chat bots (Li et al., 2017), image captioning (Xu et al., 2014), question answering and information retrieval (Wang et al., 2017). Recurrent neural network language models (RNNLMs) (Mikolov et al., 2010) is the most popular approach for text generation which rely on maximum likelihood estimation (MLE) solutions such as teacher forcing (Williams and Zipser, 1989) (i.e. the model is trained to predict the next word given all the previous predicted words); however, it is well-known in the literature that MLE is a simplistic objective for this complex NLP task (Li et al., 2017). It is reported that MLE-based methods suffer from exposure bias (Huszr, 2015), which means that at training time the model is exposed to gold data only, but at test time it observes its own predictions. Hence, wrong predictions quickly accumulate and result in poor text generation quality.

However, generative adversarial networks (GANs) (Goodfellow et al., 2014) which are based on an adversarial loss function suffers less from the mentioned problems of the MLE solutions. The great success of GANs in image generation framework (Salimans et al., 2016) motivated researchers to apply its framework to NLP applications as well. GANs have been extensively used recently in various NLP applications such as machine translation (Wu et al., 2017; Yang et al., 2017a), dialogue models (Li et al., 2017), question answering (Yang et al., 2017b), and natural language generation (Gulrajani et al., 2017; Rajeswar et al., 2017; Press et al., 2017; Kim et al., 2017; Zhang et al., 2017; Cifka et al., 2018; Spinks and Moens, 2018; Haidar and Rezagholizadeh, 2019; Gagnon-Marchand et al., 2019; Rashid et al., 2019). However, applying GAN in NLP is challenging due to the discrete nature of the text. Consequently, back-propagation would not be feasible for discrete outputs and it is not straightforward to pass the gradients through the discrete output words of the generator.

Traditional methods for GAN-based text generation can be categorized according to the type of the signal used for discrimination into two categories: text-based and code-based techniques. Code-based methods such as adversarial autoencoder (AAE) (Makhzani et al., 2015) and adversarially regularized AE (ARAE) (Kim et al., 2017) derive a latent space representation of the text using an AE and attempt to learn data manifold of that latent space (Kim et al., 2017) instead of mod-

Proceedings of NAACL-HLT 2019, pages 2248–2258
Minneapolis, Minnesota, June 2 - June 7, 2019.

eling text directly. Text-based solutions, such as reinforcement learning (RL) based methods or approaches based on continuous approximation of discrete sampling, focus on generating text directly from the generator. RL-based methods treat the distribution of GAN generator as a stochastic policy and hold the discriminator responsible for providing proper reward for the generator's actions. However, the RL-based methods often need pre-training and are computationally more expensive compared to the methods of the other two categories. In the continuous approximation approach for generating text with GANs, the goal is to find a continuous approximation of the discrete sampling by using the Gumbel Softmax technique (Kusner and Hernández-Lobato, 2016) or approximating the non-differentiable argmax operator with a continuous function (Zhang et al., 2017; Gulrajani et al., 2017).

In this paper, we introduce Soft-GAN as a new solution for the main bottleneck of using GAN for text generation. Our solution is based on an AE to derive a soft representation of the real text (i.e. soft-text). This soft-text is fed to the GAN discriminator instead of the conventional one-hot representation used in (Gulrajani et al., 2017). Furthermore, we propose hybrid latent code and text-based GAN (LATEXT-GAN) approaches and show that how we can improve code-based and text-based text generation techniques by considering both signals in the GAN framework. We summarize the main contributions of this paper as:

- We introduce a new text-based solution Soft-GAN using the above soft-text discrimination. We also demonstrate the rationale behind this approach.

- We introduce LATEXT-GAN approaches for GAN-based text generation using both latent code and soft-text discrimination. To the best of our knowledge, this is the first time where a GAN-based text generation framework uses both code and text-based discrimination.

- We evaluate our methods using subjective and objective evaluation metrics. We show that our proposed approaches outperform the conventional GAN-based text generation techniques that do not need pre-training.

2 Background

Generative adversarial networks include two separate deep networks: a generator and a discriminator. The generator G_θ takes in a random variable, z following a distribution $P_z(z)$ and attempt to map it to the real data distribution $P_x(x)$. The output distribution of the generator is expected to converge to the real data distribution during the training. On the other hand, the discriminator f_w is expected to discern real samples from generated ones by outputting zeros and ones, respectively. During training, the generator and discriminator generate samples and classify them, respectively by adversarially affecting the performance of each other. In this regard, an adversarial loss function is employed for training (Goodfellow et al., 2014):

$$\begin{aligned}\min_{\theta}\max_{w}(&E_{x\sim P_x(x)}f_w(x)+\\ &E_{z\sim P_z(z)}(1-f_w(G_\theta(z))))\end{aligned} \tag{1}$$

As stated, using GANs for text generation is challenging because of the discrete nature of text. The main bottleneck is the *argmax* operator which is not differentiable and blocks the gradient flow from the discriminator to the generator.

$$\min_{\theta} E_{z\sim P_z(z)}(1-f_w(\text{argmax}(G_\theta(z)))) \tag{2}$$

3 Related Work

Text-based Solutions Generating text using pure GANs was inspired by improved Wasserstein GAN (IWGAN) work (Gulrajani et al., 2017). In IWGAN, a character level language model was developed based on adversarial training of a generator and a discriminator. Their generator is a convolution neural network (CNN) generating fixed-length texts. The discriminator is another CNN receiving 3D tensors as input sentences. The real sentences and the generated ones are represented using one-hot and softmax representations, respectively. A similar approach to IWGAN was proposed in (Rajeswar et al., 2017) with a recurrent neural network (RNN) based generator. In (Press et al., 2017), RNN is trained to generate text with GAN using curriculum learning (Bengio et al., 2009). The TextGAN (Zhang et al., 2017) method was proposed to alleviate the mode-collapsing problem by matching the high-dimensional latent feature distributions of real and synthetic sentences (Salimans et al., 2016).

Morever, several versions of the RL-based techniques using GAN have been introduced in the literature including Seq-GAN (Yu et al., 2017), RankGAN (Lin et al., 2017), MaliGAN (Che et al., 2017), LeakGAN (Guo et al., 2017), and MaskGAN (Fedus et al., 2018).

Code-based Solutions AEs have been exploited along with GANs in different architectures for computer vision application such as AAE (Makhzani et al., 2015), ALI (Dumoulin et al., 2016), and HALI (Belghazi et al., 2018). Similarly, AEs can be used with GANs for generating text. For instance, ARAE was proposed in (Kim et al., 2017) where it employs a discrete auto-encoder to learn continuous codes based on discrete inputs with a WGAN objective to learn an implicit probabilistic model over these codes. ARAE aims at exploiting GANs ability to push the generator to follow a continuous code space corresponding to the encoded real text in the AE. The generated code is then used by the decoder to generate the synthetic texts. A different version of the ARAE method was also introduced in (Spinks and Moens, 2018). In (Subramanian et al., 2018), sentence embeddings were learned by a generator to model a pre-trained sentence representation obtained by a general-purpose sentence encoder. A temperature sweeping framework was discussed in (Caccia et al., 2018) to evaluate the text generation models over whole quality-diversity spectrum and pointed out the fundamental flaws of quality-only evaluation. The Variational autoencoders (VAEs) (Kingma and Welling, 2013) were also applied for text generation in (Bowman et al., 2015; Hu et al., 2017).

4 Methodology

In this section, we introduce a new text-based solution by discriminating the reconstructed output of an AE (i.e., soft-text) with the synthesized generated text and we call it as Soft-GAN. Here, we use the decoder of the AE as the generator to generate the synthesized texts from random noise data z. The model is described in Figure 1a. We demonstrate the rationale behind this soft-GAN approach, which is to make the discrimination task of the discriminator between the real and synthetic texts more difficult and consequently providing a richer signal to the generator. We also introduce three LATEXT-GAN approaches where both code and text-based signals will be used in the GAN framework. We introduce LATEXT-GAN I approach on top of the AAE method. LATEXT-GAN II and III approaches will be proposed based on the ARAE approach. In the LATEXT-GAN I and II techniques, we use separate discriminators for the code and text discriminations. In the LATEXT-GAN III approach, the concatenation of the synthetic code and the synthetic text tries to mimic the concatenation of the latent code and the soft-text using a discriminator. The schematic diagram of the LATEXT-GAN I, II, and III approaches are described in Figures 1b, 1c, and 1d respectively. We share the parameters of the decoder of the AE to generate the synthesized text $\hat{x}$. In order to train these approaches, we train the auto-encoder and the GAN alternatingly by minimizing their loss functions using the WGAN-gradient penalty (WGAN-GP) approach (Gulrajani et al., 2017). In each iteration, the first step is the AE training in all of these techniques followed by the GAN loss functions. The autoencoder can be trained by using a cross-entropy or mean-squared loss functions. The input x to the AE is mapped to a latent code representation c which is decoded to soft-text $\tilde{x}$. In our experiments, we train the auto-encoder using mean-squared loss $\min\limits_{(\phi,\psi)} ||x - \tilde{x}||^2$. We describe the training details of the Soft-GAN, LATEXT-GAN I, II, and III methods in the following subsections where the term critic and discriminator used interchangeably. The notations that are used in this paper are described in Table 1.

x	One-hot representation of the training text
$\tilde{x}$	Soft-text: Reconstructed output of the AE
$\hat{x}$	Synthesized generated text
$\bar{x}$	$[\bar{x} \sim P_{\bar{x}}] \leftarrow \alpha\, [\tilde{x} \sim P_{\tilde{x}}] + (1-\alpha)\, [\hat{x} \sim P_{\hat{x}}]$
$z \sim N$	Random data drawn from a normal distribution
c	Latent code representation of the training text
$\hat{c}$	Synthesized generated code
$\bar{c}$	$[\bar{c} \sim P_{\bar{c}}] \leftarrow \alpha\, [c \sim P_c] + (1-\alpha)\, [\hat{c} \sim P_{\hat{c}}]$
$\bar{cz}$	$[\bar{cz} \sim P_{\bar{cz}}] \leftarrow \alpha\, [c \sim P_c] + (1-\alpha)\, [z \sim P_z]$
w_{t+c}	Parameters of the combination of text and code-based discriminator
w_t	Parameters of the text-based discriminator
w_c	Parameters of the code-based discriminator
ϕ	Parameters of the encoder
ψ	Parameters of the decoder
θ	Parameters of the generator
λ	Gradient penalty co-efficient
∇	describes gradient

Figure 1: Proposed Approaches

4.1 Soft-GAN

As stated, in conventional text-based discrimination approach IWGAN (Gulrajani et al., 2017), the real and the synthesized generated text are described by the one-hot and the softmax represenation respectively. A disadvantage of this technique is that the discriminator is able to tell apart the one-hot input from the softmax input very easily. One way to avoid this issue is to derive a continuous representation of words rather than their one-hot and train the discriminator to differentiate between the continuous representations. We use a conventional AE to replace the one-hot representation with softmax reconstructed output ($\tilde{x}$), which we refer to as soft-text. This soft-text representation is used as the real input to the discriminator. The synthetic generated text $\hat{x}$ is obtained by inputting the random noise data z to the shared decoder. We define the proposed method as Soft-GAN. In each iteration, the model is trained using the following steps after the AE training step:

- Train the text-based discriminator f_{w_t} for k times and the decoder once using the loss L_{critic_t} to maximize the ability of the f_{w_t} to discriminate between $\tilde{x}$ and $\hat{x}$:

$$L_{critic_t} = \min_{(w_t,\psi)} (-E_{\tilde{x}\sim P_{\tilde{x}}}[f_{w_t}(\tilde{x})] + E_{\hat{x}\sim P_{\hat{x}}}$$
$$[f_{w_t}(\hat{x})] + \lambda E_{\bar{x}\sim P_{\bar{x}}}[(||\nabla_{\bar{x}} f_{w_t}(\bar{x})||_2 - 1)^2]) \tag{3}$$

- Train the decoder based on the loss L_{gen} to fool the discriminator with improving the representation $\hat{x}$:

$$L_{gen} = \min_{\psi}(-E_{\hat{x}\sim P_{\hat{x}}}[f_{w_t}(\hat{x})] + E_{\tilde{x}\sim P_{\tilde{x}}}$$
$$[f_{w_t}(\tilde{x})]) \tag{4}$$

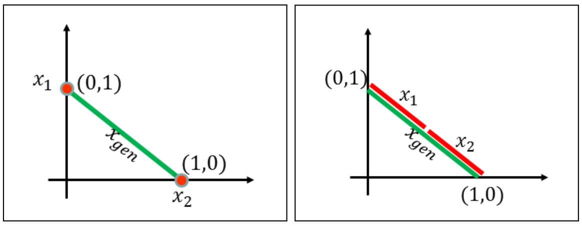

Figure 2: Locus of the input vectors to the discriminator f_{w_t} for a two-word language; Left panel: IWGAN, Right panel: Soft-GAN

4.1.1 Rationale: Why Soft-GAN should Work Better than IWGAN?

Suppose we have a language of vocabulary size of two words: x_1 and x_2. In the IWGAN approach, the one-hot representation of these two words (as two points in the Cartesian coordinates) and the span of the generated softmax outputs (as a line segment connecting them) is depicted in the left panel of Figure 2. As evident graphically, the task of the critic is to discriminate the points from the line connecting them, which is a rather simple very easy task, which makes it more prone to vanishing gradient.

On the other hand, the output locus of the soft-GAN decoder would be two red line segments as depicted in Figure 2 (Right panel) instead of two points (in the one-hot case). The two line segments lie on the output locus of the generator, which will make the generator more successful in fooling the critic.

4.2 LATEXT-GAN I

In the LATEXT-GAN I approach (Figure 1b), we deploy two critics: one for the soft-text discrimination and the other for the latent code discrimination. The text-based discriminator f_{w_t} is used to discriminate the soft-text output $\tilde{x}$ with the synthesized text $\hat{x}$ which is obtained by inputting the random noise data to the shared decoder. The code-based discriminator f_{w_c} is used to discriminate the random noise data z with the latent code c in the AAE setting which was explored for image generation. In the AAE setting (Makhzani et al., 2015), the encoder enhances its representation to a prior distribution z. It can be seen that the LATEXT-GAN I can be obtained by adding the above code-based discriminator f_{w_c} into the Soft-GAN. In each iteration, the model is trained using the following steps after the AE training step and the Equation 3 step of the Soft-GAN in section 4.1:

- Train the code-based discriminator f_{w_c} for k times using the loss L_{critic_c} to maximize the ability of the f_{w_c} to discriminate between c and z:
$$\begin{aligned} L_{critic_c} = \min_{w_c}(&E_{c\sim P_c}[f_{w_c}(c)]- \\ &E_{z\sim P_z}[f_{w_c}(z)]+ \\ &\lambda E_{\bar{c}z\sim P_{\bar{c}z}}[(||\nabla_{\bar{c}z} f_{w_c}(\bar{c}z)||_2 - 1)^2]) \end{aligned} \tag{5}$$
- Train the encoder and the decoder neural networks once with the loss L_{gen} to fool the discriminators f_{w_c} and f_{w_t} with improving the representations c and $\hat{x}$ respectively:
$$\begin{aligned} L_{\text{gen}} = \min_{(\phi,\psi)}(&-E_{\hat{x}\sim P_{\hat{x}}}[f_{w_t}(\hat{x})] + E_{\tilde{x}\sim P_{\tilde{x}}} \\ &[f_{w_t}(\tilde{x})] + E_{z\sim P_z}[f_{w_c}(z)] - E_{c\sim P_c}[f_{w_c}(c)]) \end{aligned} \tag{6}$$

4.3 LATEXT-GAN II

The LATEXT-GAN II approach (Figure 1c) is similar to the LATEXT-GAN I approach except the training of the code-based discriminator f_{w_c} is done as the ARAE training. The critic f_{w_c} is used to discriminate the synthetic code $\hat{c}$ with the latent code c. Here, the synthetic code is formed by using the ARAE method (Spinks and Moens, 2018). For each iteration in the model training, the AE training step and the Equation 3 step of the Soft-GAN in section 4.1 are carried out first. Then the following two steps are performed:

- Train the code-based discriminator f_{w_c} for k times and the encoder once using the loss L_{critic_c} to maximize the ability of the f_{w_c} to discriminate between c and $\hat{c}$:
$$\begin{aligned} L_{critic_c} = \min_{(w_c,\phi)}(&-E_{c\sim P_c}[f_{w_c}(c)] + E_{\hat{c}\sim P_{\hat{c}}} \\ &[f_{w_c}(\hat{c})] + \lambda E_{\bar{c}\sim P_{\bar{c}}}[(||\nabla_{\bar{c}} f_{w_c}(\bar{c})||_2 - 1)^2]) \end{aligned} \tag{7}$$
- Train the generator and the decoder neural networks once using the loss L_{gen} to fool the discriminators f_{w_t} and f_{w_c} with improving the representations $\hat{x}$ and $\hat{c}$ respectively:
$$\begin{aligned} L_{\text{gen}} = \min_{(\theta,\psi)}(&-E_{\hat{x}\sim P_{\hat{x}}}[f_{w_t}(\hat{x})] + E_{\tilde{x}\sim P_{\tilde{x}}} \\ &[f_{w_t}(\tilde{x})] - E_{\hat{c}\sim P_{\hat{c}}}[f_{w_c}(\hat{c})] + E_{c\sim P_c}[f_{w_c}(c)]) \end{aligned} \tag{8}$$

4.4 LATEXT-GAN III

In the third approach (Figure 1d), the combination of latent code c generated by ARAE (Spinks and Moens, 2018) and the soft-text output $\tilde{x}$ of an AE is used to signal the discriminator. We performed this combination by getting inspiration from an Adversarially Learned Inference (ALI) paper (Dumoulin et al., 2016) introduced for image generation. We call it as LATEXT-GAN III. Here, the discriminator $f_{w_{t+c}}$ tries to determine which combination of the samples derive from the latent code and the soft-text, ($\tilde{x}$,c), and which ($\hat{x}$, $\hat{c}$) are generated from the noise z. After the AE training step $\min\limits_{(\phi,\psi)} ||x - \tilde{x}||^2$, the LATEXT-GAN III model is trained using the next two steps in each iteration:

- Train the discriminator $f_{w_{t+c}}$ for k times, the encoder and the decoder once using the loss $L_{critic_{t+c}}$ to maximize the ability of the discriminator network to discriminate between ($\tilde{x}$,c) and ($\hat{x}$, $\hat{c}$):
$$\begin{aligned} L_{critic_{t+c}} = \min_{(w_{t+c},\phi,\psi)}(&-E_{(\tilde{x},c)\sim P_{\tilde{x}},P_c} \\ &[f_{w_{t+c}}(\tilde{x}, c)] + E_{(\hat{x},\hat{c})\sim P_{\hat{x}},P_{\hat{c}}}[f_{w_{t+c}}(\hat{x}, \hat{c})]+ \\ &\lambda E_{(\bar{x},\bar{c})\sim P_{\bar{x}},P_{\bar{c}}}[(||\nabla_{(\bar{x},\bar{c})} f_{w_{t+c}}(\bar{x}, \bar{c})||_2 - 1)^2]) \end{aligned} \tag{9}$$
- Train the generator and the decoder once based on L_{gen} to fool the discriminator $f_{w_{t+c}}$ with improving the representation ($\hat{x}$, $\hat{c}$):
$$\begin{aligned} L_{\text{gen}} = \min_{(\theta,\psi)}(&-E_{(\hat{x},\hat{c})\sim P_{\hat{x}},P_{\hat{c}}}[f_{w_{t+c}}(\hat{x}, \hat{c})] \\ &+ E_{(\tilde{x},c)\sim P_{\tilde{x}},P_c}[f_{w_{t+c}}(\tilde{x}, c)]) \end{aligned} \tag{10}$$

5 Experiments

5.1 Dataset and Experimental Procedures

We do our experiments on two different datasets: the Stanford Natural Language Inference (SNLI) corpus [1], which contains 714,667 sentences for

---

[1] https://github.com/aboev/arae-tf/tree/master/data_snli

training and 13323 sentences for testing, and the Image COCO [2] dataset's image caption annotations, where we sample [3] 10,000 sentences as training set and another 10,000 as test set (Zhu et al., 2018). We perform word-based experiments. For the SNLI dataset, we use a vocabulary size of 10000 words and use the maximum sentence length of size 15. For the COCO dataset, we use a vocabulary size of 5000 and perform experiments using the maximum sentence length of sizes 15 and 20. We train a simple AE using one layer with 512 LSTM cells (Hochreiter and Schmidhuber, 1997) for both the encoder and the decoder. For decoding, the output from the previous time step is used as the input to the next time step. We use the hidden code c from the last time step of the encoder and applied as an additional input at each time step of decoding. We normalize the code and then added an exponentially decaying noise before decoding. The greedy search approach is applied to get the best output. We train the auto-encoder using Adam (Diederik and Jimmy, 2014) optimizer with learning rate = 0.001, β_1= 0.9, and β_2= 0.999. We use CNN-based generator and discriminator with residual blocks (Gulrajani et al., 2017). The $tanh$ function is applied on the output of the ARAE generator (Kim et al., 2017). We train the generator and the discriminator using Adam optimizer with learning rate = 0.0001, β_1= 0.5, and β_2= 0.9. We do not apply any kind of attention mechanisms (Bahdanau et al., 2014; Zhang et al., 2018) and pre-training (Zhu et al., 2018) in our experiments. We use the WGAN-GP (Gulrajani et al., 2017) approach with 5 discriminator updates for every generator update and a gradient penalty co-efficient of λ=10 unlike a setup in (Zhu et al., 2018). For the AAE-based experiments, we normalize the data drawn from a prior distribution z. We train the models for 200000 iterations where in each iteration we sample a random batch and train the networks of the models.

5.2 Quantitative Evaluation

We use the frequently used BLEU metric (Papineni et al., 2002) to evaluate the word similarity between sentences and the perplexity to evaluate our techniques. We calculate BLEU-n scores for n-grams without a brevity penalty (Zhu et al., 2018). The results with the best BLEU-n scores in the synthesized generated texts are reported. To calculate the BLEU-n scores, we generate ten batches of sentences as candidate texts, i.e. 640 sentences and use the entire test set as reference texts. As the GAN-based models usually suffer from mode collapse (i.e., generating same samples over and over again), evaluating models by only BLEU metric is not appropriate. So, we also calculate recently proposed self-BLEU scores for the COCO dataset using maximum sentence length of size 20 and 10k synthetic sentences to evaluate the diversity (Zhu et al., 2018). Using one synthetic sentence as hypothesis and others as reference, the BLEU is calculated for every synthetic sentence, and define the average BLEU score as the self-BLEU (Zhu et al., 2018). A higher self-BLEU score describe less diversity. For the perplexity evaluations, we generate 100k and 10k sentences for the SNLI and the COCO datasets respectively using the models of the last iteration.

5.2.1 BLEU-n Scores evaluation

The BLEU score results for the n-grams of the synthesized texts are depicted in Table 2 and 3 with maximum sentence length of 15 for the SNLI and the COCO datasets respectively. We also report experimental results with a longer maximum sentence length of 20 using the COCO dataset to differentiate the effectiveness of code and text-based solutions (in Table 4). Furthermore, we report the BLEU and self-BLEU score results of our proposed approaches in Table 5 and 6 respectively for the COCO dataset to compare with the results of the existing approaches reported in (Zhu et al., 2018).

Model	B-2	B-3	B-4	B-5
AAE	0.797	0.614	0.449	0.294
ARAE	0.73	0.575	0.431	0.297
IWGAN	0.70	0.518	0.369	0.246
Soft-GAN	0.849	0.648	0.446	0.252
LATEXT-GAN I	**0.87**	**0.679**	**0.508**	0.336
LATEXT-GAN II	0.793	0.631	0.48	**0.338**
LATEXT-GAN III	0.782	0.617	0.466	0.33

Table 2: BLEU-n (B-n) scores results using SNLI dataset and 640 synthetic sentences

From tables 2, 3, and 4, we can see that our proposed approaches outperform the standalone code (AAE or ARAE) and text-based (IWGAN) solutions. For the maximum sentence length of size 15 experiments, the LATEXT-GAN I is better than LATEXT-GAN II and III for shorter length text (e.g., 2,3-grams). The performance of the LATEXT-GAN II and III degrades with increasing maximum sentence length to 20. This is be-

Table 4: BLEU-n (B-n) scores results for COCO dataset with maximum sentence length of size 20 and over 640 synthetic sentences

cause for longer sequence length experiments, the hidden code of the last time step might not be able to keep all the information from the earlier time steps. On the other hand, the LATEXT-GAN I and the Soft-GAN improve their performance with increasing maximum sentence length to 20. This might be because of the encoder enhances its representation better to the prior distribution, z from which the text is generated. Furthermore, the Soft-GAN outperforms all the proposed LATEXT GAN approaches.

We also compare our proposed approaches with TextGAN (Zhang et al., 2017), some RL-based approaches (SeqGAN (Yu et al., 2017), RankGAN (Lin et al., 2017), MaliGAN (Che et al., 2017)) and MLE approach described in a benchmark platform (Zhu et al., 2018) where they apply pre-training before applying adversarial training. We evaluate the BLEU and Self-BLEU score results on 10k synthetic sentences using the maximum sentence length of size 20 for the COCO dataset with a vocabulary of size 5000 as in (Zhu et al., 2018). The BLEU and the self-BLEU score results are reported in Table 5 and 6 respectively. From Table 5, it can be noted that our proposed approaches show comparable results to the RL-based solutions for the BLEU score results. We can also see that our proposed LATEXT-GAN III approach gives lower self-BLEU scores in Table 6. From the above experimental results, we can note that LATEXT-GAN III can generate real-like and more diverse sentences compare to some approaches reported in (Zhu et al., 2018) and our other proposed approaches.

5.2.2 Perplexity Evaluation

The forward and reverse perplexities of the LMs trained with maximum sentence length of 15 and 20 using the SNLI and the COCO datasets respectively are described in Table 7. The forward perplexities (F-PPL) are calculated by training an RNN language model (Zaremba et al., 2015) on real training data and evaluated on the synthetic samples. This measure describe the fluency of the synthetic samples. We also calculate the reverse perplexities (R-PPL) by training an RNNLM on the synthetic samples and evaluated on the real test data. We can easily compare the performance of the LMs by using the forward perplexities while it is not possible by using the reverse perplexities as the models are trained using the synthetic samples with different vocabulary sizes. The perplexities of the LMs using real data are 16.01 and 67.05 for the SNLI and the COCO datasets respectively reported in F-PPL column. From the tables, we can note the models with lower forward perplexities (higher fluency) for the synthetic samples tend to have higher reverse perplexities except the AAE-based models (Cifka et al.,

2018) and/or the IWGAN. The forward perplexity for the IWGAN is the worst which means that the synthetic sentences of the IWGAN model are not fluent or real-like sentences. For the SNLI dataset, we can note that the LATEXT-GAN II and III approaches can generate more fluent sentences than the other approaches. For the COCO dataset, it can be seen that the forward perplexity of the LATEXT-GAN I (51.39) is far lower than the real data (67.05) which means the model suffers from mode-collapse. The Soft-GAN, the LATEXT-GAN II and III approaches suffer less from the mode-collapse.

Models	F-PPL SNLI	R-PPL SNLI	F-PPL COCO	R-PPL COCO
Real	16.01	-	67.05	-
AAE	74.56	48.04	83.34	257.21
ARAE	66.70	315.58	64.63	185.20
IWGAN	193.30	53.96	94.95	80.99
Soft-GAN	110.95	142.13	61.42	170.17
LATEXT-GAN I	86.24	56.78	**51.39**	158.21
LATEXT-GAN II	**53.22**	144.80	63.32	203.39
LATEXT-GAN III	54.80	143.42	71.60	214.76

Table 7: Forward (F) and Reverse (R) perplexity (PPL) results for the SNLI and COCO datasets using synthetic sentences of maximum length 15 and 20 respectively.

5.3 Human Evaluation

The subjective judgments of the synthetic sentences of the models trained using the COCO dataset with maximum sentence length of size 20 is reported in Table 8. We used 20 different random synthetic sentences generated by using the last iteration of each model and gave them to a group of 5 people. We asked them to rate the sentences based on a 5-point Likert scale according to their fluency. The raters are asked to score 1 which corresponds to gibberish, 3 corresponds to understandable but ungrammatical, and 5 correspond to naturally constructed and understandable sentences (Cifka et al., 2018). From Table 8, we can note that the proposed LATEXT-GAN III approach get the higher rate compare to the other approaches. From all the above different evaluations, we can note that the synthetic sentences by using the LATEXT-GAN II and III approaches are more balanced in diversity and fluency compare to the other approaches. We also depicted some examples of the synthetic sentences for the COCO and the SNLI datasets in Table 9 and 10 respectively.

Model	Fluency
Real	4.32
AAE	1.72
ARAE	2.60
IWGAN	1.58
Soft-GAN	1.66
LATEXT-GAN I	1.82
LATEXT-GAN II	2.48
LATEXT-GAN III	**2.70**

6 Conclusion and Future Work

In this paper, we introduced Soft-GAN as a new solution for the main bottleneck of using GAN for generating text, which is the discontinuity of text. This is based on applying soft-text to the GAN discriminator instead of the one-hot representation in the traditional approach. We also introduced three LATEXT-GAN approaches by combining the reconstructed output (soft-text) of an auto-encoder to the latent code-based GAN approaches (AAE and ARAE) for text generation. LATEXT-GAN I is formed on top of AAE method. LATEXT-GAN II and III approaches were formed based on ARAE. The LATEXT-GAN I and II approaches used separate discriminators for the synthetic text and the synthetic code discriminations. The LATEXT-GAN III used the combination of the soft-text and the latent code to compare with the concatenation of the synthetic text and the synthetic code by using a single discriminator. We evaluated the proposed approaches over the SNLI and the COCO datasets using subjective and objective evaluation metrics. The results of the experiments are consistent with different evaluation metrics. We showed the superiority of our proposed techniques, especially the LATEXT-GAN III method over other conventional GAN-based techniques which does not require pre-training. Finally, we summarize our plan for future work in the following:

1. We trained the GAN using WGAN-GP approach. Spectral normalization technique (Miyato et al., 2018) can be applied to stabilize the GAN training which could generate more diverse text in our settings.

2. The proposed approaches are the pure GAN-based techniques for text generation and they are not very powerful in generating long sentences. RL or self-attention (Zhang et al., 2018) techniques can be used as a tool to ac-

commodate this weakness.

3. We used the hidden code from the last time step of the encoder. Attention mechanism can be applied for decoding. Furthermore, the powerful transformer (Vaswani et al., 2017) can be applied for the auto-encoder which could improve the performance of the proposed approaches. Pre-train the auto-encoder before adversarial training can also improve the performance.

Acknowledgments

We would like to thank Professor Qun Liu, Chief Scientist of Speech and Language Computing, Huawei Noah's Ark Lab for his valuable comments on the paper.

Abstract

We propose neural models to generate high-quality text from structured representations based on Minimal Recursion Semantics (MRS). MRS is a rich semantic representation that encodes more precise semantic detail than other representations such as Abstract Meaning Representation (AMR). We show that a sequence-to-sequence model that maps a linearization of Dependency MRS, a graph-based representation of MRS, to English text can achieve a BLEU score of 66.11 when trained on gold data. The performance can be improved further using a high-precision, broad coverage grammar-based parser to generate a large silver training corpus, achieving a final BLEU score of 77.17 on the full test set, and 83.37 on the subset of test data most closely matching the silver data domain. Our results suggest that MRS-based representations are a good choice for applications that need both structured semantics and the ability to produce natural language text as output.

1 Introduction

Text generation systems often generate their output from an intermediate semantic representation (Yao et al., 2012; Takase et al., 2016). However many semantic representations are task- or domain-specific (He and Young, 2003; Wong and Mooney, 2007), while rule-based text generation systems often have incomplete coverage (Langkilde-Geary, 2002; Oepen et al., 2007).

In this work we combine the advantages of Minimal Recursion Semantics (MRS; Copestake et al., 2005) with the robustness and fluency of neural sequence-to-sequence models trained on large datasets. We hypothesize that MRS is particularly well-suited for text generation, as it is explicitly compositional, capturing the contribution to sentence meaning of all parts of the surface form (Bender et al., 2015).

In contrast, semantic representations such as Abstract Meaning Representation (AMR; Banarescu et al., 2013) seek to abstract away from the syntax of a sentence as much as possible. Therefore MRS captures meaning distinctions that AMR fails to represent (see Fig. 1).

Our approach (§2) uses neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2014) to map linearizations of directed acyclic graphs (DAGs) to text, similar to the approach proposed by Konstas et al. (2017) to generate text from AMR. We use Dependency MRS (DMRS; Copestake, 2009), a graph-based representation in which nodes are MRS predicates (annotated with additional attributes) and edges represent relations between predicates. MRS and DMRS are interconvertible and the graph-based representation enables more convenient linearization and manipulation than MRS's variable-based representation (Copestake et al., 2016).

Results (§3) show that neural DMRS to English text generation can obtain up to 83.37 BLEU and 32% exact match, substantially higher than previous work. In particular, we obtain an 11.6 BLEU improvement through semi-supervised training using the output of a grammar-based parser, compared to training on gold data only. In comparison a grammar-based generator obtained 62.05 BLEU, and an approach based on DAG Transducers (Ye et al., 2018) 68.07 BLEU. Ablation experiments show that node attributes encoding fine-grained morpho-semantic information such as number and tense contribute more than 12 BLEU points. The highest reported result for AMR generation is 33.8 BLEU (Konstas et al., 2017); on the same dataset our best model obtains 75.8 BLEU. While a more detailed meaning representation is harder to produce, our results suggest that MRS could be suitable for text generation applications where precise semantic representations are required.

Proceedings of NAACL-HLT 2019, pages 2259–2266
Minneapolis, Minnesota, June 2 - June 7, 2019.

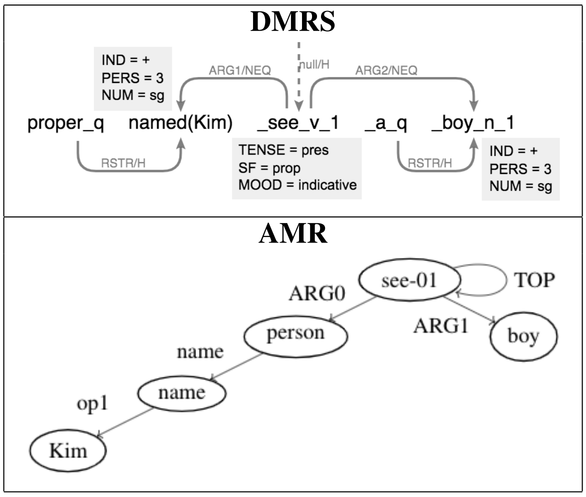

Figure 1: DMRS and AMR graphs for the sentence *Kim sees a boy*. Because DMRS includes tense and number, and has a node for the determiner, it can distinguish between, e.g. *Kim sees a boy* and *Kim saw the boys*, which AMR does not do.

2 Approach

2.1 Data

Our gold training data are parallel MRS and English text corpora, derived from the 1214 release of the Redwoods Treebank (Oepen et al., 2002).[1] MRS is implemented as the semantic layer of the English Resource Grammar (ERG; Flickinger, 2000, 2011), a broad-coverage, hand-engineered computational grammar of English. The Redwoods annotation was produced in conjunction with the ERG by parsing each sentence into a forest (discarding unparsable sentences), followed by manual disambiguation (Flickinger et al., 2017).

About half of the training data comes from the Wall Street Journal (sections 00-21), while the rest spans a range of domains, including Wikipedia, e-commerce dialogues, tourism brochures, and the Brown corpus. The data is split into training, development and test sets with 72,190, 5,288, and 10,201 sentences, respectively.

2.2 Graph linearization

We use PyDelphin[2] to convert MRS annotations to DMRS. In order to apply sequence-to-sequence models to graph-to-text generation, we then linearize the DMRS into PENMAN format (which is also used to represent AMR). We follow Goodman (2018, pp. 82–86) in finding normalized spanning trees through depth-first traversal over the directed acyclic DMRS graphs.[3] The PENMAN format defines each node once, supports node attributes and edge labels, marks edges whose direction is reversed in the traversal, and represents edges which are not covered by the spanning tree.

The PENMAN format is processed further to obtain a linearization appropriate as input to sequence-to-sequence models, similar to the approach proposed by Konstas et al. (2017) for AMR linearization (see Fig. 2). Node variable identifiers are removed, node attributes are concatenated, and named entities are anonymized. Predicates that appear only once in the training data are treated as unknowns. Preprocessing and unknown word handling are described in greater detail in Appendices A and B.

2.3 Model

Our neural generator follows the standard encoder-decoder paradigm (Bahdanau et al., 2014). The encoder is a two-layer bidirectional LSTM. Predicates and their attributes are embedded separately; their embeddings are then concatenated (Sennrich and Haddow, 2016). The

[2] https://github.com/delph-in/pydelphin

[3] https://github.com/goodmami/mrs-to-penman

decoder uses global soft attention for alignment (Luong et al., 2015), and pointer attention to copy unknown tokens directly to the output (Gulcehre et al., 2016). The models are trained using Adam (Kingma and Ba, 2014). Dropout is applied to non-recurrent connections. Decoding uses beam search (width 5). The generator is implemented using OpenNMT-py (Klein et al., 2017). Hyperparameter details are given in Appendix C. Our code is available online.[4]

2.4 Semi-supervised training

We augment the gold training data with a *silver* dataset generated using ACE,[5] a parser for the ERG, to parse sentences to MRS. We sample one million sentences from the Gigaword corpus (Parker et al., 2011), restricted to articles published before the year 2000, to match the domain of the Wall Street Journal data. The parser failed to parse about 10.3% of the Gigaword sentences, so these were discarded. While there are robust MRS parsers (Buys and Blunsom, 2017; Chen et al., 2018), the MRSs they produce are less accurate and not guaranteed to be well-formed. Our approach thus differs from Konstas et al. (2017), who used self-training to improve AMR to text generation by iteratively training on larger amounts of data parsed by their neural parser.[6]

3 Results

We compare the performance of our neural generator when trained on either gold, silver, or gold and silver data (Table 1). Generation quality is primarily evaluated with BLEU (Papineni et al., 2002), using SacreBLEU (Post, 2018).[7] We evaluate the neural models on both the full Redwoods test set ('All') and the WSJ subset.

The results show that our neural generator obtains very strong performance. Semi-supervised training leveraging the ERG parser leads to an 11 BLEU point improvement on Redwoods, comparing to supervised training only. We found that the best semi-supervised results are obtained by upsampling the gold data so that the gold to silver ratio in training examples is 1:2. Interestingly, training on silver data performs only slightly worse than training on both gold and silver.

3.1 Baselines

Our baselines are the ERG's grammar-based generator (Carroll et al., 1999; Carroll and Oepen, 2005) and the DAG transducer generator of Ye et al. (2018). To compare our models against the grammar-based generator, implemented in ACE, we need to restrict the evaluation to examples from which ACE is able to generate ('All overlap').[8] In addition to BLEU, we also report exact match accuracy on the overlapping subset.

Results show that our neural models outperform the grammar-based generator by a large margin. ACE ranks candidate generations with a discriminative ranker based on structural features over its derivations (Velldal and Oepen, 2006). However, it does not use a language model trained on large amounts of text, which would likely improve fluency substantially.

The DAG transducer was trained to generate from Elementary Dependency Structures (EDS; Oepen and Lønning, 2006), an MRS-derived representation almost equivalent to DMRS (after edge properties are removed, which Table 3 shows has an effect of less than 1 BLEU point). It was evaluated against the same WSJ test set reference generations, but trained using both less gold data (only the WSJ subsection) and less silver data (300K vs 900K sentences). Our model trained on WSJ gold data performs only slightly worse (65.78 BLEU; see Table 2) and all our semi-supervised models obtain substantially higher results.

3.2 Out of domain evaluation

We evaluate the in- and out-of-domain performance of our approach by training models on either WSJ gold data only, or both WSJ gold data and Gigaword silver data, and evaluating on different domains. The results in Table 2 show that while the generator performs best on test data which matches the training domain (news), semi-supervised training leads to substantial out-of-domain improvements on the Wikipedia and the Brown corpus portions of the test set.

[5] ACE version 0.9.25, with the 1214 ERG release, available at `http://sweaglesw.org/linguistics/ace`

[6] The ACE parser obtained 93.5 Smatch score on parsable sentences (Buys and Blunsom, 2017), while the neural AMR parser (Konstas et al., 2017) obtained 62.1 Smatch (on a different domain).

[7] `https://github.com/mjpost/sacreBLEU`

[8] Despite all test sentences being *parsable* by the ERG, there are gaps in generation coverage, primarily because ACE is unable to generate words outside the grammar's vocabulary.

Model	BLEU (All)	BLEU (WSJ)	BLEU (All overlap)	Exact Match%	Coverage%
Neural MRS (gold)	66.11	73.12	69.27	24.09	100
Neural MRS (silver)	75.43	81.76	77.13	25.82	100
Neural MRS (gold + silver)	77.17	83.37	79.15	32.07	100
ACE (ERG)	–	–	62.05	15.08	78
DAG transducer (Ye et al., 2018)	–	68.07	–	–	100

Table 1: BLEU and exact-match scores over held-out test set

	Training Data	
Test domain	WSJ	WSJ + Giga
WSJ	65.78	83.42
Brown	45.00	76.99
Wikipedia	35.90	62.26

Table 2: BLEU scores for domain match experiments

Ablation	BLEU
All attributes	72.06
No node attributes	59.37
No node attr except num, tense	67.34
No edge features	71.27

Table 3: Results of semantic feature ablation, model trained with gold data only

3.3 Attribute ablations

To understand which elements of MRS contribute most to our generator's performance, we ablate node (predicate) and edge attributes from both the training and test DMRS graphs (Table 3). In the training data, number and tense show the most variation among node attributes, and subsequently have the largest effect on the reported BLEU score. The most common value for number is SG, but 62.36% of sentences contain a node with PL. Similarly, 42.41% of sentences contain a tense value other than PRES or UNTENSED. Many other attributes are less informative: Mood has a value other than INDICATIVE in only 0.38% of sentences, and perf is + in just 9.74% of sentences. Edge features (including H, EQ and NEQ) encode constraints on scopal relationships (see Copestake 2009). Removing them, which makes the DMRS representation close to equivalent to EDS, has only a small impact on performance.

Representation	Train on Gold	Train on Gold+Silver
AMR	22.0	33.8
DMRS - no attributes	40.1	63.6
DMRS - all attributes	56.9	75.8

Table 4: BLEU scores for evaluating AMR and DMRS generators on an AMR test set

3.4 Comparison with AMR generation

We compare our approach to AMR-to-text generation by evaluating our generator on a standard AMR test set (LDC2015E86). As we do not have manually verified MRSes available on this test set, we use ACE to parse the reference sentences to silver MRSes. We then evaluate the outputs that our generator produces from those MRSes. About 20% of the examples could not be parsed by ACE, and are discarded for the MRS evaluation. We compare our generator to the neural AMR generator of Konstas et al. (2017) for models trained on gold as well as gold plus silver data.[9]

We evaluate DMRS models both with and without predicate and edge attributes, as these attributes contain information that is absent from AMR.[10] The results in Table 4 show that our MRS generator performs better than the AMR generator by a large margin, even when the additional MRS attributes are excluded. Our system results are reported on the subset for which we obtained MRS parses. AMR results are as given by Konstas et al. (2017) and cover the entire test set.

---

[9] The AMR and DMRS systems have different gold training data, but the same source of silver data.

[10] Recently, Donatelli et al. (2018) proposed adding tense and aspect to AMR, but this annotation is not yet available in a large AMR corpus.

Type	B80-89	B60-69	B40-49	All
Unproblematic	56.4	39.55	48.8	47.1
Slightly problematic	18.0	9.2	3.3	7.6
Moderately problematic	12.8	25.0	18.7	19.8
Ungrammatical	5.1	7.9	8.1	7.6
Other serious error	7.7	18.4	21.1	18.1
Number of errors	39	76	123	238
Errors per item	1.18	2.30	3.73	7.21

Table 5: Percentage of errors of each type, across 99 sampled items, grouped by BLEU score

3.5 Error analysis

We sampled 99 items for error analysis from the dev set, 33 each from among sentences with sentence-level BLEU scores of 80-89, 60-69, and 40-49.[11] We identified all differences between these strings and the reference strings and then labeled each difference with a fine-grained error type.[12] We classified the differences into 238 errors, distributed across five levels of severity (Table 5).

Almost half of the differences (47.1%) were unproblematic, including spelling variants, meaning-preserving punctuation variation and grammatical alternations (such as optional *that* or auxiliary contraction as in (1)). The slightly problematic category includes close synonyms (e.g. *sometime* v. *someday*), spelled out number names where Arabic numerals are preferred, and differences in formatting. The next more serious category (moderately problematic) includes meaning-changing differences in punctuation, tense or aspect, and minor grammatical errors such as swapping *who* and *which* in relative clauses or *a* v. *an*.

(1) a. I think I would like a Sony. [sys.]
    b. I think I'd like a Sony. [ref.]

Finally, among the most serious errors, we find cases where the generator provided ungrammatical output or grammatical output not conveying the correct semantics. The former include spurious additional tokens, ungrammatical word orders, and ungrammatical inflection. Serious errors that nonetheless resulted in grammatical strings include meaning-changing dropped or swapped tokens (as in (2)), spurious additional tokens, and word order changes that alter the semantics or pragmatics of the string.

(2) a. For such cases, machine learning techniques emulate human linguistics and learn from training examples to predict future events. [sys.]
    b. For such cases, machine learning techniques emulate human cognition and learn from training examples to predict future events. [ref.]

In summary, we find that the BLEU scores underestimate the quality of system outputs, due to unproblematic differences (N=112) and differences, like formatting markup (N=6), not reflected in the input semantic representations. Among the 108 moderate to serious differences, about a third (35) involve punctuation, suggesting that meaning signalled by punctuation could be better reflected in the semantic representations. About half (52) involve added, dropped, or swapped tokens, showing room for improvement in the generator's ability to learn appropriate connections between semantic predicates and surface forms. The remainder (21) involve inflection, grammatical alternations (such as *who*/*which*) and word order constraints, showing room for improvement in mimicking grammatical processes.

4 Conclusion

We have shown that neural sequence-to-sequence models can be used to generate high quality natural language text from Minimal Recursion Semantics representations, in contrast to both existing MRS-based generators and neural generators based on other broad-coverage semantic representations. Furthermore, we have demonstrated that a large hand-crafted grammar can be leveraged to produce large training sets, which improves performance of neural generators substantially. Therefore we argue that the ability to generate high quality text from MRS makes it a good choice of representation for text generation applications that require semantic structure. For future work, we are interested in applying graph-to-sequence neural networks (Beck et al., 2018; Song et al., 2018) to MRS-to-text generation.

A Preprocessing Details

We preprocess the text by removing special formatting characters such as HTML tags, converting all double quotations to the same format (i.e., ” instead of `''`) and removing double brackets ‘[[’ and ‘]]’ that represent hyperlinks in Wikipedia data. These formatting characters are somewhat arbitrary and represent content (markup) that is orthogonal to the meaning of the text, so would be difficult for a model (or a human) to predict from a semantic representation for the text alone (such as MRS). After preprocessing and normalization, sentences in the gold and silver training data identical to sentences in the test set were removed.

Named entities (as annotated in MRS) are anonymized according to the conventions described in Konstas et al. (2017) prior to training. The purpose of anonymization is to reduce the sparsity of tokens such as dates and named entities that, while having a different surface form almost every time they appear in the text, should be treated similarly by the model. These tokens are replaced, both in the DMRS graph and in the raw sentence text, with numbered placeholders like *named0*, *named1*, and *month*.

Sentences are tokenized using the NLTK's implementation (Bird et al., 2009) of Moses-style tokenization (Koehn et al., 2007). During post-processing, generated sentences are de-anonymized (by replacing the placeholder with the original surface form) and de-tokenized, reversing the NLTK tokenization.

B Unknown Word Handling

We use a combination of two methods to deal with unknown words: anonymizing words to a special *UNK0* token and using the pointer attention to copy the token with highest attention value directly from the source to the target (Gulcehre et al., 2016). There are two types of unknown words in our setup: words that are not recognized by the model because they do not appear in the training data and words that may or may not appear in the training data that are not recognized by the ERG because they are not part of its lexicon. Inspection shows that words missing from the ERG lexicon are often misspellings, uncommon proper names, or domain-specific terminology.

For words that are not part of the ERG lexicon, if the word appears only once in the training data, we replace it with *UNK0*. Otherwise, if the word appears multiple times in the training set, we include its surface form (instead of a predicate) as the node token to enable the model to learn from it. In early experiments, we also tried either anonymizing all unknowns or including all unknowns (relying on the pointer copy mechanism), and found that anonymizing singletons gave best performance while also keeping the vocabulary size reasonable.

C Model Details

The encoder and decoder each have two 800-dimension Bidirectional LSTM layers. The main input embedding layer has 500 dimensions and the size of the attribute embedding layer varies between 22 and 25 depending on the number of attribute combinations in the training data. We train using negative log likelihood loss, optimizing using Adam with initial learning rate = 0.001, β_1 = 0.9 and β_2 = 0.999. For regularization, we apply dropout of 0.3 to the non-recurrent connections of the LSTM layers and after the attention layer. The number of layers, per-layer hidden state size, and dropout rates were all chosen empirically to minimize validation perplexity.

Step-by-Step: Separating Planning from Realization in Neural Data-to-Text Generation[*]

Abstract

Data-to-text generation can be conceptually divided into two parts: ordering and structuring the information (planning), and generating fluent language describing the information (realization). Modern neural generation systems conflate these two steps into a single end-to-end differentiable system. We propose to split the generation process into a symbolic text-planning stage that is faithful to the input, followed by a neural generation stage that focuses only on realization. For training a plan-to-text generator, we present a method for matching reference texts to their corresponding text plans. For inference time, we describe a method for selecting high-quality text plans for new inputs. We implement and evaluate our approach on the WebNLG benchmark. Our results demonstrate that decoupling text planning from neural realization indeed improves the system's reliability and adequacy while maintaining fluent output. We observe improvements both in BLEU scores and in manual evaluations. Another benefit of our approach is the ability to output diverse realizations of the same input, paving the way to explicit control over the generated text structure.

1 Introduction

Consider the task of data-to-text generation, as exemplified in the WebNLG corpus (Colin et al., 2016). The system is given a set of RDF triplets describing facts (entities and relations between them) and has to produce a fluent text that is faithful to the facts. An example of such triplets is:

`John, birthPlace, London`
`John, employer, IBM`

With a possible output:

1. John, who was born in London, works for IBM.

Other outputs are also possible:

2. John, who works for IBM, was born in London.
3. London is the birthplace of John, who works for IBM.
4. IBM employs John, who was born in London.

These variations result from different ways of structuring the information: choosing which fact to mention first, and in which direction to express each fact. Another choice is to split the text into two different sentences, e.g.,

5. John works for IBM. John was born in London.

Overall, the choice of fact ordering, entity ordering, and sentence splits for these facts give rise to 12 different structures, each of them putting the focus on somewhat different aspect of the information. Realistic inputs include more than two facts, greatly increasing the number of possibilities.

Another axis of variation is in how to verbalize the information for a given structure. For example, (2) can also be verbalized as

2a. John works for IBM and was born in London.

and (5) as:

5a. John is employed by IBM. He was born in London.

We refer to the first set of choices (how to structure the information) as *text planning* and to the second (how to verbalize a plan) as *plan realization*.[1]

The distinction between planning and realization is at the core of classic natural language generation (NLG) works (Reiter and Dale, 2000; Gatt and Krahmer, 2017). However, a recent wave of *neural NLG systems* ignores this distinction

[1] Note that the variation from 5 to 5a includes the introduction of a pronoun. This is traditionally referred to as *referring expression generation* (REG), and falls between the planning and realization stages. We do not treat REG in this work, but our approach allows natural integration REG systems' outputs.

Proceedings of NAACL-HLT 2019, pages 2267–2277
Minneapolis, Minnesota, June 2 - June 7, 2019.

and treat the problem as a single end-to-end task of learning to map facts from the input to the output text (Gardent et al., 2017; Dušek et al., 2018). These neural systems encode the input facts into an intermediary vector-based representation, which is then decoded into text. While not stated in these terms, the neural system designers hope for the network to take care of both the planning and realization aspect of text generation. A notable exception is the work of Puduppully et al. (2018), who introduce a neural content-planning module in the end-to-end architecture.

While the neural methods achieve impressive levels of output fluency, they also struggle to maintain coherency on longer texts (Wiseman et al., 2017), struggle to produce a coherent order of facts, and are often not faithful to the input facts, either omitting, repeating, hallucinating or changing facts (the NLG community refers to such errors as errors in *adequacy* or *correctness* of the generated text). When compared to template-based methods, the neural systems win in fluency but fall short regarding content selection and faithfulness to the input (Puzikov and Gurevych, 2018). Also, they do not allow control over the output's structure. We speculate that this is due to demanding too much of the network: while the neural system excels at capturing the language details required for fluent realization, they are less well equipped to deal with the higher levels text structuring in a consistent and verifiable manner.

Proposal we propose an explicit, symbolic, text planning stage, whose output is fed into a neural generation system. The text planner determines the information structure and expresses it unambiguously—in our case as a sequence of ordered trees. This stage is performed symbolically and is guaranteed to remain faithful and complete with regards to the input facts. Once the plan is determined,[2] a neural generation system is used to transform it into fluent, natural language text. By being able to follow the plan structure closely, the network is alleviated from the need to determine higher-level structural decisions and can track what was already covered more easily. This allows the network to perform the task it excels in, producing fluent, natural language outputs.

We demonstrate our approach on the WebNLG corpus and show it results in outputs which are as fluent as neural systems, but more faithful to the input facts. The method also allows explicit control of the output structure and the generation of diverse outputs (some diversity examples are available in the Appendix). We release our code and the corpus extended with matching plans in `https://github.com/AmitMY/chimera`.

2 Overview of the Approach

Task Description Our method is concerned with the task of generating texts from inputs in the form of RDF sets. Each input can be considered as a graph, where the entities are nodes, and the RDF relations are directed labeled edges. Each input is paired with one or more reference texts describing these triplets. The reference can be either a single sentence or a sequence of sentences. Formally, each input G consists of a set of triplets of the form (s_i, r_i, o_i), where $s_i, o_i \in V$ ("subject" and "object") correspond to entities from DBPedia, and $r_i \in R$ is a labeled DBPedia relation (V and R are the sets of entities and relations, respectively). For example, Figure 1a shows a triplet set G and Figure 1d shows a reference text. We consider the data set as a set of input-output pairs (G, ref), where the same G may appear in several pairs, each time with a different reference.

Method Overview We split the generation process into two parts: text planning and sentence realization. Given an input G, we first generate a text plan $plan(G)$ specifying the division of facts to sentences, the order in which the facts are expressed in each sentence, and the ordering of the sentences. This data-to-plan step is non-neural (Section 3). Then, we generate each sentence according to the plan. This plan-to-sentence step is achieved through an NMT system (Section 4).

Figure 1 demonstrates the entire process.

To facilitate our plan-based architecture, we devise a method to annotate (G, ref) pairs with the corresponding plans (Section 3.1), and use it to construct a dataset which is used to train the plan-to-text translation. The same dataset is also used to devise a plan selection method (Section 3.2).

General Applicability It is worth considering the dataset-specific vs. general applicability aspects of our method. On the low-level details, this

---

[2] The exact plan can be determined based on a data-driven scoring function that ranks possible suggestions, as in this work, or by other user provided heuristics or a trained ML model. The plans' symbolic nature and precise relation to the input structures allow verification of their correctness.

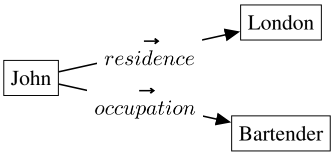
Figure 1: Summary of our proposed generation process: the planner takes the input RDF triplets in (a), and generates the explicit plan in (b). The plan is then linearized (c) and passed to a neural generation system, producing the output (d).

work is very much dataset dependent. We show how to represent plans for specific datasets, and, importantly for this work, how to automatically construct plans for this dataset given inputs and expected natural language outputs. The method of plan construction will likely not generalize “as is” to other datasets, and the plan structure itself may also be found to be lacking for more demanding generation tasks. However, on a higher level, our proposal is very general: intermediary plan structures can be helpful, and one should consider ways of obtaining them, and of using them. In the short term, this will likely take the form of ad-hoc explorations of plan structures for specific tasks, as we do here, to establish their utility. In the longer term, research may evolve to looking into how general-purpose plan are structured. Our main message is that the separation of planning from realization, even in the context of neural generation, is a useful one to be considered.

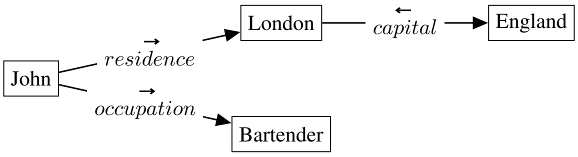
3 Text Planning

Plan structure Our text plans capture the division of facts to sentences and the ordering of the sentences. Additionally, for each sentence, the plan captures (1) the ordering of facts within the sentence; (2) The ordering of entities within a fact, which we call the *direction* of the relation. For example, the {`A, location, B`} relation can be expressed as either *A is located in B* or *B is the location of A*; (3) the structure between facts that share an entity, namely chains and sibling structures as described below.

(a) Chain: John lives in London, the capital of England.



(b) Sibling: John lives in London and works as a bartender.



(c) Combination: John lives in London, the capital of England, and works as a bartender.

Figure 2: Fact construction structure.

A text plan is modeled as a sequence of sentence plans, to be realized in order. Each sentence plan is modeled as an ordered tree, specifying the structure in which the information should be realized. Structuring each sentence as a tree enables a clear succession between different facts through shared entities. Our text-plan design assumes that each entity is mentioned only once in a sentence, which holds in the WebNLG corpus. The ordering of the entities and relations within a sentence is determined by a pre-order traversal of the tree.

Figure 1b shows an example of a text plan. Formally, given the input G, a text plan T is a sequences of sentence plans $T = s_1, ..., s_{N_T}$. A sentence plan s is a labeled, ordered tree, with arcs of the form (h, ℓ, m), where $h, m \in V$ are head and modifier nodes, each corresponding to an input entity, and $\ell = (r, d)$ is the relation between nodes, where $r \in R$ is the RDF relation, and $d \in \{\rightarrow, \leftarrow\}$ denotes the direction in which the relation is expressed: $d = \rightarrow$ if $(h, r, m) \in G$, and $d = \leftarrow$ if $(m, r, h) \in G$. A text plan T is said to match an input G iff every triplet (s, r, o) in G is expressed in T exactly once, either as an edge $(s, (r, \rightarrow), o)$ or as an edge $(o, (r_i, \leftarrow), s)$.

Chains $(h, \ell_1, m), (m, \ell_2, x)$ represent a succession of facts that share a middle entity (Figure 2a), while siblings — nodes with the same parent — $(h, \ell_1, m_1), (h, \ell_2, m_2)$ represents a succession of facts about the same entity (Figure 2b). Sibling and chain structures can be combined (Figure 2c). An example of an input we addressed in the WebNLG corpus, and matching text plan is given in Figure 1b.

Exhaustive generation For small-ish input graphs G—such as those in the WebNLG task we consider here—it is trivial to generate all possible plans by first considering all the ways of grouping the input into sets, then from each set generating all possible trees by arranging it as an undirected graph and performing several DFS traversals starting from each node, where each DFS traversal follows a different order of children.[3]

3.1 Adding Plans to Training Data

While the input RDFs and references are present in the training dataset, the plans are not. We devise a method to recover the latent plans for most of the input-reference pairs in the training set, constructing a new dataset of (G, ref, T) triplets of inputs, reference texts, and corresponding plans.

We define the reference ref, and the text-plan T to be consistent with each other iff (a) they exhibit the same splitting into sentences—the facts in every sentence in ref are grouped as a sentence plan in T, and (b) for each corresponding sentence and sentence-plan, the order of the entities is identical.

The matching of plans to references is based on the observations that (a) it is relatively easy to identify entities in the reference texts, and a pair of entities in an input is unique to a fact; (b) it is relatively easy to identify sentence splits; (c) a reference text and its matching plan must share the same entities in the same order, and with the same sentence splits.

Sentence split consistency We define a set of triplets to be *potentially consistent* with a sentence iff each triplet contains at least one entity from the sentence (either its subject or object appear in the sentence), and each entity in the sentence is covered by at least one triplet. Given a reference text, we split it into sentences using NLTK (Bird and Loper, 2004), and look for divisions of G into disjoint sets such that each set is consistent with a corresponding sentence. For each such division, we consider the exhaustive set of all induced plans.

Facts order consistency A natural criterion would be to consider a reference sentence and a sentence-plan originating from the corresponding RDF as matching iff the sets of entities in the sentence and the plan are identical, and all entities appear in the same order.[4] Based on this, we could represent each sentence and each plan as a sequence of entities, and verify the sequences match.

However, using this criterion is complicated by the fact that it is not trivial to map between the entities in the plan (that originate from the RDF triplets) and the entities in the text. In particular, due to language variability, the same plan entity may appear in several forms in the textual sentences. Some of these variations (i.e. "A.F.C Fylde" vs. "AFC Fylde") can be recognized heuristically, while others require external knowledge ("UK conservative party" vs. "the Tories"), and some are ambiguous and require full-fledged co-reference resolution ("them", "he", "the former"). Hence, we relax our matching criterion to allow for possible unrecognized entities in the text.

Concretely, we represent each sentence plan as a sequence of its entities $(pe_1, ..., pe_k)$, and each sentence as the sequence of its entities which we managed to recognize and to match with an input entity $(se_1, ..., se_m), m \leq k$.[5]

We then consider a sentence and a sentence-plan to be *consistent* if the following two condi-

---

[3] If a graph includes a cycle (0.4% of the graphs in the WebNLG corpus contain cycles) we skip it, as it is guaranteed that a different split will result in cycle-free graphs.

[4] An additional constraint is that no two triplets in the RDFs set share the same entities. This is to ensure that if two entities appeared in a structure, only one relation could have been expressed there. This almost always holds in the WebNLG corpus, failing on only 15 out of 6,940 input sets.

[5] We match plan entities to sentence entities using greedy string matching with Levenshtein distance (Levenshtein, 1966) for each token and a manually tuned threshold for a match. While this approach results in occasional false positives, most cases are detected correctly. We match dates by using the chrono-python package that parses dates from natural language texts.

tions hold: (1) The sentence entities $(se_1, ..., se_m)$ are a proper sub-sequence of the plan entities $(pe_1, ..., pe_k)$; and (2) each of the remaining entities in the plan already appeared previously in the plan. The second condition accounts for the fact that most un-identified entities are due to pronouns and similar non-lexicalized referring expressions, and that these only appear after a previous occurrence of the same entity in the text.[6]

3.2 Test-time Plan Selection

To select the plan to be realized, we propose a mechanism for ranking the possible plans. Our plan scoring method is a product-of-experts model, where each expert is a conditional probability estimate for some property of the plan. The conditional probabilities are MLE estimates based on the plans in the training set constructed in section 3.1. Estimates involving relation names are smoothed using Lidstone smoothing to account for unseen relations. We use the following experts:

Relation direction For every relation $r \in R$, we compute its probability to be expressed in the plan in its original order $(d = \rightarrow)$ or in the reverse order $(d = \leftarrow)$: $p_{dir}(d = \rightarrow | R)$. This captures the tendency of certain relations to be realized in the reversed order to how they are defined in the knowledge base. For example, in the WebNLG corpus the relation "manager" is expressed as a variation of "is managed by" instead of one of "is the manager of" in 68% of its occurrences $(p_{dir}(d = \leftarrow |\text{manager}) = 0.68)$.

Global direction We find that while the probability of each relation to be realized in a reversed order is usually below 0.5, still in most plans of longer texts there are one or two relations that appear in the reversed order. We capture this tendency using an expert that considers the conditional probability $p_{gd}(nr = n| \ |G|)$ of observing n reversed edges in an input with $|G|$ triplets.

Splitting tendencies For each input size, we keep track of the possible ways in which the set of facts can be split to subsets of particular sizes. That is, we keep track of probabilities such as $p_s(s = [3, 2, 2] \mid 7)$ of realizing an input of 7 RDF triplets as three sentences, each realizing the corresponding number of facts.

Relation transitions We consider each sentence plan as a sequence of the relation types expressed in it $r_1, \ldots, r_k$ followed by an EOS symbol, and compute the markov transition probabilities over this sequence: $p_{trans}(r_1, r_2, \ldots, r_k, EOS) = \prod_{i=1,k} p_t(r_{i+1}|r_i)$. The expert is the product of the transition probabilities of the individual sentence plans in the text plan. This captures the tendencies of relations to follow each other and in particular, the tendencies of related relations such as birth-place and birth-date to group, allowing their aggregation in the generated text (*John was born in London on Dec 12th, 1980*).

Each of the possible plans are then scored based on the product of the above quantities.[7]

The scores work well for separating good from lousy text plans, and we observe a threshold above which most generated plans result in adequate texts. We demonstrate in Section 6 that realizing highly-ranked plans manages to obtain good automatic realization scores. We note that the plan in Figure 1b is the one our ranking algorithm ranked first for the input in Figure 1a.

Possible Alternatives In addition to the single plan selection, the explicit planning stage opens up additional possibilities. Instead of choosing and realizing a single plan, we can realize **a diverse set** of high-scoring plans, or realizing a random high-scoring plan, resulting in a diverse and less templatic set of texts across runs. This relies on the combination of two factors: the ability of the scoring component to select plans that correspond to plausible human-authored texts, and the ability of the neural realizer to faithfully realize the plan into fluent text. While it is challenging to directly evaluate the plans adequacy, we later show an evaluation of the plan realization component. Figure 3 shows three random plans for the same graph and their realizations. Further examples of the diversity of generation are given in the appendix.

The explicit and symbolic planning stage also allows for **user control** over the generated text, either by supplying constraints on the possible plans (e.g., number of sentences, entities to focus on, the order of entities/relations, or others) or by supplying complete plans. We leave these options for future work.

---

[6] A sensible alternative would be to use a coreference resolution system at this stage. In our case it turned out to not help, and even performed somewhat worse.

[7] We note that for an input of n triplets, there are $\mathcal{O}(2^{2n} + n * n!)$ possible plans, making this method prohibitive for even moderately sized input graphs. However, it is sufficient for the WebNLG dataset in which $n \leq 7$. For larger graphs, better plan scoring and more efficient search algorithms should be devised. We leave this for future work.

(a) **Dessert** ← course [**Bionico** → country [**Mexico**] → ingredient [**Granola**] → region [**Jalisco**]]
*The **Dessert** **Bionico** requires **Granola** as one of its ingredients and originates from the **Jalisco** region of **Mexico** .*

(b) **Bionico** → country [**Mexico**] → region [**Jalisco**] .
Dessert ← course [**Bionico** → ingredient [**Granola**]]
***Bionico** is a food found in the **Mexico** region **Jalisco**.*
*The **Dessert** **Bionico** requires **Granola** as an ingredient.*

(c) **Bionico** → ingredient [**Granola**] → course [**Dessert**] .
Bionico → region [**Jalisco**] → country [**Mexico**]
***Bionico** contains **Granola** and is served as a **Dessert**.*
Bionico** is a food found in the region of **Jalisco**, **Mexico

Figure 3: Three random linearized plans for the same input graph, and their text realizations. All taken from the top 10% scoring plans. (a) structures the output as a single sentence, while (b) and (c) as two sentences. The second sentence in (b) puts emphasis on Bionico being a dessert, while in (c) the emphasis is on the ingredients.

4 Plan Realization

For plan realization, we use an off-the-shelf vanilla neural machine translation (NMT) system to translate plans to texts. The explicit division to sentences in the text plan allows us to realize each sentence plan individually which allows the realizer to follow the plan structure within each (rather short) sentence, reducing the amount of information that the model needs to remember. As a result, we expect a significant reduction in over- and under-generation of facts, which are common when generating longer texts. Currently, this comes at the expense of not modeling discourse structure (i.e., referring expressions). This deficiency may be handled by integrating the discourse into the text plan, or as a post-processing step.[8]. We leave this for future work.

To use text plans as inputs to the NMT, we linearize each sentence plan by performing a pre-order traversal of the tree, while indicating the tree structure with brackets (Figure 1c). The directed relations (r, d) are expressed as a sequence of two or more tokens, the first indicating the direction and the rest expressing the relation.[9] Entities that are identified in the reference text are replaced with single, entity-unique tokens. This allows the NMT system to copy such entities from the input rather than generating them. Figure 1d is an example of possible text resulting from such linearization.

Training details We use a standard NMT setup with a copy-attention mechanism (Gulcehre et al., 2016)[10] and the pre-trained GloVe.6B word embeddings[11] (Pennington et al., 2014). The pre-trained embeddings are used to initialize the relation tokens in the plans, as well as the tokens in the reference texts.

Generation details We translate each sentence plan individually. Once the text is generated, we replace the entity tokens with the full entity string as it appears in the input graph, and lexicalize all dates as *Month DAY+ordinal, YEAR* (i.e., *July 4th, 1776*) and for numbers with units (i.e., *"5"(minutes)*) we remove the parenthesis and quotation marks (*5 minutes*).

5 Experimental Setup

The WebNLG challenge (Colin et al., 2016) consists of mapping sets of RDF triplets to text including referring expression generation, aggregation, lexicalization, surface realization, and sentence segmentation. It contains sets with up to 7 triplets each along with one or more reference texts for each set. The test set is split into two parts: *seen*, containing inputs created for entities and relations belonging to DBpedia categories that were seen in the training data, and *unseen*, containing inputs extracted for entities and relations belonging to 5 unseen categories. While the unseen category is conceptually appealing, we view the seen category as the more relevant setup: generating fluent, adequate and diverse text for a mix of known relation types is enough of a challenge also without requiring the system to invent verbalizations for unknown relation types. Any realistic generation system could afford to provide at least a few verbalizations for each relation of interest. We thus focus our attention mostly on the seen case (though our system does also perform well on the unseen case).

Following Section 3.1, we manage to match a

---

[8] Minimally, each entity occurrence can keep track of the number of times it was already mentioned in the plan. Other alternatives include using a full-fledged referring expression generation system such as NeuralREG (Ferreira et al., 2018)

[9] We map DBPedia relations to sequences of tokens by splitting on underscores and CamelCase.

[10] Concretely, we use the OpenNMT toolkit (Klein et al., 2017) with the `copy_attn` flag. Exact parameter values are detailed in the appendix.

[11] `nlp.stanford.edu/data/glove.6B.zip`

consistent plan for 76% of the reference texts and use these plan-text pairs to train the plan realization NMT component. Overall, the WebNLG training set contains 18,102 RDF-text pairs while our plan-enhanced corpus contains 13,828 plan-text pairs.[12]

Compared Systems We compare to the best submissions in the WebNLG challenge (Gardent et al., 2017): Melbourne, an end-to-end system that scored best on all categories in the automatic evaluation, and UPF-FORGe (Mille et al., 2017), a classic grammar-based NLG system that scored best in the human evaluation.

Additionally, we developed an end-to-end neural baseline which outperforms the WebNLG neural systems. It uses a set encoder, an LSTM (Hochreiter and Schmidhuber, 1997) decoder with attention (Bahdanau et al., 2014), a copy-attention mechanism (Gulcehre et al., 2016) and a neural checklist model (Kiddon et al., 2016), as well as applying entity dropout. The entity-dropout and checklist component are the key differentiators from previous systems. We refer to this system as **StrongNeural**.

6 Experiments and Results

6.1 Automatic Metrics

We begin by comparing our plan-based system (**BestPlan**) to the state-of-the-art using the common automatic metrics: BLEU (Papineni et al., 2002), Meteor (Banerjee and Lavie, 2005), ROUGE$_L$ (Lin, 2004) and CIDEr (Vedantam et al., 2015), using the nlg-eval[13] tool (Sharma et al., 2017) on the entire test set and on each part separately (seen and unseen).

In the original challenge, the best performing system in automatic metric was based on end-to-end NMT (**Melbourne**). Both the **StrongNeural** and **BestPlan** systems outperform all the WebNLG participating systems on all automatic metrics (Table 1). **BestPlan** is competitive with **StrongNeural** in all metrics, with small differences either way per metric.[14]

	BLEU	**METEOR**	**ROUGE$_\mathrm{L}$**	**CIDEr**
UPF-FORGe$^{\heartsuit}$	38.5	0.390	60.9	2.500
Melbourne$^{\diamondsuit}$	45.0	0.376	63.5	2.814
RandomPlan-1$^{\spadesuit}$	43.3	0.384	57.6	2.342
RandomPlan-2$^{\spadesuit}$	43.5	0.384	57.4	2.332
RandomPlan-3$^{\spadesuit}$	43.5	0.384	57.4	2.303
StrongNeural$^{\diamondsuit}$	46.5	**0.392**	**65.4**	**2.866**
BestPlan$^{\spadesuit}$	**47.4**	0.391	63.1	2.692

Table 1: Results for all categories. Team color indicates the type of system used (NMT$^{\diamondsuit}$, Rule-Based$^{\heartsuit}$, Rule-Based + NMT$^{\spadesuit}$).

6.2 Manual Evaluation

Next, we turn to manually evaluate our system's performance regarding faithfulness to the input on the one hand and fluency on the other. We describe here the main points of the manual evaluation setup, with finer details in the appendix.

Faithfulness As explained in Section 3, the first benefit we expect of our plan-based architecture is to make the neural systems task simpler, helping it to remain faithful to the semantics expressed in the plan which in turn is guaranteed to be faithful to the original RDF input (by faithfulness, we mean expressing all facts in the graph and only facts from the graph: not dropping, repeating or hallucinating facts). We conduct a manual evaluation over the seen portion of the WebNLG human evaluated test set (139 input sets). We compare **BestPlan** and **StrongNeural**.[15] For each output text, we manually mark which relations are expressed in it, which are omitted, and which relations exist with the wrong lexicalization. We also count the number of relations the system over generated, either repeating facts or inventing new facts.[16]

Table 2 shows the results. **BestPlan** reduces all error types compared to **StrongNeural**, by 85%, 56% and 90% respectively. While on-par regarding automatic metrics, **BestPlan** substantially outperforms the new state-of-the-art end-to-end neural system in semantic faithfulness.

For example, Figure 4 compares the output of

---

[12] Note that this only affects the training stage. At test time, we do not require gold plans, and evaluate on all sentences.

[13] `https://github.com/Maluuba/nlg-eval`

[14] At least part of the stronger results for **StrongNeural** can be attributed to its ability to generate referring expressions, which we currently do not support.

[15] We do not evaluate **UPF-FORGe** as it is a verifiable grammar-based system that is fully faithful by design.

[16] This evaluation was conducted by the first author, on a set of shuffled examples from the **BestPlan** and **StrongNeural** systems, without knowing which outputs belongs to which system. We further note that evaluating for faithfulness requires careful attention to detail (making it less suitable for crowd-workers), but has a precise task definition which does not involve subjective judgment, making it possible to annotate without annotator biases influencing the results. We release our judgments for this stage together with the code.

1. William_Anders | dateOfRetirement | ”1969-09-01”
2. William_Anders | was selected by NASA | 1963
3. William_Anders | timeInSpace | ”8820.0”(minutes)
4. William_Anders | birthDate | ”1933-10-17”
5. William_Anders | occupation | Fighter_pilot
6. William_Anders | birthPlace | British_Hong_Kong
7. William_Anders | was a crew member of | Apollo_8

(a) The last RDF in the seen test-set

William Anders was born on **October 17th, 1933** in **British Hong Kong**.
He was selected by nasa in **1963** and became a crew member on the **Apollo 8** flight mission.
He retired on **September 1st, 1969**.

(b) Output from StrongNeural

William Anders was a **fighter pilot** who joined nasa in **1963** and served as a crew member of **Apollo 8**.
William Anders retired on **September 1st, 1969** and spent **8820.0 minutes** in space.
William Anders was born in **British Hong Kong** on october **October 17th, 1933**.

(c) Output from BestPlan

Figure 4: Comparing end-to-end neural generation with our plan based system.

StrongNeural (4b) and **BestPlan** (4c) on the last input in the seen test set (4b). While both systems chose three sentences split and aggregated details about birth in one sentence and details about the occupation in another, **StrongNeural** also expressed the information in chronological order. However, **StrongNeural** failed to generate facts 3 and 5. **BestPlan** made a lexicalization mistake in the third sentence by expressing “October” before the actual date, which is probably caused by faulty entity matching for one of the references, and (by design) did not generate any referring expression, which we leave for future work.

	BestPlan	StrongNeural
Expressed	417	360
Omitted	6	41
Wrong-lexicalization	17	39
Over-generation	3	29

Table 2: Semantic faithfulness of each system regarding 440 RDF triplets from 139 input sets in the seen part of the manually evaluated test set.

Fluency Next, we assess whether our systems succeed at maintaining the high-quality fluency of the neural systems. We perform pairwise evaluation via Amazon Mechanical Turk wherein each task the worker is presented with an RDF set (both in a graph form, and textually), and two texts in random order, one from **BestPlan**, the other from a competing system. We compare **BestPlan** against a strong end-to-end neural system (**StrongNeural**), a grammar-based system which is the state-of-the-art in human evaluation (**UPF-FORGe**), and the human-supplied WebNLG references (**Reference**). The workers were presented with three possible answers: **BestPlan** text is better (scored as 1), the other text is better (scored as -1), and both texts are equally fluent (scored as 0). Table 3 shows the average worker score given to each pair divided by the number of texts compared. **BestPlan** performed on-par with **StrongNeural**, and surpassed the previous state-of-the-art **UPF-FORGe**. It, however, scored worse than the reference texts, which is expected given that it does not produce referring expressions. Our approach manages to keep the same fluency level typical to end-to-end neural systems, thanks to the NMT realization component.

	StrongNeural	Reference	UPF-FORGe
BestPlan	-0.6%	-5.4%	+5.1%

Table 3: MTurk average worker score for *BestPlan* compared to each system. It is a worse than the reference texts, on-par with the neural end-to-end system, and a better than the previous state-of-the-art.

6.3 Plan Realization Consistency

We test the extent to which the realizer generates texts that are consistent with the plans. For several subsets of ranked plans (best plan, top 1%, and top 10%) for the seen and unseen test sets separately, we realize up to 100 randomly selected text-plans per input. We realize each sentence plan and evaluate using two criteria: (1) Do all entities from the plan appear in the realization; (2) Like the consis-

	Best Plan		Top 1% Plans		Top 10% Plans	
	Entities	**Order**	**Entities**	**Order**	**Entities**	**Order**
Seen	98.9%	100%	95.9%	99.9%	93.6%	100%
Unseen	66.7%	100%	45.3%	100%	41.3%	100%

Table 4: Surface realizer performance. *Entities:* Percent of sentence plans that were realized with all the requested entities. *Order*: of the sentences that were realized with all requested entities, percentage of realizations that followed the requested entity order.

tency we defined above, do all entities appear in the same order in the plan and the realization.

Table 4 indicates that for decreasingly probable plans our realizer does worse in the first criterion. However, for both parts of the test set, if the realizer managed to express all of the entities, it expressed them in the requested order, meaning the outputs are consistent with plans. This opens up a potential for user control and diverse outputs, by choosing different plans for realization.

Finally, we verify that the realization of potentially diverse plans is not only consistent with each given plan but also preserves output quality. For each input, we realize a random plan from the top 10%. We repeat this process three times with different random seeds to generate different outputs, and mark these systems as **RandomPlan-1/2/3**. Table 1 shows that these random plans maintain decent quality on the automatic metrics, with a limited performance drop, and the automatic score is stable across random seeds.[17]

7 Related Work

Text planning is a major component in classic NLG. For example, Stent et al. (2004) shows a method of producing coherent sentence plans by exhaustively generating as many as 20 sentence plan trees for each document plan, manually tagging them, and learning to rank them using the RankBoost algorithm (Schapire, 1999). Our planning approach is similar, but we only have a set of "good" reference plans without internal ranks. While the sentence planning decides on the aggregation, one crucial decision left is sentence order. We currently determine order based on a splitting heuristic which relies on the number of facts in every sentence, not on the content. Lapata (2003) devised a probabilistic model for sentence ordering which correlated well with human ordering. Our plan selection procedure is admittedly simple, and can be improved by integrating insights from previous text planning works (Barzilay and Lapata, 2006; Konstas and Lapata, 2012, 2013).

Many generation systems (Gardent et al., 2017; Dušek et al., 2018) are based on a black-box NMT component, with various pre-processing transformation of the inputs (such as delexicalization) and outputs to aid the generation process.

Generation from structured data often requires referring to a knowledge base (Mei et al., 2015; Kiddon et al., 2016; Wen et al., 2015). This led to input-coverage tracking neural components such as the checklist model (Kiddon et al., 2016) and copy-mechanism (Gulcehre et al., 2016). Such methods are effective for ensuring coverage and reducing the number of over-generated facts and are in some ways orthogonal to our approach. While our explicit planning stage reduces the amount of over-generation, our realizer may be further improved by using a checklist model.

More complex tasks, like RotoWire (Wiseman et al., 2017) require modeling also document-level planning. Puduppully et al. (2018) explored a method to explicitly model document planning using the attention mechanism.

The neural text generation community has also recently been interested in "controllable" text generation (Hu et al., 2017), where various aspects of the text (often sentiment) are manipulated (Ficler and Goldberg, 2017) or transferred (Shen et al., 2017; Zhao et al., 2017; Li et al., 2018). In contrast, like in (Wiseman et al., 2018), here we focused on controlling either the content of a generation or the way it is expressed by manipulating the sentence plan used in realizing the generation.

8 Conclusion

We proposed adding an explicit symbolic planning component to a neural data-to-text NLG system, which eases the burden on the neural component concerning text structuring and fact tracking. Consequently, while the plan-based system performs on par with a strong end-to-end neural system regarding automatic evaluation metrics and human fluency evaluation, it substantially outperforms the end-to-end system regarding faithfulness to the input. Additionally, the planning stage allows explicit user-control and generating diverse sentences, to be pursued in future work.

---

[17] While the scores for the different sets are very similar, the plans are very different from each other. See for examples the plans in Figure 3.

Evaluating Rewards for Question Generation Models

Tom Hosking
University College London
`thomas.hosking.17@ucl.ac.uk`

Sebastian Riedel
University College London
`sriedel@ucl.ac.uk`

Abstract

Recent approaches to question generation have used modifications to a Seq2Seq architecture inspired by advances in machine translation. Models are trained using teacher forcing to optimise only the one-step-ahead prediction. However, at test time, the model is asked to generate a whole sequence, causing errors to propagate through the generation process (exposure bias). A number of authors have suggested that optimising for rewards less tightly coupled to the training data might counter this mismatch. We therefore optimise directly for various objectives beyond simply replicating the ground truth questions, including a novel approach using an adversarial discriminator that seeks to generate questions that are indistinguishable from real examples. We confirm that training with policy gradient methods leads to increases in the metrics used as rewards. We perform a human evaluation, and show that although these metrics have previously been assumed to be good proxies for question quality, they are poorly aligned with human judgement and the model simply learns to exploit the weaknesses of the reward source.

1 Introduction

Posing questions about a document in natural language is a crucial aspect of the effort to automatically process natural language data, enabling machines to ask clarification questions (Saeidi et al., 2018), become more robust to queries (Yu et al., 2018), and to act as automatic tutors (Heilman and Smith, 2010).

Recent approaches to question generation have used Seq2Seq (Sutskever et al., 2014) models with attention (Bahdanau et al., 2014) and a form of copy mechanism (Vinyals et al., 2015; Gulcehre et al., 2016). Such models are trained to generate a plausible question, conditioned on an input document and answer span within that document (Zhou et al., 2018; Du et al., 2017; Du and Cardie, 2018; Yuan et al., 2017).

There are currently no dedicated question generation datasets, and authors have used the context-question-answer triples available in SQuAD. Only a single question is available for each context-answer pair, and models are trained using teacher forcing (Williams and Zipser, 1989). This lack of diverse training data combined with the one-step-ahead training procedure exacerbates the problem of exposure bias (Ranzato et al., 2015). The model does not learn how to distribute probability mass over sequences that are valid but different to the ground truth; during inference, the model must predict the whole sequence, and may not be robust to mistakes during decoding.

Recent work has investigated training the models directly on a performance based objective, either by optimising for BLEU score (Kumar et al., 2018a) or other quality metrics (Yuan et al., 2017). By decoupling the training procedure from the ground truth data, the model is able to explore the space of possible questions and learn to recover from suboptimal predictions during decoding. While the metrics used seem to be intuitively good choices, there is an assumption that they are good proxies for question quality which has not yet been confirmed.

Our contributions are as follows. We perform fine tuning using a range of rewards, including a novel adversarial objective that directly estimates the probability that a question was generated or came from the ground truth data. We show that although fine tuning leads to increases in reward scores, the resulting models perform worse when evaluated by human workers. We also demonstrate that the generated questions exploit weaknesses in the reward models.

Table 1: Example generated questions for various fine-tuning objectives. The answer is highlighted in bold. The model trained on a QA reward has learned to simply point at the answer and exploit the QA model, while the model trained on a language model objective has learned to repeat common phrase templates.

2 Background

Many of the advances in natural language generation have been led by machine translation (MT) (Sutskever et al., 2014; Bahdanau et al., 2014; Gulcehre et al., 2016).

Previous work on question generation has made extensive use of MT techniques. Du et al. (2017) use a Seq2Seq based model to generate questions conditioned on context-answer pairs, and build on this work by preprocessing the context to resolve coreferences and adding a pointer network (Du and Cardie, 2018). Similarly, Zhou et al. (2018) use a part-of-speech tagger to augment the embedding vectors. Both authors perform a human evaluation of their models, and show significant improvement over their baseline. Kumar et al. (2018a) use a similar model, but apply it to the task of generating questions without conditioning on a specific answer span. Song et al. (2018) use a modified context encoder based on multi-perspective context matching (Wang et al., 2016).

Kumar et al. (2018b) propose a framework for fine tuning using policy gradients and perform a human evaluation showing promising results. However, they use as rewards various similarity metrics that are still coupled to the ground truth. Yuan et al. (2017) describe a Seq2Seq model with attention and a pointer network, with an additional encoding layer for the answer. They also describe a method for further tuning their model using policy gradients, with rewards given by an external language model and question answering (QA) system. Unfortunately they do not perform any human evaluation to determine whether this tuning led to improved question quality.

For the related task of summarisation, Paulus et al. (2017) propose a framework for fine tuning a summarisation model using reinforcement learning, with the ROUGE similarity metric used as the reward.

3 Experimental setup

The task is to generate a natural language question, conditioned on a document and the location of an answer within that document. For example, given the input document “this paper investigates rewards for question generation” and answer “question generation”, the model should produce a question such as “what is investigated in the paper?”

3.1 Model description

We use the model architecture described by Yuan et al. (2017). Briefly, this is a Seq2Seq model (Sutskever et al., 2014) with attention (Bahdanau et al., 2014) and copy mechanism (Vinyals et al., 2015; Gulcehre et al., 2016). Yuan et al. (2017) also add an additional answer encoder layer, and initialise the decoder with a hidden state constructed from the final state of the encoder. Beam search (Graves, 2012) is used to sample from the model at inference time. We train the model using maximum likelihood before fine tuning. Our implementation achieves a BLEU-4 score (Papineni et al., 2002) of 13.5 on the test set used by Du et al. (2017), before fine tuning.

Features				Metrics				
QA reward	LM reward	Discriminator reward	Adversarial discriminator	NLL	BLEU	QA	LM	Discriminator
-	✓	-	-	-0.7	-1.9	-3.7	-13.4	+1.5
✓	-	-	-	+1.7	-4.5	**+3.9**	+226	+5.4
✓	✓	-	-	-0.5	-2.6	+2.0	**-16.3**	+2.9
-	-	✓	-	**-0.8**	-1.8	-2.1	-9.4	+2.5
-	-	✓	✓	+6.4	-2.7	-2.5	-1.0	**+10.8**
✓	✓	✓	✓	+1.0	-2.4	+1.3	-6.2	+10.0

Table 2: Changes in automatic evaluation metrics after models were fine tuned on various objectives. QA refers to the F1 score obtained by a question answering system on the generated questions. LM refers to the perplexity of generated questions under a separate language model. The discriminator reward refers to the percentage of generated sequences that fooled the discriminator. Lower LM and NLL scores are better. BLEU scores decreased in all cases.

Model	Fluency	Relevance
No fine tuning	**3.34**	**3.12**
+QA, LM rewards	3.05	2.75
+QA, LM, discriminator rewards +Adversarial discriminator	2.89	2.82
Ground Truth	4.67	4.72

Table 3: Summary of human evaluation of selected models

3.2 Fine tuning

Generated questions should be formed of language that is both *fluent* and *relevant* to the context and answer. Following (Yuan et al., 2017), we perform fine tuning on a trained model, using rewards given either by the negative perplexity under a LSTM language model, or the F1 score attained by a question answering (QA) system, or a weighted combination of both. The language model is a standard recurrent neural network formed of a single LSTM layer. For the QA system, we use QANet (Yu et al., 2018) as implemented by Kim (2018).

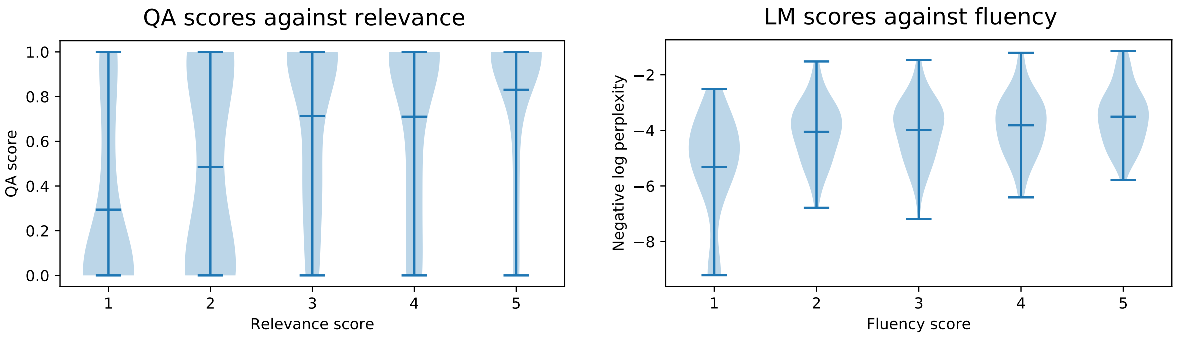
3.3 Adversarial training

Additionally, we propose a novel approach by learning the reward directly from the training data, using a *discriminator* detailed in Appendix A. We generate questions for each context-answer pair in the training set using a generator trained by maximum likelihood, and train the discriminator to predict whether an input question was generated by our model, or originated from the training data. Keeping the discriminator fixed, we then fine-tune the generator, using as reward the probability estimated by the discriminator that a generated question was in fact real. In other words, the generator is rewarded for successfully fooling the discriminator. We also experiment with interleaving updates to the discriminator within the fine tuning phase, allowing the discriminator to become adversarial and adapt alongside the generator.

The rewards described above are used to update the model parameters via the REINFORCE policy gradient algorithm (Williams, 1992). We teacher force the decoder with the generated sequence to reproduce the activations calculated during beam search, to enable backpropagation. All rewards are normalised with a simple form of PopArt (Hasselt et al., 2016), with the running mean μ_R and standard deviation σ_R updated online during training. We continue to apply a maximum likelihood training objective during this fine tuning.

3.4 Evaluation

We report the negative log-likelihood (NLL) of the test set under the different models, as well as the corpus level BLEU-4 score (Papineni et al., 2002) of the generated questions compared to the ground truth. We also report the rewards achieved on the



(a) QA scores plotted against human relevance scores for all rated questions.

(b) LM scores plotted against human fluency scores for all rated questions.

Figure 1: Comparison of human and automatic metrics.

test set, as the QA, LM and discriminator scores.

For the human evaluation, we follow the standard approach in evaluating machine translation systems (Koehn and Monz, 2006), as used for question generation by Du and Cardie (2018). We ask three workers to rate 300 generated questions between 1 (poor) and 5 (good) on two separate criteria: the fluency of the language used, and the relevance of the question to the context document and answer.

4 Results

Table 2 shows the changes in automatic metrics for models fine tuned on various combinations of rewards, compared to the model without tuning. In all cases, the BLEU score reduces, as the training objective is no longer closely coupled to the training data. In general, models achieve better scores on the metrics on which they were fine tuned. Jointly training on a QA *and* LM reward results in better LM scores than training on only a LM reward; the LM score did not increase smoothly when used as the sole objective, and we believe the additional QA reward acts as a form of regularisation. We conclude that fine tuning using policy gradients can be used to attain higher rewards, as expected.

Table 3 shows the human evaluation scores for a subset of the fine tuned models. The model fine tuned on a QA and LM objective is rated as significantly worse by human annotators, despite achieving higher scores in the automatic metrics. In other words, the training objective given by these reward sources does not correspond to true question quality, despite them being intuitively good choices.

The model fine tuned using an adversarial discriminator has also failed to achieve better human ratings, with the discriminator model unable to learn a useful reward source. Although the training process was stable and robust to different initialisations, and the outputs do not appear to be significantly worse, we conclude that the discriminator was unable to learn a sufficiently useful distinction between generated and real questions, and the additional fine tuning procedure simply added unwanted noise to the model predictions.

Table 1 shows an example where fine tuning has not only failed to improve the quality of generated questions, but has caused the model to exploit the reward source. The model fine tuned on a LM reward has degenerated into producing a loop of words that is evidently deemed probable, while the model trained on a QA reward has learned that it can simply point at the location of the answer. This observation is supported by the metrics; the model fine tuned on a QA reward has suffered a catastrophic worsening in LM score of +226.

Figure 1 shows the automatic scores against human ratings for all rated questions. The correlation coefficient between human relevance and automatic QA scores was 0.439, and between fluency and LM score was only 0.355. While the automatic scores are good indicators of whether a question will achieve the lowest human rating or not, they do not differentiate clearly between the higher ratings: training a model on these objectives will not necessarily learn to generate better questions. A good question will likely attain a high QA and LM score, but the inverse is not true; a sequence may exploit the weaknesses of the metrics and achieve a high score *despite* being unintelligible to a human. We conclude that fine tuning a question generation model on these rewards does not lead to better quality questions.

5 Conclusion

In this paper, we investigate the use of external reward sources for fine tuning question generation models to counteract the lack of task-specific training data. We show that although fine tuning can be used to attain higher rewards, this does not equate to better quality questions when rated by humans. Using QA and LM rewards as a training objective causes the generator to expose the weaknesses in these models, which in turn suggests a possible use of this approach for generating adversarial training examples for QA models. The QA and LM scores are well correlated with human ratings at the lower end of the scale, suggesting they could successfully be used as part of a reranking or filtering system. We plan to research overgenerating questions and using the reward signals to rerank the outputs, thereby including the inductive bias the rewards represent without allowing the model to exploit them.

A Discriminator architecture

Figure 2: Discriminator architecture diagram.

We use an architecture based on a modified QANet as shown in Figure 2, replacing the output layers of the model to produce a single probability. Since the discriminator is also able to consider a full context-question-answer triple as input (as opposed to a context-question pair for the QA task), we fuse this information in the output layers.

Specifically, we apply max pooling over time to the output of the first two encoders, and we took the mean of the outputs of the third encoder that formed part of the answer span. These three reduced encodings were concatenated, a 64 unit hidden layer with ReLU activation applied, and the output passed through a single unit sigmoid output layer to give the estimated probability that an input context-question-answer triple originated from the ground truth dataset or was generated.

Text Generation from Knowledge Graphs with Graph Transformers

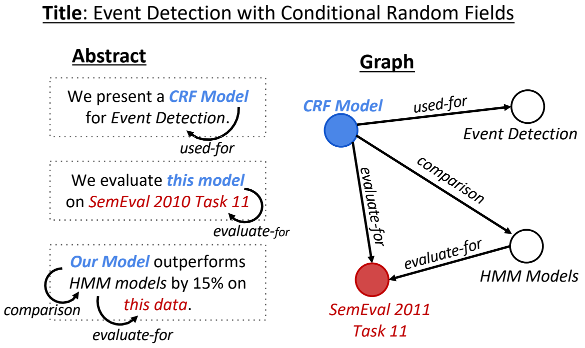
Abstract

Generating texts which express complex ideas spanning multiple sentences requires a structured representation of their content (document plan), but these representations are prohibitively expensive to manually produce. In this work, we address the problem of generating coherent multi-sentence texts from the output of an information extraction system, and in particular a knowledge graph. Graphical knowledge representations are ubiquitous in computing, but pose a significant challenge for text generation techniques due to their non-hierarchical nature, collapsing of long-distance dependencies, and structural variety. We introduce a novel graph transforming encoder which can leverage the relational structure of such knowledge graphs without imposing linearization or hierarchical constraints. Incorporated into an encoder-decoder setup, we provide an end-to-end trainable system for graph-to-text generation that we apply to the domain of scientific text. Automatic and human evaluations show that our technique produces more informative texts which exhibit better document structure than competitive encoder-decoder methods. [1]

1 Introduction

Increases in computing power and model capacity have made it possible to generate mostly-grammatical sentence-length strings of natural language text. However, generating several sentences related to a topic and which display overall coherence and discourse-relatedness is an open challenge. The difficulties are compounded in domains of interest such as scientific writing. Here the variety of possible topics is great (e.g. topics as diverse as driving, writing poetry, and picking stocks are all referenced in one subfield of one scientific discipline). Additionally, there are strong constraints on document structure, as scientific communication requires carefully ordered explanations of processes and phenomena.



We present a CRF Model for Event Detection.

We evaluate this model on SemEval 2010 Task 11

Our Model outperforms HMM models by 15% on this data.

Figure 1: A scientific text showing the annotations of an information extraction system and the corresponding graphical representation. Coreference annotations shown in color. Our model learns to generate texts from automatically extracted knowledge using a graph encoder decoder setup.

Many researchers have sought to address these issues by working with structured inputs. Data-to-text generation models (Konstas and Lapata, 2013; Lebret et al., 2016; Wiseman et al., 2017; Puduppully et al., 2019) condition text generation on table-structured inputs. Tabular input representations provide more guidance for producing longer texts, but are only available for limited domains as they are assembled at great expense by manual annotation processes.

The current work explores the possibility of using information extraction (IE) systems to automatically provide context for generating longer texts (Figure 1). Robust IE systems are available and have support over a large variety of textual domains, and often provide rich annotations of relationships that extend beyond the scope of

Proceedings of NAACL-HLT 2019, pages 2284–2293
Minneapolis, Minnesota, June 2 - June 7, 2019.

a single sentence. But due to their automatic nature, they also introduce challenges for generation such as erroneous annotations, structural variety, and significant abstraction of surface textual features (such as grammatical relations or predicate-argument structure).

To effect our study, we use a collection of abstracts from a corpus of scientific articles (Ammar et al., 2018). We extract entity, coreference, and relation annotations for each abstract with a state-of-the-art information extraction system (Luan et al., 2018), and represent the annotations as a *knowledge graph* which collapses co-referential entities. An example of a text and graph are shown in Figure 1. We use these graph/text pairs to train a novel attention-based encoder-decoder model for knowledge-graph-to-text generation. Our model, GraphWriter, extends the successful Transformer for text encoding (Vaswani et al., 2017) to graph-structured inputs, building on the recent Graph Attention Network architecture (Veličković et al., 2018). The result is a powerful, general model for graph encoding which can incorporate global structural information when contextualizing vertices in their local neighborhoods.

The main contributions of this work include:

1. We propose a new graph transformer encoder that applies the successful sequence transformer to graph structured inputs.
2. We show how IE output can be formed as a connected unlabeled graph for use in attention-based encoders.
3. We provide a large dataset of knowledge-graphs paired with scientific texts for further study.

Through detailed automatic and human evaluations, we demonstrate that automatically extracted knowledge can be used for multi-sentence text generation. We further show that structuring and encoding this knowledge as a graph leads to improved generation performance compared to other encoder-decoder setups. Finally, we show that GraphWriter's transformer-style encoder is more effective than Graph Attention Networks on the knowledge-graph-to-text task.

2 Related Work

Our work falls under the larger scope of concept-to-text generation. Barzilay and Lapata (2005) introduced a collective content selection model for generating summaries of football games from tables of game statistics. Liang et al. (2009) jointly learn to segment and align text with records, reducing the supervision needed for learning. Kim and Mooney (2010) improve this technique by learning a semantic parse to logical forms. Konstas and Lapata (2013) focus on the generation objective, jointly learning planning and generating using a rhetorical (RST) grammar induction approach.

These earlier works often focused on smaller record generation datasets such as WeatherGov and RoboCup, but recently Mei et al. (2016) showed how neural models can achieve strong results on these standards, prompting researchers to investigate more challenging domains such as ours.

Lebret et al. (2016) tackles the task of generating the first sentence of a Wikipedia entry from the associated infobox. They provide a large dataset of such entries and a language model conditioned on tables. Our work focuses on a multi-sentence task where relations can extend beyond sentence boundaries.

Wiseman et al. (2017) study the difficulty of applying neural models to the data-to-text task. They introduce a large dataset where a text summary of a basketball game is paired with two tables of relevant statistics and show that neural models struggle to compete with template based methods over this data. We propose generating from graphs rather than tables, and show that graphs can be effectively encoded to capture both local and global structure in the input.

We show that modeling knowledge as a graph improves generation results, connecting our work to other graph-to-text tasks such as generating from Abstract Meaning Representation (AMR) graphs. Konstas et al. (2017) provide the first neural model for this task, and show that pretraining on a large dataset of noisy automatic parses can improve results. However, they do not directly model the graph structure, relying on linearization and sequence encoding instead. Current works improve this through more sophisticated graph encoding techniques. Marcheggiani and Perez-Beltrachini (2018) encode input graphs directly using a graph convolution encoder (Kipf and Welling, 2017). Our model extends the graph attention networks of Veličković et al. (2018), a direct descendant of the convolutional approach which offers more modeling power and has been

shown to improve performance. Song et al. (2018) uses a graph LSTM model to effect information propagation. At each timestep, a vertex is represented by a gated combination of the vertices to which it is connected and the labeled edges connecting them. Beck et al. (2018) use a similar gated graph neural network. Both of these gated models make heavy use of label information, which is much sparser in our knowledge graphs than in AMR. Generally, AMR graphs are denser, rooted, and connected, whereas the knowledge our model works with lacks these characteristics. For this reason, we focus on attention-based models such as Veličković et al. (2018), which impose fewer constraints on their input.

Finally, our work is related to Wang et al. (2018) who offer a method for generating scientific abstracts from titles. Their model uses a gated rewriter network to write and revise several draft outputs in several sequence-to-sequence steps. While we operate in the same general domain as this work, our task setup is ultimately different due to the use of extracted information as input. We argue that our setup improves the task defined in Wang et al. (2018), and our more general model can be applied across tasks and domains.

3 The AGENDA Dataset

We consider the problem of generating a text from automatically extracted information (*knowledge*). IE systems can produce high quality knowledge for a variety of domains, synthesizing information from across sentence and even document boundaries. Generating coherent text from knowledge requires a model which considers global characteristics of the knowledge as well as local characteristics of each entity. This feature of the task motivates our use of graphs for representing knowledge, where neighborhoods localize important information and paths through the graph build connections between distant nodes through intermediate ones. An example knowledge graph can be seen in Figure 1.

We formulate our problem as follows: given the title of a scientific article and a knowledge graph constructed by an automatic information extraction system, the goal is to generate an abstract that a) is appropriate for the given title and b) expresses the content of the knowledge graph in natural language text. To evaluate how well a model accomplishes this goal, we introduce the Abstract GENeration DAtaset (AGENDA), a dataset of knowledge graphs paired with scientific abstracts. Our dataset consists of 40k paper titles and abstracts from the Semantic Scholar Corpus taken from the proceedings of 12 top AI conferences (Ammar et al., 2018).

For each abstract, we create a knowledge graph in two steps. First, we apply the SciIE system of Luan et al. (2018), a state-of-the-art science-domain information extraction system. This system provides named entity recognition for scientific terms, with entity types Task, Method, Metric, Material, or Other Scientific Term. The model also produces co-reference annotations as well as seven relations that can obtain between different entities (Compare, Used-for, Feature-of, Hyponym-of, Evaluate-for, and Conjunction). For example, in Figure 1, the node labeled "SemEval 2011 Task 11" is of type 'Task', "HMM Models" is of type 'Model', and there is a 'Evaluate-For' relation showing that the models are evaluated on the task.

We form these annotations into knowledge graphs. We collapse co-referential entities into a single node associated with the longest mention (on the assumption that these will be the most informative). We then connect nodes to one another using the relation annotations, treating these as labeled edges in the graph. The result is a possibly unconnected graph representation of the SciIE annotations for a given abstract.

Statistics of the AGENDA dataset are available in Table 1. We split the AGENDA dataset into 38,720 training, 1000 validation, and 1000 test datapoints. We offer standardized data splits to facilitate comparison.

4 Model

Following most work on neural generation we adopt an encoder-decoder architecture, shown in

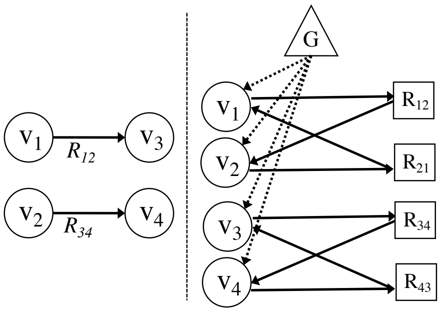

Figure 2: Converting disconnected labeled graph to connected unlabeled graph for use in attention-based encoder. v_i refer to vertices, R_{ij} to relations, and G is a global context node.

Figure 3, which we call GraphWriter. The input to GraphWriter is a title and a knowledge graph which are encoded respectively with a bidirectional recurrent neural network and a novel Graph Transformer architecture (to be discussed in Section 4.1). At each decoder time step, we attend on encodings of the knowledge graph and document title using the decoder hidden state $\mathbf{h}_t \in \mathbb{R}^d$. The resulting vectors are used to select output w_t either from the decoder's vocabulary or by copying an entity from the knowledge graph. Details of our decoding process are described in Section 4.2. The model is trained end-to-end to minimize the negative log likelihood of the mixed copy and vocabulary probability distribution and the human authored text.

4.1 Encoder

The AGENDA dataset contains a knowledge graph for each datapoint, but our model requires unlabeled, connected graphs as input. To encode knowledge graphs with this model, we restructure each graph as an unlabeled connected graph, preserving label information by the method described below and sketched in Figure 2.

Graph Preparation We convert each graph to an unlabeled connected bipartite graphs following a similar procedure to Beck et al. (2018). In this process, each labeled edge is replaced with two vertices: one representing the forward direction of the relation and one representing the reverse. These new vertices are then connected to the entity vertices so that the directionality of the former edge is maintained. This restructures the original knowledge graph as an unlabeled directed graph where all vertices correspond to entities and relations in the SciIE annotations without loss of information. To promote information flow between disconnected parts of the graph, we add a global vertex which connects all entity vertices. This global vertex will be used to initialize the decoder, analogously to the final encoder hidden state in a traditional sequence to sequence model. The final result of these restructuring operations is a connected, unlabeled graph $G = (V, E)$, where V is a list of entities, relations, and a global node and E is an adjacency matrix describing the directed edges.

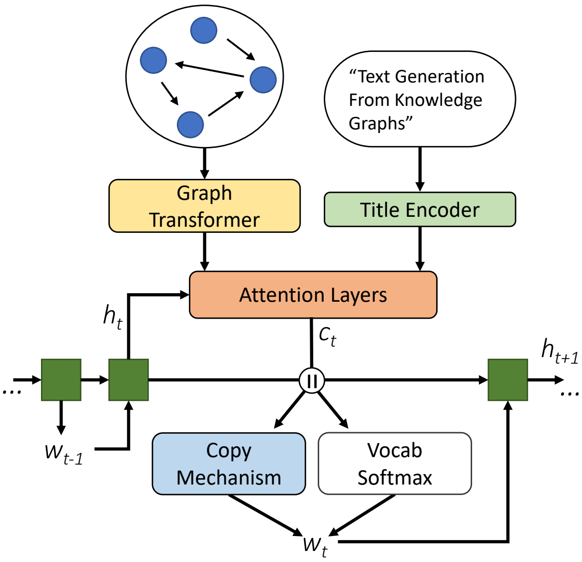

Figure 3: GraphWriter Model Overview

Graph Transformer Our model is most similar to the Graph Attention Network (GAT) of Veličković et al. (2018), which computes the hidden representations of each node in a graph by attending over its neighbors following a self-attention strategy. The use of self-attention in GAT addresses the shortcomings of prior methods based on graph convolutions (Defferrard et al., 2016; Kipf and Welling, 2017), but limits vertex updates to information from adjacent nodes. Our model allows for a more global contextualization of each vertex through the use of a transformer-style architecture. The recently proposed Transformer (Vaswani et al., 2017) addresses the inherent sequential computation shortcoming of recurrent neural networks, enabling efficient and paralleled computation by invoking a self-attention mechanism for global context modeling. These models have shown promising results in a variety of text processing tasks (Radford et al., 2018).

Our Graph Transformer encoder starts with self-

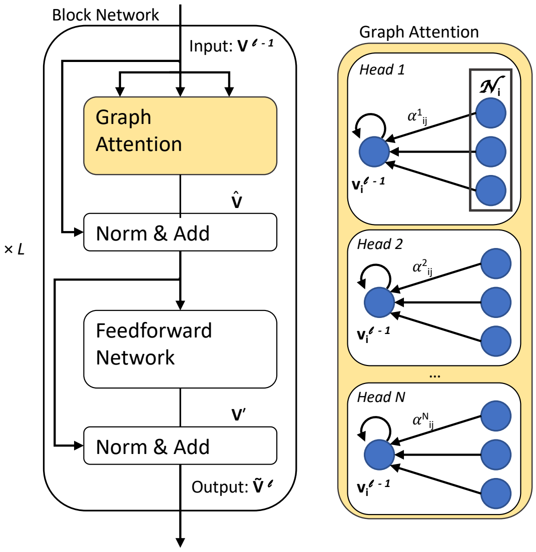

Figure 4: Graph Transformer

attention of local neighborhoods of vertices; the key difference with GAT is that our model includes additional mechanisms for capturing global context. This additional modeling power allows the Graph Transformer to better articulate how a vertex should be updated given the content of its neighbors, as well as to learn global patterns of graph structure relevant to the model's objective.

Specifically, V is embedded in a dense continuous space by the embedding process described at the end of this section, resulting in matrix $\mathbf{V}^0 = [\mathbf{v}_i], \mathbf{v}_i \in \mathbb{R}^d$ which will serve as input to the graph transformer model shown in Figure 4. Each vertex representation $\mathbf{v}_i$ is contextualized by attending over the other vertices to which v_i is connected in G. We use an N-headed self attention setup, where N independent attentions are calculated and concatenated before a residual connection is applied:

$$
\begin{aligned}
\hat{\mathbf{v}}_i &= \mathbf{v}_i + \mathop{\Big\Vert}_{n=1}^{N} \sum_{j \in \mathcal{N}_i} \alpha_{ij}^n \mathbf{W}_V^n \mathbf{v}_j && (1) \\
\alpha_{ij}^n &= a^n(\mathbf{v}_i, \mathbf{v}_j) && (2)
\end{aligned}
$$

Here, $\Vert$ denotes the concatenation of the N attention heads, $\mathcal{N}_i$ denotes the neighborhood of v_i in G, $\mathbf{W}_V^n \in \mathbb{R}^{d \times d}$, and where a^n are attention mechanisms parameterized per head. In this work, we use attention functions of the following form:

$$
a(\mathbf{q}_i, \mathbf{k}_j) = \frac{\exp((\mathbf{W}_K \mathbf{k}_j)^\top \mathbf{W}_Q \mathbf{q}_i)}{\sum_{z \in \mathcal{N}_i} \exp((\mathbf{W}_K \mathbf{k}_z)^\top \mathbf{W}_Q \mathbf{q}_i)} \quad (3)
$$

Each a learns independent transformations $\mathbf{W}_Q, \mathbf{W}_K \in \mathbb{R}^{d \times d}$ of $\mathbf{q}$ and $\mathbf{k}$ respectively, and the resulting product is normalized across all connected edges. To reduce the tendency of these dot products to impede gradient flow, we scale them by $\frac{1}{\sqrt{d}}$, following Vaswani et al. (2017).

The Graph Transformer then augments these multi-headed attention layers with *block* networks. Each block applies the following transformations:

$$
\begin{aligned}
\tilde{\mathbf{v}}_i &= \text{LayerNorm}(\mathbf{v}'_i + \text{LayerNorm}(\hat{\mathbf{v}}_i)) && (4) \\
\mathbf{v}'_i &= \text{FFN}(\text{LayerNorm}(\hat{\mathbf{v}}_i)) && (5)
\end{aligned}
$$

Where $\text{FFN}(\mathbf{x})$ is a two layer feedforward network with a non-linear transformation f between layers i.e. $f(\mathbf{x}\mathbf{W}_1 + b_1)\mathbf{W}_2 + b_2$.

Stacking multiple blocks allows information to propagate through the graph. Blocks are stacked L times, with the output of layer $l-1$ taken as the input to layer l, so that $\mathbf{v}_i^l = \tilde{\mathbf{v}}_i^{l-1}$. The resulting vertex encodings $\mathbf{V}^L = [\mathbf{v}_i^L]$ represent entities, relations, and the global node contextualized by their relationships in the graph structure. We refer to the resulting encodings as *graph contextualized vertex encodings*.

Embedding Vertices, Encoding Title As stated above, the vertices of our graph correspond to entities and relations from the SciIE annotations. Because each relation is represented as both a forward- and backward-looking vertex, we learn two embeddings per relation as well as an initial embedding for the global node. Entities correspond to scientific terms which are often multi-word expressions. To produce a single d-dimensional embedding per phrase, we use the last hidden state of a bidirectional RNN run over embeddings of each word in the entity phrase, i.e. $\text{BiRNN}(\mathbf{x}_1 \ldots \mathbf{x}_m)$ for dense embeddings $\mathbf{x}$ and phrase length m. The output of our embedding step is a collection $\mathbf{V}^0$ of d-dimensional vectors representing each vertex in V.

The title input is also a short string, and so we encode it with another BiRNN to produce $\mathbf{T} = \text{BiRNN}(x'_1 \ldots x'_m)$ for title word embedding $\mathbf{x}'$.

4.2 Decoder

We decode with an attention-based decoder with a copy mechanism for copying input from the knowledge graph and title. At each decoding timestep t we use decoder hidden state $\mathbf{h}_t$ to compute context vectors $\mathbf{c}_g$ and $\mathbf{c}_s$ for the graph and title sequence respectively. $\mathbf{c}_g$ is computed using multi-headed attention contextualized by $\mathbf{h}_t$:

$$\mathbf{c}_g = \mathbf{h}_t + \Big\Vert_{n=1}^{N} \sum_{j \in V} \alpha_j^n \mathbf{W}_G^n \mathbf{v^L}_j \quad (6)$$

$$\alpha_j = a(\mathbf{h}_t, \mathbf{v^L}_j) \quad (7)$$

for a as described in Equation (1) by attending over the graph contextualized encodings $\mathbf{V}^L$. $\mathbf{c}_s$ is computed similarly, attending over the title encoding $\mathbf{T}$. We then construct the final context vector by concatenation, $\mathbf{c}_t = [\mathbf{c}_g \Vert \mathbf{c}_s]$. We use an input-feeding decoder (Luong et al., 2015) where both $\mathbf{h}_t$ and $\mathbf{c}_t$ are passed as input to the next RNN timestep.

We compute a probability p of copying from the input using $\mathbf{h}_t$ and $\mathbf{c}_t$ in a fashion similar to See et al. (2017), that is:

$$p = \sigma(\mathbf{W}_{copy}[\mathbf{h}_t \Vert \mathbf{c}_t] + b_{copy}) \quad (8)$$

The final next-token probability distribution is:

$$p * \alpha^{copy} + (1-p) * \alpha^{vocab}, \quad (9)$$

Where the probability distribution α^{copy} over entities and input tokens is computed as $\alpha_j^{copy} = a([\mathbf{h}_t \Vert \mathbf{c}_t], \mathbf{x}_j)$ for $\mathbf{x}_j \in \mathbf{V} \Vert \mathbf{T}$. The remaining $1-p$ probability is given to α^{vocab}, which is calculated by scaling $[\mathbf{h}_t \Vert \mathbf{c}_t]$ to the vocabulary size and taking a softmax.

5 Experiments

Evaluation Metrics We evaluate using a combination of human and automatic evaluations. For **human** evaluation, participants were asked to compare abstracts generated by various models and those written by the authors of the scientific articles. We used Best-Worst Scaling (BWS; (Louviere and Woodworth, 1991; Louviere et al., 2015)), a less labor-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2016). Participants were presented with two or three abstracts and asked to decide which one was better and which one was worse in order of grammar and fluency (is the abstract written in well-formed English?), coherence (does the abstract have an introduction, state the problem or task, describe a solution, and discuss evaluations or results?), and informativeness (does the abstract relate to the provided title and make use of appropriate scientific terms?). We provided examples of good and bad abstracts and explain how they succeed or fail to meet the defined criteria.

Because our dataset is scientific in nature, evaluations must be done by experts and we can only collect a limited number of these high quality datapoints.[2] The study was conducted by 15 experts (i.e. computer science students) who were familiar with the abstract writing task and the content of the abstracts they judged. To supplement this, we also provide **automatic** metrics. We use BLEU (Papineni et al., 2002), an n-gram overlap measure popular in text generation tasks, and METEOR (Denkowski and Lavie, 2014), a machine translation with paraphrase and language-specific considerations.

Comparisons We compare our GraphWriter against several strong baselines. In GAT, we replace our Graph Transformer encoder with a Graph Attention Network of (Veličković et al., 2018). This encoder consists of PReLU activations stacked between 6 self-attention layers. To determine the usefulness of including graph relations, we compare to a model which uses only entities and title (EntityWriter). Finally, we compare with the gated rewriter model of Wang et al. (2018) (Rewriter). This model uses only the document title to iteratively rewrite drafts of its output. [3]

Implementation Details Our models are trained end-to-end to minimize the negative joint log likelihood of the target text vocabulary and the copied entity indices. We use SGD optimization with momentum (Qian, 1999) and "warm restarts", a cyclical regiment that reduces the learning rate from 0.25 to 0.05 over the course of 5 epochs, then resets for the following epoch. Models are trained for 15 epochs with early stopping (Prechelt, 1998) based on the validation loss, with most models stopping between 8 and 13 epochs. We use single-layer LSTMs (Hochreiter and Schmidhuber, 1997) as recurrent networks. We use dropout (Srivastava et al., 2014) in self attention layers set to 0.3. Hidden states and embedding dimensions are fixed at 500 and attentions learn 500 dimen-

---

[2] Attempts to crowd source this evaluation failed.

[3] Due to the larger size and greater variety of our dataset and accompanying vocabularies compared to theirs, we were unable to train this model with the reported batch size of 240. We use batch size 24 instead, which is partially responsible for the lower performance.

	BLEU	METEOR
GraphWriter	**14.3** ± 1.01	**18.8** ± 0.28
GAT	12.2 ± 0.44	17.2 ± 0.63
EntityWriter	10.38	16.53
Rewriter	1.05	8.38

Table 2: Automatic Evaluations of Generation Systems.

sional projections. In Block layers, the feedforward network has an intermediate size of 2000, and we use a PReLU activation function (He et al., 2015). GraphWriter and GAT use $L = 6$ layers. The number of attention heads is set to 4. In all models, for both inputs and output, we replace words occurring fewer than 5 times with <*unk*> tokens. In each abstract, we replace all mentions in a coreference chain in the abstract with the canonical mention used in the graph. We decode with beam search (Graves, 2012; Sutskever et al., 2014) with a beam size of 4. A post-processing step deletes repeated sentences and repeated coordinated clauses.

5.1 Results

A comparison of all systems in terms of automatic metrics is shown in Table 2. Our GraphWriter model outperforms other methods. We see that models which leverage title, entities, and relations (GraphWriter and GAT) outperform models which use less information (EntityWriter and Rewriter).

We see that GraphWriter outperforms GAT across metrics, indicating that the global contextualization provided by GraphWriter improves generation. To verify the performance gap between GraphWriter and GAT, we report the average test metrics for 4 training runs of each model along with their variances. We see that the variance of the different models is non-overlapping, and in fact all training runs of GraphWriter outperformed all runs of GAT on these metrics.

Does Knowledge Help? To evaluate the value of knowledge in the generation task we compare our GraphWriter model to a model which does not generate from knowledge. We provide expert annotators with 50 randomly-selected paper titles from the test set and ask them for a single judgment according to the criteria described in Section 5. We pair each paper title with the generated abstracts produced by GraphWriter (a knowledge-informed modes), Rewriter (a knowledge-agnostic model), and the gold abstract (with canonicalized coreferential mentions).

	Best	Worst
Rewriter (No knowledge)	12%	64%
GraphWriter (Knowledge)	24%	36%
Human Authored	64%	0%

Table 3: Does knowledge improve generation? Human evaluations of best and worst abstract.

	Win	Lose	Tie
Structure	63%	17%	20%
Informativeness	43%	23%	33%
Grammar	63%	23%	13%
Overall	63%	17%	20%

Table 4: Human Judgments of GraphWriter and EntityWriter models.

Results of this comparison can be seen in Table 3. We see that GraphWriter is selected as "Best" more often than Rewriter, and is less often selected as "Worst", attesting to the value of including knowledge in the text generation process. We see that sometimes generated texts are preferred to human authored text, which is due in part to the disfluencies introduced by canonicalization of entity mentions.

To further understand the advantages of using knowledge graphs, we provide a more detailed comparison of the GraphWriter and EntityWriter models. We select 30 additional test datapoints and ask experts to provide per-criterion judgments of the outputs of the two systems. Since both models make use of extracted entities, we show this list along with the title for each datapoint, and modify the description of Informativeness to include "making use of the provided entities". Results of this evaluation are shown in Table 4. Here we see that including structured knowledge in the form of a graph improves abstract generation compared to generating from an unstructured collection of entities. The largest gains are made in terms of document structure and grammar, indicating that the structure of the input knowledge is being translated into the surface form.

Generating from Title The Rewriter model (Wang et al., 2018) considers the task of generating an abstract with only the paper's title as input. We compare against this model because it is among the first end-to-end systems to attempt to write scientific abstracts. However, the task setup used in Wang et al. (2018) differs significantly from the task introduced in this work. In order

Title	Block and Group Regularized Sparse Modeling for Dictionary Learning
Knowledge	(dictionary learning, CONJUNCTION, sparse coding) ; (optimization problems, USED-FOR, dictionary learning) ; (optimization problems, USED-FOR, sparse coding)...
GraphWriter	Sparse representations have recently been shown to be effective in many optimization problems. However, existing dictionary learning methods are limited in the number of dictionary blocks, which can be expensive to obtain. In this paper, we propose a novel approach to dictionary learning based on sparse coding ...
GAT	In this paper, we consider the problem of dictionary learning in well-known datasets. In particular, we consider the problem of dictionary learning, where the goal is to find a set of dictionary blocks that maximize the likelihood of a given set of dictionary blocks ...
EntityWriter	We propose a novel dictionary learning framework for reconstructed block/group sparse coding schemes. The dictionary learning framework is based on the descent, which is a block structure of the group structure ...
Rewriter	This paper presents a new approach to the k-means of the algorithm. The proposed approach is based on the basis of the stationarity algorithm. The algorithm is based on the fact that the number of bits is a constant of the base of the base of the input ...
Gold	This paper proposes a dictionary learning framework that combines the proposed block/group (BGSC) or reconstructed block/group (R-BGSC) sparse coding schemes with the novel Intra-block Coherence Suppression Dictionary Learning algorithm. An important and distinguishing feature of the proposed framework is that all dictionary blocks are trained simultaneously ...

Table 5: Example outputs of various systems versus Gold.

to make a fair comparison, we construct a variant of our model which is only provided with a title as input. We develop a model that predicts entities from the title, and then uses our knowledge-aware model to generate the abstract. For this comparison we use the EntityWriter model with a collection of entities inferred from the title alone (InferEntityWriter).

To infer relevant entities, we learn to embed titles and entities extracted from the corresponding abstract in a shared dense vector space by minimizing their cosine distance. We use negative sampling to provide definition to this vector space. At test time, we use the title embedding to infer the $K = 12$ closest entities to feed into the InferEntityWriter model. Results are shown in Table 6, which shows that InferEntityWriter achieves better results than Rewriter, indicating that the intermediate entity prediction step is helpful in abstract generation.

	BLEU	METEOR
Rewriter	1.05	8.38
InferEntityWriter	3.60	12.2

Table 6: Comparison of generation without knowledge and with Inferred Knowledge (InferEntityWriter)

5.2 Analysis

Table 5 shows examples of various system outputs for a particular test instance.We see that GraphWriter makes use of more entities from the input, arranged with more articulated textual context. It demonstrates less repetition than GAT. Both GraphWriter and GAT show much better coherence than EntityWriter, which copies entities from the input into unreasonable contexts. Rewriter, while fluent and grammatical, jumps from topic to topic, failing to relate as strongly to the input as the knowledge-aware models.

To determine the shortcomings of our model, we calculate rough error statistics over the outputs of the GraphWriter on the test set. We notice that 40% of entities in the knowledge graphs do not appear in the generated text. Future work should address this coverage problem, perhaps through modifications to the inference procedure or a coverage loss (Tu et al., 2016) modified to the specifics of this task. We find that 18% of all sentences generated by our model repeat sentences or clauses and are subjected to the post-processing pruning mentioned in Section 5. While this step is a simple solution to improve generated outputs, a more advanced solution is required.

6 Conclusion

We have studied the problem of generating multi-sentence text from the output of automatic information extraction systems, and have shown that incorporating knowledge as graphs improves performance. We introduced GraphWriter, featuring a new attention model for graph encoding, and demonstrated its utility through human and automatic evaluation compared to strong baselines. Lastly, we provide a new resource for the generation community, the AGENDA dataset of abstracts and knowledge. Future work could address the problem of repetition and entity coverage in the generated texts.

Abstract

Open Information Extraction (OPENIE) extracts meaningful structured tuples from free-form text. Most previous work on OPENIE considers extracting data from one sentence at a time. We describe NEURON, a system for extracting tuples from question-answer pairs. Since real questions and answers often contain precisely the information that users care about, such information is particularly desirable to extend a knowledge base with.

NEURON addresses several challenges. First, an answer text is often hard to understand without knowing the question, and second, relevant information can span multiple sentences. To address these, NEURON formulates extraction as a multi-source sequence-to-sequence learning task, wherein it combines distributed representations of a question and an answer to generate knowledge facts. We describe experiments on two real-world datasets that demonstrate that NEURON can find a significant number of new and interesting facts to extend a knowledge base compared to state-of-the-art OPENIE methods.

1 Introduction

Open Information Extraction (OPENIE) (Banko et al., 2007) is the problem of extracting structured data from a text corpus, without knowing a priori which relations will be extracted. It is one of the primary technologies used in building knowledge bases (KBs) that, in turn, power question answering (Berant et al., 2013). The vast majority of previous work on OPENIE extracts structured information (e.g., triples) from individual sentences.

This paper addresses the problem of extracting structured data from conversational question-answer (CQA) data. Often, CQA data contains precisely the knowledge that users care about. As such, this data offers a goal-directed method for extending existing knowledge bases. Consider, for example, a KB about a hotel that is used to power its website and/or a conversational interface for hotel guests. The KB provides information about the hotel's services: complimentary breakfast, free wifi, spa. However, it may not include information about the menu/times for the breakfast, credentials for the wifi, or the cancellation policy for a spa appointment at the hotel. Given the wide range of information that may be of interest to guests, it is not clear how to extend the KB in the most effective way. However, the conversational logs, which many hotels keep, contain the actual questions from guests, and can therefore be used as a resource for extending the KB. Following examples illustrate the kind of data we aim to extract:

Example 1. *Q: Does the hotel have a gym?*
A: It is located on the third floor and is 24/7.
Tuple: ⟨*gym, is located on, third floor*⟩

Example 2. *Q: What time does the pool open?*
A: 6:00am daily.
Tuple: ⟨*pool, open, 6:00am daily*⟩

As can be seen from these examples, harvesting facts from CQA data presents significant challenges. In particular, the system must interpret information collectively between the questions and answers. In this case, it must realize that *'third floor'* refers to the location of the *'gym'* and that *6:00am* refers to the opening time of the pool. OPENIE systems that operate over individual sentences ignore the discourse and context in a QA pair. Without knowing the question, they either fail to or incorrectly interpret the answer.

This paper describes NEURON, an end-to-end system for extracting information from CQA data. We cast OPENIE from CQA as a multi-source sequence-to-sequence generation problem to explicitly model both the question and answer

---

[*] Part of the work was done while the author was at Megagon Labs.

Proceedings of NAACL-HLT 2019, pages 2294–2305
Minneapolis, Minnesota, June 2 - June 7, 2019.

in a QA pair. We propose a multi-encoder, constrained-decoder framework that uses two encoders to encode each of the question and answer to an internal representation. The two representations are then used by a decoder to generate an output sequence corresponding to an extracted tuple. For example, the output sequence of Example 2 is:

⟨*arg*$_1$⟩ pool ⟨/*arg*$_1$⟩⟨*rel*⟩ open ⟨/*rel*⟩⟨*arg*$_2$⟩ 6:00am daily ⟨/*arg*$_2$⟩

While encoder-decoder frameworks have been used extensively for machine translation and summarization, there are two key technical challenges in extending them for information extraction from cQA data. First, it is vital for the translation model to learn constraints such as, arguments and relations are sub-spans from the input sequence, output sequence must have a valid syntax (e.g., ⟨*arg*$_1$⟩ must precede ⟨*rel*⟩). These and other constraints can be integrated as *hard* constraints in the decoder. Second, the model must recognize auxiliary information that is irrelevant to the KB. For example, in the hotel application, NeurON must learn to discard greetings in the data. Since existing facts in the KB are representative of the domain of the KB, this prior knowledge can be incorporated as *soft* constraints in the decoder to rank various output sequences based on their relevance. Our contributions are summarized below:

- We develop NeurON, a system for extracting information from cQA data. NeurON is a novel multi-encoder constrained-decoder method that explicitly models both the question and the answer of a QA pair. It incorporates vocabulary and syntax as *hard* constraints and prior knowledge as *soft* constraints in the decoder.
- We conduct comprehensive experiments on two real-world cQA datasets. Our experimental results show that the use of hard and soft constraints improves the extraction accuracy and NeurON achieves the highest accuracy in extracting tuples from QA pairs compared with state-of-the-art sentence-based models, with a relative improvement as high as 13.3%. NeurON's higher accuracy and ability to discover 15-25% tuples that are not extracted by state-of-the-art models make it suitable as a tuple extraction tool for KB extension.
- We present a case study to demonstrate how a KB can be extended iteratively using tuples extracted using NeurON. In each iteration, only relevant tuples are included in the KB. In turn, the extended KB is used to improve relevance scoring for subsequent iterations.

2 Task Formulation

In this work, we choose to model an OpenIE extraction from a question-answer (QA) pair as a tuple consisting of a single relation with two arguments, where the relation and arguments are contiguous spans from the QA pair. Formally, let (q, a) be a QA pair, where question $q = (q_1, q_2, ..., q_m)$ and answer $a = (a_1, a_2, ..., a_n)$ are word sequences. The output is a triple (arg_1,rel,arg_2) extracted from (q, a). The output triple can be naturally interpreted as a sequence $y = (y_1, y_2, ..., y_o)$ where y_i is either a word or a placeholder tag (⟨*arg*$_1$⟩, ⟨*rel*⟩, ⟨*arg*$_2$⟩) that marks relevant portions of the triple. In OpenIE, the extracted tuple should be asserted by the input QA pair. Formulating this, therefore, requires the vocabulary of y to be restricted to the vocabulary of (q, a) and placeholder tags.

Following this definition, our aim is to directly model the conditional probability $p(y|q, a)$ of mapping input sequences q and a into an output sequence:

$$P(y|q, a) = \prod_{i=1}^{o} p(y_i|y_1, \ldots, y_{i-1}, q, a). \quad (1)$$

In our formulation, a triple is generated as a sequence: a *head* argument phrase arg_1, followed by a relation phrase *rel* and a *tail* argument phrase arg_2. It is possible to consider different orderings in the output sequence (such as (rel,arg_1,arg_2)). However, the goal of OpenIE is to identify the relation phrase that holds between a pair of arguments. Our representation is, thus, consistent with this definition as it models the relation phrase to depend on the head argument.

3 NeurON: A Multi-Encoder Constrained-Decoder Model

Overview of NeurON We propose to extract tuples using a variation of an encoder-decoder RNN architecture (Cho et al., 2014) operating on variable-length sequences of tokens. Fig. 1 shows the architecture of NeurON. It uses two encoders to encode question and answer sequences in a QA pair separately into fixed-length vector representations. A decoder then decodes the vector representations into a variable-length sequence corresponding to the tuple. The decoder is integrated

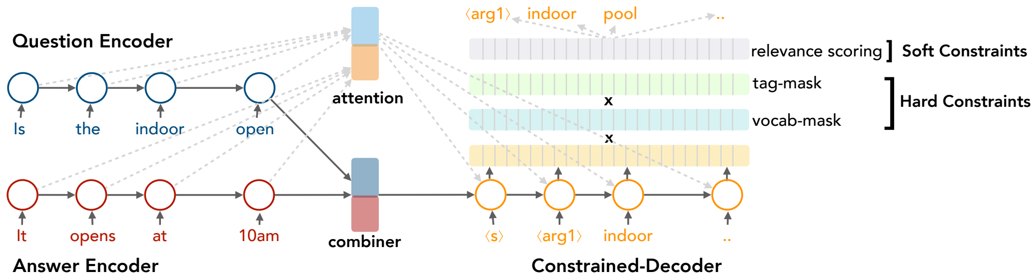

Figure 1: Multi-Encoder, Constrained-Decoder model for tuple extraction from (q, a).

with a set of *hard constraints* (e.g., output vocabulary) and *soft constraints* (e.g., relevance scoring) suited for the extraction task.

3.1 Multiple Encoders

Given an input QA pair, two RNN encoders separately encode the question and answer. The question encoder converts q into hidden representation $h^q = (h_1^q, ..., h_m^q)$ and the answer encoder converts a into $h^a = (h_1^a, ..., h_n^q)$, where $h_t^q = \text{lstm}(q_t, h_{t-1}^q)$ is a non-linear function represented by the long short-term memory (LSTM) cell. The combiner combines the encoders' states and initializes the hidden states $\mathbf{h}$ for the decoder:

$$h = \tanh(W_c[h^q \circ h^a]),$$

where $\circ$ denotes concatenation. The decoder stage uses the hidden states to generate the output y with another LSTM-based RNN. The probability of each token is defined as:

$$p(y_t) = \text{softmax}((s_t \circ c_t^q \circ c_t^a)W_y), \qquad (2)$$

where s_t denotes the decoder state, $s_0 = h$ and $s_t = \text{lstm}((y_{t-1} \circ c_t^q \circ c_t^a)W_s, s_{t-1})$. The decoder is initialized by the last hidden state from the combiner. It uses the previous output token at each step. Both W_y and W_s are learned matrices. Each decoder state is concatenated with *context vectors* derived from the hidden states of the encoders. Context vector c_t is the weighted sum of the encoder hidden states, i.e. $c_t^q = \sum_{i=1}^m \alpha_{t_i} h_i^q$, where α_{t_i} corresponds to an attention weight. The attention model (Bahdanau et al., 2015) helps the model learn to focus on specific parts of the input sequences, instead of solely relying on hidden vectors of the decoders' LSTM. This is crucial for extraction from (q, a) pairs where input sequences tend to be long.

3.2 Constrained Decoder

The decoder finds the best hypothesis (i.e., the best output sequence) for the given input representations. Typically, the output sequence is generated, one unit at a time, using *beam search*. At each time step, the decoder stores the top-k scoring partial sequences, considers all possible single token extensions of them, and keeps k most-likely sequences based on model's probabilities (Eq. 1). As soon as the $\langle/S\rangle$ symbol is appended, the sequence is removed from the beam and added to the set of complete sequences. The most-likely complete sequence is finally generated.

Hard Constraints While such encoder-decoder models typically outperform conventional approaches (Cho et al., 2014; Zoph and Knight, 2016; Xiong et al., 2017) on a wide variety of tasks including machine translation and question answering, the accuracy and training efficiency has been shown to improve when the model is integrated with the constraints of the output domain (Xiao et al., 2016; Yin and Neubig, 2017). Motivated by these, NEURON allows constraints relevant to information extraction to be incorporated in the model. Specifically, we describe how the decoder can enforce vocabulary and structural constraints on the output.

- **Vocabulary constraints.** Since the arguments and relations in the extracted tuples typically correspond to the input QA pair, the decoder must constraint the space of next valid tokens when generating the output sequence. NEURON uses a masking technique in the decoder to mask the probability of tokens (as in Eq. 2) that do not appear in the input (q, a) pair. Specifically, it computes a binary mask vector v, where $|v|$ is vocabulary size and $v_i = 1$ if and only if i-th token appears in q or a. The probability of each token is modified as:

$$p(y_t) = \text{softmax}((s_t \circ c_t^q \circ c_t^a)W_y \otimes v), \qquad (3)$$

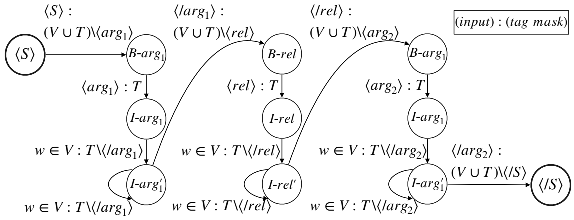

Figure 2: State diagram for tag masking rules. V is the vocabulary including placeholder tags, T is the set of placeholder tags.

where $\otimes$ indicates element-wise multiplication.

- **Structural constraints.** For the output sequence to correspond to a valid tuple with non-empty arguments, the decoding process must conform to the underlying grammar of a tuple. For instance, decoding should always begin in the $\langle S \rangle$ state, where only $\langle arg_1 \rangle$ can be generated. In subsequent time steps, all other placeholders except $\langle /arg_1 \rangle$ should be restricted to ensure a non-empty argument. Once $\langle /arg_1 \rangle$ is generated, $\langle rel \rangle$ must be generated in the next time step and so on. The various states and grammar rules can be described as a finite state transducer as shown in Figure 2.

Depending upon the state, NeurON generates a mask r based on this grammar and uses r to further modify the probabilities of the tokens as follows:

$$p(y_t) = \text{softmax}((s_t \circ c_t^q \circ c_t^a) W_y \otimes v \otimes r). \quad (4)$$

Soft Constraints OpenIE systems are typically used to extract broad-coverage facts to extend existing KBs. Facts already existing in the KB are representative of the domain of the KB. It is, therefore, useful to incorporate this prior knowledge in the extraction itself. NeurON is able to use prior knowledge (incorporated as soft constraints) in the decoder to understand the relevance of candidate extractions and adjust the ranking of various output sequences accordingly. To see why such soft constraints can be useful, consider the example:

Example 3. *Q: "Is the pool open?"*
A: "I am sorry but our pool reopens at 7:00am."
Tuple: ⟨I, am, sorry⟩; ⟨pool, reopens at, 7:00am⟩

Both the tuple facts are correct given the input QA pair but only the second tuple contains useful information. Filtering such irrelevant facts is difficult without additional evidence.

The multi-encoder and constrained-decoder in NeurON are jointly optimized to maximize the log probability of output sequence conditioned on the input sequences. At inference, the decoder estimates the likelihood of various candidate sequences and generates the sequence with the highest likelihood. As shown in Eq. 1, this likelihood is conditioned solely on the input (q, a) pair, thus increasing the possibility of obtaining facts that may be correct but irrelevant. Instead, if a relevance scoring function were integrated at extraction time, the candidate output sequences could be re-ranked so that the predicted output sequence is likely to be both correct and relevant.

Learning a relevance scoring function can be modeled as a KB completion task, where missing facts have to be inferred from existing ones. A promising approach is to learn vector representations of entities and relations in a KB by maximizing the total plausibility of existing facts in the KB (Wang et al., 2017). For a new candidate output sequence, its plausibility can be predicted using the learned embeddings for the entities and relation in the sequence.

In NeurON, we learn the entity and relation embeddings using Knowledge Embedding (KE) methods such as TransE (Bordes et al., 2013) and HolE (Nickel et al., 2016). Note that NeurON is flexible with how the relevance scoring function is learned or which KE method is chosen. In this paper, we use TransE for evaluation. TransE computes the plausibility score S of a tuple $y = \langle arg_1, rel, arg_2 \rangle$ as:

$$S(y) = ||\mathbf{v}_{arg_1} + \mathbf{v}_{rel} - \mathbf{v}_{arg_2}||,$$

where $\mathbf{v}_{arg_1}$, $\mathbf{v}_{rel}$, and $\mathbf{v}_{arg_2}$ are embedding vectors for arg_1, rel, and arg_2 respectively. Following (Jain et al., 2018), we compute the embedding vectors of out-of-vocabulary arguments (and relations) as the average of embedding vectors of known arguments (and relations). We generate the most-likely output based on its conditional probability and plausibility score:

$$\hat{y} = \underset{y}{\text{argmax}}(\log P(y|q, a) + \gamma \log S(y)). \quad (5)$$

To implement the tuple relevance scoring function, we employ the re-ranking approach, which is a common technique for sequence generation methods (Luong et al., 2015b). Our re-ranking method first obtains candidates from a beam search decoder and then re-ranks the candidates based on the objective function (Eq. 5).

4 Experiments

We evaluated the performance of NEURON on two cQA datasets. In our analysis, we find that integrating hard and soft constraints in the decoder improved the extraction performance irrespective of the number of encoders used. Also, 15-25% of the tuples extracted by NEURON were not extracted by state-of-the-art sentence-based methods.

4.1 Datasets and Data Preparation

ConciergeQA is a real-world internal corpus of 33,158 QA pairs collected via a multi-channel communication platform for guests and hotel staff. Questions (answers) are always made by guests (staff). An utterance has 36 tokens on average, and there are 25k unique tokens in the dataset. A QA utterance has 2.8 sentences on average, with the question utterance having 1.02 sentences on average and answer utterance having 1.78 sentences on average.

AmazonQA (Wan and McAuley, 2016; McAuley and Yang, 2016) is a public dataset with 314,264 QA pairs about electronic products on *amazon.com*. The dataset contains longer and more diverse utterances than the *ConciergeQA* dataset: utterances have an average of 45 tokens and the vocabulary has more than 50k unique tokens. A QA utterance has 3.5 sentences on average. The question utterances had 1.5 sentences on average and the answer having 2 sentences.

For training NEURON, we bootstrapped a large number of high-quality training examples using a state-of-the-art OPENIE system. Such bootstrapping has been shown to be effective in information extraction tasks (Mausam et al., 2012; Saha et al., 2017). The StanfordIE (Angeli et al., 2015) system is used to extract tuples from QA pairs for training examples. To further obtain high-quality tuples, we filtered out tuples that occur too infrequently (< 5) or too frequently (> 100). For each tuple in the set, we retrieved all QA pairs that contain all the content words of the tuple and included them in the training set. This helps create a training set encapsulating the multiplicity of ways in which tuples are expressed across QA pairs. We randomly sampled 100 QA pairs from our bootstrapping set and found 74 of them supported the corresponding tuples. We find this quality of bootstrapped dataset satisfactory, since the seed tuples for bootstrapping could be noisy as they were generated by another OPENIE system.

Instance type	*ConciergeQA*	*AmazonQA*
Exclusively from question	13.9%	13.8%
Exclusively from answer	25.8%	17.6%
Ambiguous	36.9%	29.8%
Jointly from Q-A	23.4%	38.8%

Table 1: Various types of training instances.

Dataset	Q-A	|V|	Train	Dev	Test (Q-A)
ConciergeQA	33k	25k	1.25M	128k	2,905
AmazonQA	314k	50k	1.43M	159k	39,663

Table 2: Training, Dev and Test splits.

Our bootstrapped dataset included training instances where a tuple matched (a) tokens in the questions exclusively, (b) tokens in the answers exclusively, (c) tokens from both questions and answers. Table 1 shows the distribution of the various types of training instances. Less than 40% (30%) of ground truth tuples for *ConciergeQA* (*AmazonQA*) exclusively appear in the questions or answers. Also, 22.1% (37.2%) of ground truth tuples for *ConciergeQA* (*AmazonQA*) are extracted from the combination of questions and answers. These numbers support our motivation of extracting tuples from QA pairs. We used standard techniques to construct training/dev/test splits so that QA pairs in the three sets are disjoint. Table 2 shows the details of the various subsets.

4.2 Baseline Approaches

We compared NEURON with two methods that can be trained for tuple extraction from QA pairs: BILSTM-CRF (Huang et al., 2015) and NEURALOPENIE (Cui et al., 2018). BILSTM-CRF is a sequence tagging model that has achieved state-of-the-art accuracy on POS, chunking, NER and OPENIE (Stanovsky et al., 2018) tasks. For OPENIE, the model predicts boundary labels (e.g., B-ARG1, I-ARG1, B-ARG2, O) for the various tokens in a QA pair. NEURALOPENIE is an encoder-decoder model that generates a tuple sequence given an input sequence. Since it uses a single encoder, we generate the input sequence by concatenating the question and answer in a QA pair. We trained all the models using the same training data.

4.3 Performance Metrics

We examine the performance of different methods using three metrics: *precision*, *recall*, and *relative coverage* (RC). Given a QA pair, each system returns a sequence. We label the sequence correct if it matches one of the ground-truth tuples for the QA pair, incorrect otherwise. We then measure precision of a method (i.e., # of correct predictions of the method / # of question-answer pairs) and recall (i.e., # of correct predictions of the method / # of correct predictions of any method) following (Stanovsky and Dagan, 2016). To compare the coverage of sequences extracted by NEURON against the baseline method, we compute relative coverage of NEURON as the fraction of all correct predictions that were generated exclusively by NEURON. Specifically,

$$RC = \frac{|\mathrm{TP}_{\text{NEURON}} \setminus \mathrm{TP}_{baseline}|}{|\mathrm{TP}_{\text{NEURON}} \bigcup \mathrm{TP}_{baseline}|},$$

where TP denotes the correct predictions.

4.4 Model Training and Optimization

We implemented NEURON using OpenNMT-tf (Klein et al., 2017) , an open-source neural machine translation system that supports multi-source encoder-decoder models. We implemented NEURALOPENIE using the same system. We used the open-source implementation of BILSTM-CRF (Reimers and Gurevych, 2017). For fair comparison, we used identical configurations for NEURON and NEURALOPENIE. Each encoder used a 3-layer bidirectional LSTM and the decoder used a 3-layer bidirectional LSTM. The models used 256-dimensional hidden states, 300-dimensional word embeddings, and a vocabulary size of 50k. The word embeddings were initialized with pre-trained GloVe embeddings (glove.6B) (Pennington et al., 2014). We used an initial learning rate of 1 and optimized the model with stochastic gradient descent. We used a decay rate of 0.7, a dropout rate of 0.3 and a batch size of 64. The models were trained for 1M steps for the *ConciergeQA* dataset and 100k steps for the *AmazonQA* dataset. We used TESLA K80 16GB GPU for training the models. We trained the KE models for relevance scoring using our bootstrapped training dataset. For integrating the relevance scoring function, we experimented with different values for γ and found it not have a major impact within a range of 0.02 to 0.2. We used a value of 0.05 in all the experiments.

4.5 Experimental Results

The BILSTM-CRF model showed extremely low (2-15%) precision values. Very few of the tagged sequences (32-39%) could be converted to a tuple. Most tagged sequences had multiple relations and arguments, indicating that it is difficult to learn how to tag a sequence corresponding to a tuple. The model only learns how to best predict tags for each token in the sequence, and does not take into account the long-range dependencies to previously predicted tags. This is still an open problem and is outside the scope of this paper.

Method	P	R	RC
NEURALOPENIE (baseline)	0.769	0.580	-
+ hard constraints	0.776	0.585	-
+ hard and soft constraints	0.796	0.600	-
NEURON (our method)	0.791	0.597	0.224
+ hard constraints	0.792	0.597	0.204
+ hard and soft constraints	**0.807**	**0.608**	**0.245**

Table 3: Precision (P), Recall (R), and Relative Coverage (RC) results on *ConciergeQA*.

Tables 3 and 4 show the performance of NEURALOPENIE and NEURON on the two CQA datasets. NEURON achieves higher precision on both the datasets. This is because NEURALOPENIE uses a single encoder to interpret the question and answer in the same vector space, which leads to lower performance. Furthermore, concatenating the question and answer makes the input sequence too long for the decoder to capture long-distance dependencies in history (Zhang et al., 2016; Toral and Sánchez-Cartagena, 2017). Despite the attention mechanism, the model ignores past alignment information. This makes it less effective than the dual-encoder model used in NEURON.

The tables also show that incorporating task-specific hard constraints helps further improve the overall precision and recall, regardless of the methods and the datasets. Re-ranking the tuples based on the soft constraints derived from the existing KB further improves the performance of both methods in *ConciergeQA* and NEURALOPENIE in *AmazonQA*. The existing KB also helps boost the likelihood of a correct candidate tuple sequence that was otherwise scored to be less likely. Lastly, we found that NEURON has significant relative coverage; it discovered significant additional, unique tuples missed by NEURALOPENIE.

Table 4 shows a slight decrease in performance for NEURON after soft constraints are added. This is likely caused by the lower quality KE model due to the larger vocabulary in *AmazonQA*. In contrast, even with the lower quality KE model, NEU-

Method	P	R	RC
NeuralOpenIE (baseline)	0.557	0.594	-
+ hard constraints	0.563	0.601	-
+ hard and soft constraints	0.571	0.610	-
NeurON (our method)	0.610	0.652	0.139
+ hard constraints	**0.631**	**0.674**	**0.164**
+ hard and soft constraints	0.624	0.666	0.149

Table 4: Precision (P), Recall (R), and Relative Coverage (RC) results on *AmazonQA* dataset.

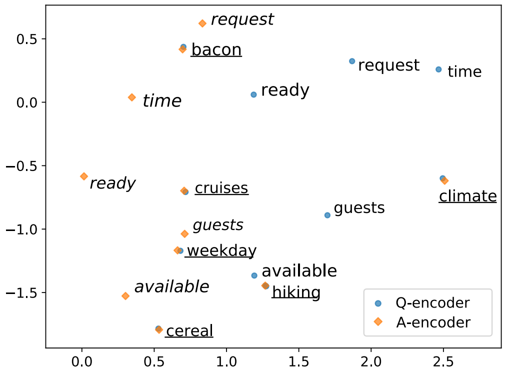

Figure 3: Example embedding vectors from question and answer encoders. Underlines denote similar embedding vectors in both the encoders.

ralOpenIE improved slightly. This is likely because the NeuralOpenIE model, at this stage, still had a larger margin for improvement. We note however that learning the best KE model is not the focus of this work.

AmazonQA is a more challenging dataset than *ConciergeQA*: longer utterances (avg. 45 tokens vs. 36 tokens) and richer vocabulary ($>$ 50k unique tokens vs. $<$ 25k unique tokens). This is reflected in lower precision and recall values of both the systems on the *AmazonQA* dataset. While the performance of end-to-end extraction systems depends on the complexity and diversity of the dataset, incorporating hard and soft constraints alleviates the problem to some extent.

End-to-end extraction systems tend to outperform rule-based systems on extraction from cQA datasets. We observed that training data for *ConciergeQA* had a large number ($>$ 750k) dependency-based pattern rules, of which $<$ 5% matched more than 5 QA pairs. The set of rules is too large, diverse and sparse to train an accurate rule-based extractor. Even though our training data was generated by bootstrapping from a rule-based extractor StanfordIE, we found only 51.5% (30.7%) of correct tuples from NeurON exactly matched the tuples from StanfordIE in *ConciergeQA* (*AmazonQA*). This indicates that NeurON combined information from question and answer, otherwise not accessible to sentence-wise extractors. As an evidence, we found 11.4% (6.1%) of tuples were extracted from answers, 16.8% (5.0%) from questions, while 79.6% (82.5%) combined information from questions and answers in *ConciergeQA* (*AmazonQA*).

Multiple Encoders: Our motivation to use different encoders for questions and answers is based on the assumption that they use different vocabulary and semantics. We found that there were 8k (72k) unique words in questions, 18k (114k) unique words in answers, and the Jaccard coefficient between two vocabulary sets was 0.25 (0.25) in *ConciergeQA* (*AmazonQA*), indicating that two sources use significantly different vocabulary. Also, the same word can have different meanings depending on a speaker, and thus such words in the two sources should be embedded differently. To visualize the embedding vectors of common words in *ConciergeQA*, we mapped them into 2D space using t-SNE (Maaten and Hinton, 2008). Fig. 3 shows that *subjective* words that represents speakers attitude (e.g., “ready”, “guests”, “time”) had significantly different embeddings in the question and answer encoders. In contrast, *objective* words such as menu, or activity (e.g., “bacon”, “cruise”, “weekday”) had similar embeddings although the two encoders do not directly share the embedding parameters. This indicates that multiple encoders not only capture the different meanings in questions and answers but also retain consistent meanings for words that keep the same meanings in the two sources.

Relevance Scoring: We compared with another NeurON model that uses HolE (Nickel et al., 2016) for relevance scoring. Both the HolE and TransE models achieved the same precision of 80.7%, with HolE achieving slightly higher recall (+1.4%). This suggests that incorporating relevance scoring in NeurON can robustly improve the extraction accuracy, regardless of the choice of the knowledge embedding method. We also estimated the upper-bound precision by evaluating if the correct tuple was included in the top-500 candidates. The upper-bound precision was 85.0% on *ConciergeQA*, indicating that there is still room for improvement on incorporating relevance scoring.

1	**Q**: Tell me what the username and password is for WiFi **A**: Absolutely! Both the username and passcode is C800. **StanfordIE**: ⟨ passcode, is, C800 ⟩ **NeurON**: ⟨ password, is, C800 ⟩
2	**Q**: Do hotel guys have ice? **A**: There is an ice machine on first floor lobby. **StanfordIE**: ⟨ hotel, do, ice ⟩ **NeurON**: ⟨ hotel, have, ice machine ⟩
3	**Q**: Is there a charge for parking rental car on the property? **A**: Self-parking will be $15 per night. **StanfordIE**: None **NeurON**: ⟨ parking, will, charge ⟩
4	**Q**: arrange late check out for tomorrow? **A**: I have notated a 12 pm check out. Normal check out time is at 11 am. **StanfordIE**: ⟨ normal check, is at, 11 am ⟩ **NeurON**: ⟨ check, is at, 11 ⟩

Table 5: Examples of successful cases (1 and 2) and failed cases (3 and 4) from test data.

4.6 Error Analysis

We examined a random sample of 100 errors shared by all the systems across the tested datasets. Arguably, encoder-decoder models suffer when extracting tuples from long utterances (avg. of 54 tokens), contributing to 43% of the errors. 34% of the incorrectly extracted tuples used words that were shared across the two sources. This indicates that the extractor makes errors when resolving ambiguity in tokens. 28% of the error cases used informal language that is generally difficult for any extractor to understand. We show some examples (1 and 2 in Table 5) where NeurON successfully combined information across two sources and examples (3 and 4 in Table 5) where it failed.

We further examined three different scenarios: a) errors are shared by both NeurON and NeuralOpenIE, b) errors are made exclusively by NeurON, c) errors are made exclusively by NeuralOpenIE. For each scenario, we examined a random sample of 100 errors. We categorize the different sources of errors and report the results in Table 6. As shown, NeurON is superior on longer utterances compared to NeuralOpenIE (54 tokens vs. 49 tokens). However, ambiguity in tokens in the two sources is a concern for NeurON because it has the flexibility to interpret the question and answer differently. Not surprisingly, informal utterances are hard to translate for both the systems.

Error Category	$\overline{N}, \overline{B}$	$N, \overline{B}$	$\overline{N}, B$
long utterances	43%	45%	40%
avg. length of utterance	54 tokens	49 tokens	54 tokens
ambiguity	34%	36%	48%
informal language	28%	36%	34%

Table 6: Different errors $\overline{N}$ and $\overline{B}$ made by NeurON (N) and NeuralOpenIE (B) respectively.

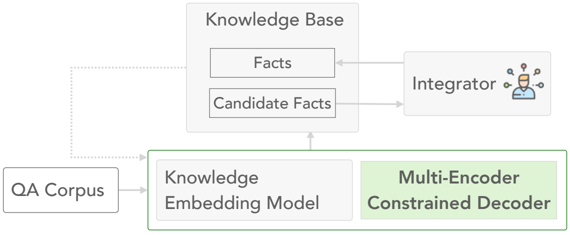

Figure 4: Human-in-the-loop system for extending a domain-specific KB.

5 Case Study - KB Extension

The extracted tuples from NeurON can be used to extend a KB for a specific domain. However, automatically fusing the tuples with existing facts in the KB can have limited accuracy. This can be due to noise in the source conversation, no prior knowledge of join rules and more. One possible solution is to design a human-in-the-loop system that iteratively extracts tuples and filters them based on human feedback (Fig. 4). In each iteration, a set of tuples is annotated by human annotators based on their relevance to the domain of the KB. The tuples marked relevant are added to the KB and the relevance scoring function is updated for extracting more relevant tuples from the corpus in the next iteration.

We conducted a crowdsourced experiment[1], simulating the first iteration of the procedure i.e., when no KE model is available. We collected annotations on top-5 tuples extracted by NeurON for 200 QA pairs in the *ConciergeQA* dataset. For reliability, we hired five workers for each extraction. The workers were asked to judge if a tuple is relevant to the hotel domain and represents concrete information to be added to a KB. We found precision@5 was 41.4%, and NeurON extracted at least one useful tuple for 83.0% of the 200 QA pairs. Overall, the system added 243 unique tuples (out of 414 tuples extracted by NeurON) to the KB. We also collected annotations for the tuples extracted by NeuralOpenIE. The precision@5 and recall@5 values were 41.3% and 79.0% respectively. Although the precision values are quite similar, NeurON can extract correct tuples from more QA pairs than NeuralOpenIE. While the precision can further be improved, the preliminary results support that NeurON is a good candidate for extraction in

---

[1] `https://www.figure-eight.com/`

a human-in-the-loop system for KB extension. We did not use any sophisticated methods for ranking tuples in our experiment. Thus, a better ranking algorithm might lead to improved precision.

6 Related Work

There is a long history of OpenIE systems for extracting tuples from plain text. They are built on hand-crafted patterns over an intermediate representation of a sentence (e.g., POS tags (Yates et al., 2007; Fader et al., 2011), dependency trees (Bhutani et al., 2016; Mausam et al., 2012)). Such rule-based systems require extensive engineering when the patterns become diverse and sparse. Recently, OpenIE systems based on end-to-end frameworks, such as sequence tagging (Stanovsky et al., 2018) or sequence-to-sequence generation (Cui et al., 2018), have been shown to alleviate such engineering efforts. However, all these systems focus on sentence-level extraction. We are the first to address the problem of extracting tuples from question-answer pairs.

Our proposed system is based on an encoder-decoder architecture, which was first introduced by Cho et al. for machine translation. Attention mechanisms (Bahdanau et al., 2015; Luong et al., 2015b) have been shown to be effective for mitigating the problem of poor translation performance on long sequences. Their model can learn how much information to retrieve from specific parts of the input sequence at decoding time. There is abundant research on generalizing such frameworks for multiple tasks, specially by employing multiple encoders. Using multiple encoders has been shown to be useful in mutli-task learning (Luong et al., 2015a), multi-source translation (Zoph and Knight, 2016) and reading comprehension (Xiong et al., 2017). We are the first to explore a multi-source encoder-decoder architecture for extracting tuples from cQA datasets.

Traditional encoder-decoder architectures are not tailored for information extraction and knowledge harvesting. To make them suitable for information extraction, the sequence generation must be subjected to several constraints on the vocabulary, grammar etc. Recently, grammar structures have been integrated into encoder-decoder models (Iyer et al., 2017; Zhang et al., 2017). There are variations such as Pointer Networks (Vinyals et al., 2015) that yield a succession of pointers to tokens in the input sequence. All these studies share a common idea with our paper, which is to enforce constraints at sequence generation time. Since we focus on extraction from cQA datasets, our work is broadly related to the literature on relation extraction (Savenkov et al., 2015; Hixon et al., 2015; Wu et al., 2018) and ontology extraction (S and Kumar, 2018) from community generated question-answer datasets. However, we differ in our underlying assumption that the relations and entities of interest are not known in advance. Alternatively, a cQA dataset could be transformed into declarative sentences (Demszky et al., 2018) for a conventional OpenIE system. However, such a two-stage approach is susceptible to error propagation. We adopt an end-to-end solution that is applicable to generic cQA datasets.

7 Conclusions and Future Work

We have presented NeurON, a system for extracting structured data from QA pairs for the purpose of enriching knowledge bases. NeurON uses a multi-encoder, constrained-decoder framework to generate quality tuples from QA pairs.

NeurON achieves the highest precision and recall in extracting tuples from QA pairs compared with state-of-the-art sentence-based models, with a relative improvement as high as 13.3%. It can discover 15-25% more tuples which makes it suitable as a tuple extraction tool for KB extension.

There are several directions for future research. One interesting direction is to investigate whether NeurON can be extended to work on *open-domain QA corpus*, which may not be restricted to any specific domain.

A Supplementary Material

This supplementary material contains details of the analysis settings described in Section 4 and additional results not reported in the main paper.

A.1 Word Embedding Analysis

We investigated the embedding layers of the question encoder and the answer encoder of the NEURON model trained on the *ConciergeQA* dataset.

For robust analysis, we ignored non-English words and any words that contained numerical digits (e.g., #18D, $10). We used PYENCHANT[2] for filtering English words. For the remaining words, we find their embedding vectors from the two encoders, concatenate them to create a single matrix. This ensures that same embedding vectors are mapped to the same point in the visualization space. We used t-SNE[3] to map embedding vectors into 2D space for visualization.

A.2 Crowdsourced Evaluation

Figure 5 shows the instructions and examples of the crowdsouced task. In the crowdsourcing task, crowdsourced workers were asked to judge after reading an extracted tuple with the original QA pair. Since it is difficult to define the usefulness of the tuples without assuming a KB, we used *relevance* and *concreteness* as criteria to grade extracted tuples. Specifically, each worker was asked to choose one option from the three options: `Not relevant or unclear` (0), `Relevant` (1), `Relevant and concrete` (2).

We set $0.05 as payment for each annotation. We carefully created 51 test questions which were used to filter out untrusted judgments and workers. The platform increases the number of annotators so each tuple should always have 5 trusted annotators. The 5 annotations for each tuple were aggregated into a single label with a confidence value that takes into account the accuracy rates of the annotators based on the test questions.

Triple Evaluation Task (Hotel Domain) - 6

Overview

In this task, you will be asked to evaluate triples extracted from conversations about hotel-related topics between two persons. Each triple consists of three pieces of information: subject, verb phrase, and object. For example, a triple

- (pool, open at, 7am)

can be extracted from a conversation

- **Q: "Is the pool open?"**
- **A: "I am sorry, it will open at7am"**

The purpose of extracting such triples is to organize the knowledge of a domain (e.g., hotel information) so a computer system can retrieve information effectively.

We would like to evaluate triples whether they are (1) **relevant** and **(2) concrete**. In this task, you will judge if a triple is relevant to hotel-related topics.

For each task, a triple will be shown with the original conversation from which the triple was extracted in order to help you judge if the triple is relevant and concrete. You will see the **following three choices**:

- 0: Not relevant or too unclear
- 1: Relevant
- 2: Relevant and concrete

Please choose the best option from the choices.

- Q: Is it possible to get more pillows ?
- A: Marie - absolutely - hotel 'll drop off a couple more today .

Extracted triple: < it, Is, possible >

Is this triple relevant to hotel domain? If yes, does it look concrete? (required)

○ 0: Not relevant or too unclear
○ 1: Relevant (not concrete)
○ 2: Relevant and concrete

- Q: Is it possible to get more pillows ?
- A: Marie - absolutely - hotel 'll drop off a couple more today .

Extracted triple: < hotel, get, it >

Is this triple relevant to hotel domain? If yes, does it look concrete? (required)

○ 0: Not relevant or too unclear
○ 1: Relevant (not concrete)
○ 2: Relevant and concrete

Abstract

Most research in reading comprehension has focused on answering questions based on individual documents or even single paragraphs. We introduce a neural model which integrates and reasons relying on information spread within documents and across multiple documents. We frame it as an inference problem on a graph. Mentions of entities are nodes of this graph while edges encode relations between different mentions (e.g., within- and cross-document coreference). Graph convolutional networks (GCNs) are applied to these graphs and trained to perform multi-step reasoning. Our Entity-GCN method is scalable and compact, and it achieves state-of-the-art results on a multi-document question answering dataset, WIKIHOP (Welbl et al., 2018).

1 Introduction

The long-standing goal of natural language understanding is the development of systems which can acquire knowledge from text collections. Fresh interest in reading comprehension tasks was sparked by the availability of large-scale datasets, such as SQuAD (Rajpurkar et al., 2016) and CNN/Daily Mail (Hermann et al., 2015), enabling end-to-end training of neural models (Seo et al., 2016; Xiong et al., 2016; Shen et al., 2017). These systems, given a text and a question, need to answer the query relying on the given document. Recently, it has been observed that most questions in these datasets do not require reasoning across the document, but they can be answered relying on information contained in a single sentence (Weissenborn et al., 2017). The last generation of large-scale reading comprehension datasets, such as a NarrativeQA (Kocisky et al., 2018), TriviaQA (Joshi et al., 2017), and RACE (Lai et al., 2017), have been created in such a way as to address this shortcoming and to ensure that systems relying only on local information cannot achieve competitive performance.

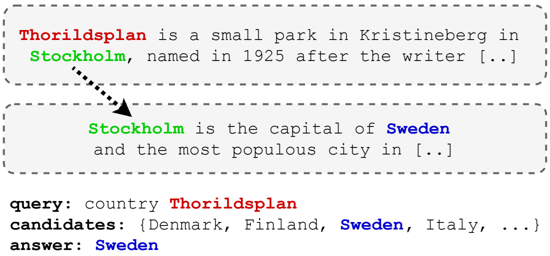

Figure 1: A sample from WIKIHOP where multi-step reasoning and information combination from different documents is necessary to infer the correct answer.

Even though these new datasets are challenging and require reasoning within documents, many question answering and search applications require aggregation of information across multiple documents. The WIKIHOP dataset (Welbl et al., 2018) was explicitly created to facilitate the development of systems dealing with these scenarios. Each example in WIKIHOP consists of a collection of documents, a query and a set of candidate answers (Figure 1). Though there is no guarantee that a question cannot be answered by relying just on a single sentence, the authors ensure that it is answerable using a chain of reasoning crossing document boundaries.

Though an important practical problem, the multi-hop setting has so far received little attention. The methods reported by Welbl et al. (2018) approach the task by merely concatenating all documents into a single long text and training a standard RNN-based reading comprehension model, namely, BiDAF (Seo et al., 2016) and FastQA (Weissenborn et al., 2017). Document concatenation in this setting is also used in Weaver (Raison et al., 2018) and MHPGM (Bauer et al., 2018). The only published paper which

Proceedings of NAACL-HLT 2019, pages 2306–2317
Minneapolis, Minnesota, June 2 - June 7, 2019.

goes beyond concatenation is due to Dhingra et al. (2018), where they augment RNNs with jump-links corresponding to co-reference edges. Though these edges provide a structural bias, the RNN states are still tasked with passing the information across the document and performing multi-hop reasoning.

Instead, we frame question answering as an inference problem on a graph representing the document collection. Nodes in this graph correspond to named entities in a document whereas edges encode relations between them (e.g., cross- and within-document coreference links or simply co-occurrence in a document). We assume that reasoning chains can be captured by propagating local contextual information along edges in this graph using a graph convolutional network (GCN) (Kipf and Welling, 2017).

The multi-document setting imposes scalability challenges. In realistic scenarios, a system needs to learn to answer a query for a given collection (e.g., Wikipedia or a domain-specific set of documents). In such scenarios one cannot afford to run expensive document encoders (e.g., RNN or transformer-like self-attention (Vaswani et al., 2017)), unless the computation can be preprocessed both at train and test time. Even if (similarly to WIKIHOP creators) one considers a coarse-to-fine approach, where a set of potentially relevant documents is provided, re-encoding them in a query-specific way remains the bottleneck. In contrast to other proposed methods (e.g., (Dhingra et al., 2018; Raison et al., 2018; Seo et al., 2016)), we avoid training expensive document encoders.

In our approach, only a small query encoder, the GCN layers and a simple feed-forward answer selection component are learned. Instead of training RNN encoders, we use contextualized embeddings (ELMo) to obtain initial (local) representations of nodes. This implies that only a lightweight computation has to be performed online, both at train and test time, whereas the rest is preprocessed. Even in the somewhat contrived WIKIHOP setting, where fairly small sets of candidates are provided, the model is at least 5 times faster to train than BiDAF.[1] Interestingly, when we substitute ELMo with simple pre-trained word embeddings, Entity-GCN still performs on par with many techniques that use expensive question-aware recurrent document encoders.

Despite not using recurrent document encoders, the full Entity-GCN model achieves over 2% improvement over the best previously-published results. As our model is efficient, we also reported results of an ensemble which brings further 3.6% of improvement and only 3% below the human performance reported by Welbl et al. (2018). Our contributions can be summarized as follows:

- we present a novel approach for multi-hop QA that relies on a (pre-trained) document encoder and information propagation across multiple documents using graph neural networks;
- we provide an efficient training technique which relies on a slower offline and a faster on-line computation that does not require expensive document processing;
- we empirically show that our algorithm is effective, presenting an improvement over previous results.

2 Method

In this section we explain our method. We first introduce the dataset we focus on, WIKIHOP by Welbl et al. (2018), as well as the task abstraction. We then present the building blocks that make up our Entity-GCN model, namely, an *entity graph* used to relate mentions to entities within and across documents, a *document encoder* used to obtain representations of mentions in context, and a *relational graph convolutional network* that propagates information through the entity graph.

2.1 Dataset and Task Abstraction

Data The WIKIHOP dataset comprises of tuples $\langle q, S_q, C_q, a^\star \rangle$ where: q is a query/question, S_q is a set of supporting documents, C_q is a set of candidate answers (all of which are entities mentioned in S_q), and $a^\star \in C_q$ is the entity that correctly answers the question. WIKIHOP is assembled assuming that there exists a corpus and a knowledge base (KB) related to each other. The KB contains triples $\langle s, r, o \rangle$ where s is a subject entity, o an object entity, and r a unidirectional relation between them. Welbl et al. (2018) used WIKIPEDIA as corpus and WIKIDATA (Vrandečić, 2012) as KB. The KB is only used for constructing WIKIHOP: Welbl

---

[1] When compared to the ‘small’ and hence fast BiDAF model reported in Welbl et al. (2018), which is 25% less accurate than our Entity-GCN. Larger RNN models are problematic also because of GPU memory constraints.

et al. (2018) retrieved the supporting documents S_q from the corpus looking at mentions of subject and object entities in the text. Note that the set S_q (not the KB) is provided to the QA system, and not all of the supporting documents are relevant for the query but some of them act as distractors. Queries, on the other hand, are not expressed in natural language, but instead consist of tuples $\langle s, r, ? \rangle$ where the object entity is unknown and it has to be inferred by reading the support documents. Therefore, answering a query corresponds to finding the entity $a^\star$ that is the object of a tuple in the KB with subject s and relation r among the provided set of candidate answers C_q.

Task The goal is to learn a model that can identify the correct answer $a^\star$ from the set of supporting documents S_q. To that end, we exploit the available supervision to train a neural network that computes scores for candidates in C_q. We estimate the parameters of the architecture by maximizing the likelihood of observations. For prediction, we then output the candidate that achieves the highest probability. In the following, we present our model discussing the design decisions that enable multi-step reasoning and an efficient computation.

2.2 Reasoning on an Entity Graph

Entity graph In an offline step, we organize the content of each training instance in a graph connecting mentions of candidate answers within and across supporting documents. For a given query $q = \langle s, r, ? \rangle$, we identify mentions in S_q of the entities in $C_q \cup \{s\}$ and create one node per mention. This process is based on the following heuristic:

1. we consider mentions spans in S_q exactly matching an element of $C_q \cup \{s\}$. Admittedly, this is a rather simple strategy which may suffer from low recall.

2. we use predictions from a coreference resolution system to add mentions of elements in $C_q \cup \{s\}$ beyond exact matching (including both noun phrases and anaphoric pronouns). In particular, we use the end-to-end coreference resolution by Lee et al. (2017).

3. we discard mentions which are ambiguously resolved to multiple coreference chains; this may sacrifice recall, but avoids propagating ambiguity.

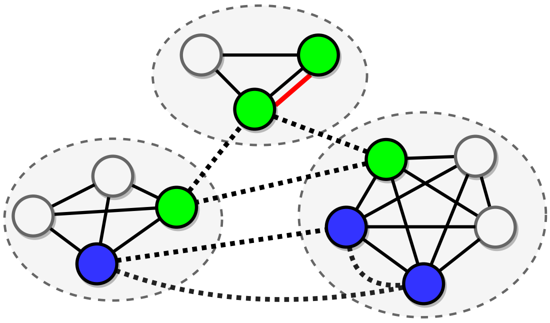

Figure 2: Supporting documents (dashed ellipses) organized as a graph where nodes are mentions of either candidate entities or query entities. Nodes with the same color indicates they refer to the same entity (exact match, coreference or both). Nodes are connected by three simple relations: one indicating co-occurrence in the same document (solid edges), another connecting mentions that exactly match (dashed edges), and a third one indicating a coreference (bold-red line).

To each node v_i, we associate a continuous annotation $\mathbf{x}_i \in \mathbb{R}^D$ which represents an entity in the context where it was mentioned (details in Section 2.3). We then proceed to connect these mentions i) if they co-occur within the same document (we will refer to this as `DOC-BASED` edges), ii) if the pair of named entity mentions is identical (`MATCH` edges—these may connect nodes across and within documents), or iii) if they are in the same coreference chain, as predicted by the external coreference system (`COREF` edges). Note that `MATCH` edges when connecting mentions in the same document are mostly included in the set of edges predicted by the coreference system. Having the two types of edges lets us distinguish between less reliable edges provided by the coreference system and more reliable (but also more sparse) edges given by the exact-match heuristic. We treat these three types of connections as three different types of relations. See Figure 2 for an illustration. In addition to that, and to prevent having disconnected graphs, we add a fourth type of relation (`COMPLEMENT` edge) between any two nodes that are not connected with any of the other relations. We can think of these edges as those in the complement set of the entity graph with respect to a fully connected graph.

Multi-step reasoning Our model then approaches multi-step reasoning by transforming node representations (Section 2.3 for details) with a differentiable message passing algorithm that propagates information through the entity graph. The algorithm is parameterized by a graph convolutional network (GCN) (Kipf and Welling, 2017), in particular, we employ relational-GCNs (Schlichtkrull et al., 2018), an extended version that accommodates edges of different types. In Section 2.4 we describe the propagation rule.

Each step of the algorithm (also referred to as a *hop*) updates all node representations in parallel. In particular, a node is updated as a function of messages from its direct neighbours, and a message is possibly specific to a certain relation. At the end of the first step, every node is aware of every other node it connects directly to. Besides, the neighbourhood of a node may include mentions of the same entity as well as others (e.g., same-document relation), and these mentions may have occurred in different documents. Taking this idea recursively, each further step of the algorithm allows a node to indirectly interact with nodes already known to their neighbours. After L layers of R-GCN, information has been propagated through paths connecting up to $L + 1$ nodes.

We start with node representations $\{\mathbf{h}_i^{(0)}\}_{i=1}^N$, and transform them by applying L layers of R-GCN obtaining $\{\mathbf{h}_i^{(L)}\}_{i=1}^N$. Together with a representation $\mathbf{q}$ of the query, we define a distribution over candidate answers and we train maximizing the likelihood of observations. The probability of selecting a candidate $c \in C_q$ as an answer is then

$$P(c|q, C_q, S_q) \propto \exp\left(\max_{i \in \mathcal{M}_c} f_o([\mathbf{q}, \mathbf{h}_i^{(L)}])\right) , \tag{1}$$

where f_o is a parameterized affine transformation, and $\mathcal{M}_c$ is the set of node indices such that $i \in \mathcal{M}_c$ only if node v_i is a mention of c. The $\max$ operator in Equation 1 is necessary to select the node with highest predicted probability since a candidate answer is realized in multiple locations via different nodes.

2.3 Node Annotations

Keeping in mind we want an efficient model, we encode words in supporting documents and in the query using only a pre-trained model for contextualized word representations rather than training our own encoder. Specifically, we use ELMo[2] (Peters et al., 2018), a pre-trained bi-directional language model that relies on character-based input representation. ELMo representations, differently from other pre-trained word-based models (e.g., *word2vec* (Mikolov et al., 2013) or GloVe (Pennington et al., 2014)), are contextualized since each token representation depends on the entire text excerpt (i.e., the whole sentence).

We choose not to fine tune nor propagate gradients through the ELMo architecture, as it would have defied the goal of not having specialized RNN encoders. In the experiments, we will also ablate the use of ELMo showing how our model behaves using non-contextualized word representations (we use GloVe).

Documents pre-processing ELMo encodings are used to produce a set of representations $\{\mathbf{x}_i\}_{i=1}^N$, where $\mathbf{x}_i \in \mathbb{R}^D$ denotes the ith candidate mention in context. Note that these representations do not depend on the query yet and no trainable model was used to process the documents so far, that is, we use ELMo as a fixed pre-trained encoder. Therefore, we can pre-compute representation of mentions once and store them for later use.

Query-dependent mention encodings ELMo encodings are used to produce a query representation $\mathbf{q} \in \mathbb{R}^K$ as well. Here, $\mathbf{q}$ is a concatenation of the final outputs from a bidirectional RNN layer trained to re-encode ELMo representations of words in the query. The vector $\mathbf{q}$ is used to compute a query-dependent representation of mentions $\{\hat{\mathbf{x}}_i\}_{i=1}^N$ as well as to compute a probability distribution over candidates (as in Equation 1). Query-dependent mention encodings $\hat{\mathbf{x}}_i = f_x(\mathbf{q}, \mathbf{x}_i)$ are generated by a trainable function f_x which is parameterized by a feed-forward neural network.

2.4 Entity Relational Graph Convolutional Network

Our model uses a gated version of the original R-GCN propagation rule. At the first layer, all hidden node representation are initialized with the query-aware encodings $\mathbf{h}_i^{(0)} = \hat{\mathbf{x}}_i$. Then, at each layer $0 \leq \ell \leq L$, the update message $\mathbf{u}_i^{(\ell)}$ to the ith node is a sum of a transformation f_s of the current node representation $\mathbf{h}_i^{(\ell)}$ and transformations of its neighbours:

$$\mathbf{u}_i^{(\ell)} = f_s(\mathbf{h}_i^{(\ell)}) + \frac{1}{|\mathcal{N}_i|} \sum_{j \in \mathcal{N}_i} \sum_{r \in \mathcal{R}_{ij}} f_r(\mathbf{h}_j^{(\ell)}) , \tag{2}$$

---

[2] The use of ELMo is an implementation choice, and, in principle, any other contextual pre-trained model could be used (Radford et al., 2018; Devlin et al., 2018).

where $\mathcal{N}_i$ is the set of indices of nodes neighbouring the ith node, $\mathcal{R}_{ij}$ is the set of edge annotations between i and j, and f_r is a parametrized function specific to an edge type $r \in \mathcal{R}$. Recall the available relations from Section 2.2, namely, $\mathcal{R} = \{\texttt{DOC-BASED}, \texttt{MATCH}, \texttt{COREF}, \texttt{COMPLEMENT}\}$.

A gating mechanism regulates how much of the update message propagates to the next step. This provides the model a way to prevent completely overwriting past information. Indeed, if all necessary information to answer a question is present at a layer which is not the last, then the model should learn to stop using neighbouring information for the next steps. Gate levels are computed as

$$\mathbf{a}_i^{(\ell)} = \sigma\left(f_a\left([\mathbf{u}_i^{(\ell)}, \mathbf{h}_i^{(\ell)}]\right)\right) , \tag{3}$$

where $\sigma(\cdot)$ is the sigmoid function and f_a a parametrized transformation. Ultimately, the updated representation is a gated combination of the previous representation and a non-linear transformation of the update message:

$$\mathbf{h}_i^{(\ell+1)} = \phi(\mathbf{u}_i^{(\ell)}) \odot \mathbf{a}_i^{(\ell)} + \mathbf{h}_i^{(\ell)} \odot (1 - \mathbf{a}_i^{(\ell)}) , \tag{4}$$

where $\phi(\cdot)$ is any nonlinear function (we used $\tanh$) and $\odot$ stands for element-wise multiplication. All transformations f_* are affine and they are not layer-dependent (since we would like to use as few parameters as possible to decrease model complexity promoting efficiency and scalability).

3 Experiments

In this section, we compare our method against recent work as well as preforming an ablation study using the WikiHop dataset (Welbl et al., 2018). See Appendix A in the supplementary material for a description of the hyper-parameters of our model and training details.

WikiHop We use WikiHop for training, validation/development and test. The test set is not publicly available and therefore we measure performance on the validation set in almost all experiments. WikiHop has 43,738/ 5,129/ 2,451 query-documents samples in the training, validation and test sets respectively for a total of 51,318 samples. Authors constructed the dataset as described in Section 2.1 selecting samples with a graph traversal up to a maximum chain length of 3 documents (see Table 1 for additional dataset statistics). WikiHop comes in two versions, a standard (unmasked) one and a masked one. The masked version was created by the authors to test whether methods are able to learn lexical abstraction. In this version, all candidates and all mentions of them in the support documents are replaced by random but consistent placeholder tokens. Thus, in the masked version, mentions are always referred to via unambiguous surface forms. We do not use coreference systems in the masked version as they rely crucially on lexical realization of mentions and cannot operate on masked tokens.

	Min	**Max**	**Avg.**	**Median**
# candidates	2	79	19.8	14
# documents	3	63	13.7	11
# tokens/doc.	4	2,046	100.4	91

Table 1: WikiHop dataset statistics from Welbl et al. (2018): number of candidates and documents per sample and document length.

3.1 Comparison

In this experiment, we compare our Entity-GCN against recent prior work on the same task. We present test and development results (when present) for both versions of the dataset in Table 2. From Welbl et al. (2018), we list an oracle based on human performance as well as two standard reading comprehension models, namely BiDAF (Seo et al., 2016) and FastQA (Weissenborn et al., 2017). We also compare against Coref-GRU (Dhingra et al., 2018), MHPGM (Bauer et al., 2018), and Weaver (Raison et al., 2018). Additionally, we include results of MHQA-GRN (Song et al., 2018), from a recent arXiv preprint describing concurrent work. They jointly train graph neural networks and recurrent encoders. We report single runs of our two best single models and an ensemble one on the unmasked test set (recall that the test set is not publicly available and the task organizers only report unmasked results) as well as both versions of the validation set.

Entity-GCN (best single model without coreference edges) outperforms all previous work by over 2% points. We additionally re-ran BiDAF baseline to compare training time: when using a single Titan X GPU, BiDAF and Entity-GCN process 12.5 and 57.8 document sets per second, respectively. Note that Welbl et al. (2018) had to use BiDAF with very small state dimensionalities

Model	Unmasked Test	Unmasked Dev	Masked Test	Masked Dev
Human (Welbl et al., 2018)	74.1	–	–	–
FastQA (Welbl et al., 2018)	25.7	–	35.8	–
BiDAF (Welbl et al., 2018)	42.9	–	54.5	–
Coref-GRU (Dhingra et al., 2018)	59.3	56.0	–	–
MHPGM (Bauer et al., 2018)	–	58.2	–	–
Weaver / Jenga (Raison et al., 2018)	65.3	64.1	–	–
MHQA-GRN (Song et al., 2018)	65.4	62.8	–	–
Entity-GCN without coreference (single model)	**67.6**	**64.8**	–	70.5
Entity-GCN with coreference (single model)	**66.4**	**65.3**	–	–
Entity-GCN* (ensemble 5 models)	**71.2**	**68.5**	–	71.6

Table 2: Accuracy of different models on WIKIHOP closed test set and public validation set. Our Entity-GCN outperforms recent prior work without learning any language model to process the input but relying on a pre-trained one (ELMo – without fine-tunning it) and applying R-GCN to reason among entities in the text. * with coreference for unmasked dataset and without coreference for the masked one.

(20), and smaller batch size due to the scalability issues (both memory and computation costs). We compare applying the same reductions.[3] Eventually, we also report an ensemble of 5 independently trained models. All models are trained on the same dataset splits with different weight initializations. The ensemble prediction is obtained as $\arg\max_c \prod_{i=1}^{5} P_i(c|q, C_q, S_q)$ from each model.

3.2 Ablation Study

To help determine the sources of improvements, we perform an ablation study using the publicly available validation set (see Table 3). We perform two groups of ablation, one on the embedding layer, to study the effect of ELMo, and one on the edges, to study how different relations affect the overall model performance.

Embedding ablation We argue that ELMo is crucial, since we do not rely on any other context encoder. However, it is interesting to explore how our R-GCN performs without it. Therefore, in this experiment, we replace the deep contextualized embeddings of both the query and the nodes with GloVe (Pennington et al., 2014) vectors (insensitive to context). Since we do not have any component in our model that processes the documents, we expect a drop in performance. In other words, in this ablation our model tries to answer questions *without reading the context at all*. For example, in Figure 1, our model would be aware that "Stockholm" and "Sweden" appear in the same document but any context words, including the ones encoding relations (e.g., "is the capital of") will be hidden. Besides, in the masked case all mentions become 'unknown' tokens with GloVe and therefore the predictions are equivalent to a random guess. Once the strong pre-trained encoder is out of the way, we also ablate the use of our R-GCN component, thus completely depriving the model from inductive biases that aim at multi-hop reasoning.

The first important observation is that replacing ELMo by GloVe (GloVe with R-GCN in Table 3) still yields a competitive system that ranks far above baselines from (Welbl et al., 2018) and even above the Coref-GRU of Dhingra et al. (2018), in terms of accuracy on (unmasked) validation set. The second important observation is that if we then remove R-GCN (GloVe w/o R-GCN in Table 3), we lose 8.0 points. That is, the R-GCN component pushes the model to perform above Coref-GRU still without accessing context, but rather by updating mention representations based on their relation to other ones. These results highlight the impact of our R-GCN component.

Graph edges ablation In this experiment we investigate the effect of the different relations available in the entity graph and processed by the R-GCN module. We start off by testing our stronger encoder (i.e., ELMo) in absence of edges connecting mentions in the supporting documents (i.e., us-

---

[3] Besides, we could not run any other method we compare with combined with ELMo without reducing the dimensionality further or having to implement a distributed version.

Model	unmasked	masked
full (ensemble)	**68.5**	**71.6**
full (single)	**65.1** ± 0.11	**70.4** ± 0.12
GloVe with R-GCN	59.2	11.1
GloVe w/o R-GCN	51.2	11.6
No R-GCN	62.4	63.2
No relation types	62.7	63.9
No `DOC-BASED`	62.9	65.8
No `MATCH`	64.3	67.4
No `COREF`	64.8	–
No `COMPLEMENT`	64.1	70.3
Induced edges	61.5	56.4

Table 3: Ablation study on WikiHop validation set. The *full model* is our Entity-GCN with all of its components and other rows indicate models trained without a component of interest. We also report baselines using GloVe instead of ELMo with and without R-GCN. For the *full model* we report $\text{mean} \pm 1 \text{ std}$ over 5 runs.

ing only self-loops – No R-GCN in Table 3). The results suggest that WikipHop genuinely requires multihop inference, as our best model is 6.1% and 8.4% more accurate than this local model, in unmasked and masked settings, respectively.[4] However, it also shows that ELMo representations capture predictive context features, without being explicitly trained for the task. It confirms that our goal of getting away with training expensive document encoders is a realistic one.

We then inspect our model's effectiveness in making use of the structure encoded in the graph. We start naively by fully-connecting all nodes within and across documents without distinguishing edges by type (No relation types in Table 3). We observe only marginal improvements with respect to ELMo alone (No R-GCN in Table 3) in both the unmasked and masked setting suggesting that a GCN operating over a naive entity graph would not add much to this task and a more informative graph construction and/or a more sophisticated parameterization is indeed needed.

Next, we ablate each type of relations independently, that is, we either remove connections of mentions that co-occur in the same document (`DOC-BASED`), connections between mentions matching exactly (`MATCH`), or edges predicted by the coreference system (`COREF`). The first thing to note is that the model makes better use of `DOC-BASED` connections than `MATCH` or `COREF` connections. This is mostly because i) the majority of the connections are indeed between mentions in the same document, and ii) without connecting mentions within the same document we remove important information since the model is unaware they appear closely in the document. Secondly, we notice that coreference links and complement edges seem to play a more marginal role. Though it may be surprising for coreference edges, recall that the `MATCH` heuristic already captures the easiest coreference cases, and for the rest the out-of-domain coreference system may not be reliable. Still, modelling all these different relations together gives our Entity-GCN a clear advantage. This is our best system evaluating on the development. Since Entity-GCN seems to gain little advantage using the coreference system, we report test results both with and without using it. Surprisingly, with coreference, we observe performance degradation on the test set. It is likely that the test documents are harder for the coreference system.[5]

We do perform one last ablation, namely, we replace our heuristic for assigning edges and their labels by a model component that predicts them. The last row of Table 3 (Induced edges) shows model performance when edges are not predetermined but predicted. For this experiment, we use a bilinear function $f_e(\hat{\mathbf{x}}_i, \hat{\mathbf{x}}_j) = \sigma\left(\hat{\mathbf{x}}_i^\top \mathbf{W}_e \hat{\mathbf{x}}_j\right)$ that predicts the importance of a single edge connecting two nodes i, j using the query-dependent representation of mentions (see Section 2.3). The performance drops below 'No R-GCN' suggesting that it cannot learn these dependencies on its own.

Most results are stronger for the masked settings even though we do not apply the coreference resolution system in this setting due to masking. It is not surprising as coreferred mentions are labeled with the same identifier in the masked version, even if their original surface forms did not match (Welbl et al. (2018) used Wikipedia links for masking). Indeed, in the masked version, an entity is always referred to via the same unique surface form (e.g., `MASK1`) within and across documents. In the unmasked setting, on the other hand, mentions to an entity may differ (e.g., "US" vs "United States") and they might not be retrieved by the coreference system we are employing, mak-

---

[4] Recall that all models in the ensemble use the same local representations, ELMo.

[5] Since the test set is hidden from us, we cannot analyze this difference further.

	Relation	Accuracy	P@2	P@5	Avg. $\vert C_q \vert$	Supports
	overall (ensemble)	68.5	81.0	94.1	20.4 ± 16.6	5129
	overall (single model)	65.3	79.7	92.9	20.4 ± 16.6	5129
3 best	member_of_political_party	85.5	95.7	98.6	5.4 ± 2.4	70
	record_label	83.0	93.6	99.3	12.4 ± 6.1	283
	publisher	81.5	96.3	100.0	9.6 ± 5.1	54
3 worst	place_of_birth	51.0	67.2	86.8	27.2 ± 14.5	309
	place_of_death	50.0	67.3	89.1	25.1 ± 14.3	159
	inception	29.9	53.2	83.1	21.9 ± 11.0	77

Table 4: Accuracy and precision at K (P@K in the table) analysis overall and per query type. Avg. $|C_q|$ indicates the average number of candidates with one standard deviation.

ing the task harder for all models. Therefore, as we rely mostly on exact matching when constructing our graph for the masked case, we are more effective in recovering coreference links on the masked rather than unmasked version.[6]

4 Error Analysis

In this section we provide an error analysis for our best single model predictions. First of all, we look at which type of questions our model performs well or poorly. There are more than 150 query types in the validation set but we filtered the three with the best and with the worst accuracy that have at least 50 supporting documents and at least 5 candidates. We show results in Table 4. We observe that questions regarding places (birth and death) are considered harder for Entity-GCN. We then inspect samples where our model fails while assigning highest likelihood and noticed two principal sources of failure i) a mismatch between what is written in WIKIPEDIA and what is annotated in WIKIDATA, and ii) a different degree of granularity (e.g., born in “London” vs “UK” could be considered both correct by a human but not when measuring accuracy). See Table 6 in the supplement material for some reported samples.

Secondly, we study how the model performance degrades when the input graph is large. In particular, we observe a negative Pearson’s correlation (-0.687) between accuracy and the number of candidate answers. However, the performance does not decrease steeply. The distribution of the number of candidates in the dataset peaks at 5 and has an average of approximately 20. Therefore, the model does not see many samples where there are a large number of candidate entities during training. Differently, we notice that as the number of nodes in the graph increases, the model performance drops but more gently (negative but closer to zero Pearson’s correlation). This is important as document sets can be large in practical applications. See Figure 3 in the supplemental material for plots.

5 Related Work

In previous work, BiDAF (Seo et al., 2016), FastQA (Weissenborn et al., 2017), Coref-GRU (Dhingra et al., 2018), MHPGM (Bauer et al., 2018), and Weaver / Jenga (Raison et al., 2018) have been applied to multi-document question answering. The first two mainly focus on single document QA and Welbl et al. (2018) adapted both of them to work with WIKIHOP. They process each instance of the dataset by concatenating all $d \in S_q$ in a random order adding document separator tokens. They trained using the first answer mention in the concatenated document and evaluating exact match at test time. Coref-GRU, similarly to us, encodes relations between entity mentions in the document. Instead of using graph neural network layers, as we do, they augment RNNs with jump links corresponding to pairs of corefereed mentions. MHPGM uses a multi-attention mechanism in combination with external commonsense relations to perform multiple hops of reasoning. Weaver is a deep co-encoding model that uses several alternating bi-LSTMs to process the concatenated documents and the query.

Graph neural networks have been shown successful on a number of NLP tasks (Marcheggiani and Titov, 2017; Bastings et al., 2017; Zhang et al.,

---

[6] Though other systems do not explicitly link matching mentions, they similarly benefit from masking (e.g., masks essentially single out spans that contain candidate answers).

2018a), including those involving document level modeling (Peng et al., 2017). They have also been applied in the context of asking questions about knowledge contained in a knowledge base (Zhang et al., 2018b). In Schlichtkrull et al. (2018), GCNs are used to capture reasoning chains in a knowledge base. Our work and unpublished concurrent work by Song et al. (2018) are the first to study graph neural networks in the context of multi-document QA. Besides differences in the architecture, Song et al. (2018) propose to train a combination of a graph recurrent network and an RNN encoder. We do not train any RNN document encoders in this work.

6 Conclusion

We designed a graph neural network that operates over a compact graph representation of a set of documents where nodes are mentions to entities and edges signal relations such as within and cross-document coreference. The model learns to answer questions by gathering evidence from different documents via a differentiable message passing algorithm that updates node representations based on their neighbourhood. Our model outperforms published results where ablations show substantial evidence in favour of multi-step reasoning. Moreover, we make the model fast by using pre-trained (contextual) embeddings.

A Implementation and Experiments Details

A.1 Architecture

See table 5 for an outline of Entity-GCN architectural detail. Here the computational steps

1. ELMo embeddings are a concatenation of three 1024-dimensional vectors resulting in 3072-dimensional input vectors $\{\mathbf{x}_i\}_{i=1}^N$.

2. For the query representation $\mathbf{q}$, we apply 2 bi-LSTM layers of 256 and 128 hidden units to its ELMo vectors. The concatenation of the forward and backward states results in a 256-dimensional question representation.

3. ELMo embeddings of candidates are projected to 256-dimensional vectors, concatenated to the $\mathbf{q}$, and further transformed with a two layers MLP of 1024 and 512 hidden units in 512-dimensional query aware entity representations $\{\hat{\mathbf{x}}_i\}_{i=1}^N \in \mathbb{R}^{512}$.

4. All transformations f_* in R-GCN-layers are affine and they do maintain the input and output dimensionality of node representations the same (512-dimensional).

5. Eventually, a 2-layers MLP with [256, 128] hidden units takes the concatenation between $\{\mathbf{h}_i^{(L)}\}_{i=1}^N$ and $\mathbf{q}$ to predict the probability that a candidate node v_i may be the answer to the query q (see Equation 1).

During preliminary trials, we experimented with different numbers of R-GCN-layers (in the range 1-7). We observed that with WIKIHOP, for $L \geq 3$ models reach essentially the same performance, but more layers increase the time required to train them. Besides, we observed that the gating mechanism learns to keep more and more information from the past at each layer making unnecessary to have more layers than required.

A.2 Training Details

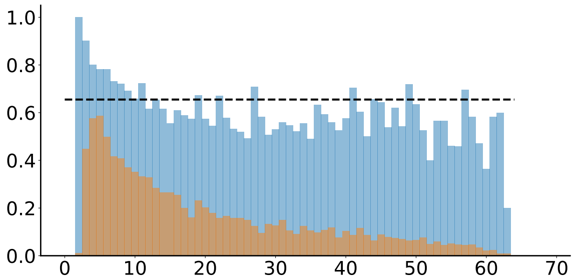
We train our models with a batch size of 32 for at most 20 epochs using the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and a learning rate of 10^{-4}. To help against overfitting, we employ dropout (drop rate $\in 0, 0.1, 0.15, 0.2, 0.25$) (Srivastava et al., 2014) and early-stopping on validation accuracy. We report the best results of each experiment based on accuracy on validation set.

B Error Analysis

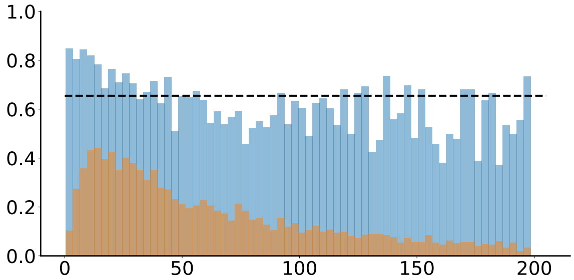
In Table 6, we report three samples from WIKIHOP development set where out Entity-GCN fails. In particular, we show two instances where our model presents high confidence on the answer, and one where is not. We commented these samples explaining why our model might fail in these cases.

C Ablation Study

In Figure 3, we show how the model performance goes when the input graph is large. In particular, how Entity-GCN performs as the number of candidate answers or the number of nodes increases.



(a) Candidates set size (x-axis) and accuracy (y-axis). Pearson's correlation of -0.687 ($p < 10^{-7}$).



(b) Nodes set size (x-axis) and accuracy (y-axis). Pearson's correlation of -0.385 ($p < 10^{-7}$).

Figure 3: Accuracy (blue) of our best single model with respect to the candidate set size (on the *top*) and nodes set size (on the *bottom*) on the validation set. Rescaled data distributions (orange) per number of candidate (*top*) and nodes (*bottom*). Dashed lines indicate average accuracy.

A Qualitative Comparison of CoQA, SQuAD 2.0 and QuAC

Mark Yatskar
Allen Institute for Artificial Intelligence
`marky@allenai.org`

Abstract

We compare three new datasets for question answering: SQuAD 2.0, QuAC, and CoQA, along several of their new features: (1) unanswerable questions, (2) multi-turn interactions, and (3) abstractive answers. We show that the datasets provide complementary coverage of the first two aspects, but weak coverage of the third. Because of the datasets' structural similarity, a single extractive model can be easily adapted to any of the datasets and we show improved baseline results on both SQuAD 2.0 and CoQA. Despite the similarity, models trained on one dataset are ineffective on another dataset, but we find moderate performance improvement through pretraining. To encourage cross-evaluation, we release code for conversion between datasets at https://github.com/my89/co-squac.

1 Introduction

Question answering on textual data has served as a challenge problem for the NLP community (Voorhees, 2001; Richardson et al., 2013). With the development of large scale benchmarks and sufficiently simple evaluations (Trischler et al., 2016; Nguyen et al., 2016; Hermann et al., 2015) progress has been rapid. In recent evaluation on SQuAD (Rajpurkar et al., 2016), performance exceeded that of annotators (Wang et al., 2018; Hu et al., 2017; Wang et al., 2017).

In response to this development, there have been a flurry of new datasets. In this work, we analyze three such new proposed datasets, SQuAD 2.0 (Rajpurkar et al., 2018), QuAC (Choi et al., 2018), and CoQA (Reddy et al., 2018).[1] In each of these datasets, crowd workers are asked to (1) produce questions about a paragraph of text (context) and (2) produce a reply by either indicating there is no answer, or providing an extractive answer from the context by highlighting one contiguous span. QuAC and CoQA contain two other features: questions are asked in the form of a dialog, where co-reference to previous interactions is possible and directly answering yes/no is possible. CoQA also allows workers to edit the spans to provide abstractive answers.[2]

We compare these three datasets along several of their new features: (1) unanswerable questions, (2) multi-turn interactions, and (3) abstractive answers. Unanswerable question coverage is complementary among datasets; SQuAD 2.0 focuses more on questions of extreme confusion, such as false premise questions, while QuAC primarily focuses on missing information. QuAC and CoQA dialogs simulate different types of user behavior: QuAC dialogs often switch topics while CoQA dialogs include more queries for details. Unfortunately, no dataset provides significant coverage of abstractive answers beyond yes/no answers, and we show that a method can achieve an extractive answer upper bound of 100 and 97.8 F1 on QuAC and CoQA , respectively.

Motivated by the above analysis, we apply the baseline presented in QuAC (Choi et al., 2018), BiDAF++, a model based on BiDAF (Seo et al., 2016), augmented with self attention (Clark and Gardner, 2018) and ELMo contextualized embeddings (Peters et al., 2018) to all datasets. Experiments show that this extractive baseline outperforms existing extractive and abstractive baselines on CoQA by 14.2 and 2.7 F1 respectively. Finally, we show models can transfer between datasets with pretraining yielding moderate gains.[3]

---

[1] A review of other new datasets is in the related work.

[2] Also, SQuAD 2.0 and QuAC cover only Wikipedia text, CoQA covers six other domains and QuAC is the only one of these datasets that doesn't allow the questioner to see the context before formulating a question.

[3] To facilitate easy future cross-evaluation, we release tools for conversion between these dataset.

Proceedings of NAACL-HLT 2019, pages 2318–2323
Minneapolis, Minnesota, June 2 - June 7, 2019.

Dataset	Entity Salad	False Premise	Topic Error	Missing Information	Content Negation	Answerable Questions	Total Questions
CoQA	0.0	0.0	0.0	60.0	0.0	40.0	5 (0.5%)
SQuAD 2.0	21.3	21.3	13.5	16.1	16.1	10.9	230 (50.1%)
QuAC	5.5	0.0	16.4	71.2	0.0	6.8	73 (20.2%)

Table 1: Comparison of unanswerable questions on 50 random contexts from the development set of each dataset. SQuAD 2.0 contains a diverse set of circumstances that make questions unanswerable, QuAC focuses on information that could plausibly be in context material and CoQA does not significantly cover unanswerable questions.

Dataset	Topic Shift	Drill Down	Return to Topic	Clarification Question	Definition Question	Sentence Coverage	Total Questions
CoQA	21.6	72.0	2.9	0.0	0.7	63.3	722
QuAC	35.4	55.3	5.6	0.7	3.0	28.4	302

Table 2: Comparison of dialog features in 50 random contexts from the development set of each dataset. CoQA contains questions that drill into details about topics and cover 60% of sentences in the context while in QuAC dialog switch topic more often and cover less than 30% of sentences. Neither dataset has a significant number of returns to previous topics, clarifications, or definitional interactions.

2 Dataset Analysis

In this section we analyze unanswerable questions, dialog features, abstractive answers in SQuAD 2.0, QuAC, and CoQA. All analysis was performed by the authors, on a random sample of 50 contexts (300-700 questions) from the development set of each dataset.

2.1 Unanswerable Questions

In Table 1 we compare types of unanswerable questions across dataset. We identify five types of questions found between the datasets:

1. Entity Salad A nonsensical reference to entities found in the context or made-up entities (e.g. *"What infinite hierarchy implies that the graph isomorphism problem s NQ-complete?"*). Such questions are unanswerable for any context.

2. False Premise A fact that contradicts the context is asserted in the question (e.g. *"When is the correlation positive?"* but in the context says *"the correlation is strictly negative"*).

3. Topic Error A questions that references an entity in the context but the context does not focus on that entity (e.g *"How many earthquakes occur in California?"* when the article focus is actually about *"Southern California"*). Such questions potentially have answers, but it would be unlikely for the answer to be found in the context.

4. Missing Information A question who's answer could be plausibly in the context but is not (e.g. *"What is the record high in January?"* and the article is about temperature extremes). Such questions have an answer but it is not mentioned.

5. Content Negation A question which asks for the opposite information of something mentioned in the context (e.g. *"Who* **didnt** *cause the dissolution of the Holy Roman Empire?"*). Such questions either have answers that are the set of all entities other than the one mentioned or answers that could be found in some other context.

Results SQuAD 2.0 contains the highest diversity of unanswerable questions of all datasets analyzed. Some SQuAD 2.0 questions are unlikely to be asked without significant foreknowledge of the context material and do not occur in QuAC. [4] Both SQuAD 2.0 and QuAC cover a significant number of unanswerable questions that could be plausibly in the article. The difference in settings and distributions of unanswerable questions in SQuAD 2.0 and QuAC appear to be complementary: SQuAD 2.0 focuses more on questions simulating questioner confusion, while QuAC primarily focuses on missing information. [5]

2.2 Dialog Features

In Table 2 we analyze five dialog behaviors:

1. Topic Shift A question about something previously discussed (e.g. "Q: How does he try to take over? ... Q: Where do they live?").

2. Drill Down A request for more information about a topic being discussed (e.g. "A: The Sherpas call Mount Everest Chomolungma. Q: Is Mt. Everest a holy site for them?")

3. Topic Return Asking about a topic again after it had previously been shifted away from.

---

[4] Such questions resemble text from entailment datasets such as SNLI (Bowman et al., 2015) and seem more likely to arise if questioners are receiving very complex information and become confused.

[5] CoQA does not contain a significant number of unanswerable questions, and many of the ones that do exist are erroneously marked.

Dataset	Yes/No	Coref	Counting	Picking	Fluency	Max F1
CoQA	21.4	3.2	1.3	0.6	4.2	97.8
QuAC	21.1	0.0	0.0	0.0	0.0	100.0

Table 3: Comparison of abstractive features in 50 random contexts in the develoment set of each dataset. Both QuAC and CoQA contain yes/no questions while CoQA also contains answers that improve fluency through abstractive behavior. The extractive upper bound from CoQA is high because most absractivive answers involve adding a pronoun (Coref) or inserting prepositions and changing word forms (Fluency) to existing extractive answers, resulting in extremely high overlap with possible extractive answers.

4. Clarification Reformulating a question that had previously been asked.

5. Definition Asking what is meant by a term (e.g. "What are polygenes?")

Results QuAC and CoQA contain many similar features but at very different rates, offering complementary coverage of types of user behavior. CoQA dialogs drill down for details significantly more frequently and cover more than 60% of sentences in the context material (Sentence Coverage). QuAC dialogs shift to new topics frequently and cover less than 30% of sentences in the context. Both datasets contain only a small numbers of definition questions and returns to previous topics and few requests for clarification.

2.3 Abstractive Answers

Table 3 compares abstractive behavior in CoQA and QuAC. We observed five phenomena:

1. Yes/No Questions annotated with yes/no. In QuAC such questions and their corresponding yes or no are marked in addition to an extractive answer. In CoQA, the single token "yes" or "no" is simply asserted as the abstractive answer, with an extractive answer provided in the rationale (e.g. "Q: Is atmosphere one of them? A: yes").

2. Coref Coreference is added to previously mentioned entities in either context or question (e.g. "Q: How was France's economy in the late 2000s? A: **it** entered the recession").

3. Count Counting how many entities of some type were mentioned (e.g. "Q: how many specific genetic traits are named? A: five")

4. Picking A question that requires the answer to pick from a set defined in the question (e.g. "Q: Is this a boy or a girl? A: boy)

5. Fluency Adding a preposition, changing the form of a word, or merging two non-contiguous spans (e.g. "Q: how did he get away? A: **by** foot)

Results Both QuAC and CoQA have a similar rate of yes/no questions. QuAC contains no other abstractive phenomena while CoQA contains a small number of predominately insertions, often at the beginning of an extractive span, for coreference and or other fluency improvements. Because abstractive behavior in CoQA includes mostly small modifications to spans in the context, the maximum achievable performance by a model that predicts spans from the context is 97.8 F1. [6]

	Overall F1
DrQA (Extractive)	54.7
DrQA + PGNet (Abstractive)	66.2
BiDAF++ w/ 0-ctx	63.4
BiDAF++ w/ 3-ctx	**69.2**

Table 4: Development set performance by training BiDAF++ (Choi et al., 2018) models (extractive) on CoQA data with handling yes/no and no-answer questions as in QuAC. Despite being extractive, these models significantly outperform reported baselines, DrQA and DrQA + PGNet (Reddy et al., 2018).

	in-F1	out-F1	F1
DrQA	54.5	47.9	52.6
DrQA + PGNet	67.0	60.4	65.1
BiDAF++ w/ 3-ctx	**69.4**	**63.8**	**67.8**

Table 5: Test set results on CoQA. We report in domain F1 (in-F1), out of domain F1 on two held out domains, Reddit and Science (out-F1) and the overall F1 (F1).

3 New Extractive Baseline for CoQA

Our analysis strongly implies that beyond yes/no questions, abstractive behavior is not a significant component in either QuAC or CoQA. As such, QuAC models can be trivially adapted to CoQA.

We train a set of BiDAF++ baselines from the original QuAC dataset release (Choi et al., 2018) by optimizing the model to predict the span with maximum F1 overlap with respect to annotated abstractive answers.[7] If the abstractive answer is ex-

---

[6] To compute the upper bound, if abstractive answer is exactly "yes", "no", or "unknown", we consider the upper bound to be 100. Otherwise, we use the CoQA evaluation script to find a span in the context that has maximum F1 with respect to the abstractive answer.

[7] We use the implementation on http://allennlp.org, and do not modify any hyper-parameters except the the maximum dialog length and that models were allowed to train up to 65 epochs.

	F1	HEQQ	HEQD
BiDAF++ w/ 2-ctx	60.6	55.7	4.0
Train SQuAD 2.0	34.3	18.0	0.3
Train CoQA	31.2	19.2	0.0
Ft from SQuAD 2.0	62.6	58.3	**5.9**
Ft from CoQA	**63.3**	**59.2**	5.1

Table 6: Cross dataset transfer to QuAC development set. Models do not transfer directly (rows 3 and 4), but after fine tuning improve performance (rows 5 and 6).

actly "yes" or "no", we train the model to output the whole rationale span, and classify the question as yes/no with the appropriate answer. At evaluation time, if the model predicts a question is a yes/no question, instead of returning the extracted span, we simply return "yes" or "no".

Results Table 4 and Table 5 summarize our results for training BiDAF++ with varying contexts on CoQA. Beyond the difference of underlying base question-answer models (DrQA (Chen et al., 2017) vs. BiDAF (Seo et al., 2016) with self attention (Clark and Gardner, 2018)), BiDAF++ has two core differences with respect to DRQA+PGNet: (1) instead of appending previous questions and answers to input question tokens, BiDAF++ marks answers of previous questions directly on the context, and (2) BiDAF++ uses contextualized word embeddings through ELMo (Peters et al., 2018). These differences, in combination with appropriate handling of yes/no and unanswerable questions significantly improves on the existing extractive baseline **(+14.2 F1)** and even on the existing abstractive baseline **(+2.7 F1)**.

4 Cross-Dataset Experiments

In this section we consider whether models can benefit from transfer between SQuAD 2.0, QuAC, and CoQA, and show that the datasets, while ineffective for direct transfer, can be used as pretraining. In all experiments, we use BiDAF++, either with two context or no context, depending on if we are training for dialog settings or not, with default configurations. Models are trained by initializing from other models trained on different datasets and we do not decrease initial learning rates from just training directly on the target dataset. When SQuAD 2.0 is used to initialize models that use context, we randomly order questions in SQuAD 2.0 and train as if questions were asked in the form of a dialog. [8]

	In Domain F1
DrQA + PGNet	66.2
BiDAF++ w/ 2-ctx	67.6
SQuAD 2.0	41.4
QuAC	29.1
Ft from SQuAD 2.0	**69.2**
Ft from QuAC	68.0

Table 7: Cross dataset transfer to CoQA development set. Models do not transfer directly (rows 3 and 4), but after fine tuning improve performance (rows 5 and 6). For an explanation of why BiDAF++ outperforms DrQA + PGNet, see Section 3.

	F1	EM
Baseline	67.6	65.1
BiDAF++	70.5	67.4
CoQA	38.1	32.4
QuAC	25.4	16.8
Ft from CoQA	**72.5**	**69.4**
Ft from QuAC	69.5	66.8

Table 8: Cross dataset transfer to SQuAD 2.0 development set. BiDAF++ (Choi et al., 2018) outperforms the baseline, a different implementation of the same model (Rajpurkar et al., 2018) likely because of better hyper parameter tuning.

Results Tables 6-8 summarize our results. Across all of the datasets, BiDAF++ outperforms other baselines, and there exists at least one other dataset that significantly improves performance on a target dataset on average **+2.1 F1**. Experiments do not support that direct transfer is possible.

5 Related Work

Other proposals exist other than the three we analyzed that expand on features in SQuAD (Rajpurkar et al., 2016). For example, maintaining question independence of context to reduce the role of string matching and having long context length (Joshi et al., 2017; Kociský et al., 2017), higher level reasoning (Khashabi et al., 2018; Clark et al., 2018; Yang et al., 2018), multi-turn information seeking interactions, in either table settings (Iyyer et al., 2017; Talmor and Berant, 2018; Saha et al., 2018), regulation settings (Saeidi et al., 2018), or Quiz Bowl settings (Elgohary et al., 2018). Other work considers multi-modal contexts where interactions are a single turn (Tapaswi et al., 2016; Antol et al., 2015; Lei et al., 2018) or multi-turn (Das et al., 2017; Pasunuru and Bansal, 2018). These efforts contain alternative challenges than ones we analyze in this paper.

---

[8] Likely a better strategy exists but we would like to demonstrate transfer in the simplest way. We only report development numbers as these experiments are meant to be exploratory.

Abstract

Question-answering plays an important role in e-commerce as it allows potential customers to actively seek crucial information about products or services to help their purchase decision making. Inspired by the recent success of machine reading comprehension (MRC) on formal documents, this paper explores the potential of turning customer reviews into a large source of knowledge that can be exploited to answer user questions. We call this problem *Review Reading Comprehension* (RRC). To the best of our knowledge, no existing work has been done on RRC. In this work, we first build an RRC dataset called ReviewRC based on a popular benchmark for aspect-based sentiment analysis. Since ReviewRC has limited training examples for RRC (and also for aspect-based sentiment analysis), we then explore a novel post-training approach on the popular language model BERT to enhance the performance of fine-tuning of BERT for RRC. To show the generality of the approach, the proposed post-training is also applied to some other review-based tasks such as aspect extraction and aspect sentiment classification in aspect-based sentiment analysis. Experimental results demonstrate that the proposed post-training is highly effective[1].

1 Introduction

For online commerce, question-answering (QA) serves either as a standalone application of customer service or as a crucial component of a dialogue system that answers user questions. Many intelligent personal assistants (such as Amazon Alexa and Google Assistant) support online shopping by allowing the user to speak directly to the assistants. One major hindrance for this mode of shopping is that such systems have limited capability to answer user questions about products (or services), which are vital for customer decision making. As such, an intelligent agent that can automatically answer customers' questions is very important for the success of online businesses.

Given the ever-changing environment of products and services, it is very hard, if not impossible, to pre-compile an up-to-date and reliable knowledge base to cover a wide assortment of questions that customers may ask, such as in factoid-based KB-QA (Xu et al., 2016; Fader et al., 2014; Kwok et al., 2001; Yin et al., 2015). As a compromise, many online businesses leverage community question-answering (CQA) (McAuley and Yang, 2016) to crowdsource answers from existing customers. However, the problem with this approach is that many questions are not answered, and if they are answered, the answers are delayed, which is not suitable for interactive QA. In this paper, we explore the potential of using product reviews as a large source of user experiences that can be exploited to obtain answers to user questions. Although there are existing studies that have used information retrieval (IR) techniques (McAuley and Yang, 2016; Yu and Lam, 2018) to find a whole review as the response to a user question, giving the whole review to the user is undesirable as it is quite time-consuming for the user to read it.

Inspired by the success of Machine Reading Comphrenesions (MRC) (Rajpurkar et al., 2016, 2018), we propose a novel task called Review Reading Comprehension (RRC) as following.

Problem Definition: Given a question $q = (q_1, \dots, q_m)$ from a customer (or user) about a product and a review $d = (d_1, \dots, d_n)$ for that product containing the information to answer q, find a sequence of tokens (a text span) $a = (d_s, \dots, d_e)$ in d that answers q correctly, where $1 \leq s \leq n$, $1 \leq e \leq n$, and $s \leq e$.

A sample *laptop* review is shown in Table 1. We can see that customers may not only ask factoid

Questions
Q1: Does it have an internal hard drive ?
Q2: How large is the internal hard drive ?
Q3: is the capacity of the internal hard drive OK ?
Review
Excellent value and a must buy for someone looking for a Macbook . You ca n't get any better than this price and it **come with**$_{A1}$ an internal disk drive . All the newer MacBooks do not . Plus you get **500GB**$_{A2}$ which is also a **great**$_{A3}$ feature . Also , the resale value on this will keep . I highly recommend you get one before they are gone .

Table 1: An example of review reading comprehension: we show 3 questions and their corresponding answer spans from a review.

questions such as the specs about some aspects of the laptop as in the first and second questions but also subjective or opinion questions about some aspects (capacity of the hard drive), as in the third question. RRC poses some *domain challenges* compared to the traditional MRC on Wikipedia, such as the need for rich product knowledge, informal text, and fine-grained opinions (there is almost no subjective content in Wikipedia articles). Research also shows that yes/no questions are very frequent for products with complicated specifications (McAuley and Yang, 2016; Xu et al., 2018b).

To the best of our knowledge, no existing work has been done in RRC. This work first builds an RRC dataset called ReviewRC, using reviews from SemEval 2016 Task 5[2], which is a popular dataset for aspect-based sentiment analysis (ABSA) (Hu and Liu, 2004) in the domains of *laptop* and *restaurant*. We detail ReviewRC in Sec. 5. Given the wide spectrum of domains (types of products or services) in online businesses and the prohibitive cost of annotation, ReviewRC can only be considered to have a limited number of annotated examples for supervised training, which still leaves the domain challenges partially unresolved.

This work adopts BERT (Devlin et al., 2018) as the base model as it achieves the state-of-the-art performance on MRC (Rajpurkar et al., 2016, 2018). Although BERT aims to learn contextualized representations across a wide range of NLP tasks (to be task-agnostic), leveraging BERT alone still leaves the domain challenges unresolved (as BERT is trained on Wikipedia articles and has almost no understanding of opinion text), and it also introduces another challenge of task-awareness (the RRC task), called the *task challenge*. This challenge arises when the task-agnostic BERT meets the limited number of fine-tuning examples in ReviewRC (see Sec. 5) for RRC, which is insufficient to fine-tune BERT to ensure full task-awareness of the system[3]. To address all the above challenges, we propose a novel joint post-training technique that takes BERT's pre-trained weights as the initialization[4] for basic language understanding and adapt BERT with both domain knowledge and task (MRC) knowledge before fine-tuning using the domain end task annotated data for the domain RRC. This technique leverages knowledge from two sources: unsupervised domain reviews and supervised (yet out-of-domain) MRC data [5], where the former enhances domain-awareness and the latter strengthens MRC task-awareness. As a general-purpose approach, we show that the proposed method can also benefit ABSA tasks such as aspect extraction (AE) and aspect sentiment classification (ASC).

The main contributions of this paper are as follows. (1) It proposes the new problem of *review reading comprehension* (RRC). (2) To solve this new problem, an annotated dataset for RRC is created. (3) It proposes a general-purpose post-training approach to improve RRC, AE, and ASC. Experimental results demonstrate that the proposed approach is effective.

2 Related Works

Many datasets have been created for MRC from formally written and objective texts, e.g., Wikipedia (WikiReading (Hewlett et al., 2016), SQuAD (Rajpurkar et al., 2016, 2018), WikiHop (Welbl et al., 2018), DRCD (Shao et al., 2018), QuAC (Choi et al., 2018), HotpotQA (Yang et al., 2018)) news and other articles (CNN/Daily Mail (Hermann et al., 2015), NewsQA (Trischler et al., 2016), RACE (Lai et al., 2017)), fictional stories (MCTest (Richardson et al., 2013),

---

[2] `http://alt.qcri.org/semeval2016/task5/`. We choose these review datasets to align RRC with existing research on sentiment analysis.

[3] The end tasks from the original BERT paper typically use tens of thousands of examples to ensure that the system is task-aware.

[4] Due to limited computation resources, it is impractical for us to pre-train BERT directly on reviews from scratch (Devlin et al., 2018).

[5] To simplify the writing, we refer MRC as a general-purpose RC task on formal text (non-review) and RRC as an end-task specifically focused on reviews.

CBT (Hill et al., 2015), NarrativeQA (Kočiskỳ et al., 2018)), and general Web documents (MS MARCO (Nguyen et al., 2016), TriviaQA (Joshi et al., 2017), SearchQA (Dunn et al., 2017)). Also, CoQA (Reddy et al., 2018) is built from multiple sources, such as Wikipedia, Reddit, News, Mid/High School Exams, Literature, etc. To the best of our knowledge, MRC has not been used on reviews, which are primarily subjective. As such, we created a review-based MRC dataset called ReviewRC. Answers from ReviewRC are extractive (similar to SQuAD (Rajpurkar et al., 2016, 2018)) rather than abstractive (or generative) (such as in MS MARCO (Nguyen et al., 2016) and CoQA (Reddy et al., 2018)). This is crucial because online businesses are typically cost-sensitive and extractive answers written by humans can avoid generating incorrect answers beyond the contents in reviews by an AI agent.

Community QA (CQA) is widely adopted by online businesses (McAuley and Yang, 2016) to help users. However, since it solely relies on humans to give answers, it often takes a long time to get a question answered or even not answered at all as we discussed in the introduction. Although there exist researches that align reviews to questions as an information retrieval task (McAuley and Yang, 2016; Yu and Lam, 2018), giving a whole review to the user to read is time-consuming and not suitable for customer service settings that require interactive responses.

Knowledge bases (KBs) (such as Freebase (Dong et al., 2015; Xu et al., 2016; Yao and Van Durme, 2014) or DBpedia (Lopez et al., 2010; Unger et al., 2012)) have been used for question answering (Yu and Lam, 2018). However, the ever-changing nature of online businesses, where new products and services appear constantly, makes it prohibitive to build a high-quality KB to cover all new products and services.

Reviews also serve as a rich resource for sentiment analysis (Pang et al., 2002; Hu and Liu, 2004; Liu, 2012, 2015). Although document-level (review) sentiment classification may be considered as a solved problem (given ratings are largely available), aspect-based sentiment analysis (ABSA) is still an open challenge, where alleviating the cost of human annotation is also a major issue. ABSA aims to turn unstructured reviews into structured fine-grained aspects (such as the “battery” of a laptop) and their associated opinions (e.g., “good battery” is *positive* about the aspect battery). Two important tasks in ABSA are aspect extraction (AE) and aspect sentiment classification (ASC) (Hu and Liu, 2004), where the former aims to extract aspects (e.g., “battery”) and the latter targets to identify the polarity for a given aspect (e.g., *positive* for *battery*). Recently, supervised deep learning models dominate both tasks (Wang et al., 2016, 2017; Xu et al., 2018a; Tang et al., 2016; He et al., 2018) and many of these models use handcrafted features, lexicons, and complicated neural network architectures to remedy the insufficient training examples from both tasks. Although these approaches may achieve better performances by manually injecting human knowledge into the model, human baby-sat models may not be intelligent enough[6] and automated representation learning from review corpora is always preferred (Xu et al., 2018a; He et al., 2018). We push forward this trend with the recent advance in pre-trained language models from deep learning (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2018; Radford et al., 2018a,b). Although it is practical to train domain word embeddings from scratch on large-scale review corpora (Xu et al., 2018a), it is impractical to train language models from scratch with limited computational resources. As such, we show that it is practical to adapt language models pre-trained from formal texts to domain reviews.

3 BERT and Review-based Tasks

In this section, we briefly review BERT and derive its fine-tuning formulation on three (3) review-based end tasks.

3.1 BERT

BERT is one of the key innovations in the recent progress of contextualized representation learning (Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2018a; Devlin et al., 2018). The idea behind the progress is that even though the word embedding (Mikolov et al., 2013; Pennington et al., 2014) layer (in a typical neural network for NLP) is trained from large-scale corpora, training a wide variety of neural architectures that encode contextual representations only from the limited supervised data on end tasks is insufficient. Unlike ELMo (Peters et al., 2018) and ULMFiT

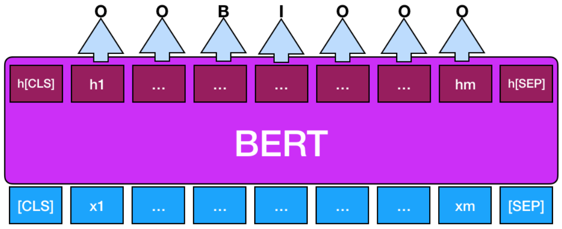
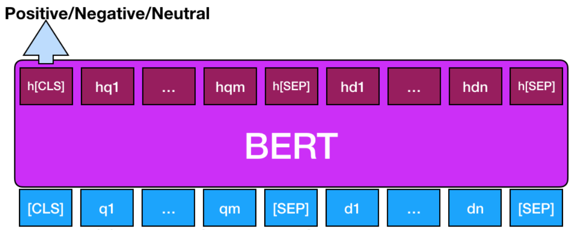
(1) Review Reading Comprehension



(2) Aspect Extraction



(3) Aspect Sentiment Classification

Figure 1: Overview of BERT settings for review reading comprehension (RRC), aspect extraction (AE) and aspect sentiment classification (ASC).

(Howard and Ruder, 2018) that are intended to provide additional features for a particular architecture that bears human's understanding of the end task, BERT adopts a fine-tuning approach that requires almost no specific architecture for each end task. This is desired as an intelligent agent should minimize the use of prior human knowledge in the model design. Instead, it should learn such knowledge from data. BERT has two parameter intensive settings:

BERT$_{\text{BASE}}$: 12 layers, 768 hidden dimensions and 12 attention heads (in transformer) with the total number of parameters, 110M;

BERT$_{\text{LARGE}}$: 24 layers, 1024 hidden dimensions and 16 attention heads (in transformer) with the total number of parameters, 340M.

We only extend BERT with one extra task-specific layer and fine-tune BERT on each end task. We focus on three (3) review-based tasks: review reading comprehension (RRC), aspect extraction (AE) and aspect sentiment classification (ASC). The inputs/outputs settings are depicted in Figure 1 and detailed in the following subsections.

3.2 Review Reading Comprehension (RRC)

Following the success of SQuAD (Rajpurkar et al., 2016) and BERT's SQuAD implementation, we design review reading comprehension as follows. Given a question $q = (q_1, \dots, q_m)$ asking for an answer from a review $d = (d_1, \dots, d_n)$, we formulate the input as a sequence $x = (\texttt{[CLS]}, q_1, \dots, q_m, \texttt{[SEP]}, d_1, \dots, d_n, \texttt{[SEP]})$, where `[CLS]` is a dummy token not used for RRC and `[SEP]` is intended to separate q and d. Let $\text{BERT}(\cdot)$ be the pre-trained (or post-trained as in the next section) BERT model. We first obtain the hidden representation as $h = \text{BERT}(x) \in \mathbb{R}^{r_h * |x|}$, where $|x|$ is the length of the input sequence and r_h is the size of the hidden dimension. Then the hidden representation is passed to two separate dense layers followed by softmax functions: $l_1 = \text{softmax}(W_1 \cdot h + b_1)$ and $l_2 = \text{softmax}(W_2 \cdot h + b_2)$, where W_1, $W_2 \in \mathbb{R}^{r_h}$ and $b_1, b_2 \in \mathbb{R}$. The softmax is applied along the dimension of the sequence. The output is a span across the positions in d (after the `[SEP]` token of the input), indicated by two pointers (indexes) s and e computed from l_1 and l_2: $s = \arg\max_{\text{Idx}_{\texttt{[SEP]}} < s < |x|}(l_1)$ and $e = \arg\max_{s \le e < |x|}(l_2)$, where $\text{Idx}_{\texttt{[SEP]}}$ is the position of token `[SEP]` (so the pointers will never point to tokens from the question). As such, the final answer will always be a valid text span from the review as $a = (d_s, \dots, d_e)$.

Training the RRC model involves minimizing the loss that is designed as the averaged cross entropy on the two pointers:

$$\mathcal{L}_{\text{RRC}} = -\frac{\sum \log l_1 \mathbb{I}(s) + \sum \log l_2 \mathbb{I}(e)}{2},$$

where $\mathbb{I}(s)$ and $\mathbb{I}(e)$ are one-hot vectors representing the ground truths of pointers.

RRC may suffer from the prohibitive cost of annotating large-scale training data covering a wide range of domains. And BERT severely lacks two kinds of prior knowledge: (1) large-scale domain knowledge (e.g., about a specific product category), and (2) task-awareness knowledge (MRC/RRC in this case). We detail the technique of jointly incorporating these two types of knowledge in Sec. 4.

3.3 Aspect Extraction

As a core task in ABSA, aspect extraction (AE) aims to find aspects that reviewers have expressed opinions on (Hu and Liu, 2004). In supervised settings, it is typically modeled as a sequence labeling task, where each token from a sentence is labeled as one of $\{\underline{B}egin, \underline{I}nside, \underline{O}utside\}$. A continuous chunk of tokens that are labeled as one *B* and followed by zero or more *I*s forms an aspect. The input sentence with m words is constructed as $x = (\texttt{[CLS]}, x_1, \ldots, x_m, \texttt{[SEP]})$. After $h = \text{BERT}(x)$, we apply a dense layer and a softmax for each position of the sequence: $l_3 = \text{softmax}(W_3 \cdot h + b_3)$, where $W_3 \in \mathbb{R}^{3*r_h}$ and $b_3 \in \mathbb{R}^3$ (3 is the total number of labels (*BIO*)). Softmax is applied along the dimension of labels for each position and $l_3 \in [0, 1]^{3*|x|}$. The labels are predicted as taking argmax function at each position of l_3 and the loss function is the averaged cross entropy across all positions of a sequence.

AE is a task that requires intensive domain knowledge (e.g., knowing that "screen" is a part of a laptop). Previous study (Xu et al., 2018a) has shown that incorporating domain word embeddings greatly improve the performance. Adapting BERT's general language models to domain reviews is crucial for AE, as shown in Sec. 5.

3.4 Aspect Sentiment Classification

As a subsequent task of AE, aspect sentiment classification (ASC) aims to classify the sentiment polarity (positive, negative, or neutral) expressed on an aspect extracted from a review sentence. There are two inputs to ASC: an aspect and a review sentence mentioning that aspect. Consequently, ASC is close to RRC as the question is just about an aspect and the review is just a review sentence but ASC only needs to output a class of polarity instead of a textual span.

Let $x = (\texttt{[CLS]}, q_1, \ldots, q_m, \texttt{[SEP]}, d_1, \ldots, d_n, \texttt{[SEP]})$, where $q_1, \ldots, q_m$ now is an aspect (with m tokens) and $d_1, \ldots, d_n$ is a review sentence containing that aspect. After $h = \text{BERT}(x)$, we leverage the representations of `[CLS]` $h_{\text{[CLS]}}$, which is the aspect-aware representation of the whole input. The distribution of polarity is predicted as $l_4 = \text{softmax}(W_4 \cdot h_{\text{[CLS]}} + b_4)$, where $W_4 \in \mathbb{R}^{3*r_h}$ and $b_4 \in \mathbb{R}^3$ (3 is the number of polarities). Softmax is applied along the dimension of labels on `[CLS]`: $l_4 \in [0, 1]^3$. Training loss is the cross entropy on the polarities.

As a summary of these tasks, insufficient supervised training data significantly limits the performance gain across these 3 review-based tasks. Although BERT's pre-trained weights strongly boost the performance of many other NLP tasks on formal texts, we observe in Sec. 5 that BERT's weights only result in limited gain or worse performance compared with existing baselines. In the next section, we introduce the post-training step to boost the performance of all these 3 tasks.

4 Post-training

As discussed in the introduction, fine-tuning BERT directly on the end task that has limited tuning data faces both domain challenges and task-awareness challenge. To enhance the performance of RRC (and also AE and ASC), we may need to reduce the bias introduced by non-review knowledge (e.g., from Wikipedia corpora) and fuse domain knowledge (DK) (from unsupervised domain data) and task knowledge (from supervised MRC task but out-of-domain data). Given MRC is a general task with answers of questions covering almost all document contents, a large-scale MRC supervised corpus may also benefit AE and ASC. Eventually, we aim to have a general-purpose post-training strategy that can exploit the above two kinds of knowledge for end tasks.

To post-train on domain knowledge, we leverage the two novel pre-training objectives from BERT: masked language model (MLM) and next sentence[7] prediction (NSP). The former predicts randomly masked words and the latter detects whether two sides of the input are from the same document or not. A training example is formulated as $(\texttt{[CLS]}, x_{1:j}, \texttt{[SEP]}, x_{j+1:n}, \texttt{[SEP]})$, where $x_{1:n}$ is a document (with randomly masked words) split into two sides $x_{1:j}$ and $x_{j+1:n}$ and `[SEP]` separates those two.

MLM is crucial for injecting review domain knowledge and for alleviating the bias of the knowledge from Wikipedia. For example, in the Wikipedia domain, BERT may learn to guess the `[MASK]` in "The `[MASK]` is bright" as "sun". But in a laptop domain, it could be "screen". Further, if the `[MASK]`ed word is an opinion word in "The touch screen is `[MASK]`", this objective challenges BERT to learn the representations for fine-grained opinion words like "great" or "terrible" for `[MASK]`. The objective of NSP further encourages BERT to learn contextual representation beyond word-level. In the context of reviews,

---

[7] The BERT paper refers a sentence as a piece of text with one to many natural language sentences.

NSP formulates a task of "artificial review prediction", where a negative example is an original review but a positive example is a synthesized fake review by combining two different reviews. This task exploits the rich relationships between two sides in the input, such as whether two sides of texts have the same rating or not (when two reviews with different ratings are combined as a positive example), or whether two sides are targeting the same product or not (when two reviews from different products are merged as a positive example). In summary, these two objectives encourage to learn a myriad of fine-grained features for potential end tasks.

We let the loss function of MLM be $\mathcal{L}_{\text{MLM}}$ and the loss function of next text piece prediction be $\mathcal{L}_{\text{NSP}}$, the total loss of the domain knowledge post-training is $\mathcal{L}_{\text{DK}} = \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{NSP}}$.

To post-train BERT on task-aware knowledge, we use SQuAD (1.1), which is a popular large-scale MRC dataset. Although BERT gains great success on SQuAD, this success is based on the huge amount of training examples of SQuAD (100,000+). This amount is large enough to ameliorate the flaws of BERT that has almost no questions on the left side and no textual span predictions based on both the question and the document on the right side. However, a small amount of fine-tuning examples is not sufficient to turn BERT to be more task-aware, as shown in Sec. 5. We let the loss on SQuAD be $\mathcal{L}_{\text{MRC}}$, which is in a similar setting as the loss $\mathcal{L}_{\text{RRC}}$ for RRC. As a result, the joint loss of post-training is defined as $\mathcal{L} = \mathcal{L}_{\text{DK}} + \mathcal{L}_{\text{MRC}}$.

One major issue of post-training on such a loss is the prohibitive cost of GPU memory usage. Instead of updating parameters over a batch, we divide a batch into multiple sub-batches and accumulate gradients on those sub-batches before parameter updates. This allows for a smaller sub-batch to be consumed in each iteration.

Algorithm 1: Post-training Algorithm

```
Input: $\mathcal{D}_{\text{DK}}$: one batch of DK data;
       $\mathcal{D}_{\text{MRC}}$ one batch of MRC data;
       $u$: number of sub-batches.
1 $\nabla_\Theta \mathcal{L} \leftarrow 0$
2 $\{\mathcal{D}_{\text{DK},1}, \ldots, \mathcal{D}_{\text{DK},u}\} \leftarrow \text{Split}(\mathcal{D}_{\text{DK}}, u)$
3 $\{\mathcal{D}_{\text{MRC},1}, \ldots, \mathcal{D}_{\text{MRC},u}\} \leftarrow \text{Split}(\mathcal{D}_{\text{MRC}}, u)$
4 for $i \in \{1, \ldots, u\}$ do
5     $\mathcal{L}_{\text{partial}} \leftarrow \frac{\mathcal{L}_{\text{DK}}(\mathcal{D}_{\text{DK},i}) + \mathcal{L}_{\text{MRC}}(\mathcal{D}_{\text{MRC},i})}{u}$
6     $\nabla_\Theta \mathcal{L} \leftarrow \nabla_\Theta \mathcal{L} + \text{BackProp}(\mathcal{L}_{\text{partial}})$
7 end
8 $\Theta \leftarrow \text{ParameterUpdates}(\nabla_\Theta \mathcal{L})$
```

Algorithm 1 describes one training step and takes one batch of data on domain knowledge (DK) $\mathcal{D}_{\text{DK}}$ and one batch of MRC training data $\mathcal{D}_{\text{MRC}}$ to update the parameters Θ of BERT. In line 1, it first initializes the gradients ∇_Θ of all parameters as 0 to prepare gradient computation. Then in lines 2 and 3, each batch of training data is split into u sub-batches. Lines 4-7 spread the calculation of gradients to u iterations, where the data from each iteration of sub-batches are supposed to be able to fit into GPU memory. In line 5, it computes the partial joint loss $\mathcal{L}_{\text{partial}}$ of two sub-batches $\mathcal{D}_{\text{DK},i}$ and $\mathcal{D}_{\text{MRC},i}$ from the i-th iteration through forward pass. Note that the summation of two sub-batches' losses is divided by u, which compensate the scale change introduced by gradient accumulation in line 6. Line 6 accumulates the gradients produced by backpropagation from the partial joint loss. To this end, accumulating the gradients u times is equivalent to computing the gradients on the whole batch once. But the sub-batches and their intermediate hidden representations during the i-th forward pass can be discarded to save memory space. Only the gradients ∇_Θ are kept throughout all iterations and used to update parameters (based on the chosen optimizer) in line 8. We detail the hyper-parameter settings of this algorithm in Sec. 5.3.

5 Experiments

We aim to answer the following research questions (RQs) in the experiment:

RQ1: what is the performance gain of post-training for each review-based task, with respect to the state-of-the-art performance?

RQ2: what is the performance of BERT's pre-trained weights on three review-based tasks without any domain and task adaptation?

RQ3: upon ablation studies of separate domain knowledge post-training and task-awareness post-training, what is their respective contribution to the whole post-training performance gain?

5.1 End Task Datasets

As there are no existing datasets for RRC and to be consistent with existing research on sentiment analysis, we adopt the *laptop* and *restaurant* reviews of SemEval 2016 Task 5 as the source to create datasets for RRC. We do not use SemEval 2014 Task 4 or SemEval 2015 Task 12 because these datasets do not come with the review(document)-level XML tags to recover whole reviews from review sentences. We keep the split of training and testing of the SemEval 2016 Task 5 datasets and annotate multiple QAs for each review following the way of constructing QAs for the SQuAD 1.1 datasets (Rajpurkar et al., 2016).

To make sure our questions are close to real-world questions, 2 annotators are first exposed to 400 QAs from CQA (under the laptop category in Amazon.com or popular restaurants in Yelp.com) to get familiar with real questions. Then they are asked to read reviews and independently label textual spans and ask corresponding questions when they feel the textual spans contain valuable information that customers may care about. The textual spans are labeled to be as concise as possible but still human-readable. Note that the annotations for sentiment analysis tasks are not exposed to annotators to avoid biased annotation on RRC. Since it is unlikely that the two annotators can label the same QAs (the same questions with the same answer spans), they further mutually check each other's annotations and disagreements are discussed until agreements are reached. Annotators are encouraged to label as many questions as possible from testing reviews to get more test examples. A training review is encouraged to have 2 questions (training examples) on average to have good coverage of reviews.

The annotated data is in the format of SQuAD 1.1 (Rajpurkar et al., 2016) to ensure compatibility with existing implementations of MRC models. The statistics of the RRC dataset (ReviewRC) are shown in Table 2. Since SemEval datasets do not come with a validation set, we further split 20% of reviews from the training set for validation.

Statistics of datasets for AE and ASC are given in Table 3. For AE, we choose SemEval 2014 Task 4 for laptop and SemEval-2016 Task 5 for restaurant to be consistent with (Xu et al., 2018a) and other previous works. For ASC, we use SemEval 2014 Task 4 for both laptop and restaurant as existing research frequently uses this version. We use 150 examples from the training set of all these datasets for validation.

5.2 Post-training datasets

For domain knowledge post-training, we use Amazon laptop reviews (He and McAuley, 2016) and Yelp Dataset Challenge reviews[8]. For laptop, we filtered out reviewed products that have appeared in the validation/test reviews to avoid training bias for test data (Yelp reviews do not have this issue as the source reviews of SemEval are not from Yelp). Since the number of reviews is small, we choose a duplicate factor of 5 (each review generates about 5 training examples) during BERT data pre-processing. This gives us 1,151,863 post-training examples for laptop domain knowledge.

For the restaurant domain, we use Yelp reviews from restaurant categories that the SemEval reviews also belong to (Xu et al., 2018a). We choose 700K reviews to ensure it is large enough to generate training examples (with a duplicate factor of 1) to cover all post-training steps that we can afford (discussed in Section 5.3)[9]. This gives us 2,677,025 post-training examples for restaurant domain knowledge learning.

For MRC task-awareness post-training, we leverage SQuAD 1.1 (Rajpurkar et al., 2016) that come with 87,599 training examples from 442 Wikipedia articles.

5.3 Hyper-parameters

We adopt **BERT$_{\text{BASE}}$** (uncased) as the basis for all experiments[10]. Since post-training may take a large footprint on GPU memory (as BERT pre-training), we leverage FP16 computation[11] to reduce the size of both the model and hidden representations of data. We set a static loss scale of 2 in FP16, which can avoid any over/under-flow of floating point computation. The maximum length of post-training is set to 320 with a batch size of 16 for each type of knowledge. The number of sub-batch u is set to 2, which is good enough to store each sub-batch iteration into a GPU memory of 11G. We use Adam optimizer and set the learning rate to be 3e-5. We train 70,000 steps for the laptop domain and 140,000 steps for the restaurant

---

[8] `https://www.yelp.com/dataset/challenge`

[9] We expect that using more reviews can have even better results but we limit the amount of reviews based on our computational power.

[10] We expect **BERT$_{\text{LARGE}}$** to have better performance but leave that to future work due to limited computational power.

domain, which roughly have one pass over the pre-processed data on the respective domain.

5.4 Compared Methods

As BERT outperforms existing open source MRC baselines by a large margin, we do not intend to exhaust existing implementations but focus on variants of BERT introduced in this paper.

DrQA is a baseline from the document reader[12] of DrQA (Chen et al., 2017). We adopt this baseline because of its simple implementation for reproducibility. We run the document reader with random initialization and train it directly on ReviewRC. We use all default hyper-parameter settings for this baseline except the number of epochs, which is set as 60 for better convergence.

DrQA+MRC is derived from the above baseline with official pre-trained weights on SQuAD. We fine-tune document reader with ReviewRC. We expand the vocabulary of the embedding layer from the pre-trained model on ReviewRC since reviews may have words that are rare in Wikipedia and keep other hyper-parameters as their defaults.

For AE and ASC, we summarize the scores of the state-of-the-arts on SemEval (based the best of our knowledge) for brevity.

DE-CNN (Xu et al., 2018a) reaches the state-of-the-arts for AE by leveraging domain embeddings.

MGAN (Li et al., 2018) reaches the state-of-the-art ASC on SemEval 2014 task 4.

Lastly, to answer RQ1, RQ2, and RQ3, we have the following BERT variants.

BERT leverages the vanilla BERT pre-trained weights and fine-tunes on all 3 end tasks. We use this baseline to answer RQ2 and show that BERT's pre-trained weights alone have limited performance gains on review-based tasks.

BERT-DK post-trains BERT's weights only on domain knowledge (reviews) and fine-tunes on the 3 end tasks. We use BERT-DK and the following BERT-MRC to answer RQ3.

BERT-MRC post-trains BERT's weights on SQuAD 1.1 and then fine-tunes on the 3 end tasks.

BERT-PT (proposed method) post-trains BERT's weights using the joint post-training algorithm in Section 4 and then fine-tunes on the 3 end tasks.

5.5 Evaluation Metrics and Model Selection

To be consistent with existing research on MRC, we use the same evaluation script from SQuAD 1.1 (Rajpurkar et al., 2016) for RRC, which reports Exact Match (EM) and F1 scores. EM requires the answers to have exact string match with human annotated answer spans. F1 score is the averaged F1 scores of individual answers, which is typically higher than EM and is the major metric. Each individual F1 score is the harmonic mean of individual precision and recall computed based on the number of overlapped words between the predicted answer and human annotated answers.

For AE, we use the standard evaluation scripts come with the SemEval datasets and report the F1 score. For ASC, we compute both accuracy and Macro-F1 over 3 classes of polarities, where Macro-F1 is the major metric as the imbalanced classes introduce biases on accuracy. To be consistent with existing research (Tang et al., 2016), examples belonging to the *conflict* polarity are dropped due to a very small number of examples.

We set the maximum number of epochs to 4 for BERT variants, though most runs converge just within 2 epochs. Results are reported as averages of **9** runs (9 different random seeds for random batch generation).[13]

5.6 Result Analysis

The results of RRC, AE and ASC are shown in Tables 4, 5 and 6, respectively. To answer RQ1, we observed that the proposed joint post-training (BERT-PT) has the best performance over all tasks in all domains, which show the benefits of having two types of knowledge.

---

[12] https://github.com/facebookresearch/DrQA

[13] We notice that adopting 5 runs used by existing researches still has a high variance for a fair comparison.

Domain	Laptop		Rest.	
Methods	**EM**	**F1**	**EM**	**F1**
DrQA(Chen et al., 2017)	38.26	50.99	49.52	63.73
DrQA+MRC(Chen et al., 2017)	40.43	58.16	52.39	67.77
BERT	39.54	54.72	44.39	58.76
BERT-DK	42.67	57.56	48.93	62.81
BERT-MRC	47.01	63.87	54.78	68.84
BERT-PT	48.05	**64.51**	59.22	**73.08**

Domain	Laptop	Rest.
Methods	**F1**	**F1**
DE-CNN(Xu et al., 2018a)	81.59	74.37
BERT	79.28	74.1
BERT-DK	83.55	77.02
BERT-MRC	81.06	74.21
BERT-PT	**84.26**	**77.97**

Table 5: AE in F1.

To answer RQ2, to our surprise we found that the vanilla pre-trained weights of BERT do not work well for review-based tasks, although it achieves state-of-the-art results on many other NLP tasks (Devlin et al., 2018). This justifies the need to adapt BERT to review-based tasks.

To answer RQ3, we noticed that the roles of domain knowledge and task knowledge vary for different tasks and domains. For RRC, we found that the performance gain of BERT-PT mostly comes from task-awareness (MRC) post-training (as indicated by BERT-MRC). The domain knowledge helps more for restaurant than for laptop. We suspect the reason is that certain types of knowledge (such as specifications) of laptop are already present in Wikipedia, whereas Wikipedia has little knowledge about restaurant. We further investigated the examples improved by BERT-MRC and found that the boundaries of spans (especially short spans) were greatly improved.

For AE, we found that great performance boost comes mostly from domain knowledge post-training, which indicates that contextualized representations of domain knowledge are very important for AE. BERT-MRC has almost no improvement on restaurant, which indicates Wikipedia may have no knowledge about aspects of restaurant. We suspect that the improvements on laptop come from the fact that many answer spans in SQuAD are noun terms, which bear a closer relationship with laptop aspects.

For ASC, we observed that large-scale annotated MRC data is very useful. We suspect the reason is that ASC can be interpreted as a special MRC problem, where all questions are about the polarity of a given aspect. MRC training data may help BERT to understand the input format of ASC given their closer input formulation. Again, domain knowledge post-training also helps ASC.

Domain	Laptop		Rest.	
Methods	**Acc.**	**MF1**	**Acc.**	**MF1**
MGAN (Li et al., 2018)	76.21	71.42	81.49	71.48
BERT	75.29	71.91	81.54	71.94
BERT-DK	77.01	73.72	83.96	75.45
BERT-MRC	77.19	74.1	83.17	74.97
BERT-PT	78.07	**75.08**	84.95	**76.96**

Table 6: ASC in Accuracy and Macro-F1(MF1).

We further investigated the errors from BERT-PT over the 3 tasks. The errors on RRC mainly come from boundaries of spans that are not concise enough and incorrect location of spans that may have certain nearby words related to the question. We believe precisely understanding user's experience is challenging from only domain post-training given limited help from the RRC data and no help from the Wikipedia data. For AE, errors mostly come from annotation inconsistency and boundaries of aspects (e.g., apple OS is predicted as OS). Restaurant suffers from rare aspects like the names of dishes. ASC tends to have more errors as the decision boundary between the negative and neutral examples is unclear (e.g., even annotators may not sure whether the reviewer shows no opinion or slight negative opinion when mentioning an aspect). Also, BERT-PT has the problem of dealing with one sentence with two opposite opinions ("The screen is good but not for windows."). We believe that such training examples are rare.

6 Conclusions

We proposed a new task called *review reading comprehension* (RRC) and investigated the possibility of turning reviews as a valuable resource for answering user questions. We adopted BERT as our base model and proposed a joint post-training approach to enhancing both the domain and task knowledge. We further explored the use of this approach in two other review-based tasks: aspect extraction and aspect sentiment classification. Experimental results show that the post-training approach before fine-tuning is effective.

Abstract

Short texts challenge NLP tasks such as named entity recognition, disambiguation, linking and relation inference because they do not provide sufficient context or are partially malformed (e.g. wrt. capitalization, long tail entities, implicit relations). In this work, we present the Falcon approach which effectively maps entities and relations within a short text to its mentions of a background knowledge graph. Falcon overcomes the challenges of short text using a light-weight linguistic approach relying on a background knowledge graph. Falcon performs joint entity and relation linking of a short text by leveraging several fundamental principles of English morphology (e.g. compounding, headword identification) and utilizes an extended knowledge graph created by merging entities and relations from various knowledge sources. It uses the context of entities for finding relations and does not require training data. Our empirical study using several standard benchmarks and datasets show that Falcon significantly outperforms state-of-the-art entity and relation linking for short text query inventories.

1 Introduction

Entity Linking (EL) task annotates surface forms in the text with the corresponding reference mentions in knowledge bases such as Wikipedia. It involves the two sub-tasks, i.e. Named Entity Recognition and Disambiguation (NER and NED) tasks. The state of the art contains considerable research body for EL from text to its Wikipedia mention (Cucerzan, 2007; Ferragina and Scaiella, 2010; Hoffart et al., 2011; Balog, 2018; Shen et al., 2015; Ferragina and Scaiella, 2010; Hoffart et al., 2014). With the emergence of Knowledge Graphs (KGs) which represent data in a higher structured and semantic format such as DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008) and Wikidata (Vrandecic, 2012) that utilize Wikipedia as familiar knowledge source, retrieval-based applications such as question answering (QA) systems or keyword-based semantic search systems are empowered to provide more cognitive capabilities. Entity linking is a crucial component for a variety of applications built on knowledge graphs. For instance, an ideal NED tool on DBpedia recognizes the entities embedded in the question 'Who wrote the book The Pillars of The Earth?' and links them to the corresponding DBpedia entity (e.g. 'Pillars of The Earth' to `dbr:The_Pillars_of_the_Earth`)[1]. Another important NLP task is relation linking; it is about linking surface forms in text representing a relation to equivalent relations (predicates) of a KG. In our example question, an ideal relation linking (RL) tool links '`wrote`' to `dbo:author`[2]. There are existing approaches which address EL and RL tasks either jointly or independently (Miwa and Sasaki, 2014; Kirschnick et al., 2016; Wang et al., 2018; Dubey et al., 2018; Singh et al., 2017). However, they mostly fail in case of short text (e.g. question or key words based query) because the short text does not provide sufficient context which is essential for the disambiguation process. More importantly, a short text is often malformed meaning the text is incomplete,

[2] dbo is the prefix for `http://dbpedia.org/ontology/`

Proceedings of NAACL-HLT 2019, pages 2336–2346
Minneapolis, Minnesota, June 2 - June 7, 2019.

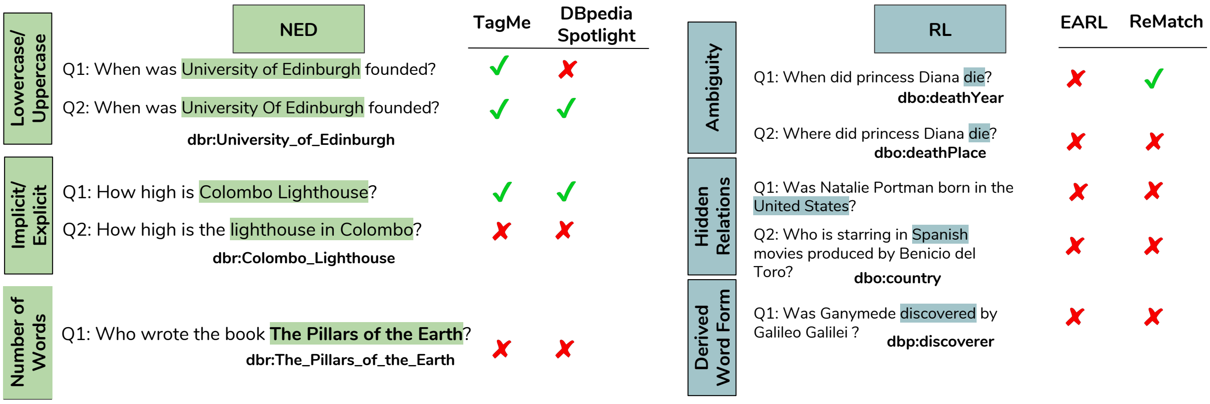

Figure 1: Performance of two EL and RL approaches on Specific Questions. TagMe and DBpedia Spotlight are the top-2 NED systems over the LC-QuAD QA dataset. However, considering short text questions, their behavior varies concerning question features, e.g., lowercase vs. uppercase, having implicit vs. explicit mappings, etc. Similar behavior has been observed for the top relation linking tools.

inexpressive, or implicit which is the case, particularly for relations in short sentences.

In this paper, we contribute to proposing a novel approach for jointly linking entities and relations within a short text into the entities and relations of DBpedia KG. This approach is robust to the challenges of short text, and moreover, it is efficient.

Research Objectives. Existing approaches and systems for NER, NED, EL, and RL resort to machine learning and deep learning approaches that require a large training data (Cao et al., 2018; Mudgal et al., 2018). These approaches achieve high performance on data similar to seen data. For instance, Singh et al. (2018c) evaluated 20 NED tools for question answering over the DBpedia KG including TagMe (Ferragina and Scaiella, 2012), DBpedia Spotlight (Mendes et al., 2011), Babelfy (Moro et al., 2014), and several APIs released by industry including Ambiverse (Ambiverse, 2018), TextRazor (TextRazor, 2018), and Dandelion (Dati, 2018). Among all, TagMe reports the highest F-score (0.67) over the complex question answering dataset LC-QuAD (TagMe is one of the top performing tools with an F-score of 0.91 on the generic WikiDisamb30 dataset (Ferragina and Scaiella, 2012)). Please be noted that TagMe was explicitly released for short text. However, when the input text is from a domain different from the training domain, its performance significantly falls down. Regarding the performance of various RL approaches such as ReMatch (Mulang' et al., 2017), SIBKB (Singh et al., 2017) is still low concerning accuracy and run-time even if they are purposefully developed for a particular domain or task. This deficiency is due to disregarding the context of the entities (Singh et al., 2018c,b). Therefore, when aiming for annotating entities and relations of short text, it is important to develop an approach which a) is agnostic of the requirement of large training data and b) jointly links entities and relations to its KG equivalence.

Approach. We target the problem of joint entity and relation linking within short text using the DBpedia KG as background knowledge. We propose a novel approach that resorts to several fundamental principles of English morphology such as compounding (Bauer and Laurie, 1983), right-hand rule for headword identification (Williams, 1981) and utilizes an extended knowledge graph created by merging entities and relations from various knowledge sources. The approach focuses on capturing semantics underlying the input text by using the context of entities for finding relations and does not require any training data. Albeit simple, to the best of our knowledge, the combination of strategies and optimization of our approach is unique. Our evaluations show that it leads to substantial gains in recall, precision, and F-score on various benchmarks and domains.

Resource. Falcon is available as an open Web API[3], and its source code is released to ensure reproducibility. Another open source contribution is an extended knowledge graph which we built by merging information from several sources, e.g. DBpedia, Wikidata, Oxford dictionary, and Wordnet. These contributions are in our public Github[4].

The paper is structured as follows: the next sec-

[3] `https://labs.tib.eu/falcon/`

[4] `https://github.com/AhmadSakor/falcon`

tion motivates our work by illustrating several limitations of state of the art over short text. Section 3 detailed our approach and we present evaluation results in Section 4. We describe related literature in Section 5 and Section 6 concludes our findings.

2 Motivating Example

We motivate our work by analyzing the performance of state-of-the-art EL and RL tools regarding query inventories on the DBpedia KG. In the following, we categorize the observed limitations. **Effect of Capitalization on EL tools** TagMe and DBpedia Spotlight are the best two performing EL systems for question answering over DBpedia (Singh et al., 2018c). Considering the question 'When was University of Edinburgh founded', where the entity `University of Edinburgh` has one word (i.e. 'of') starting with lowercase letters. TagMe can identify this entity and link to its corresponding DBpedia entity `dbr:University_of_Edinburgh` but DBpedia Spotlight fails. However, when all words in the entity label are in uppercase, both tools recognize and link entities correctly (cf. Figure 1).

Effect of Implicit/Explicit Entities on EL tools The vocabulary mismatch problem (Shekarpour et al., 2017) is common for text paraphrasing and significantly affects the performance of EL approaches. In Figure 1, both EL tools can correctly link the entity in the question 'How high is Colombo Lighthouse?' but fail when the question is rephrased to 'How high is the lighthouse in Colombo?' due to the vocabulary mismatch problem. In the first representation of the question, the entity label `Colombo Lighthouse` exactly matches to the DBpedia entity `dbr:Colombo_Lighthouse` which is not the case in the rephrased question (`dbr:Colombo_Lighthouse` is expected entity for `lighthouse in Colombo`).

Effect of the Number of Words in an Entity Label on EL tools Long tail entities were studied as a separate phenomenon such as in news (Esquivel et al., 2017). For question answering, an increasing number of words jeopardizes entity linking performance. In our motivating example, both EL tools can not link the entity present from the question 'Who wrote the book The Pillars of the Earth?' where the entity label ('The Pillars of the Earth') has five words (a question from LC-QuAD dataset (Trivedi et al., 2017)).

Effect of Ambiguity of Question on RL tools EARL (Dubey et al., 2018) and Rematch (Mulang' et al., 2017) are the two top performing relation linking tools for question answering over two different datasets QALD-5 (Unger et al., 2015) and LC-QuAD respectively. In Figure 1, for the question 'When did princess Diana die', Rematch correctly recognizes the relation `die` and links it to `dbo:deathYear`. However, when the question slightly changed to "Where did princess Diana die?" in which the expected relation is `dbo:deathPlace`, both tools fail to understand the ambiguity of the question intent and cannot provide the correct DBpedia IRIs.

Effect of Hidden Relation in a Question on RL tools Questions are typically relatively short and sometimes there is no natural language label for the relation. For example, to correctly answer the LC-QuAD question 'Was Natalie Portman born in the United States?' contains two relations: 1) the relational label `born` needs to be linked to `dbo:birthPlace` and 2) `dbo:country` is the hidden relation for which no relation surface form is present. A similar case can be observed in another question from the same dataset 'Who is starring in Spanish movies produced by Benicio del Toro?' where one of the expected relations is `dbo:country` for which no relation label is present. For both questions, EARL and ReMatch cannot identify hidden relations.

Effect of Derived Word Form of Relation Label on RL tools Consider the question 'Was Ganymede discovered by Galileo Galilei?' in which the relation label `discovered` is expected to link to the DBpedia ontology `dbo:discoverer`. The word `discoverer` is the derived word form of relation label `discovered`, and due to this, both tools fail to provide correct relation linking.

3 The Falcon Approach

The Falcon approach maps the surface forms within the short text into the textual representation of entities in KG. This mapping follows a particular strategy which is formalized in the following. Formally, a given short text is a set of tokens $\mathcal{T} = \{t_1, ..., t_n\}$. The set of entities in KG is the union of all KG resources $\mathcal{E} = C \cup P \cup I$ (where C, P, I are respectively a set of classes, properties, and instances), and L is the set of literals associated with entities. The task of entity linking is

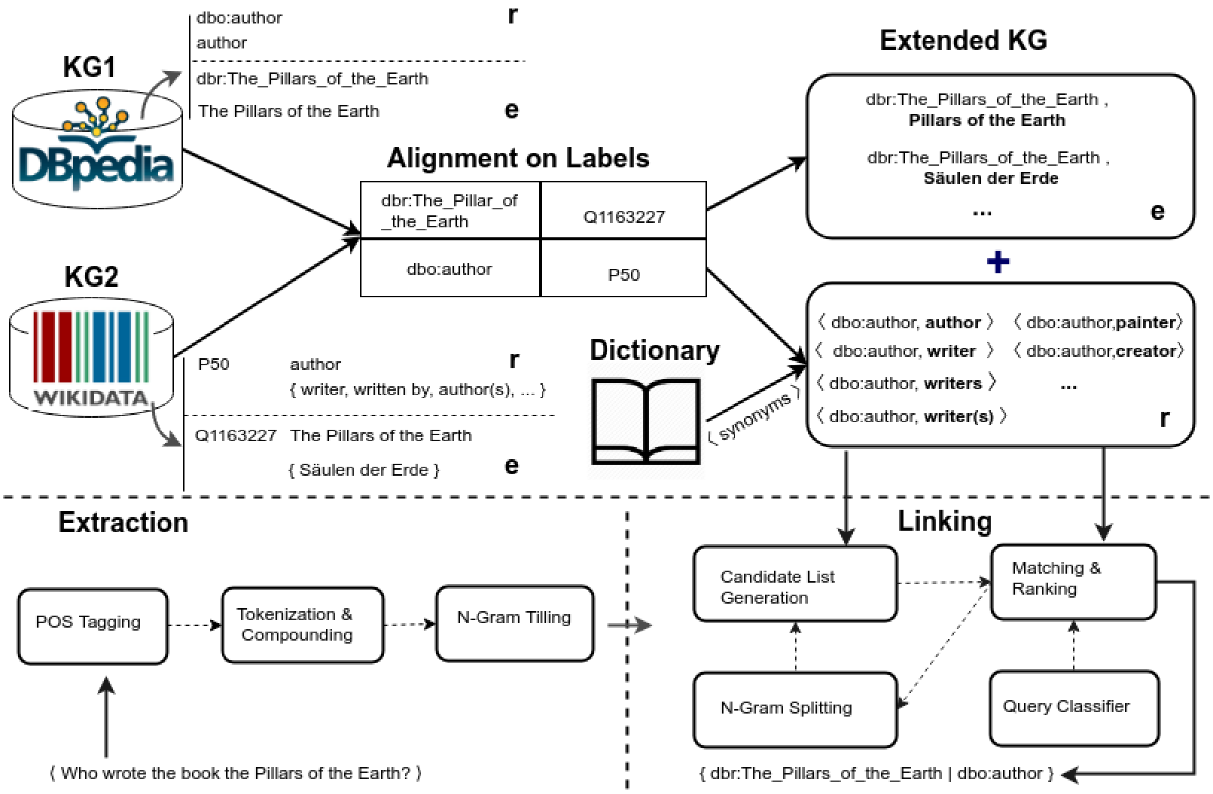

Figure 2: Overview of Falcon Approach. Falcon consists of two building blocks: 1) An extended knowledge graph which is built by merging information from various knowledge sources such as DBpedia, Wikidata, Oxford Dictionary, and WordNet. 2) Falcon architecture that has several modules focusing on surface form extraction and linking them to KG.

about mapping a subset of the input tokens denoted by $\mathcal{S} \in \mathcal{P}(\mathcal{T})$ (where $\mathcal{P}(\mathcal{T})$ is the power set of $\mathcal{T}$) to a set of entities denoted by $\mathcal{S}' \in \mathcal{P}(\mathcal{E})$ (where $\mathcal{P}(\mathcal{E})$ is the power set of $\mathcal{E}$), this mapping formally is represented as $\rho : \mathcal{S} \to \mathcal{S}'$. The Falcon approach deals with two optimization tasks as while it tries to maximize the number of tokens included in the set $\mathcal{S}$ (equation 1), it reduces the number of mapped entities in the set $\mathcal{S}'$ (eq. 2).

$$\gamma = \arg \max_{t_i \in \mathcal{A} | \mathcal{S} \in \mathcal{S}} \{\#t_i\} \tag{1}$$

$$\omega = \arg \min_{e_i \in \mathcal{A} | \mathcal{A} \in \mathcal{S}'} \{\#e_i\} \tag{2}$$

Extended Knowledge Graph The DBpedia KG contains over 5.6 million entities and 111 million facts (consisting of subject-predicate-object triples) which require overall 14.2GB storage (Auer et al., 2007). A major portion of this large information is not useful for EL/RL. Therefore we sliced DBpedia and extracted all the entity and relation labels to create a local KG. For example, the entity `Barack Obama`[5] in DBpedia has the natural language label 'Barack Obama' but DBpedia does not contain another representation of this label. However, the Wikidata KG is much richer and contains several aliases (or `known_as` labels) of Barack Obama such as Hussein Obama II, Barack Obama II , Obama, Barak Obama, President Obama, BHO and others[6]. We extended our local KG with this information from Wikidata. Similarly, for relation labels, the local KG is enriched with traditional linguistic resources such as Oxford dictionary (OED, 1989), and semantic dictionaries like WordNet (Miller, 1995a) to provide synonyms, derived word forms, etc. Use of background knowledge is common in question answering over DBpedia such as AskNow (Dubey et al., 2016) uses Wordnet to support relation linking. However, we also propose extending entity labels using Wikidata which is not yet used in literature. These two separate extended KGs with a total size of 1.4GB are used as an underlying

---

[6] `https://www.wikidata.org/wiki/Q76`

source of knowledge and act as the core of our approach (cf. Figure 2).

POS Tagging In the first module illustrated in Figure 2, short input text annotated with POS tag information using spaCy (Honnibal and Johnson, 2015). This step is used primarily to identify verb and noun phrases in the sentence.

Tokenization and Compounding The next module creates tokens from the input sentence removing the stop words. In the first step, we break the sentence into potential tokens by removing all the stop words, and we use the stopword list provided by Fox (1990). For creating tokens, we also reuse basic compounding principle of English morphology. Compound words are lexeme that contains two or more stems (Bauer and Laurie, 1983). The words which do not have any stop words between them considered as one compound word during token formation. For example, in question "Who is the wife of Barack Obama?", Barack Obama is noun phrases which do not have any stop word between, they considered as a single compound word. Compounding allows us to reduce the total number of tokens.

N-gram Tiling Typically, approaches described in (Shekarpour et al., 2017, 2013) dealing with short text start with the shortest token (or N-gram) to search associated candidates in the knowledge graph. This approach is not effective when an entity has many words in its label as it creates several additional tokens. For example in question "Who wrote the book The Pillars of the Earth?", It may generate several little tokens such as book, Pillars, Earth and it will result in several potential candidates in KG. In contrast, Bill et al. (2002) applied an N-gram tiling algorithm in a question answering system to find the long answer in case of overlapping small answers. For example, answers "PQR" and "QRS" merged into single long answer "PQRS." This algorithm proceeds greedily until high scoring longest tilled N-gram found. We applied a similar approach to find the longest possible token for extracting the potential entity label. In the exemplary question " Who wrote the book The Pillars of the Earth?", The previous module generates tokens "wrote, book, Pillars, Earth." In N-gram tiling algorithm, we do not consider identified verbs of the sentence because in most cases a verb cannot be an entity label. Hence three tokens "book, Pillars, Earth" are merged as a single token. Also, verb token acts as a division point of the sentence in case of two entities, and we do not merge tokens from either side of the verb. In this process, the N-gram tiling algorithm starts with the first token from either side of the verb (which is a case of two entities in a sentence) and ends at the last non-stop word. The tiling algorithm also considers the stop words and provide the longest tilled N-gram. After N-gram tiling, we have two tokens: "wrote" and "book The Pillars of the Earth."

Candidate List Generation From the tokens, we create two list 1) `potential relation candidates` which contain verbs ("wrote") 2) `potential entity candidates` ("book The Pillars of the Earth"). We first search tokens of potential relation candidates in an extended KG of relations and get all the possible `DBpedia relation candidates.` Similar process has been repeated separately for `potential entity candidates` and all the `DBpedia entity candidates` are generated. For search, we use elastic search (elasticsearch, 2015) over indexed extended KG. The reason behind the use of elastic search is its effectiveness over indexed KGs as reported by Dubey et al. (2018). In few cases, it is also possible that there is no verb in a sentence (e.g. Who is the prime minister of USA?). Then, we keep the list `potential relation candidates` empty, and search all the tokens of `potential entity candidates` into extended KG of DBpedia relations because number of relations in DBpedia are very less and when tokens in `potential entity candidates` find any match, they are pushed to `potential relation candidates.`

Candidate Ranking To rank best DBpedia candidates, we utilize the fundamental principle of knowledge graph creation. In any knowledge graph, a sentence is represented as triple with <subject, predicate, object>. Therefore, we rank the candidates by creating a triple consisting of the relation and entity candidates from `DBpedia entity candidates` and `DBpedia relation candidates,` then check if these triples exist in the DBpedia KG. We do it by passing the triple to DBpedia SPARQL endpoint. This can be done by executing a simple Ask query against a KG endpoint which would return a boolean value indicative of the existence of triple or otherwise of this triple. For each existing triple, we increase the weight of the entities and relations involved in the triple.

While ranking, we also consider question headwords (who, what, when, etc.) for question classification (Huang et al., 2009). Each relation in DBpedia has its domain and range associated with an entity such as person, place, date, etc. The headwords are used to determine the correct range and domain of the DBpedia relation. For example in the question "Who is starring in Spanish movies produced by Benicio del Toro?" there is a hidden relation `dbo:country` for which no surface form is present. While checking the domain of each token in relation and entity candidate lists, we can extract that word "Spanish" has the domain country; therefore, it is also an expected relation.

N-Gram Splitting In the previous module, if we do not get any triple in DBpedia for candidates present in `potential entity candidates` and `potential relation candidates`, we split the tokens (N-grams). To split the tokens, we again use the fundamentals of English morphology. The compound words in English have their headword always towards right side (Williams, 1981). Therefore, we start splitting tokens from "N-Gram tiling" module from the right side and pass these tokens to candidate generation module. This greedy algorithm stops when it finds triple(s) of DBpedia candidate list.

4 Experimental Study

Experiment Setup. We used a local laptop machine, with eight cores and 16GB RAM running Ubuntu 18.04 for implementation. Falcon is deployed as public API on a server with 723GB RAM, 96 cores (Intel(R) Xeon(R) Platinum 8160 CPU with 2.10GHz) running Ubuntu 18.04. This API is used for calculating all the results. The EL systems have been evaluated on different settings in literature, therefore to provide a fair evaluation we utilize Gerbil (Usbeck et al., 2015), which is a benchmarking framework for EL systems and integrated Falcon API into the Gerbil architecture. We report macro precision (P), macro recall (R), and macro F-score[7] in the tables. Falcon average run time is 1.9 seconds per question. Gerbil does not benchmark RL systems; therefore, RL systems are benchmarked using Frankenstein platform (Singh et al., 2018a). Our code, Extended KG, and data is in Github.[8]

Datasets. We employ two distinct datasets: 1) the LC-QuAD (Trivedi et al., 2017) dataset comprises 5,000 complex questions for DBpedia (80 percent questions are with more than one entity and relation) where average question length is 12.29 words. 2) QALD-7 (Usbeck et al., 2017) is the most popular benchmarking dataset for QA over DBpedia comprising 215 questions. In QALD, the average question length is 7.41 words and over 50% of the questions include a single entity and relation. For our linguistic based approach, we randomly selected 100 questions each from SimpleQuestions dataset (Bordes et al., 2015) and complex questions[9] for the formation of rules.

System	**Dataset**	**P**	**R**	**F**
KEA (Waitelonis and Sack, 2016)	QALD-7	0.06	0.06	0.06

Table 1: Performance of the Falcon Framework compared to various entity linking tools.

Baselines. The state-of-the-art outperforming tools are TagMe and DBpedia Spotlight reported in (2018c). These two systems in addition to the systems already integrated in Gerbil i.e., KEA (Waitelonis and Sack, 2016), FOX (Speck and Ngomo, 2014), Babelfy (Moro et al., 2014), AIDA (Hoffart et al., 2011) are included in our benchmark. We also report the performance of EARL (Dubey et al., 2018) for entity linking as it jointly performs EL and RL. For relation linking, the recently released EARL system is our baseline. We evaluate NED and RL systems on the LC-QuAD3253 subset of the LC-QuAD dataset (containing 3,253 LC-QuAD questions) to compare the

performance with the 20 NED and five RL systems evaluated by Singh et al. (2018c). Many of these 20 tools are APIs from industry (Ambiverse (Ambiverse, 2018), TextRazor (TextRazor, 2018), and Dandelion (Dati, 2018)) which use state of the art machine learning approaches.

Table 2: Performance of the Falcon Framework compared to various Relation Linking tools.

Performance Evaluation Table 1 summarizes Falcon's performance compared to state-of-the-art systems integrated in Gerbil. For the QALD and LC-QuAD datasets, Falcon significantly outperforms the baseline. Similar observations are made for relation linking, where the performance of Falcon is approximately twice as high as the next best competitor on all datasets (cf. Table 2).

Success cases of Falcon: Falcon overcomes several major issues of short text such as capitalization of surface forms, derived word forms of relation labels and successfully handles long tail entities. For entity linking, we achieve slightly better performance on LC-QuAD than QALD. This is due to the fact that LC-QuAD questions mostly contain more than one entity and relation and thus provide more context to understand the short text. Also, major failure cases of state-of-the-art EL systems over these datasets are due to the short length and limitation to exploit the context. For example the question 'Give me the count of all people who ascended a peak in California.' (`dbr:California` is correct entity), TagMe provides two entities: `dbr:California` (for surface form California) and `dbr:Give_In_to_Me` (for "Give me"). Fundamental principles such as compounding and N-gram tiling have positive impact on the Falcon performance and we can correctly annotate several long tail entities and entities containing compound words. For example, Falcon correctly annotates question from LC-QuAD: 'Name the military unit whose garrison is Arlington County, Virginia and command structure is United States Department of Defense' where expected entities are `dbr:Arlington_County,_Virginia` and `dbr:United_States_Department_of_Defense`. Also, extended local KG has provided several interpretation of entities and their derived forms. The extended KG act as source of background knowledge during the linking process and provide extra information about entities. Generally, other entity linking tools directly map surface forms to the underlying KG using several novel techniques. However, this concept of enriching a local extended KG is not exploited in the literature and it has positively impacted the performance of the Falcon.

For relation linking, taking the context of the entities into account improved the overall performance of the Falcon. In our example question 'Who wrote the book The Pillars of the Earth?', EARL, SIBKB and Rematch aim for directly mapping `wrote` to DBpedia which results in several wrong relations such as `dbo:writer`, `dbo:creator` but when Falcon considers entity references of the question to verify which triples exist with the given entity `dbr:The_Pillars_of_the_Earth`, Falcon determines the correct relation `dbo:author`. It is important to note that existing relation linking tools completely ignore the context of the entities. Secondly, Falcon uses a fundamental principle of creating an RDF knowledge graph. While ranking the candidates in the Candidate List Ranking step, Falcon verifies the presence of the correct triple containing entity and associated relation in the KG. It has been done by cross-checking all the combinations of `potential entity candidates` and `potential relation candidates` as triple using an ASK query. Three concepts (utilization of entity context, ranking the candidates based on the presence of triple in the KG, and use of extended KG) have collectively resulted into a significant jump over other relation linking tools as observed in the Table 2.

Failure cases of Falcon: There are few EL cases where Falcon fails. For example, in question 'How many writers worked on the album Main Course?', the expected entity is `dbr:Main_Course`. However, Falcon returns `dbr:Critters_2:_The_Main_Course`. This is caused by compounding and the resulting token for this question was 'album Main Course'. For the same question Falcon correctly links the relations. We further analyzed failure cases of Falcon for RL. We found that more than half of the questions which were unanswered have implicit relations. For example, for the question 'In what city is the Heineken brewery?' with the two relations `dbo:locationCity` and `dbo:manufacturer`, Falcon returns `dbo:city` as relation. There are few types of questions ('Count all the scientologists.') for which Falcon fails both for EL and RL tasks. This question is relatively short and requires reasoning to provide correct entities and relations (`dbr:Scientology` and `dbo:religion`).

5 Related Work

A wide range of tools and research work exist in the area of NER and NED (please see (Balog, 2018; Shen et al., 2015) for a detailed survey). Mostly, research in this domain targets news corpus, documents and Wikipedia abstract having long sentences. Such systems have been trained and benchmarked for NER/NED performance over several related datasets such as ACE2004, IITB, AIDA/CoNLL, Wiki-Disamb30, Spotlight Corpus, etc (Usbeck et al., 2015). It is important to note that most of these approaches use state of the art machine learning techniques and require a large amount of training data. However, when these tools applied to short text in a new domain such as question answering (QA) or key word based search, the performance is limited. (Singh et al., 2018c; Derczynski et al., 2015). Considering short text, the tool TagMe (Ferragina and Scaiella, 2010) is one of the popular works in this area, and uses a dictionary of entity surface forms extracted from Wikipedia to detect entity mentions in the parsed input text. These mentions passed through a voting scheme that computes the score for each mention-entity pair as the sum of votes given by candidate entities of all other mentions in the text (Ferragina and Scaiella, 2010), finally a pruning step filters out less relevant annotations. However, TagMe considered sentence length 30 for referring it as short text; in contrast for Falcon we target relatively more shorter text such as questions where average length is much less than 30 words (e.g., average question length in LC-QuAD dataset is 12.29 (Trivedi et al., 2017)). Following the popularity of KGs, scholars have shifted focus to use KGs such as DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008) and Wikidata (Vrandecic, 2012) for the NED task. DBpedia Spotlight (Mendes et al., 2011) is one such tool that performs NED on DBpedia. After an initial step of entity spotting, DBpedia Spotlight uses contextual information to resolve the surface forms of an entity to corresponding DBpedia resources. DBpedia Spotlight has also been reused in question answering systems (Dubey et al., 2016). Relation extraction from a sentence have been long-standing research field (Zelenko et al., 2003; Bunescu and Mooney, 2005; Banko and Etzioni, 2008; Zhu et al., 2009; Fundel et al., 2007). However, linking relation label to its KG mention as independent approach is a relatively new field of research. Mulang' et al. (Mulang' et al., 2017) had the first attempt in this direction and developed Rematch. ReMatch characterizes both the properties in a KG and the relations in a question as comparable triples, then leverages both synonyms and semantic similarity measures based on graph distances from the lexical knowledge base - Wordnet (Miller, 1995b). SIBKB (Singh et al., 2017) approach for relation linking uses PATTY to derive word embeddings for a bipartite semantically indexed knowledge base which assist in RL, likewise also in full QA systems such as AskNow (Dubey et al., 2016) where PATTY is deployed as an underlying source of relation patterns. Since NER/D and RE/L are parallel tasks and the occurrence of a named entity is often accompanied by relations, recent research has attempted to perform NED and RL as a joined process. EARL (Dubey et al., 2018) is a tool for joined NED and RL that relies on Generalized Travelling Salesman Problem to find the right path between entities in the question. Several techniques exist in the literature for the collective entity and relation extraction in a text (Miwa and Sasaki, 2014; Kirschnick et al., 2016; Wang et al., 2018) but we are not aware of any other approach besides EARL that perform joint entity and relation linking to a KG.

6 Conclusion

In this article we presented Falcon, an approach for linking Named Entities (EL) and Relations (RL) in short text to corresponding Knowledge Graph entities. The Falcon approach adopts two novel concepts. First we demonstrated how a fused KG comprising several complimentary semantic and linguistic resources can be employed as background knowledge. Secondly, we devised a linguistic understanding based method for processing the text, that leverages the extended background KG for EL/RL. Our comprehensive empirical evaluations provide evidence that the approach outperforms the state-of-the-art on several benchmarks. Although, we evaluate our approach on DBpedia, there is no specific assumption in our work on the structure or schema of the underlying knowledge graph, and our method should be equally applicable and can be extended to any other knowledge graph. Additionally, Falcon is offered as an online tool as well as an API.

Our approach provides considerable benefits over machine learning based approaches for short text. While Falcon achieves better results, it does not require training data and is easily adaptable to new domains. This work has highlighted the importance of background knowledge available in fused KGs as well as the linguistic understanding of the text. The linguistic methods (e.g. compounding) employed in Falcon can made more robust by using dependency parsing information. In future, we plan to explore the option of augmenting Falcon with deep learning methods for further improvement in performance specially in entity and relation extraction module.

Abstract

Our goal is procedural text comprehension, namely tracking how the properties of entities (e.g., their location) change with time given a procedural text (e.g., a paragraph about photosynthesis, a recipe). This task is challenging as the world is changing throughout the text, and despite recent advances, current systems still struggle with this task. Our approach is to leverage the fact that, for many procedural texts, multiple independent descriptions are readily available, and that predictions from them should be consistent (label consistency). We present a new learning framework that leverages label consistency during training, allowing consistency bias to be built into the model. Evaluation on a standard benchmark dataset for procedural text, ProPara (Dalvi et al., 2018), shows that our approach significantly improves prediction performance (F1) over prior state-of-the-art systems.

1 Introduction

We address the task of procedural text comprehension, namely tracking how the properties of entities (e.g., their location) change with time throughout the procedure (e.g., photosynthesis, a cooking recipe). This ability is an important part of text understanding, allowing the reader to infer unstated facts such as how ingredients change during a recipe, what the inputs and outputs of a scientific process are, or who met whom in a news article about a political meeting. Although several procedural text comprehension systems have emerged recently (e.g., EntNet (Henaff et al., 2017), NPN (Bosselut et al., 2018), and ProStruct (Tandon et al., 2018)), they still make numerous prediction errors. A major challenge is that fully annotated training data for this task is expensive to collect, because many state changes by multiple entities may occur in a single text, requiring complex annotation.

(1) ...**oxygen** is given off...
(2) ...the plant produces **oxygen**...
(3) ...is used to create sugar and **oxygen**...

Figure 1: Fragments from three independent texts about photosynthesis. Although (1) is ambiguous as to whether oxygen is being created or merely moved, evidence from (2) and (3) suggests it is being created, helping to correctly interpret (1). More generally, encouraging consistency between predictions from different paragraphs about the same process/procedure can improve performance.

To address this challenge, and thus improve performance, our goals are two-fold: first, to better leverage the training data for procedural text comprehension that *is* available, and second, to utilize additional unlabeled data for the task (semi-supervised learning). Our approach in each case is to exploit *label consistency*, the property that two distinct texts covering the same procedure should be generally consistent in terms of the state changes that they describe, which constitute the labels to be predicted for the text. For example, in different texts describing photosynthesis, we expect them to be generally consistent about what happens to oxygen (e.g., that it is created), even if the wordings differ (Figure 1).

Using multiple, distinct passages to understand a process or procedure is challenging. Although the texts describe the same process, they might express the underlying facts at different levels of granularity, using different wordings, and including or omitting different details. As a result, the details may differ between paragraphs, making them hard to align and to check for consistency. Nonetheless, even if the details differ, we conjecture that the top-level *summaries* of each paragraph, which

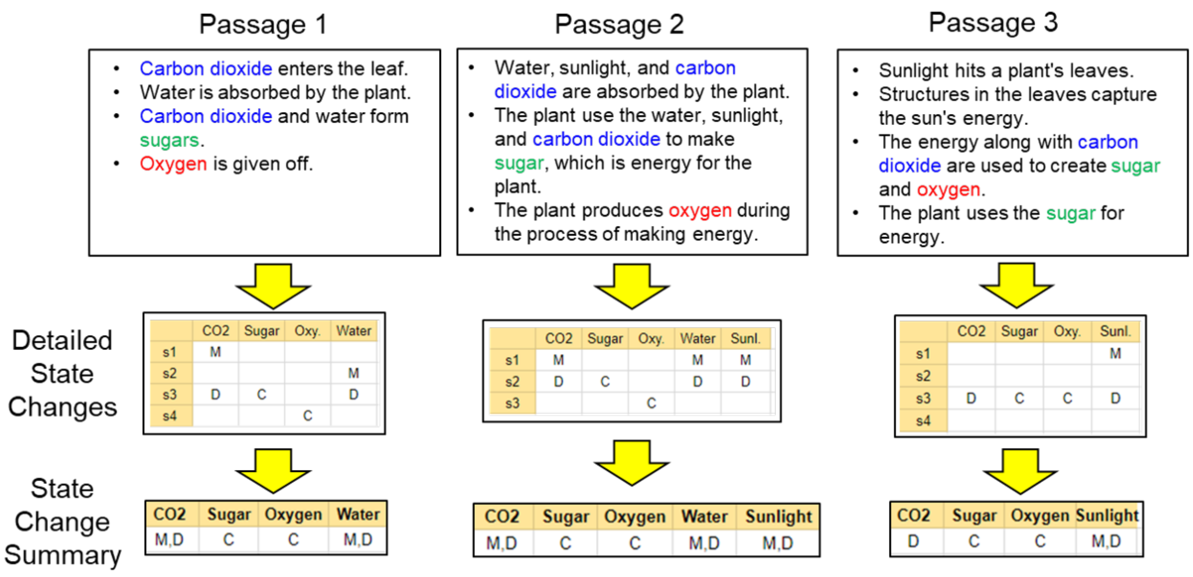
Minneapolis, Minnesota, June 2 - June 7, 2019.



Passage 1

- Carbon dioxide enters the leaf.
- Water is absorbed by the plant.
- Carbon dioxide and water form sugars.
- Oxygen is given off.

Passage 2

- Water, sunlight, and carbon dioxide are absorbed by the plant.
- The plant use the water, sunlight, and carbon dioxide to make sugar, which is energy for the plant.
- The plant produces oxygen during the process of making energy.

Passage 3

- Sunlight hits a plant's leaves.
- Structures in the leaves capture the sun's energy.
- The energy along with carbon dioxide are used to create sugar and oxygen.
- The plant uses the sugar for energy.

Figure 2: Three (simplified) passages from ProPara describing photosynthesis, the (gold) state changes each entity undergoes at each step $s_1, s_2, \ldots, s_T$, and the summary of state changes that each entity undergoes (an aggregation of the step-by-step changes), where `M = MOVED, D = DESTROYED, C = CREATED`. Although the language and detailed changes for each passage differ considerably, the **overall summaries are largely consistent** (e.g., sugar is `CREATED` in all three). We exploit this consistency when training a model to make these predictions, by biasing the model to prefer predictions whose summary is consistent with the (predicted) summaries of other passages about the same topic. Note that in the summary, we do not care about the order in which state changes happen, so summary `M, D` for participant CO_2 in passage 1 denotes a set of state changes rather than a sequence of state changes.

describe the types of state change that each entity undergoes, will be mostly consistent. For example, although independent texts describing photosynthesis vary tremendously, we expect them to be consistent about what generally happens to sugar, e.g., that it is created (Figure 2).

In this paper, we introduce a new training framework, called LaCE (Label Consistency Explorer), that leverages label consistency among paragraph summaries. In particular, it encourages label consistency during end-to-end training of a neural model, allowing consistency bias to improve the model itself, rather than be enforced in a post-processing step, e.g., posterior regularization (Ganchev et al., 2010). We evaluate on a standard benchmark for procedural text comprehension, called ProPara (Dalvi et al., 2018). We show that this approach achieves a new state-of-the-art performance in the fully supervised setting (when all paragraphs are annotated), and also demonstrate that it improves performance in the semi-supervised setting (using additional, unlabeled paragraphs) with limited training data. In the latter case, summary predictions from labeled data act as noisy gold labels for the unlabeled data, allowing additional learning to occur. Our contributions are thus:

1. A new learning framework, LaCE, applied to procedural text comprehension that improves the label consistency among different paragraphs on the same topic.
2. Experimental results demonstrating that LaCE achieves state-of-the-art performance on a standard benchmark dataset, ProPara, for procedural text.

2 Related Work

Our work is related to several important branches of work in both NLP and ML, as we now summarize.

Leveraging Label Consistency Leveraging information about label consistency (i.e., similar instances should have consistent labels at a certain granularity) is an effective idea. It has been studied in computer vision (Haeusser et al., 2017; Chen et al., 2018) and IR (Clarke et al., 2001; Dumais et al., 2002). Learning by association (Haeusser et al., 2017) establishes implicit cross-modal links between similar descriptions and leverage more unlabeled data during training. Schütze et al. (2018);

Hangya et al. (2018) adapt the similar idea to exploit unlabeled data for the cross-lingual classification. We extend this line of research in two ways: by developing a framework allowing it to be applied to the task of structure prediction; and by incorporating label consistency into the model itself via end-to-end training, rather than enforcing consistency as a post-processing step.

Semi-supervised Learning Approaches Besides utilizing the label consistency knowledge, our learning framework is also able to use unlabeled paragraphs, which fits in the literature of semi-supervised learning approaches (for NLP). Zhou et al. (2003) propose an iterative label propagation algorithm similar to spectral clustering. Zhu et al. (2003) propose a semi-supervised learning framework via harmonic energy minimization for data graph. Talukdar et al. (2008) propose a graph-based semi-supervised label propagation algorithm for acquiring open-domain labeled classes and their instances from a combination of unstructured and structured text sources. Our framework extends these ideas by introducing the notion of groups (examples that are expected to be similar) and summaries (what similarities are expected), applied in an end-to-end-framework.

Procedural Text Understanding and Reading Comprehension There has been a growing interest in procedural text understanding/QA recently. The ProcessBank dataset (Berant et al., 2014) asks questions about event ordering and event arguments for biology processes. bAbI (Weston et al., 2015) includes questions about movement of entities, however it's synthetically generated and with a small lexicon. Kiddon et al. (2015)'s RECIPES dataset introduces the task of predicting the locations of cooking ingredients, and Kiddon et al. (2016) for recipe generation. In this paper, we continue this line of exploration using ProPara, and illustrate how the previous two lines of work (label consistency and semi-supervised learning) can be integrated.

3 Problem Definition

3.1 Input and Output

A general condition for applying our method is having multiple examples where, for *some* properties, we expect to see similar values. For example, for procedural text, we expect paragraphs about the same process to be similar in terms of which entities move, are created, and destroyed; for different news stories about a political meeting, we expect top-level features (e.g., where the meeting took place, who attended) to be similar; for different recipes for the same item, we expect loosely similar ingredients and steps; and for different images of the same person, we expect some high-level characteristics (e.g., height, face shape) to be similar. Note that this condition does not apply to every learning situation; it only applies when training examples can be grouped, where all group members are expected to share some characteristics that we can identify (besides the label used to form the groups in the first place).

More formally, for training, the input is a set of labeled examples (x_{gi}, y_{gi}) (where y_{gi} are the labels for x_{gi}), partitioned into G groups, where the g subscript denotes which group each example belongs to. Groups are defined such that examples of the same group g are expected to have similar labels for a subset of labels y_{gi}. We call this subset the **summary labels**. We assume that both the groupings and the identity of the summary labels are provided. The output of training is a model M for labeling new examples. For testing, the input is the model M and a set of unlabeled (and ungrouped) examples x_t, and the output are their predicted labels $\hat{y}_t$. Note that this formulation is agnostic to the learning algorithm used. Later, we will consider both the fully supervised setting (all training examples are labeled) and semi-supervised setting (only a subset are labeled).

3.2 Instantiation

We instantiate this framework for procedural text comprehension, using the ProPara task (Dalvi et al., 2018). In this task, x_{gi} are paragraphs of text describing a process (e.g., photosynthesis), the labels y_{gi} describe the state changes that each entity in the paragraph undergoes at each step (sentence) (e.g., that oxygen is created in step 2), and the groups are paragraphs about the same topic (ProPara tags each paragraph with a topic, e.g., there are three paragraphs in ProPara describing photosynthesis). More precisely, each x_{gi} consists of:

- the name (topic) of a process, e.g., photosynthesis
- a sequence (paragraph) of sentences $S = [s_1, ..., s_T]$ that describes that process
- the set of entities E mentioned in that text, e.g., oxygen, sugar

and the targets (labels) to predict are:

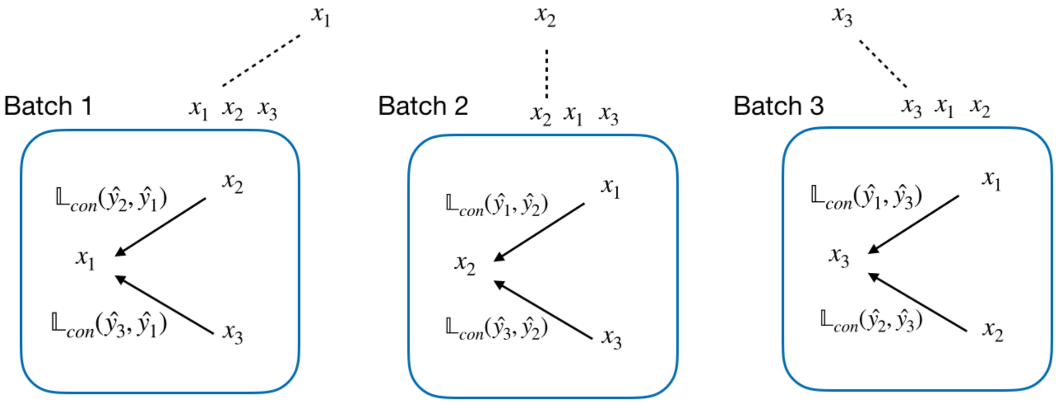

Figure 3: Example of batches constructed from a group (here, the group contains three labeled examples x_1, x_2, x_3). From three examples, three batches are constructed. Taking the predicted labels for the first element in the batch as reference we compute the consistency loss for the remaining elements.

- the state changes that each entity in E undergoes at each step (sentence) of the process, where a state change is one of {`Moved`,`Created`,`Destroyed`,`None`}. These state changes can be conveniently expressed using a $|S| \times |E|$ matrix (Figure 2). State changes also include arguments, e.g., the source and destination of a move. We omit these in this paper to simplify the description.

Finally, we define the summary labels as the set of state changes that each entity undergoes at *some* point in the process, without concern for when. For example, in Passage 1 in Figure 2, CO_2 is `Moved` (M) and `Destroyed` (D), while sugar is `Created` (C). These summary labels can be computed from the state-change matrix by aggregating the state changes for each entity over all steps. Our assumption here is that these summaries will generally be the same (i.e., consistent) for different paragraphs about the same topic. LaCE then exploits this assumption by encouraging this inter-paragraph consistency during training, as we now describe.

4 Label Consistency Explorer: LaCE

4.1 The LaCE Learning Framework

While a traditional supervised learning model operates on individual examples, LaCE operates on *batches* of grouped examples X_g. Given a group g containing N labeled examples $\{x_1, ..., x_N\}$ (we drop the g subscript for clarity), LaCE creates N batches, each containing all the examples but with a different x_i labeled as "primary", along with the gold labels y_i for (only) the primary example. (We informally refer to the primary example as the "first example" in each batch). Then for each batch, LaCE jointly optimizes the usual supervised loss $\mathbb{L}_{sup}(\hat{y}_i, y_i)$ for the primary example, along with a consistency loss between (summary) predictions for all other members of the group and the primary example, $\mathbb{L}_{con}(\hat{y}_j, \hat{y}_i)$ for all $j \neq i$. This is illustrated in Figures 4 and 3. This is repeated for all batches.

For example, for the three paragraphs about photosynthesis (Figure 2), batch 1 compares the first paragraph's predictions with its gold labels, and also compares the summary predictions of paragraphs 2 and 3 with those of the first paragraph (Figure 3). This is then repeated using paragraph 2, then paragraph 3 as primary.

The result is that LaCE jointly optimizes the supervised loss $\mathbb{L}_{sup}$ and consistency loss $\mathbb{L}_{con}$ to train a model that is both accurate for the given task as well as consistent in its predictions across examples that belong to the same group.

This process is approximately equivalent to jointly optimizing the usual supervised loss $\mathbb{L}_{sup}(\hat{y}_i, y_i)$ for all examples in the group, and the pairwise consistency loss $\mathbb{L}_{con}(\hat{y}_j, \hat{y}_i)$ for all pairs (x_j, x_i), $j \neq i$ in the group. However, there is an important difference, namely the relative contributions of $\mathbb{L}_{sup}$ and $\mathbb{L}_{con}$ is varied among batches, depending on how accurate the predictions for the primary example are (i.e., how small $\mathbb{L}_{sup}$ is), as we describe later in Section 4.3. This has the effect of paying more attention to consistency loss when predictions on the primary are more accurate.

We also extend LaCE to the semi-supervised setting as follows. For the semi-supervised setting, where only m of n ($m < n$) examples are labeled, we only form m batches, where each batch has

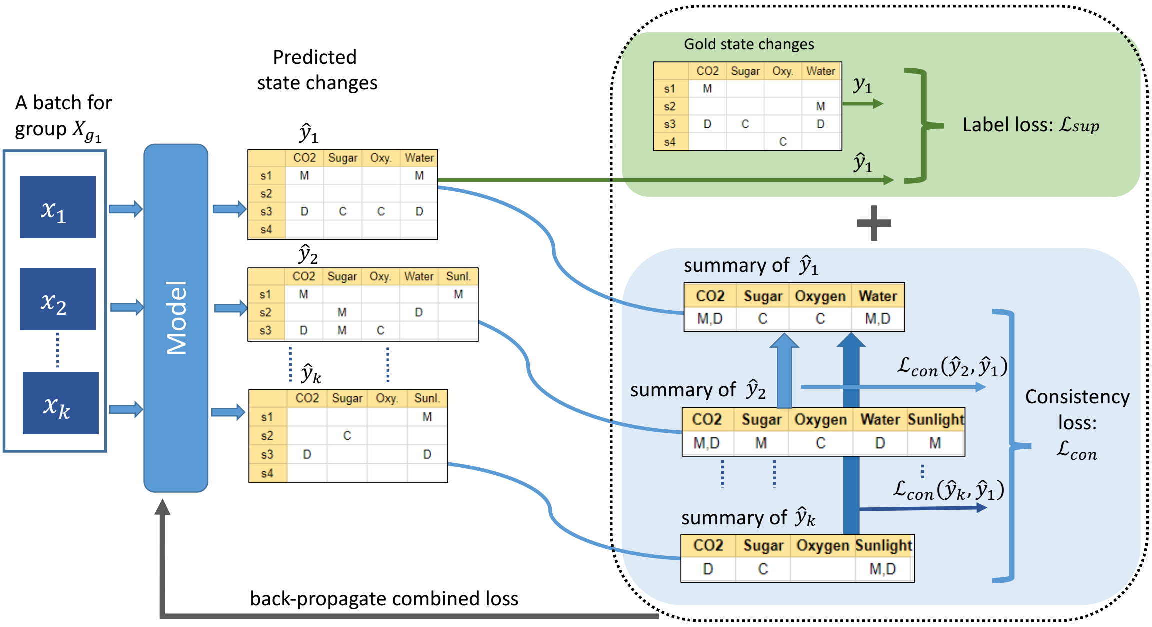

Figure 4: Overview of the LaCE training framework, illustrated for the procedural comprehension task ProPara. During training, LaCE processes *batches* of examples $\{x_1,...,x_k\}$ for each group X_g, where predictions for one example (here $\hat{y}_1$) are compared against its gold (producing loss $\mathbb{L}_{sup}$), and its summary against summaries of all other examples to encourage consistency of predictions (producing $\mathbb{L}_{con}$), repeating for each example in the batch.

a different labeled example as primary. We later report experiments results for both the fully and semi-supervised settings.

4.2 Base Model for Procedural Text

We now describe how LaCE is applied to our goal of comprehending procedural text. Note that LaCE is agnostic to the learner used within the framework. For this application, we use a simplified version of ProStruct (Tandon et al., 2018), a publicly available system designed for the ProPara task. Our implementation simplifies ProStruct by reusing its encoder, but then predicting (a distribution over) each state change label independently during decoding for every cell in the $|S| \times |E|$ grid (Figure 2). We briefly summarize this here.

4.2.1 Encoder

ProStruct uses an encoder-decoder architecture that takes procedural text as input and predicts the state changes of entities E in the text as output. During encoding, each step s_t is encoded using $|E|$ embeddings, one for each entity $e_j \in E$. Each embedding represents the action that s_t describes, applied to e_k. The model thus allows the same action to have different effects on different entities (e.g., a transformation destroys one entity, and creates another).

For each $(s_t, e_j) \in S \times E$ pair, the step is fed into a BiLSTM (Hochreiter and Schmidhuber, 1997), using pretrained GloVe (Pennington et al., 2014) vectors v_w for each word w_i concatenated with two indicator variables, one indicating whether w_i is a word referring to e_j, and one indicating whether w_i is a verb. A bilinear attention layer then computes attention over the contextualized vectors h_i output by the BiLSTM: $a_i = h_i * B * h_{ev} + b$, where B and b are learned parameters, and h_{ev} is the concatenation of h_e (the averaged contextualized embedding for the entity words w_e) and h_v (the averaged contextualized embedding for the verb words w_v).

Finally, the output vector c_{tj} is the attention-weighted sum of the h_i: $c_{tj} = \sum_{i=1}^{I} a_i * h_i$. Here, c_{tj} can be thought of as representing the action s_t applied to entity e_j. This is repeated for all steps and entities.

4.2.2 Decoder

To decode the action vectors c_{tj} into their resulting state changes they imply, each is passed through a feedforward layer to generate $logit(\pi_{tj})$, a set of logistic activations over the K possible state changes π_{tj} for entity e_j in step s_t. For ProPara, there are $K = 4$ possible state changes: `Move`, `Create`, `Destroy`, and `None`. These logits form a distribution over possible state changes to predict, for each entity and step in the text. We then compute loss, described next, using these distributions directly rather than discretizing them into exact predictions at this stage, so as not to lose information.

4.3 Applying LaCE

4.3.1 Batching

We start by creating training batches for each $X_{g_i} \in X_g$. From a group X_{g_i} comprising of n examples, we create n training batches. A batch consists of all n examples $(x_1, x_2, ..., x_n)$, but the loss computation is different in each batch. Figure 3 illustrates this.

4.3.2 Loss Computation

The loss computation in a batch is based on the usual supervised loss and additionally the consistency loss, as follows:

$$\mathbb{L}_{batch} = \lambda \underbrace{\mathbb{L}_{sup}(\hat{y}_1, y_1)}_{supervised\ loss} + (1-\lambda) \underbrace{\sum_{i=2}^{n} \mathbb{L}_{con}(\hat{y}_i, \hat{y}_1)}_{consistency\ loss} \tag{1}$$

Here, $\mathbb{L}_{sup}(\hat{y}_1, y_1)$ is the negative log likelihood loss[*] against the gold labels y_1, and λ is a hyperparameter tuned on the dev set.

To compute the consistency loss $\mathbb{L}_{con}(\hat{y}_i, \hat{y}_1)$, we compare the summaries computed from $\hat{y}_i$ and $\hat{y}_1$. In our particular application, a summary lists all the state changes each entity undergoes, formed by aggregating its step-by-step state changes. For example, for paragraph x_1 in Figure 4, as `CO2` first moves (`M`), then later is destroyed (`D`), we summarize its state changes as $s(\mathtt{CO_2}, \hat{y}_1) = \{\mathtt{M,D}\}$. In practice, as our decoder outputs distributions over the four possible values $\{\mathtt{M,C,D,N}\}$ rather than a single value, we summarize by adding and normalizing these distributions, producing a summary distribution $s(e, \hat{y}_j)$ over the four values rather than a discrete set of values.

To compute the consistency loss $\mathbb{L}_{con}(\hat{y}_i, \hat{y}_1)$ itself, we compare summaries for each entity e that occurs in both paragraph x_1 and paragraph x_i (referred to as Ent(x_1) and Ent(x_i) respectively), and compute the average mean squared error (MSE) between their summary distributions. We also tried other alternatives (e.g., Kullback-Leibler divergence) for calculating the distance between summary distributions, but mean squared error performs best. Equation 2 shows the details for computing the consistency loss.

$$\mathbb{L}_{con}(\hat{y}_i, \hat{y}_1) = \frac{\sum_{e \in Ent(x_i) \cap Ent(x_1)} \mathrm{MSE}(s(e, \hat{y}_i), s(e, \hat{y}_1))}{|Ent(x_i) \cap Ent(x_1)|} \tag{2}$$

Note that each paragraph contains varying number of entities and sentences. It is possible that some paragraphs do not mention exactly the same entities as the labeled paragraph (first element in the batch). In such cases, we penalize the model only for predictions for co-occurring entities. Unmatched entities are not penalized.

4.3.3 Adaptive Loss

The supervised loss $\mathbb{L}_{sup}(\hat{y}_1, y_1)$ is large in the early epochs when the model is not sufficiently trained. At this point, it is beneficial for the model to pay no attention to the consistency loss $\mathbb{L}_{con}(\hat{y}_j, \hat{y}_1)$ as the predicted action distributions are inaccurate. To implement this, if $\mathbb{L}_{sup}$ is above a defined threshold then the consistency loss term in Equation 1 is ignored (i.e. $\lambda = 1$). Otherwise, Equation 1 is used as is. This can loosely be seen as a form of simulated annealing (Kirkpatrick et al., 1988), using just two temperatures. Note that the time (epoch number) when the temperature (lambda) changes will vary across batches depending on the supervised loss within that batch of data, hence we call it an "adaptive" loss.

5 Experimental Results

We now present results on ProPara, the procedural text comprehension dataset introduced in (Dalvi et al., 2018). There are 187 topics in this dataset and a total of 488 labeled paragraphs (around 3 labeled paragraphs per topic). The task is to track how entities change state through the paragraph (as described in Section 3.2) and answer 4 classes of questions about those changes (7043/913/1095 questions in each of the train/dev/test partitions respectively). We compare LaCE with the baselines and prior state-of-the-art model ProStruct (Tandon et al., 2018) in two settings: (1) Fully supervised learning (using all the training data). (2) Semi-supervised learning (using some or all of the training data, plus additional unlabeled data).

5.1 Fully Supervised Learning

We evaluated LaCE by comparing its performance against published, state-of-the-art results on ProPara, using the full training set to train LaCE.

---

[*] Loss function $\mathbb{L}_{sup}$ is exactly same as the loss function used in the base model so that we can measure the effect of adding consistency loss.

Models	P	R	F1
EntNet (Henaff et al., 2017)	54.7	30.7	39.4
QRN (Seo et al., 2017)	60.9	31.1	41.1
ProLocal (Dalvi et al., 2018)	**81.7**	36.8	50.7
ProGlobal (Dalvi et al., 2018)	61.7	44.8	51.9
ProStruct (Tandon et al., 2018)	74.3	43.0	54.5
LaCE (our model)	75.3	**45.4**	**56.6**

Table 1: Comparing the performance of LaCE with prior methods on the test partition of ProPara.

Models	P	R	F1
LaCE	**75.3**	**45.4**	**56.6**
- consistency loss $\mathbb{L}_{con}$	69.6	43.1	53.2

Table 2: LaCE ablation results

The results are shown in Table 1. In Table 1, all the baseline numbers are the results reported in (Tandon et al., 2018). Note that all these baselines are trying to reduce the gap between predicted labels and gold labels on the training dataset. LaCE, however, also optimizes for consistency across labels for *groups* of paragraphs belonging to the same topic. As LaCE uses parts of ProStruct as its learning algorithm, the gains over ProStruct appear to be coming directly from its novel learning framework described in Section 4.1. To confirm this, we also performed an ablation study, removing the consistency loss term and just using the base model in LaCE. The results are shown in Table 2, and show that the F1 score drops from 56.6 to 53.2, illustrating that the consistency loss is responsible for the improvement. In addition, Table 2 indicates that consistency loss helps improve both precision and recall.

Also note that LaCE simplifies parts of ProStruct. For example, unlike ProStruct, LaCE does not use a pre-computed knowledge base during decoding. Thus LaCE is more efficient to train than ProStruct (>15x faster at training time).

5.2 Semi-Supervised Learning

Unlike the other systems in Table 1, LaCE is able to use unlabeled data during training. As described in Section 4.1, given a group containing both labeled and unlabeled paragraphs, we create as many batches as the number of labeled paragraphs in the group. Hence, paragraphs x_i with gold labels y_i can contribute to both supervised loss $\mathbb{L}_{sup}$ and consistency loss $\mathbb{L}_{con}$. Additionally, we can use unlabeled paragraphs x_j (i.e., without gold labels y_j), while computing consistency loss $\mathbb{L}_{con}$. This way LaCE can make use of unlabeled data during training.

Models	Proportion of labeled paragraphs used per training topic		
	33%	66%	100%
ProStruct	45.4	50.6	54.5
LaCE	47.3	51.2	56.6
LaCE + unlabeled data	49.9	52.9	56.7

Table 3: Comparing LaCE vs. ProStruct with varying amount of labeled paragraphs available per training topic. We compare their performance in terms of F1 on ProPara test partition.

To evaluate this, we collected 877 additional unlabeled paragraphs for ProPara topics[†]. As the original ProPara dataset makes some simplifying assumptions, in particular that events are mentioned in chronological order, we used Mechanical Turk to collect additional paragraphs that conformed to those assumptions (rather than collecting paragraphs from Wikipedia, say). Approximately 3 extra paragraphs were collected for each topic in ProPara. Note that collecting unlabeled paragraphs is substantially less expensive than labeling paragraphs.

	Train	Dev	Test	Unlabeled
# paragraphs	391	54	43	877

Table 4: ProPara Paragraphs Statistics

We then trained the ProStruct and LaCE models varying two different parameters: (1) the percentage of the labeled (ProPara) training data used to train the system (2) for LaCE only, whether the additional unlabeled data was also used. This allows us to see performance under different conditions of sparsity of labeled data, and (for LaCE) also assess how much unlabeled data can help under those conditions. During training, the unused labeled data was ignored (not used as unlabeled data). We keep the dev and test partitions the same as original dataset, picking a model based on dev performance and report results on test partition. The results are shown in Table 3. In the first two rows, ProStruct and LaCE are both trained with x% of labeled data, while the last row reports per-

---

[†] The unlabeled paragraphs are available at `http://data.allenai.org/propara/`.

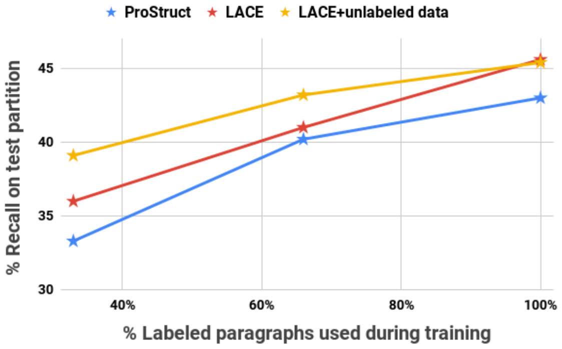

Figure 5: Comparing LaCE vs. ProStruct based on Recall on the test partition, by varying amount of labeled paragraphs available per training topic

formance of LaCE when it also has access to new unlabeled paragraphs.

Table 3 demonstrates that LaCE results in even larger improvements over ProStruct when the amount of labeled data is limited. In addition, unlabeled data adds an additional boost to this performance, in particular when labeled data is sparse. Further examination suggests that the gains in F1 are resulting mainly from improved recall, as shown in Figure 5. We believe that having access to unlabeled paragraphs and optimizing consistency across paragraphs for training topics, helps LaCE generalize better to unseen topics.

5.3 Implementation Details for LaCE

We implement our proposed model LaCE in PyTorch (Paszke et al., 2017) using the AllenNLP (Gardner et al., 2018) toolkit. We added a new data iterator that creates multiple batches per topic (Figure 3) which enables easy computation of consistency loss. We use 100D Glove embeddings (Pennington et al., 2014), trained on Wikipedia 2014 and Gigaword 5 corpora (6B tokens, 400K vocab, uncased). Starting from glove embeddings appended by entity and verb indicators, we use bidirectional LSTM layer to create contextual representation for every word in a sentence. We use 100D hidden representations for the bidirectional LSTM (Hochreiter and Schmidhuber, 1997) shared between all inputs (each direction uses 50D hidden vectors). We use attention layer on top of BiLSTM, using a bilinear similarity function similar to (Chen et al., 2016) to compute attention weights over the contextual embedding for each word in the sentence.

To compute the likelihood of all state changes individually, we use a single layer feedforward network with input dimension of 100 and output 4. In these experiments, we check if the supervised loss $\mathbb{L}_{sup}$ is less than a threshold (0.2 in our case) then we use equation 1 and $lambda = 0.05$. All hyper-parameters are tuned on the dev data.

	Consistency Score (%)	
	Train	Test
ProStruct	46.70	37.21
LaCE	54.39	38.36

Table 5: Consistency score comparison

During training we use multiple paragraphs for a topic to optimize for both supervised and consistency loss. At test time, LaCE's predictions are based on only one given paragraph. All the performance gains are due to the base model being more robust due to proposed training procedure. The code for LaCE model is published at `https://github.com/allenai/propara`.

5.4 Analysis and Discussion

We first discuss the predicted label consistency across paragraphs for LaCE vs. ProStruct. We then identify some of the limitations of LaCE.

Label Consistency

LaCE attempts to encourage consistency between paragraphs about the same topic during training, and yield similar benefit at test time. To examine whether this happens in practice, we compute and report the consistency score between paragraphs about the same topic (Table 5). Specifically, for an entity that appears in two paragraphs about the same topic, we compare whether the summaries of state change predictions for each match. The results are shown in Table 5.

The table shows that LaCE achieves greater prediction consistency during training, and that this benefit plays out to some extent at test time even though label consistency is not enforced at test time (we do not assume that examples are grouped at test time, hence consistency between groups cannot be enforced as the grouping is unknown). As an illustration, for the topic *describe the life cycle of a tree* which is unseen at training time, for the three paragraphs on the topic, ProStruct predicts that tree is created; not-changed; and created respectively, while LaCE correctly predicts that tree is created;

created; and created respectively. This illustrates a case where LaCE has learned to make predictions that are more consistent and correct.

Error Analysis for LaCE

To understand LaCE's behavior further, we examined cases where LaCE's and ProStruct's predictions differ, and examined their agreement with gold labels. In this analysis we found three major sources of errors for LaCE:

- **The label consistency assumption does not always hold:** In Section 3.1, we explain that LaCE relies on summary labels being consistent across examples in the same group. We found that for some of the topics in our training dataset this assumption is sometimes violated. E.g., for the topic *How does the body control its blood sugar level?*, there are two different paragraphs; one of them describes the entity `sugar` as being `Created` and then `Destroyed` to create `bloodsugar`, while the other paragraph describes the same event in a different way by saying that the entity `sugar` is *`Created`* and then *`Moved`* to the blood. LaCE can thus goes wrong when trying to enforce consistency in such cases.

- **Lexical variance between entities across paragraphs:** Different paragraphs about the same topic may describe the procedure using different wordings, resulting in errors. For example, in paragraphs about the topic *what happens during photosynthesis?*, the same entity (`carbon dioxide`) is referred to by two different strings, $\mathtt{CO}_2$ in one paragraph and `carbon dioxide` in another. Currently, LaCE does not take into account entity synonyms, so it is unable to encourage consistency here. An interesting line of future work would be to use the embedding space similarity between entity names, to help address this problem.

- **LaCE can make incorrect predictions to improve consistency:** For the topic *Describe how to make a cake* at training time, when presented with two paragraphs, LaCE tries to be consistent and incorrectly predicts that `cake` is *`Destroyed`* in both paragraphs. ProStruct does not attempt to improve prediction consistency, here resulting in less consistent but in this case more accurate predictions for this topic.

5.5 Directions For Enhancing LaCE

- Improve LaCE for ProPara: LaCE's performance on ProPara can be improved further by a) soft matching of entities across paragraphs instead of current exact string match b) exploring more systematic ways (e.g., simulated annealing) to define adaptive loss c) using additional sources of unlabeled data (e.g., web, textbooks) weighed by their reliability.

- Apply LaCE on other tasks: Architecturally, LaCE is a way to train any existing structured prediction model for a given task to produce consistent labels across similar datapoints. Hence it can be easily applied to other tasks where parallel data is available (grouping function) and there is a way to efficiently compare predictions (summary labels) across parallel datapoints, e.g. event extraction from parallel news articles (Chinchor, 2002).

  Further, summary labels need not be action categories (e.g., `Created`, `Destroyed`). Consistency can also be computed for QA task where multiple parallel text is available for reading comprehension. We plan to explore this direction in the future.

6 Conclusion

Our goal is procedural text comprehension, a task that current systems still struggle with. Our approach has been to exploit the fact that, for many procedures, multiple independent descriptions exist, and that we expect some consistency between those descriptions. To do this, we have presented a task- and model-general learning framework, LaCE, that can leverage this expectation, allowing consistency bias to be built into the learned model. Applying this framework to procedural text, the resulting system obtains new state-of-the-art results on the ProPara dataset, an existing benchmark for procedural text comprehension. It also demonstrates the ability to benefit from unlabeled paragraphs (semi-supervised learning), something that prior systems for this task were unable to do. We have also identified several avenues for further improvement (Section 5.4), and are optimistic that further gains can be achieved.

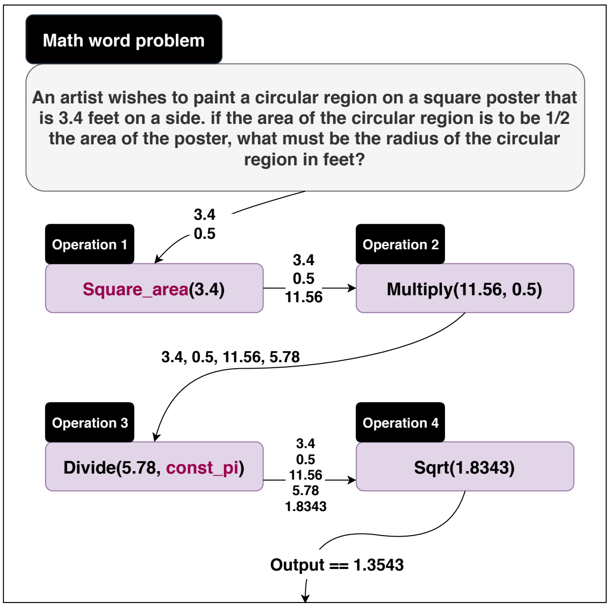
Abstract

We introduce a large-scale dataset of math word problems and an interpretable neural math problem solver that learns to map problems to operation programs. Due to annotation challenges, current datasets in this domain have been either relatively small in scale or did not offer precise operational annotations over diverse problem types. We introduce a new representation language to model precise operation programs corresponding to each math problem that aim to improve both the performance and the interpretability of the learned models. Using this representation language, our new dataset, MathQA, significantly enhances the AQuA dataset with fully-specified operational programs. We additionally introduce a neural sequence-to-program model enhanced with automatic problem categorization. Our experiments show improvements over competitive baselines in our MathQA as well as the AQuA datasets. The results are still significantly lower than human performance indicating that the dataset poses new challenges for future research. Our dataset is available at: `https://math-qa.github.io/math-QA/`.

1 Introduction

Answering math word problems poses unique challenges for logical reasoning over implicit or explicit quantities expressed in text. Math word-problem solving requires extraction of salient information from natural language narratives. Automatic solvers must transform the textual narratives into executable meaning representations, a process that requires both high precision and, in the case of story problems, significant world knowledge.

As shown by the geometry question in Figure 1, math word problems are generally narratives describing the progress of actions and relations over some entities and quantities. The operation program underlying the problem in Figure 1 highlights the complexity of the problem-solving task. Here, we need the ability to deduce implied constants (pi) and knowledge of domain-specific formulas (area of the square).



An artist wishes to paint a circular region on a square poster that is 3.4 feet on a side. if the area of the circular region is to be 1/2 the area of the poster, what must be the radius of the circular region in feet?

Figure 1: Example of a math word problem aligned with representation language by crowd-sourced annotation

In this paper, we introduce a new operation-based representation language for solving math word problems. We use this representation language to construct MathQA[1], a new large-scale, diverse dataset of 37k English multiple-choice math word problems covering multiple math domain categories by modeling operation programs corresponding to word problems in the AQuA dataset (Ling et al., 2017). We introduce a neural model for mapping problems to operation programs with domain categorization.

---

[1] The dataset is available at: `https://math-qa.github.io/math-QA/`

Proceedings of NAACL-HLT 2019, pages 2357–2367
Minneapolis, Minnesota, June 2 - June 7, 2019.

Most current datasets in this domain are small in scale (Kushman et al., 2014) or do not offer precise operational annotations over diverse problem types (Ling et al., 2017). This is mainly due to the fact that annotating math word problems precisely across diverse problem categories is challenging even for humans, requiring background math knowledge for annotators. Our representation language facilitates the annotation task for crowd-sourcing and increases the interpretability of the proposed model.

Our sequence-to-program model with categorization trained on our MathQA dataset outperforms previous state-of-the-art on the AQuA test set in spite of the smaller training size. These results indicate the superiority of our representation language and the quality of the formal annotations in our dataset. Our model achieves competitive results on MathQA, but is still lower than human performance indicating that the dataset poses new challenges for future research. Our contributions are as follows:

- We introduce a large-scale dataset of math word problems that are densely annotated with operation programs
- We introduce a new representation language to model operation programs corresponding to each math problem that aim to improve both the performance and the interpretability of the learned models.
- We introduce a neural architecture leveraging a sequence-to-program model with automatic problem categorization, achieving competitive results on our dataset as well as the AQuA dataset

2 Background and Related Work

Large-Scale Datasets Several large-scale math word problem datasets have been released in recent years. These include Dolphin18K (Huang et al., 2016), Math23K (Wang et al., 2017) and AQuA. We choose the 2017 AQUA-RAT dataset to demonstrate use of our representation language on an existing large-scale math word problem solving dataset. The AQuA provides over 100K GRE- and GMAT-level math word problems. The problems are multiple choice and come from a wide range of domains.

The scale and diversity of this dataset makes it particularly suited for use in training deep-learning models to solve word problems. However there is a significant amount of unwanted noise in the dataset, including problems with incorrect solutions, problems that are unsolvable without brute-force enumeration of solutions, and rationales that contain few or none of the steps required to solve the corresponding problem. The motivation for our dataset comes from the fact we want to maintain the challenging nature of the problems included in the AQuA dataset, while removing noise that hinders the ability of neuralized models to learn the types of signal neccessary for problem-solving by logical reasoning.

Additional Datasets Several smaller datasets have been compiled in recent years. Most of these works have focused on algebra word problems, including MaWPS (Koncel-Kedziorski et al., 2016), Alg514 (Kushman et al., 2014), and DRAW-1K (Upadhyay and Chang, 2017). Many of these datasets have sought to align underlying equations or systems of equations with word problem text. While recent works like (Liang et al., 2018; Locascio et al., 2016) have explored representing math word problems with logical formalisms and regular expressions, our work is the first to provide well-defined formalisms for representing intermediate problem-solving steps that are shown to be generalizable beyond algebra problems.

Solving with Handcrafted Features Due to sparsity of suitable data, early work on math word problem solving used pattern-matching to map word problems to mathematical expressions (Bobrow, 1964; Charniak, 1968, 1969), as well as non-neural statistical modeling and semantic parsing approaches (Liguda and Pfeiffer, 2012).

Some effort has been made on parsing the problems to extract salient entities (Hosseini et al., 2017). This approach views entities as containers, which can be composed into an equation tree representation. The equation tree representation is changed over time by operations implied by the problem text.

Many early works focused on solving addition and subtraction problems (Briars and Larkin, 1984; Dellarosa, 1986; Bakman, 2007). As word problems become more diverse and complex, we require models capable of solving simultaneous equation systems. This has led to an increasing focus on finding semantic alignment of math word problems and mentions of numbers (Roy and Roth, 2018). The main idea behind those work is to find all possible patterns of equations and rank them based on the problem.

Neural Word Problem Solvers Following the increasing availability of large-scale datasets like AQuA, several recent works have explored deep neural approaches to math word problem solving (Wang et al., 2017). Our representation language is motivated by exploration of using intermediate formalisms in the training of deep neural problem-solving networks, as is done in the work of (Huang et al., 2018b) to solve problems with sequence to sequence models. While this work focused on single-variable arithmetic problems, our work introduces a formal language of operations for covering more complex multivariate problems and systems of equations.

Interpretability of Solvers While the statistical models with handcrafted features introduced by prior work are arguably "interpretable" due to the relative sparsity of features as well as the clear alignments between inputs and outputs, new neuralized approaches present new challenges to model interpretability of math word problem solvers (Huang et al., 2018a). While this area is relatively unexplored, a prior approach to increasing robustness and interpretability of math word problem-solving models looks at using an adversarial dataset to determine if models are learning logical reasoning or exploiting dataset biases through pattern-matching (Liang et al., 2018).

3 Representing Math Word Problems

A math word problem consists of a narrative that grounds mathematical formalisms in real-world concepts. Solving these problems is a challenge for both humans and automatic methods like neural network-based solvers, since it requires logical reasoning about implied actions and relations between entities. For example, in Figure 2, operations like addition and division are not explicitly mentioned in the word problem text, but they are implied by the question. As we examine the context of a math word problem, we have to select arguments for operations based on which values are unimportant for solving the problem and which are salient. In Figure 2, the numeric value "100" appears in the context but does not appear in the underlying equation.

By selecting implied operations and arguments, we can generate a program of intermediate steps for solving a math word problem. Each step involves a mathematical operation and its related arguments. In Figure 2, there are three addition operations and one division. As illustrated in the figure, operations can be dependant to the previous ones by the values they use as arguments. Every math word problem can be solved by sequentially executing these programs of dependent operations and arguments.

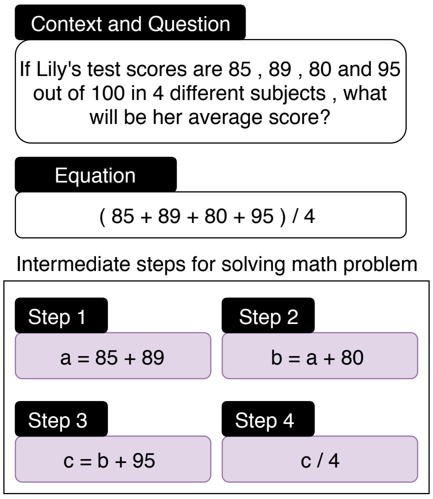


Figure 2: Example of a math word problem with its underlying equation and intermediate steps for problem-solving

We define formalisms for expressing these sequential operation programs with a domain-aware representation language. An operation program in our representation language is a sequence with n operations. The general form is shown below. Each operation o_i takes in a list of arguments $\mathbf{a}$ of length i:

$$o_1(\mathbf{a}_1)o_2(\mathbf{a}_2)...o_n(\mathbf{a}_n) \tag{1}$$

Given this general definition, the problem in Figure 2 has the following representation[2]:

$$\begin{aligned} \text{add}_1(85, 89)\text{add}_2(174, 80) \\ \text{add}_3(254, 95)\text{divide}_4(349, 4) \end{aligned} \tag{2}$$

Our representation language consists of 58 operations and is designed considering the following objectives.

- Correctness → Operation programs should result in the correct solution when all operations are executed.
- Domain-awareness → Operation problems should make use of both math knowledge and

---

[2] Here the arguments 174, 254 and 349 are the outputs of operations 1, 2 and 3 respectively.

domain knowledge associated with subfields like geometry and probability to determine which operations and arguments to use.

- Human interpretability → Each operation and argument used to obtain the correct solution should relate to part of the input word problem context or a previous step in the operation program.

Learning logical forms has led to success in other areas of semantic parsing (Cheng et al., 2017; Zelle and Mooney, 1996; Zettlemoyer and Collins, 2007, 2005) and is a natural representation for math word problem-solving steps. By augmenting our dataset with these formalisms, we are able to cover most types of math word problems[3]. In contrast to other representations like simultaneous equations, our formalisms ensure that every problem-solving step is aligned to a previous one. There are three advantages to this approach. First, we use this representation language to provide human annotators with clear steps for how a particular problem should be solved with math and domain knowledge. Second, our formalisms provide neural models with a continuous path to execute operations for problems with systems of equations, instead of forcing models to align equations before problem solving. This reduces the possibility of intermediate errors being propagated and leading to a incorrect solution. Finally, by having neural models generate a solution path in our representation language before computing the final solution, we are able to reconstruct the logical hops inferred by the model output, increasing model interpretability.

4 Dataset

Our dataset (called MathQA) consists of 37,200 math word problems, corresponding lists of multiple-choice options and aligned operation programs. We use problems in the AQuA dataset and carefully annotate those problems with formal operation programs.

Math problems are first categorized into math domains using term frequencies (more details in Section 5.2). These domains are used to prune the search space of possible operations to align with the word problem text. Figure 3 shows the category-based hierarchies for operation formalisms.

Category	#Prob.	Avg #words	#Vocab	Avg #ops
Geometry	3,316	34.3	1,839	4.8
Physics	9,830	37.3	3,340	5.0
Probability	663	38.9	937	5.0
Gain-Loss	4,377	34.3	1,533	5.7
General	17,796	38.6	6,912	5.1
Other	1,277	31.3	1,425	4.7
All	37,259	37.9	6,664	5.3

Table 1: Statistics for our dataset; the total number of operations in the dataset is 58.

We use crowdsourcing to carefully align problems with operation programs (Section 4.1). Table 1 shows overall statistics of the dataset.[4]

4.1 Annotation using Crowd Workers

Annotating GRE level math problems can be a challenging and time consuming task for humans. We design a dynamic annotation platform to annotate math word problems with formal operation programs. Our annotation platform has the following properties: (a) it provides basic math knowledge to annotators, (b) it is dynamic by iteratively calculating intermediate results after an operation submission, and (c) it employs quality control strategies.

Dynamic Annotation Platform The annotators are provided with a problem description, a list of operations related to the problem category, and a list of valid arguments. They iteratively select operations and arguments until the problem is solved.

- **Operation Selection** The annotators are instructed to sequentially select an operation from the list of operations in the problem category. Annotators are provided with math knowledge by hovering over every operation and getting the related hint that consists of arguments, formula and a short explanation of the operation.

- **Argument Selection** After selecting the operation the list of valid arguments are presented

---

[3] We omit high-order polynomials and problems where the solutions are entirely nonnumeric.

[4] We also experimented with an automatic dynamic programming approach to annotation that generates operation programs for problems using numbers in the AQuA rationales. Due to the noise in the rationales, only 61% of those problems pass our human validation. This is mainly due to the fact that the rationales are not complete programs and fail to explicitly describe all important numbers and operations required to solve the problem. To maintain interpretability of operation paths, we did not include automatic annotations from our dataset and focus on operation programs derived by crowdsourcing.

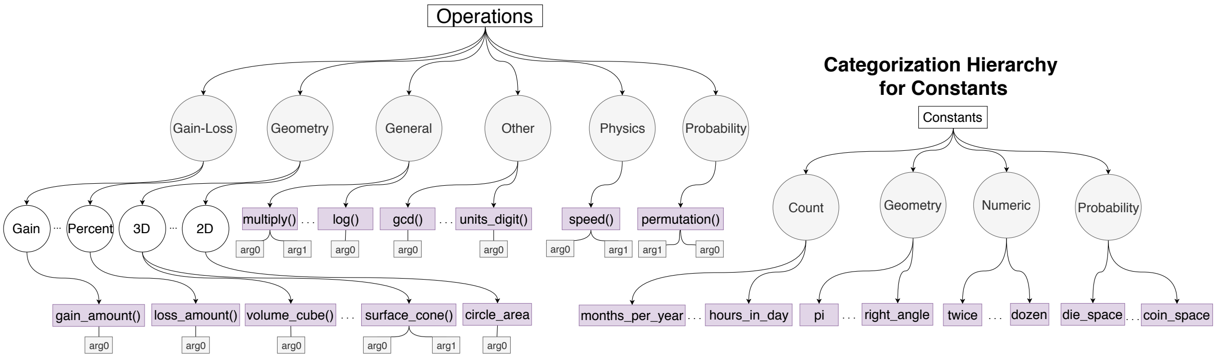

Figure 3: Category-based Hierarchies for Operation Formalisms

  to the annotators to choose from. Valid arguments consist of numbers in the problem, constants in the problem category, and the previous calculations. The annotators are restricted to select only from these valid arguments to prevent having noisy and dangling numbers. After submission of an operation and the corresponding arguments, the result of the operation is automatically calculated and will be added as a new valid argument to the argument list.

- **Program Submission** To prevent annotators from submitting arbitrary programs, we enforce restrictions to the final submission. Our platform only accepts programs which include some numbers from the problem, and whose final calculation is very close to the correct numeric solution.

High Quality Crowd Workers We dynamically evaluate and employ high-quality annotators through a collection of quality-control questions. We take advantage of the annotation platform in *Figure Eight*.[5] The annotators are randomly evaluated through a pre-defined set of test questions, and they have to maintain an accuracy threshold to be able to continue their annotations. If an annotator's accuracy drops below a threshold, their previous annotations are labeled as untrusted and will be added to the pool of annotations again.

Alignment Validation To further evaluate the quality of the annotated programs, we leverage a validation strategy to check whether the problems and annotated programs are aligned or not. According to this strategy, at least 2 out of 3 validators should rank the operation program as valid for it to be selected. The validation accuracy is 94.64% across categories.

5 Models

We develop encoder-decoder neural models to map word problems to a set of feasible operation programs. We match the result of the executed operation program against the list of multiple-choice options given for a particular problem. The matching solution is the final model output.

We frame the problem of aligning an operation program with a math word problem as a neural machine translation (NMT) task, where the word problem $\mathbf{x}$ and gold operation program $\mathbf{y}$ form a parallel text pair. The vocabulary of $\mathbf{y}$ includes all possible operations and arguments in our representation language.

5.1 Sequence-to-Program

For our initial sequence-to-program model, we follow the attention-based NMT paradigm of (Bahdanau et al., 2015; Cho et al., 2014). We encode the source word problem text $\mathbf{x} = (x_1, x_2, ..., x_M)$ using a bidirectional RNN encoder θ^{enc}. The decoder θ^{dec} predicts a distribution over the vocabulary and input tokens to generate each operation or argument in the target operation program. For our sequence-to-program model vocabulary, we use informed generation, in which the program tokens are generated separately from the vocabulary of operations O or arguments A.

The encoded text is represented by a sequence of d-dimensional hidden states $\mathbf{h}^{enc} = (h_1^{enc}, h_2^{enc}, .., h_M^{enc})$, where M is the length of the input text. A context vector a_i is computed by taking the weighted sum of the attention model weights $\alpha_{t,i}$ for each timestep $t \in (1, 2, ..., T)$ and each encoder hidden state h_i^{enc}:

$$a_i = \sum_{i=1}^{M} \alpha_{t,i} h_i^{enc}.$$

We compute the d-dimensional decoder hidden

---

[5] https://www.figure-eight.com

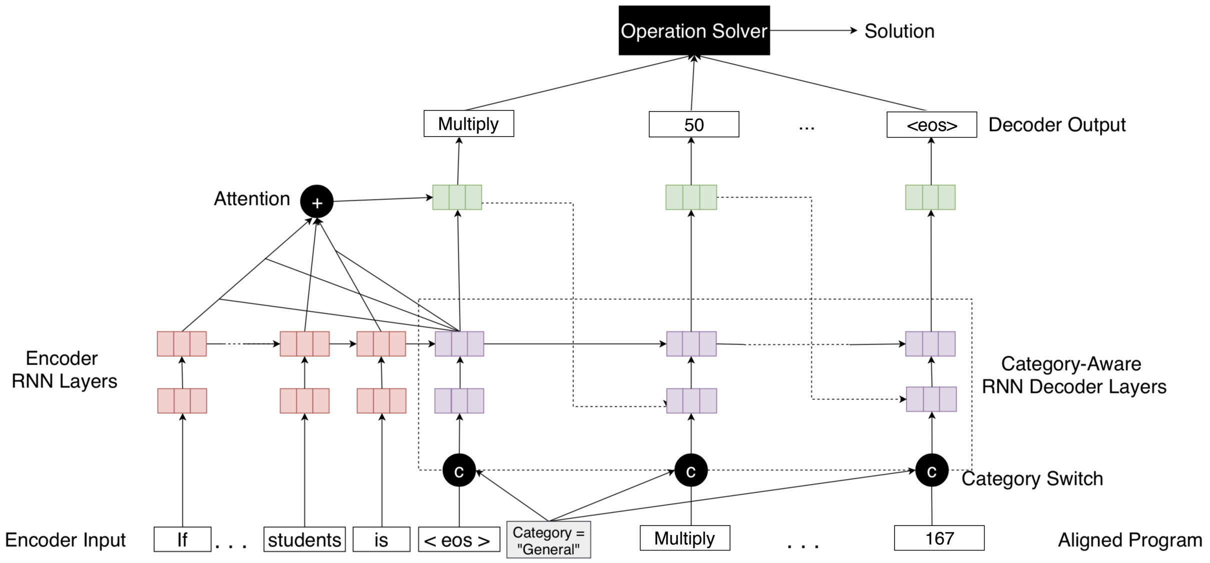

Figure 4: Architecture of sequence-to-program model with categorization. Shown with example problem "If the average marks of three batches of 62 , 60 and 45 students respectively is 50 , 55 , 60 , then the average marks of all the students is."

state h_i^{dec} using a LSTM recurrent layer:

$$h_i^{dec} = LSTM(h_{i-1}^{dec}, y_{i-1}, a_i) \tag{3}$$

At each timestep, we make a prediction for an operator op_i or argument arg_{ik}, where k corresponds to the index of the argument in operator i's argument list. This prediction is conditioned on the previous tokens $(y_1, ..., y_{i-1})$ and the input $\mathbf{x}$ to decode an entire operation program $\mathbf{y} = (y_1, y_2, ..., y_N)$ of length N:

$$P(\mathbf{y}|x) = \prod_{i=1}^{N} P(y_i|y_{<i}, \mathbf{x}) \tag{4}$$

$$P(y_i|y_{<i}, \mathbf{x}) = g(f(h_i^{dec}, y_i, a_i)) \tag{5}$$

Here f is a 1-layer feed-forward neural network and g is the softmax function. During training time, we minimize the negative log-likelihood (NLL) using the following objective:

$$\mathcal{L}(\theta^{enc}, \theta^{dec}) = -logP(\mathbf{y}|\mathbf{x}; \theta^{enc}, \theta^{dec}) \tag{6}$$

At test time, we only observe the input text when predicting operation programs:

$$\hat{\mathbf{y}} = \texttt{argmax}_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}) \tag{7}$$

5.2 Categorized Sequence-to-Program Model

We extend our base sequence-to-program model to integrate knowledge of math word problem domain categories. We modify the RNN decoder layers that compute the decoder hidden state to be category-aware. Here, the category label c is deterministically computed by the category extractor (explained below). It functions as a hard decision switch that determines which set of parameters to use for the hidden state computation:

$$h_i^{dec} = LSTM_c(h_{i-1}^{dec}, y_{i-1}, a_i) \tag{8}$$

The updated objective function from equation (7) is shown below:

$$\mathcal{L}(\theta^{enc}, \theta_c^{dec}) = -logP(\mathbf{y}|\mathbf{x}; \theta^{enc}, \theta_c^{dec}) \tag{9}$$

The full model architecture is shown in Figure 4.

Domain-Specific Category Extraction We first construct a lexicon of n-grams relating to a specific domain. The lexicon is a list consisting of domain-specific categories and associated n-grams. For each domain category c in the lexicon, we select associated n-grams $\mathbf{n}_c$ that occur frequently in word problems belonging to domain category c, but rarely appear in other domain categories. We compute n-gram frequency f_{pc} as the number of n-grams associated with a category c appearing in the text of a word problem p. We obtain a list of potential categories for p by choosing all categories for which $f_{pc} > 0$, and then assign a category label to p based on which category has the highest n-gram frequency.

5.3 Solving Operation Programs

Once a complete operation program has been decoded, each operator in the program is executed sequentially along with its predicted set of arguments to obtain a possible solution. For each word problem p and options o, we generate a beam of the top n decoded operation programs. We execute each decoded program g to find the solution from the list of options $\mathbf{o}$ of the problem. We first choose options that are within a threshold of the executed value of g. We select g as the predicted solution by checking the number of selected options and the minimum distance between the executed value of g and a possible option for p. For the problems in AQuA that do not belong in any category of MathQA, we randomly choose an option.

6 Experimental Setup

6.1 Datasets

Our dataset consists of $37k$ problems which are randomly split in $(80/12/8)\%$ training/dev/test problems. Our dataset significantly enhances the AQuA dataset by fully annotating a portion of *solvable* problems in the AQuA dataset into formal operation programs.

We carefully study the AQuA dataset. Many of the problems are near-duplicates with slight changes to the math word problem stories or numerical values since they are expanded from a set of 30,000 seed problems through crowdsourcing (Ling et al., 2017). These changes are not always reflected in the rationales, leading to incorrect solutions. There are also some problems that are not solvable given current math word problem solving frameworks because they require a level of reasoning not yet modeled by neural networks. Sequence problems, for example, require understanding of patterns that are difficult to intuit without domain knowledge like sequence formulas, and can only be solved automatically through brute-force or guessing. Table 2 shows a full breakdown of the AQuA dataset by solvability.[6]

Subset	Train	Valid
Unsolvable - No Words	37	0
Unsolvable - Sequence	1,991	4
Unsolvable - Requires Options	6,643	8
Unsolvable - Non-numeric	10,227	14
Duplicates	17,294	0
Solvable	65,991	229
Total	97,467	254

Table 2: Full original AQuA solvability statistics.

6.2 Annotation Details

We follow the annotation strategy described in Section 4 to formally annotate problems with operation programs. [7]

Annotator Agreements and Evaluations Our expert evaluation of the annotation procedure for a collection of 500 problems shows that 92% of the annotations are valid. Additionally, it has 87% agreement between the expert validation and the crowd sourcing validation task.

Annotation Expansion The AQuA dataset consists of a group of problems which share similar characteristics. These problems can be solved with similar operation programs. We find closely similar problems, replace numeric values with generic numbers, and expand annotations to cover more problems from the AQuA dataset. For similarity, we use Levenshtein distance with a threshold of 4 words in edit distance.

6.3 Model and Training Details

We use the official python implementation of OpenNMT (Klein et al.). We choose a LSTM-based encoder-decoder architecture. We use Adam optimizer (Kingma and Ba, 2015), and the learning rate for training is 0.001. The hidden size for the encoder and decoder is set to $d = 100$. Both the encoder and decoder have 2 layers. The word embedding vectors are randomly initialized. At inference time, we implemented a beam search with beam size of 200 for AQuA and 100 for MathQA.

The program vocabulary consists of the operations O in our representation language and valid arguments A. For valid arguments, we do not use their actual values since the space is very large. Instead, we keep a list of numbers according to their source. Constants are predefined numbers that are available to all problems. Problem numbers are added to the list according to their order in the problem text. Calculated numbers in the interme-

---

[6] There is overlap between unsolvable subsets. For example, a sequence problem may also be a duplicate of another problem in the AQuA dataset.

[7] We tried two other strategies of showing extra information (rationales or end solutions) to annotators to facilitate solving problems. However, our manual validation showed that annotators mostly used those extra information to artificially build an operation program without reading the problem.

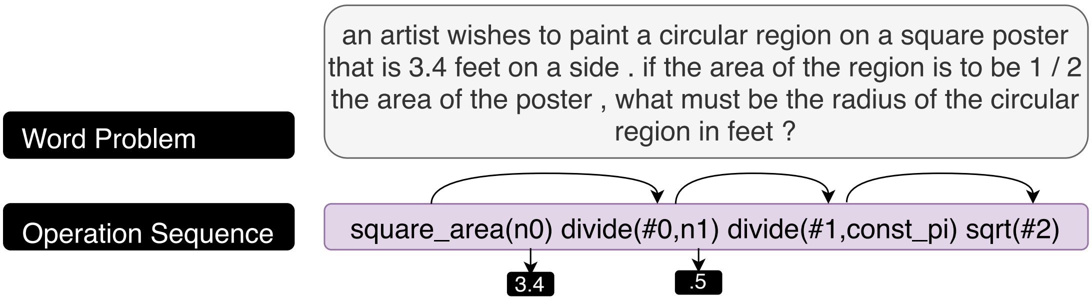

Figure 5: Example of an operation program generated by our Seq2prog model with categorization

Model	MathQA	AQuA
Random	20.0	20.0
AQuA Model	-	36.4

diate steps are added to the list according to the operation order.

7 Experimental Results

7.1 Results

Table 3 compares the performance of our sequence-to-program models trained on MathQA with baselines on MathQA and AQuA test sets. The base model is referred to as "Seq2prog," while our model with categorization is "Seq2prog + cat." For accuracy, the performance was measured in terms of how well the model would perform on an actual math test.

We observe improvement for our "Seq2prog + cat" model despite the fact that our training data is proportionally smaller than the AQuA dataset, and our model is much simpler than the state-of-the-art model on this dataset. This indicates the effectiveness of our formal representation language to incorporate domain knowledge as well as the quality of the annotations in our dataset.

7.2 Analysis

Qualitative Analysis Table 5 and Figure 5 show some examples of problems solved by our method. We analyzed 50 problems that are solved wrongly by our system on the MathQA dataset. Table 4 summarizes four major categories of errors.

The most common type of errors are problems that need complicated or long chain of mathematical reasoning. For example, the first problem in Table 4 requires reasoning that goes beyond one sentence. Other errors are due to limitations in our representation language. For example, the second problem in Table 4 requires the *factorization* operation which is not defined in our representation language. Future work can investigate more domains of mathematics such as logic, number factors, etc. Some errors are due to the slightly noisy nature of our categorization strategy. For example, the third problem in Table 4 is mistakenly categorized as belonging to *physics* domain due to the presence of words *m, cm, liter* in the problem text, while the correct category for the problem is *geometry*. The final category of errors are due to problems that do not have enough textual context or erroneous problems (e.g., fourth problem in Table 4).

Impact of Categorization Table 3 indicates that our category-aware model outperforms the base model on both AQuA and MathQA datasets. The gain is relatively small because the current model only uses categorization decisions as hard constraints at decoding time. Moreover, the problem categorization might be noisy due to our use of only one mathematical interpretation for each domain-specific n-gram. For example, the presence of the words "square" or "cube" in the text of a math word problem indicate that the word problem is related to the geometry domain, but these unigrams can also refer to an exponential operation (n^2 or n^3).

To measure the effectiveness of our categorization strategy, we used human annotation over 100 problems. The agreement between human annotators is 84% and their agreement with our model is 74.5%. As a future extension of this work, we would like to also consider the context in which domain-specific n-grams appear.

Discussions As we mentioned in section 3, the continuous nature of our formalism allows us to solve problems requiring systems of equations. However, there are other types of word prob-

Error type	**Problem**
Hard problems (45%)	Jane and Ashley take 8 days and 40 days respectively to complete a project when they work on it alone. They thought if they worked on the project together, they would take fewer days to complete it. During the period that they were working together, Jane took an eight day leave from work. This led to Jane' s working for four extra days on her own to complete the project. How long did it take to finish the project?
Limitation in representation language (25%)	How many different positive integers are factors of 25?
Categorization errors (12.5%)	A cistern of capacity 8000 litres measures externally 3.3 m by 2.6 m by 1.3 m and its walls are 5 cm thick. The thickness of the bottom is:
Incorrect or insufficient problem text) (17.5%)	45 x ? = 25 % of 900

Problem : A rectangular field is to be fenced on three sides leaving a side of 20 feet uncovered. if the area of the field is 10 sq. feet, how many feet of fencing will be required? **Operations :** `divide(10,20), multiply(#0, const_2), add(20, 1)`
Problem : How long does a train 110m long running at the speed of 72 km/hr takes to cross a bridge 132m length? **Operations :** `add(110, 132), multiply(72, const_0.2778), divide(#0, #1), floor(#2)`

Table 5: Problems solved correctly by Seq2prog+cat model.

lems that are currently unsolvable or have multiple interpretations leading to multiple correct solutions. While problems that can only be solved by brute-force instead of logical reasoning and non-narrative problems that do not fit the definition of a math word problem (in Table 2 these appear as "no word") are removed from consideration, there are other problems that are beyond the scope of current models but could pose an interesting challenge for future work. One example is the domain of sequence problems. Unlike past word problem-solving models, our models incorporate domain-specific math knowledge, which is potentially extensible to common sequence and series formulas.

8 Conclusion

In this work, we introduced a representation language and annotation system for large-scale math word problem-solving datasets that addresses unwanted noise in these datasets and lack of formal operation-based representations. We demonstrated the effectiveness of our representation language by transforming solvable AQuA word problems into operation formalisms. Experimental results show that both our base and category-aware sequence-to-program models outperform baselines and previous results on the AQuA dataset when trained on data aligned with our representation language. Our representation language provides an extra layer of supervision that can be used to reduce the influence of statistical bias in datasets like AQuA. Additionally, generated operation programs like the examples in figure 5 demonstrate the effectiveness of these operation formalisms for representing math word problems in a human interpretable form.

The gap between the performance of our models and human performance indicates that our MathQA still maintains the challenging nature of AQuA problems. In future work, we plan to extend our representation language and models to cover currently unsolvable problems, including sequence and high-order polynomial problems.

Abstract

Reading comprehension has recently seen rapid progress, with systems matching humans on the most popular datasets for the task. However, a large body of work has highlighted the brittleness of these systems, showing that there is much work left to be done. We introduce a new English reading comprehension benchmark, DROP, which requires **D**iscrete **R**easoning **O**ver the content of **P**aragraphs. In this crowdsourced, adversarially-created, 96k-question benchmark, a system must resolve references in a question, perhaps to multiple input positions, and perform discrete operations over them (such as addition, counting, or sorting). These operations require a much more comprehensive understanding of the content of paragraphs than what was necessary for prior datasets. We apply state-of-the-art methods from both the reading comprehension and semantic parsing literatures on this dataset and show that the best systems only achieve 32.7% F_1 on our generalized accuracy metric, while expert human performance is 96.4%. We additionally present a new model that combines reading comprehension methods with simple numerical reasoning to achieve 47.0% F_1.

1 Introduction

The task of *reading comprehension*, where systems must understand a single passage of text well enough to answer arbitrary questions about it, has seen significant progress in the last few years, so much that the most popular datasets available for this task have been solved (Chen et al., 2016; Devlin et al., 2019). We introduce a substantially more challenging English reading comprehension dataset aimed at pushing the field towards more comprehensive analysis of paragraphs of text. In this new benchmark, which we call DROP, a system is given a paragraph and a question and must perform some kind of **D**iscrete **R**easoning **O**ver the text in the **P**aragraph to obtain the correct answer.

These questions that require discrete reasoning (such as addition, sorting, or counting; see Table 1) are inspired by the complex, compositional questions commonly found in the semantic parsing literature. We focus on this type of questions because they force a structured analysis of the content of the paragraph that is detailed enough to permit reasoning. Our goal is to further *paragraph understanding*; complex questions allow us to test a system's understanding of the paragraph's semantics.

DROP is also designed to further research on methods that combine distributed representations with symbolic, discrete reasoning. In order to do well on this dataset, a system must be able to find multiple occurrences of an event described in a question (presumably using some kind of soft matching), extract arguments from the events, then perform a numerical operation such as a sort, to answer a question like *"Who threw the longest touchdown pass?"*.

We constructed this dataset through crowdsourcing, first collecting passages from Wikipedia that are easy to ask hard questions about, then encouraging crowd workers to produce challenging questions. This encouragement was partially through instructions given to workers, and partially through the use of an *adversarial baseline*: we ran a baseline reading comprehension method (BiDAF) (Seo et al., 2017) in the background as crowd workers were writing questions, requiring them to give questions that the baseline system could not correctly answer. This resulted in a dataset of 96,567 questions from a variety of categories in Wikipedia, with a particular emphasis on sports game summaries and history passages. The answers to the questions are required to be spans in the passage or

question, numbers, or dates, which allows for easy and accurate evaluation metrics.

We present an analysis of the resulting dataset to show what phenomena are present. We find that many questions combine complex question semantics with SQuAD-style argument finding; e.g., in the first question in Table 1, BiDAF correctly finds the amount the painting sold for, but does not understand the question semantics and cannot perform the numerical reasoning required to answer the question. Other questions, such as the fifth question in Table 1, require finding all events in the passage that match a description in the question, then aggregating them somehow (in this instance, by counting them and then performing an argmax). Very often entity coreference is required. Table 1 gives a number of different phenomena, with their proportions in the dataset.

We used three types of systems to judge baseline performance on DROP: (1) heuristic baselines, to check for biases in the data; (2) SQuAD-style reading comprehension methods; and (3) semantic parsers operating on a pipelined analysis of the passage. The reading comprehension methods perform the best, with our best baseline achieving 32.7% F_1 on our generalized accuracy metric, while expert human performance is 96.4%. Finally, we contribute a new model for this task that combines limited numerical reasoning with standard reading comprehension methods, allowing the model to answer questions involving counting, addition and subtraction. This model reaches 47% F_1, a 14.3% absolute increase over the best baseline system.

The dataset, code for the baseline systems, and a leaderboard with a hidden test set can be found at `https://allennlp.org/drop`.

2 Related Work

Question answering datasets With systems reaching human performance on the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016), many follow-on tasks are currently being proposed. All of these datasets throw in additional complexities to the reading comprehension challenge, around tracking conversational state (Reddy et al., 2019; Choi et al., 2018), requiring passage retrieval (Joshi et al., 2017; Yang et al., 2018; Talmor and Berant, 2018), mismatched passages and questions (Saha et al., 2018; Kociský et al., 2018; Rajpurkar et al., 2018), integrating knowledge from external sources (Mihaylov et al., 2018; Zhang et al., 2019), tracking entity state changes (Mishra et al., 2018; Ostermann et al., 2018) or a particular kind of "multi-step" reasoning over multiple documents (Welbl et al., 2018; Khashabi et al., 2018). Similar facets are explored in medical domain datasets (Pampari et al., 2018; Šuster and Daelemans, 2018) which contain automatically generated queries on medical records based on predefined templates. We applaud these efforts, which offer good avenues to study these additional phenomena. However, we are concerned with *paragraph understanding*, which on its own is far from solved, so DROP has none of these additional complexities. It consists of single passages of text paired with independent questions, with only linguistic facility required to answer the questions.[1] One could argue that we are adding numerical reasoning as an "additional complexity", and this is true; however, it is only simple reasoning that is relatively well-understood in the semantic parsing literature, and we use it as a necessary means to force more comprehensive passage understanding.

Many existing algebra word problem datasets also contain similar phenomena to what is in DROP (Koncel-Kedziorski et al., 2015; Kushman et al., 2014; Hosseini et al., 2014; Clark et al., 2016; Ling et al., 2017). Our dataset is different in that it uses much longer contexts, is more open domain, and requires deeper paragraph understanding.

Semantic parsing The semantic parsing literature has a long history of trying to understand complex, compositional question semantics in terms of some grounded knowledge base or other environment (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Berant et al., 2013a, *inter alia*). It is this literature that we modeled our questions on, particularly looking at the questions in the WikiTableQuestions dataset (Pasupat and Liang, 2015). If we had a structured, tabular representation of the content of our paragraphs, DROP would be largely the same as WikiTableQuestions, with similar (possibly even simpler) question semantics. Our novelty is that we are the first to combine these complex questions with paragraph understanding, with the aim of encouraging systems that can produce comprehensive structural analyses of paragraphs, either explicitly or implicitly.

Adversarial dataset construction We continue

---

[1] Some questions in our dataset require limited sports domain knowledge to answer; we expect that there are enough such questions that systems can reasonably learn this knowledge from the data.

Subtraction (28.8%)	That year, his **Untitled (1981)**, a painting of a haloed, black-headed man with a bright red skeletal body, depicted amid the artists signature scrawls, was **sold by Robert Lehrman for $16.3 million, well above its $12 million high estimate**.	How many more dollars was the Untitled (1981) painting sold for than the 12 million dollar estimation?	4300000	$16.3 million
Comparison (18.2%)	In **1517, the seventeen-year-old King sailed to Castile**. There, his Flemish court . . . . **In May 1518, Charles traveled to Barcelona in Aragon**.	Where did Charles travel to first, Castile or Barcelona?	Castile	Aragon
Selection (19.4%)	In 1970, to commemorate the 100th anniversary of the founding of Baldwin City, **Baker University professor and playwright Don Mueller and Phyllis E. Braun, Business Manager, produced a musical play entitled The Ballad Of Black Jack** to tell the story of the events that led up to the battle.	Who was the University professor that helped produce The Ballad Of Black Jack, Ivan Boyd or Don Mueller?	Don Mueller	Baker
Addition (11.7%)	Before the UNPROFOR fully deployed, the HV clashed with an armed force of the RSK in the village of Nos Kalik, located in a pink zone near Šibenik, and captured the village at 4:45 p.m. on **2 March 1992**. The JNA formed a battlegroup to counterattack the **next day**.	What date did the JNA form a battlegroup to counterattack after the village of Nos Kalik was captured?	3 March 1992	2 March 1992
Count (16.5%) and Sort (11.7%)	Denver would retake the lead with kicker **Matt Prater nailing a 43-yard field goal**, yet Carolina answered as kicker **John Kasay ties the game with a 39-yard field goal**. . . . Carolina closed out the half with **Kasay nailing a 44-yard field goal**. . . . In the fourth quarter, Carolina sealed the win with **Kasay's 42-yard field goal**.	Which kicker kicked the most field goals?	John Kasay	Matt Prater
Coreference Resolution (3.7%)	**James Douglas** was the second son of Sir George Douglas of Pittendreich, and Elizabeth Douglas, daughter David Douglas of Pittendreich. Before **1543 he married Elizabeth**, daughter of James Douglas, 3rd Earl of Morton. **In 1553 James Douglas succeeded to the title and estates of his father-in-law**.	How many years after he married Elizabeth did James Douglas succeed to the title and estates of his father-in-law?	10	1553
Other Arithmetic (3.2%)	Although the movement initially gathered some **60,000 adherents**, the subsequent establishment of the Bulgarian Exarchate **reduced their number by some 75%**.	How many adherents were left after the establishment of the Bulgarian Exarchate?	15000	60,000
Set of spans (6.0%)	According to some sources 363 civilians were killed in **Kavadarci**, 230 in **Negotino** and 40 in **Vatasha**.	What were the 3 villages that people were killed in?	Kavadarci, Negotino, Vatasha	Negotino and 40 in Vatasha
Other (6.8%)	This **Annual Financial Report** is our principal financial statement of accountability. The **AFR gives a comprehensive view** of the Department's financial activities ...	What does AFR stand for?	Annual Financial Report	one of the Big Four audit firms

Table 1: Example questions and answers from the DROP dataset, showing the relevant parts of the associated passage and the reasoning required to answer the question.

a recent trend in creating datasets with adversarial baselines in the loop (Paperno et al., 2016; Minervini and Riedel, 2018; Zellers et al., 2018; Zhang et al., 2019; Zellers et al., 2019). In our case, instead of using an adversarial baseline to filter automatically generated examples, we use it in a crowdsourcing task, to teach crowd workers to avoid easy questions, raising the difficulty level of the questions they provide.

Neural symbolic reasoning DROP is designed to encourage research on methods that combine neural methods with discrete, symbolic reasoning. We present one such model in Section 6. Other related work along these lines has been done by Reed and de Freitas (2016), Neelakantan et al. (2016), and Liang et al. (2017).

3 DROP Data Collection

In this section, we describe our annotation protocol, which consists of three phases. First, we automatically extract passages from Wikipedia which are expected to be amenable to complex questions. Second, we crowdsource question-answer pairs on these passages, eliciting questions which require discrete reasoning. Finally, we validate the development and test portions of DROP to ensure their quality and report inter-annotator agreement.

Passage extraction We searched Wikipedia for passages that had a narrative sequence of events, particularly with a high proportion of numbers, as our initial pilots indicated that these passages were the easiest to ask complex questions about. We found that National Football League (NFL) game summaries and history articles were particularly promising, and we additionally sampled from any Wikipedia passage that contained at least twenty numbers.[2] This process yielded a collection of about 7,000 passages.

Question collection We used Amazon Mechanical Turk[3] to crowdsource the collection of question-answer pairs, where each question could be answered in the context of a single Wikipedia passage. In order to allow some flexibility during the annotation process, in each human intelligence task (HIT) workers were presented with a random sample of 5 of our Wikipedia passages, and were asked to produce a total of at least 12 question-answer pairs on any of these.

We presented workers with example questions from five main categories, inspired by questions from the semantic parsing literature (addition/subtraction, minimum/maximum, counting, selection and comparison; see examples in Table 1), to elicit questions that require complex linguistic understanding and discrete reasoning. In addition, to further increase the difficulty of the questions in DROP, we employed a novel adverserial annotation setting, where workers were only allowed to submit questions which a real-time QA model BiDAF *could not* solve.[4]

Next, each worker answered their own question with one of three answer types: spans of text from either question or passage, a date (which was common in history and open-domain text) and numbers, allowed only for questions which explicitly stated a specific unit of measurement (e.g., "How many *yards* did Brady run?"), in an attempt to simplify the evaluation process.

Initially, we opened our HITs to all United States workers and gradually reduced our worker pool to workers who understood the task and annotated it well. Each HIT paid 5 USD and could be completed within 30 minutes, compensating a trained worker with an average pay of 10 USD/ hour.

Statistic	**Train**	**Dev**	**Test**
Number of passages	5565	582	588
Avg. passage len [words]	213.45	191.62	195.12
Number of questions	77,409	9,536	9,622
Avg. question len [words]	10.79	11.17	11.23
Avg. questions / passage	13.91	16.38	16.36
Question vocabulary size	29,929	8,023	8,007

Table 2: Dataset statistics across the different splits.

Overall, we collected a total of 96,567 question-answer pairs with a total Mechanical Turk budget of 60k USD (including validation). The dataset was randomly partitioned by passage into training (80%), development (10%) and test (10%) sets, so all questions about a particular passage belong to only one of the splits.

Validation In order to test inter-annotator agreement and to improve the quality of evaluation against DROP, we collected at least two additional answers for each question in the development and test sets.

In a separate HIT, workers were given context passages and a previously crowdsourced question, and were asked to either answer the question or mark it as invalid (this occurred for 0.7% of the data, which we subsequently filtered out). We found that the resulting inter-annotator agreement was good and on par with other QA tasks; overall Cohen's κ was 0.74, with 0.81 for numbers, 0.62 for spans, and 0.65 for dates.

4 DROP Data Analysis

In the following, we quantitatively analyze properties of passages, questions, and answers in DROP. Different statistics of the dataset are depicted in Table 2. Notably, questions have a diverse vocabulary of around 30k different words in our training set.

Question analysis To assess the question type distribution, we sampled 350 questions from the training and development sets and manually annotated the categories of discrete operations required to answer the question. Table 1 shows the distribution of these categories in the dataset. In addition, to get a better sense of the lexical diversity of questions in the dataset, we find the most frequent

---

[2] We used an October 2018 Wikipedia dump, as well as scraping of online Wikipedia.

[3] `www.mturk.com`

[4] While BiDAF is no longer state-of-the-art, performance is reasonable and the AllenNLP implementation (Gardner et al., 2017) made it the easiest to deploy as a server.

Answer Type	Percent	Example
NUMBER	66.1	12
PERSON	12.2	Jerry Porter
OTHER	9.4	males
OTHER ENTITIES	7.3	Seahawks
VERB PHRASE	3.5	Tom arrived at Acre
DATE	1.5	3 March 1992

Table 3: Distribution of answer types in training set, according to an automatic named entity recognition.

trigram patterns in the questions per answer type. We find that the dataset offers a huge variety of linguistic constructs, with the most frequent pattern ("Which team scored") appearing in only 4% of the span type questions. For number type questions, the 5 most frequent question patterns all start with "How many", indicating the need to perform counting and other arithmetic operations. A distribution of the trigrams containing the start of the questions are shown in Figure 1.

Answer analysis To discern the level of *passage understanding* needed to answer the questions in DROP, we annotate the set of spans in the passage that are necessary for answering the 350 questions mentioned above. We find that on an average 2.18 spans need to be considered to answer a question and the average distance between these spans is 26 words, with 20% of samples needing at least 3 spans (see appendix for examples). Finally, we assess the answer distribution in Table 3, by running the part-of-speech tagger and named entity recognizer from spaCy[5] to automatically partition all the answers into various categories. We find that a majority of the answers are numerical values and proper nouns.

5 Baseline Systems

In this section we describe the initial baselines that we evaluated on the DROP dataset. We used three types of baselines: state-of-the-art semantic parsers (§5.1), state-of-the-art reading comprehension models (§5.2), and heuristics looking for annotation artifacts (§5.3). We use two evaluation metrics to compare model performance: *Exact-Match*, and a numeracy-focused (macro-averaged) F_1 score, which measures overlap between a bag-of-words representation of the gold and predicted answers. We employ the same implementation of Exact-Match accuracy as used by SQuAD, which removes articles and does other simple normalization, and our F_1 score is based on that used by SQuAD. Since DROP is numeracy-focused, we define F_1 to be 0 when there is a number mismatch between the gold and predicted answers, regardless of other word overlap. When an answer has multiple spans, we first perform a one-to-one alignment greedily based on bag-of-word overlap on the set of spans and then compute average F_1 over each span. When there are multiple annotated answers, both metrics take a max over all gold answers.

5.1 Semantic Parsing

Semantic parsing has been used to translate natural language utterances into formal executable languages (e.g., SQL) that can perform discrete operations against a structured knowledge representation, such as knowledge graphs or tabular databases (Zettlemoyer and Collins, 2005; Berant et al., 2013b; Yin and Neubig, 2017; Chen and Mooney, 2011, *inter alia*). Since many of DROP's questions require similar discrete reasoning, it is appealing to port some of the successful work in semantic parsing to the DROP dataset. Specifically, we use the grammar-constrained semantic parsing model built by Krishnamurthy et al. (2017) (KDG) for the WIKITABLEQUESTIONS tabular dataset (Pasupat and Liang, 2015).

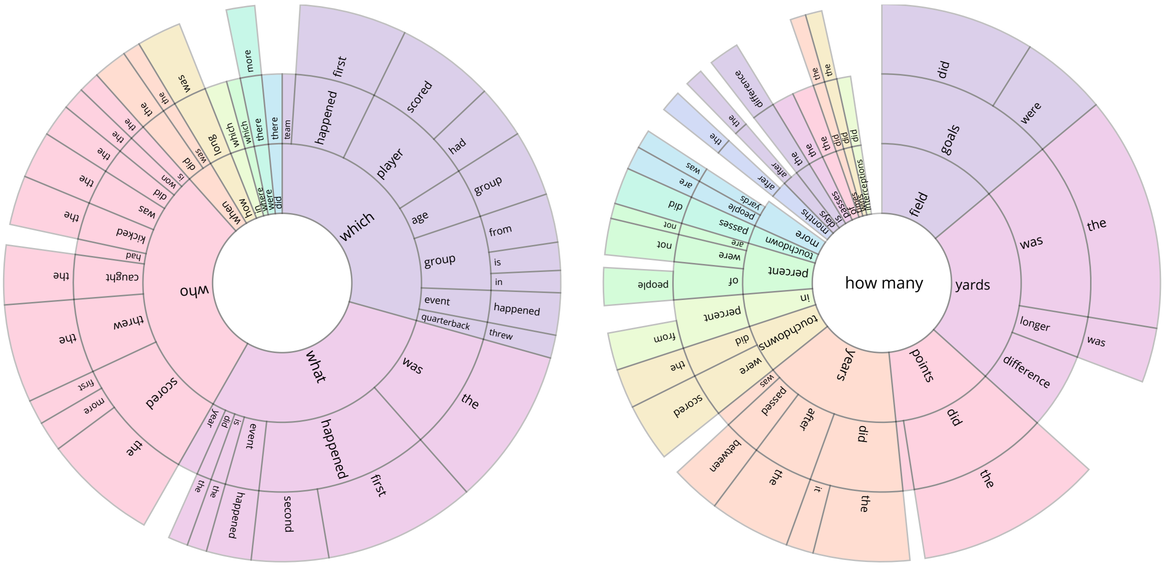
Sentence representation schemes We experimented with three paradigms to represent paragraphs as structured contexts: (1) Stanford dependencies (de Marneffe and Manning, 2008, Syn Dep); which capture word-level syntactic relations, (2) Open Information Extraction (Banko et al., 2007, Open IE), a shallow semantic representation which directly links predicates and arguments; and (3) Semantic Role Labeling (Carreras and Màrquez, 2005, SRL), which disambiguates senses for polysemous predicates and assigns predicate-specific argument roles.[6] To adhere to KDG's structured representation format, we convert each of these representations into a table, where rows are predicate-argument structures and columns correspond to different argument roles.

Logical form language Our logical form language identifies five basic elements in the table representation: *predicate-argument structures* (i.e., table rows), *relations* (column-headers), *strings*, *num-*

---

[5] https://spacy.io/

[6] We used the AllenNLP implementations of state-of-the-art models for all of these representations (Gardner et al., 2017; Dozat et al., 2017; He et al., 2017; Stanovsky et al., 2018).



(a) For span type answers

(b) For number type answers

Figure 1: Distribution of the most popular question prefixes for two different subsets of the training data.

bers, and *dates*. In addition, it defines functions that operate on these elements, such as counters and filters.[7] Following Krishnamurthy et al. (2017), we use the argument and return types of these functions to automatically induce a grammar to constrain the parser. We also add context-specific rules to produce strings occurring in both question and paragraph, and those paragraph strings that are neighbors of question tokens in the GloVe embedding space (Pennington et al., 2014), up to a cosine distance of d.[8] The complete set of functions used in our language and their induced grammar can be found in the code release.

Training and inference During training, the KDG parser maximizes the marginal likelihood of a set of (possibly spurious) question logical forms that evaluate to the correct answer. We obtain this set by performing an exhaustive search over the grammar up to a preset tree depth. At test time, we use beam search to produce the most likely logical form, which is then executed to predict an answer.

5.2 SQuAD-style Reading Comprehension

We test four different SQuAD-style reading comprehension models on DROP: (1) **BiDAF** (Seo et al., 2017), which is the adversarial baseline we used in data construction (66.8% EM on SQuAD 1.1); (2) **QANet** (Yu et al., 2018), currently the best-performing published model on SQuAD 1.1 without data augmentation or pretraining (72.7% EM); (3) **QANet + ELMo**, which enhances the QANet model by concatenating pretrained ELMo representations (Peters et al., 2018) to the original embeddings (78.7% EM); (4) **BERT** (Devlin et al., 2019), which recently achieved improvements on many NLP tasks with a novel pretraining technique (84.7% EM).[9]

These models require a few minor adaptations when training on DROP. While SQuAD provides answer indices in the passage, our dataset only provides the answer strings. To address this, we use the marginal likelihood objective function proposed by Clark and Gardner (2018), which sums over the probabilities of all the matching spans.[10] We also omitted the training questions which cannot be answered by a span in the passage (45%), and therefore cannot be represented by these systems.

For the BiDAF baseline, we use the implementation in AllenNLP but change it to use the marginal objective. For the QANet model, our settings differ from the original paper only in the batch size (16 v.s. 32) and number of blocks in the modeling layer

---

[7] For example `filter_number_greater` takes a set of predicate-argument structures, the name of a relation, and a number, and returns all those structures where the numbers in the argument specified by the relation are greater than the given number.

[8] $d = 0.3$ was manually tuned on the development set.

[9] The first three scores are based on our own implementation, while the score for BERT is based on an open-source implementation from Hugging Face: https://github.com/huggingface/pytorch-pretrained-bert

[10] For the black-box BERT model, we convert DROP to SQuAD format by using the first match as the gold span.

(6 v.s. 7) due to the GPU memory limit. We adopt the ELMo representations trained on 5.5B corpus for the QANet+ELMo baseline and the large uncased BERT model for the BERT baseline. The hyper-parameters for our NAQANet model (§6) are the same as for the QANet baseline.

5.3 Heuristic Baselines

A recent line of work (Gururangan et al., 2018; Kaushik and Lipton, 2018) has identified that popular crowdsourced NLP datasets (such as SQuAD (Rajpurkar et al., 2016) or SNLI (Bowman et al., 2015)) are prone to have artifacts and annotation biases which can be exploited by supervised algorithms that learn to pick up these artifacts as signal instead of more meaningful semantic features. We estimate artifacts by training the QANet model described in Section 5.2 on a version of DROP where either the question or the paragraph input representation vectors are zeroed out (**question-only** and **paragraph-only**, respectively). Consequently, the resulting models can then only predict answer spans from either the question or the paragraph.

In addition, we devise a baseline that estimates the answer variance in DROP. We start by counting the unigram and bigram answer frequency for each wh question-word in the train set (as the first word in the question). The **majority baseline** then predicts an answer as the set of 3 most common answer spans for the input question word (e.g., for "when", these were "quarter", "end" and "October").

6 NAQANet

DROP is designed to encourage models that combine neural reading comprehension with symbolic reasoning. None of the baselines we described in Section 5 can do this. As a preliminary attempt toward this goal, we propose a numerically-aware QANet model, NAQANet, which allows the state-of-the-art reading comprehension system to produce three new answer types: (1) spans from the question; (2) counts; (3) addition or subtraction over numbers. To predict numbers, the model first predicts whether the answer is a count or an arithmetic expression. It then predicts the specific numbers involved in the expression. This can be viewed as the neural model producing a *partially executed* logical form, leaving the final arithmetic to a symbolic system. While this model can currently only handle a very limited set of operations, we believe this is a promising approach to combining neural methods and symbolic reasoning. The model is trained by marginalizing over all execution paths that lead to the correct answer.

6.1 Model Description

Our NAQANet model follows the typical architecture of previous reading comprehension models, which is composed of embedding, encoding, passage-question attention, and output layers. We use the original QANet architecture for everything up to the output layer. This gives us a question representation $\mathbf{Q} \in \mathbb{R}^{m\times d}$, and a projected question-aware passage representation $\bar{\mathbf{P}} \in \mathbb{R}^{n\times d}$. We have four different output layers, for the four different kinds of answers the model can produce:

Passage span As in the original QANet model, to predict an answer in the passage we apply three repetitions of the QANet encoder to the passage representation $\bar{\mathbf{P}}$ and get their outputs as $\mathbf{M}_0$, $\mathbf{M}_1$, $\mathbf{M}_2$ respectively. Then the probabilities of the starting and ending positions from the passage can be computed as:

$$\mathbf{p}^{\text{p\_start}} = \text{softmax}(\text{FFN}([\mathbf{M}_0; \mathbf{M}_1]), \quad (1)$$

$$\mathbf{p}^{\text{p\_end}} = \text{softmax}(\text{FFN}([\mathbf{M}_0; \mathbf{M}_2]) \quad (2)$$

where FFN is a two-layer feed-forward network with the RELU activation.

Question span Some questions in DROP have their answer in the *question* instead of the passage. To predict an answer from the question, the model first computes a vector $\mathbf{h}^P$ that represents the information it finds in the passage:

$$\boldsymbol{\alpha}^P = \text{softmax}(\mathbf{W}^P \bar{\mathbf{P}}), \quad (3)$$

$$\mathbf{h}^P = \boldsymbol{\alpha}^P \bar{\mathbf{P}} \quad (4)$$

Then it computes the probabilities of the starting and ending positions from the question as:

$$\mathbf{p}^{\text{q\_start}} = \text{softmax}(\text{FFN}([\mathbf{Q}; \mathbf{e}^{|Q|} \otimes \mathbf{h}^P]), \quad (5)$$

$$\mathbf{p}^{\text{q\_end}} = \text{softmax}(\text{FFN}([\mathbf{Q}; \mathbf{e}^{|Q|} \otimes \mathbf{h}^P]) \quad (6)$$

where the outer product with the identity $(\mathbf{e}^{|Q|} \otimes \cdot)$ simply repeats $\mathbf{h}^P$ for each question word.

Count We model the capability of counting as a multi-class classification problem. Specifically, we consider ten numbers (0–9) in this preliminary model and the probabilities of choosing these numbers is computed based on the passage vector $\mathbf{h}^P$:

$$\mathbf{p}^{\text{count}} = \text{softmax}(\text{FFN}(\mathbf{h}^P)) \quad (7)$$

Arithmetic expression Many questions in DROP require the model to locate multiple numbers in the passage and add or subtract them to get the final answer. To model this process, we first extract all the numbers from the passage and then learn to assign a plus, minus or zero for each number. In this way, we get an arithmetic expression composed of signed numbers, which can be evaluated to give the final answer.

To do this, we first apply another QANet encoder to $\mathbf{M}_2$ and get a new passage representation $\mathbf{M}_3$. Then we select an index over the concatenation of $\mathbf{M}_0$ and $\mathbf{M}_3$, to get a representation for each number in this passage. The i^{th} number can be represented as $\mathbf{h}_i^N$ and the probabilities of this number being assigned a plus, minus or zero are:

$$\mathbf{p}_i^{\text{sign}} = \text{softmax}(\text{FFN}(\mathbf{h}_i^N)) \tag{8}$$

Answer type prediction We use a categorical variable to decide between the above four answer types, with probabilities computed as:

$$\mathbf{p}^{\text{type}} = \text{softmax}(\text{FFN}([\mathbf{h}^P, \mathbf{h}^Q])) \tag{9}$$

where $\mathbf{h}^Q$ is computed over $\mathbf{Q}$, in a similar way as we did for $\mathbf{h}^P$. At test time, we first determine this answer type greedily and then get the best answer from the selected type.

6.2 Weakly-Supervised Training

For supervision, DROP contains only the answer string, not which of the above answer types is used to arrive at the answer. To train our model, we adopt the weakly supervised training method widely used in the semantic parsing literature (Berant et al., 2013a). We find all executions that evaluate to the correct answer, including matching passage spans and question spans, correct count numbers, as well as sign assignments for numbers. Our training objective is then to maximize the marginal likelihood of these executions.[11]

7 Results and Discussion

The performance of all tested models on the DROP dataset is presented in Table 4. Most notably, all models perform significantly worse than on other prominent reading comprehension datasets, while human performance remains at similar high levels.[12] For example, BERT, the current state-of-the-art on SQuAD, *drops* by more than 50 absolute F1 points. This is a positive indication that DROP is indeed a challenging reading comprehension dataset, which opens the door for tackling new and complex reasoning problems on a large scale.

Method	**Dev**		**Test**

Table 4: Performance of the different models on our development and test set, in terms of Exact Match (EM), and numerically-focused F_1 (§5). Both metrics are calculated as the maximum against a set of gold answers.

The best performance is obtained by our NAQANet model. Table 6 shows that our gains are obtained on the challenging and frequent number answer type, which requires various complex types of reasoning. Future work may also try combining our model with BERT. Furthermore, we find that all heuristic baselines do poorly on our data, hopefully attesting to relatively small biases in DROP.

Difficulties of building semantic parsers We see that all the semantic parsing baselines perform quite poorly on DROP. This is mainly because of our pipeline of extracting tabular information from paragraphs, followed by the denotation-driven logical form search, can yield logical forms only for a subset of the training data. For SRL and syntactic dependency sentence representation schemes,

---

[11] Due to the exponential search space and the possible noise, we only search the addition/subtraction of two numbers. Given this limited search space, the search and marginalization are exact.

[12] Human performance was estimated by the authors collectively answering 560 questions from the test set, which were then evaluated using the same metric as learned systems. This is in contrast to holding out one gold annotation and evaluating it against the other annotations, as done in prior work, which underestimates human performance relative to systems.

Phenomenon	Passage Highlights	Question	Answer	Our model
Subtraction + Coreference	… Twenty-five of his 150 men were sick, and his advance stalled …	How many of Bartolom de Amsqueta's 150 men were not sick?	125	145
Count + Filter	… Macedonians were the largest ethnic group in Skopje, with 338,358 inhabitants … Then came … Serbs (14,298 inhabitants), Turks (8,595), Bosniaks (7,585) and Vlachs (2,557) …	How many ethnicities had less than 10000 people?	3	2
Domain knowledge	… Smith was sidelined by a torn pectoral muscle suffered during practice …	How many quarters did Smith play?	0	2
Addition	… culminating in the Battle of Vienna of 1683, which marked the start of the 15-year-long Great Turkish War …	What year did the Great Turkish War end?	1698	1668

Table 5: Representative examples from our model's error analysis. We list the identified semantic phenomenon, the relevant passage highlights, a gold question-answer pair, and the erroneous prediction by our model.

the search was able to yield logical forms for 34% of the training data, whereas with OpenIE, it was only 25%. On closer examination of a sample of 60 questions and the information extracted by the SRL scheme (the best performing of the three), we found that only 25% of the resulting tables contained information needed to the answer the questions. These observations show that high quality information extraction is a strong prerequisite for building semantic parsers for DROP. Additionally, the fact that this is a weakly supervised semantic parsing problem also makes training hard. The biggest challenge in this setup is the spuriousness of logical forms used for training, where the logical form evaluates to the correct denotation but does not actually reflect the semantics of the question. This makes it hard for the model trained on these spurious logical forms to generalize to unseen data. From the set of logical forms for a sample of 60 questions analyzed, we found that only 8 questions (13%) contained non-spurious logical forms.

Error Analysis Finally, in order to better understand the outstanding challenges in DROP, we conducted an error analysis on a random sample of 100 erroneous NAQANet predictions. The most common errors were on questions which required complex type of reasoning, such as arithmetic operations (evident in 51% of the errors), counting (30%), domain knowledge and common sense (23%), co-reference (6%), or a combination of different types of reasoning (40%). See Table 5 for examples of some of the common phenomena.

Type	(%)	Exact Match		F1	
		QN+	BERT	QN+	BERT
Date	1.57	28.7	38.7	35.5	42.8
Numbers	61.94	44.0	14.5	44.2	14.8

8 Conclusion

We have presented DROP, a dataset of complex reading comprehension questions that require **D**iscrete **R**easoning **O**ver **P**aragraphs. This dataset is substantially more challenging than existing datasets, with the best baseline achieving only 32.7% F1, while humans achieve 96%. We hope this dataset will spur research into more comprehensive analysis of paragraphs, and into methods that combine distributed representations with symbolic reasoning. We have additionally presented initial work in this direction, with a model that augments QANet with limited numerical reasoning capability, achieving 47% F1 on DROP.

Acknowledgments

We would like to thank Noah Smith, Yoav Goldberg, and Jonathan Berant for insightful discussions that informed the direction of this work. The computations on `beaker.org` were supported in part by credits from Google Cloud.

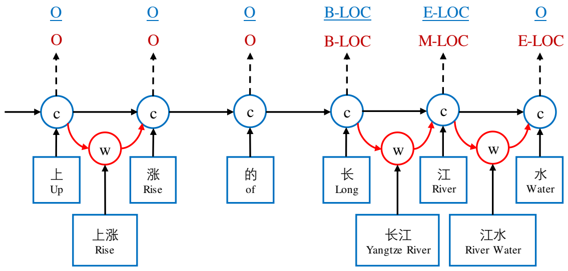
Abstract

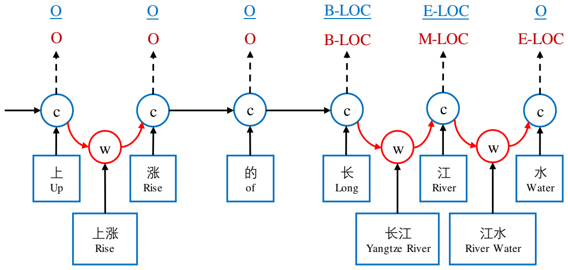
A recently proposed lattice model has demonstrated that words in character sequence can provide rich word boundary information for character-based Chinese NER model. In this model, word information is integrated into a shortcut path between the start and the end characters of the word. However, the existence of shortcut path may cause the model to degenerate into a partial word-based model, which will suffer from word segmentation errors. Furthermore, the lattice model can not be trained in batches due to its DAG structure. In this paper, we propose a novel word-character LSTM(WC-LSTM) model to add word information into the start or the end character of the word, alleviating the influence of word segmentation errors while obtaining the word boundary information. Four different strategies are explored in our model to encode word information into a fixed-sized representation for efficient batch training. Experiments on benchmark datasets show that our proposed model outperforms other state-of-the-arts models.

1 Introduction

Name Entity Recognition(NER) is a basic task of many NLP systems including Information Retrieval (Virga and Khudanpur, 2003), Relationship Extraction (Miwa and Bansal, 2016), Question Answering (Mollá et al., 2006). The main task of NER is to identify named entities such as person, location, organization, etc. in given text. Various methods have been proposed to tackle this problem, including Hidden Markov Models(HMMs) (Saito and Nagata, 2003), Maximum Entropy Models(ME) (Chieu and Ng, 2003), Support Vector Machines(SVM) (Ekbal and Bandyopadhyay, 2010) and Conditional Random Fields(CRF) (Feng et al., 2006). With the development of deep learning, neural networks (Huang et al., 2015; Lample et al., 2016; Habibi et al., 2017) have been introduced to NER task. To avoid the segmentation errors, most of neural Chinese NER models are character-based.



(a) Original lattice model



(b) Degraded lattice model in extreme cases

Figure 1: An example of the lattice model degenerates into a partial word-based model. Due to the shortcut path ”江(River)” → ”江水(River Water)” → ”水(Water)”, the model incorrectly predicts that ”江(River)” and ”水(Water)” belong to the same entity. Red labels(without underline) denote predicted labels, and blue labels(with underline) denote gold labels.

Although character-based method has achieved good performance, it does not exploit word information in character sequence. Entity boundaries usually coincide with some word boundaries, which suggests that words in character sequence can provide rich boundary information for character-based model. To integrate words information into character-based model, Zhang and Yang (2018) propose a lattice-structured LSTM

Proceedings of NAACL-HLT 2019, pages 2379–2389
Minneapolis, Minnesota, June 2 - June 7, 2019.

model to encode a sequence of input characters as well as all potential words that match a lexicon. Their model is an extension of character-based LSTM-CRF model and uses extra "shortcut paths" to link the memory cell between the start and the end characters of a word for utilizing word information. And the gated recurrent unit is used to control the contribution of shortcut paths and path between adjacent characters. However, as the study of (Yang et al., 2018) shown, the gate mechanism fails to choose the right path sometimes. As shown in Figure 1, wrong choices may cause lattice model to degenerate into a partial word-based model, which suffers from word segmentation errors. In addition, due to the variable length of words, the length of the whole path is not fixed. Besides, each character is bounded with a variable-sized candidate word sets, which means the amount of incoming and outcoming paths is not fixed either. In this case, lattice LSTM model is deprived of the power of batch training, and hence it is highly inefficient.

To address the above problems, we propose a novel word-character LSTM(WC-LSTM) to integrate word information into character-based model. To prevent our model from degenerating into a partial word-based model, we assign word information to a single character and ensure that there are no shortcut paths between characters. Specifically, word information is assigned to its end character and start character in forward WC-LSTM and backward WC-LSTM respectively. We introduce four strategies to extract fixed-sized useful information from different words, which ensures that our proposed model can perform batch training without losing word information.

We demonstrate the effectiveness of our architecture on four widely used datasets. Experimental results show that our proposed model outperforms other state-of-the-art models on the four datasets.

Our contributions of this paper can be concluded as follows:

- We propose a novel word-character LSTM(WC-LSTM) to incorporate word information into character-based model.

- We explore four different strategies to encode word information into a fixed-sized vector, which enables our proposed model to be trained in batches and adapted to various application scenarios.

- Our proposed model outperforms other models and achieves new state-of-the-art over four Chinese NER datasets. We release the source code for further research[1].

2 Related Work

Neural Networks have been shown to achieve impressive results on Name Entity Recognition task (Gregoric et al., 2018; Lin and Lu, 2018). Based on the level of granularity, most of the models can be divided into three categories: word-based models, character-based models, and hybrid models.

Word-Based Models. Collobert and Weston (2008) propose one of the first word-based models for NER, with feature constructed from orthographic features, dictionaries and lexicons (Yadav and Bethard, 2018). Collobert et al. (2011) replace the hand-crafted features with word embeddings. Huang et al. (2015) propose a BiLSTM-CRF model for NER and achieves good performance. Ma and Hovy (2016) and Chiu and Nichols (2016) use CNN to capture spelling characteristics and Lample et al. (2016) use LSTM instead. When applied to Chinese NER, the above models all suffer from segmentation errors, since Chinese word segmentation is compulsory for those models.

Character-Based Models. Peng and Dredze (2015) propose to add segmentation features for better recognition of entity boundary. Dong et al. (2016) integrate radical-level features into character-based model. To eliminate the ambiguity of character, Sun and He (2017) take the position of character into account. Although the above models have achieved good results, they all ignore word information in character sequence.

Hybrid Models. Some efforts have been made to integrate word boundary information into character-based models. Motivated by the success of multi-task learning for Natural Language Processing (Liu et al., 2016, 2017; Zhang et al., 2018), Peng and Dredze (2016) first proposed to jointly train Chinese NER with Chinese word segmentation(CWS) task. Cao et al. (2018) apply adversarial transfer learning framework to integrate the task-shared word boundary information into Chinese NER task. Another way to obtain word boundary information is proposed by (Zhang and Yang, 2018), using a lattice LSTM to integrate word information into character-based model, which is similar to what is proposed in

---

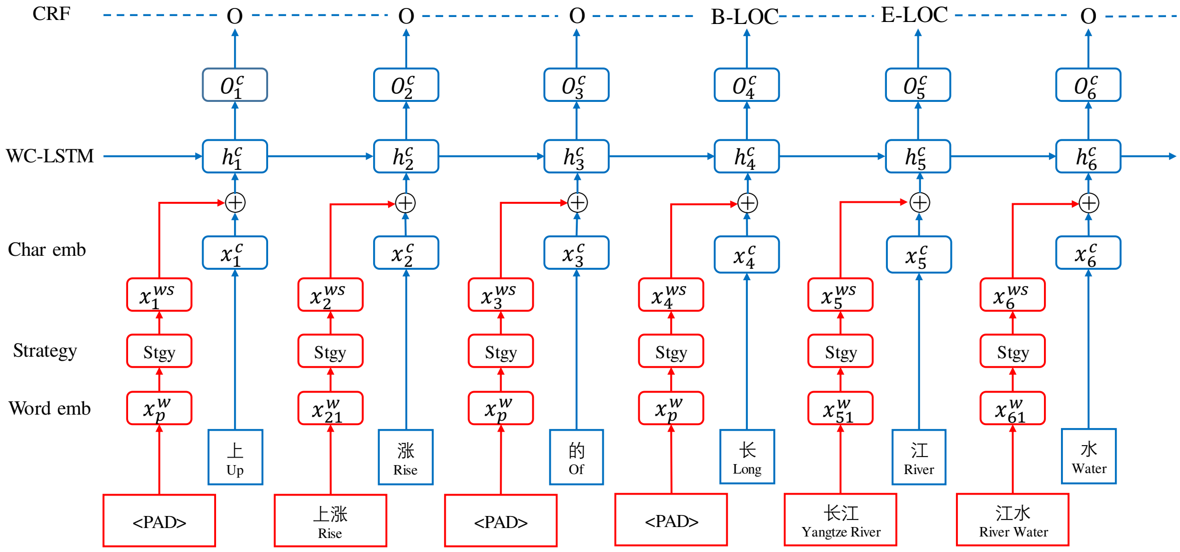

Figure 2: The architecture of our unidirectional model. The blue part can be seen as a standard character-based model but with a word-character LSTM(WC-LSTM), and the red part indicates the process of encoding word information into a fixed-size representation. Word information is integrated into the end character of the word. Where "<PAD>" denotes padding value; "Stgy" denotes a certain encoding strategy and ⊕ denotes concatenation operation.

this paper. The main differences are as follows. Firstly, they exploit word information by a DAG-structured LSTM, while we use a chain-structured LSTM. Secondly, instead of integrating to the hidden state of LSTM, our model add word information into the input vector. Finally, our model can be trained in batches and is more efficient.

3 Method

The architecture of our proposed model is shown in Figure 2. Same as the widely used neural Chinese NER model, we use LSTM-CRF as our main network structure. The differences between our model and a standard LSTM-CRF model are mainly on the embedding layer and LSTM and can be summarized as follows. First, we represent a Chinese sentence as a sequence of character-words pairs to integrate word information into each character. Second, to enable our model to train in batches and to meet different application requirements, we introduce four encoding strategies to extract fixed-sized but different information from words. Finally, a chain-structured word-character LSTM is used to extract features from both character and word for better predicting.

Next, we will explain the main ideas for each component, including word-character embedding layer, word encoding strategy, and word-character LSTM.

Formally, we denote a Chinese sentence as $\mathbf{s} = \{c_1, c_2, ..., c_n\}$, where c_i denotes the i_{th} character. We use $c_{b,e}$ to denote a character subsequence in $\mathbf{s}$, which begins with b_{th} character and ends with e_{th} character. Take the sentence in Figure 2 for example, $c_{1,2}$ is "上涨(Rise)". We use $\overrightarrow{ws_i}$ to denote words assigned to i_{th} character in forward WC-LSTM, which are a set of character subsequences $c_{b,i}$, where $b < i$ and $c_{b,i}$ matches a word in lexicon $\mathbf{D}$. The lexicon $\mathbf{D}$ is the same as the one used in (Zhang and Yang, 2018), which is built by using automatically segmented large raw text. Similarly, we use $\overleftarrow{ws_i}$ to denote the words for i_{th} character in backward WC-LSTM, which are a set of character subsequences $c_{i,e}$, where $e > i$ and $c_{i,e}$ matches a word in lexicon $\mathbf{D}$. Finally, the sentence $\mathbf{s}$ is represented as $\overrightarrow{\mathbf{rs}} = \{(c_1, \overrightarrow{ws_1}), (c_2, \overrightarrow{ws_2}), ..., (c_n, \overrightarrow{ws_n})\}$ in our model, and its reverse representation is $\overleftarrow{\mathbf{rs}} = \{(c_n, \overleftarrow{ws_n}), (c_{n-1}, \overleftarrow{ws_{n-1}}), ..., (c_1, \overleftarrow{ws_1})\}$.

3.1 Word-Character Embedding Layer

In our model, Each position i in $\overrightarrow{\mathbf{rs}}$ consists of two parts: i_{th} character c_i and the assigned words $\overrightarrow{ws_i}$. The origin number of words in $\overrightarrow{ws_i}$ is s_i^t, and words are sorted by their length. We ensure each $\overrightarrow{ws_i}$ has the same number s_i^p [2] in the whole batch by padding. We embed each character c_i in dis-

---

[2] The number depends on the maximum s_i^t in the whole batch, and it can not be less than 1.

tributional space as $\mathbf{x}_i^c$:

$$\mathbf{x}_i^c = \mathbf{e}^c(c_i) \tag{1}$$

where $\mathbf{e}^c$ denotes a pre-trained character embedding lookup table. Similarly, for each $\overrightarrow{ws_i} = \{\overrightarrow{w_{i1}}, ..., \overrightarrow{w_{is_i^p}}\}$, the l_{th} word $\overrightarrow{w_{il}}$ in $\overrightarrow{ws_i}$ is represented using

$$\mathbf{x}_{il}^{\overrightarrow{w}} = \mathbf{e}^w(\overrightarrow{w_{il}}) \tag{2}$$

where $\mathbf{e}^w$ denotes a pre-trained word embedding lookup table. As a result, the distributional representation of words $\overrightarrow{ws_i}$ is $\{\mathbf{x}_{i1}^{\overrightarrow{w}}, ..., \mathbf{x}_{is_i^p}^{\overrightarrow{w}}\}$.

3.2 Words Encoding Strategy

Although the number of assigned words s_i^p for each character c_i is same in one batch, the number varies from batch to batch. As a result, the size of input to the model is not fixed, which is not conducive to batch training. To acquire fixed-sized input, we introduce four different encoding strategies in this section. And we use $\mathbf{x}_i^{\overrightarrow{ws}}$ to denote the final representation of word information for position i in following sections.

Shortest Word First: For each word set $\overrightarrow{ws_i} = \{\overrightarrow{w_{i1}}, ..., \overrightarrow{w_{is_i^p}}\}$, we simply select word whose length is the shortest, i.e. $\overrightarrow{w_{i1}}$. Then

$$\mathbf{x}_i^{\overrightarrow{ws}} = \mathbf{x}_{i1}^{\overrightarrow{w}} \tag{3}$$

Longest Word First: Contrary to the shortest word first, we select word whose length is the longest, i.e. $\overrightarrow{w_{is_i^t}}$. Note that s_i^t may be 0, in this case, we set it to 1. Then

$$\mathbf{x}_i^{\overrightarrow{ws}} = \mathbf{x}_{is_i^t}^{\overrightarrow{w}} \tag{4}$$

Average: While the first two strategies can only use the information of partial words, we introduce an average strategy to utilize all word information. As its name indicates, the average strategy computes the centroid of the embeddings of all elements except paddings in word set , i.e. $\{\overrightarrow{w_{i1}}, ..., \overrightarrow{w_{is_i^t}}\}$. If $s_i^t = 0$, we simply average all the padding value in the word set. Then

$$\mathbf{x}_i^{\overrightarrow{ws}} = \begin{cases} \frac{1}{s_i^t}\sum_{l=1}^{s_i^t} \mathbf{x}_{il}^{\overrightarrow{w}}, & \text{if } s_i^t > 0 \\ \frac{1}{s_i^p}\sum_{l=1}^{s_i^p} \mathbf{x}_{il}^{\overrightarrow{w}}, & \text{if } s_i^t = 0 \end{cases} \tag{5}$$

Self-Attention: Inspired by self-attention mechanism applied to sentence embedding (Lin et al., 2017), we exploit self-attention to better capture useful information from assigned words. For simplicity, we denote all the $\mathbf{x}_{il}^{\overrightarrow{w}}$ as W_i, which has the size s_i^p-by-d^w, where d^w denotes the dimensionality of word embedding $\mathbf{e}^w$.

$$W_i = (\mathbf{x}_{i1}^{\overrightarrow{w}}, ..., \mathbf{x}_{is_i^p}^{\overrightarrow{w}}) \tag{6}$$

We use self-attention mechanism to obtain a linear combination of s_i^p word embeddings in W_i. The attention mechanism takes W_i as input, and generates a weight vector $\mathbf{a}_i$.

$$\mathbf{a}_i = softmax(\mathbf{w}_2 tanh(W_1 W_i^T)) \tag{7}$$

W_1 is a weight matrix with the size of d_a-by-d^w and $\mathbf{w}_2$ is a d_a dimensional vector, where d_a is a hyperparameter. Both of them are trainable parameters.

If $s_i^t > 0$, we use the mask to exclude the padding values; otherwise we reserve them. Finally, we use $\mathbf{a}_i$ to get the weighted sum of all words.

$$\mathbf{x}_i^{\overrightarrow{ws}} = \begin{cases} \sum_{l=1}^{s_i^t} a_{il}\mathbf{x}_{il}^{\overrightarrow{w}}, & \text{if } s_i^t > 0 \\ \sum_{l=1}^{s_i^p} a_{il}\mathbf{x}_{il}^{\overrightarrow{w}}, & \text{if } s_i^t = 0 \end{cases} \tag{8}$$

where a_{il} denotes the l_{th} value in $\mathbf{a}_i$.

3.3 Word-Character LSTM(WC-LSTM)

Inspired by the way character bigram is integrated into sequence labeling model (Chen et al., 2015; Yang et al., 2017), we concatenate each $\mathbf{x}_i^c$ with $\mathbf{x}_i^{\overrightarrow{ws}}$ to utilize word information. And this is quite different from the way used in (Zhang and Yang, 2018), since they use extra shortcut paths to integrate word information into the hidden layer of LSTM. By concatenating, there is no shortcut path in our model and information can only flow between adjacent characters, which ensures that our model will not degenerate into a partial word-based model. Then the WC-LSTM functions are:

$$\begin{bmatrix} \tilde{\mathbf{c}}_i \\ \mathbf{o}_i \\ \mathbf{i}_i \\ \mathbf{f}_i \end{bmatrix} = \begin{bmatrix} tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} \left(\mathbf{W}_p \begin{bmatrix} \mathbf{x}_i \\ \mathbf{h}_{i-1} \end{bmatrix} + \mathbf{b}_p \right) \tag{9}$$

$$\begin{aligned} \mathbf{x}_i &= \mathbf{x}_i^c \oplus \mathbf{x}_i^{\overrightarrow{ws}} \\ \mathbf{c}_i &= \tilde{\mathbf{c}_i} \odot \mathbf{i}_i + \mathbf{c}_{i-1} \odot \mathbf{f}_i \\ \mathbf{h}_i &= \mathbf{o}_i \odot tanh(\mathbf{c}_i) \end{aligned} \tag{10}$$

where $\mathbf{o}_i$, $\mathbf{i}_i$ and $\mathbf{f}_i$ denote output gate, input gate and forget gate respectively. $\mathbf{W}_p$ and $\mathbf{b}_p$ are parameters of affine transformation; σ denotes the logistic sigmoid function; $\oplus$ denotes concatenation operation and $\odot$ denotes elementwise multiplication.

The bidirectional WC-LSTM is applied in our model to leverage both information from the past and the future. To get the future information, we use a second WC-LSTM that reads the reverse representation of $\overrightarrow{\mathbf{rs}}$, i.e., $\overleftarrow{\mathbf{rs}} = \{(c_n, \overleftarrow{ws_n}), (c_{n-1}, \overleftarrow{ws_{n-1}}), ..., (c_1, \overleftarrow{ws_1})\}$. And the following operations to get each backward WC-LSTM hidden vector $\overleftarrow{\mathbf{h}_i}$ is the same as the one in the forward WC-LSTM. Finally, the update of each bidirectional WC-LSTM unit can be written as follows:

$$\begin{aligned}
\overrightarrow{\mathbf{x}_i} &= \mathbf{x}_i^c \oplus \mathbf{x}_i^{\overrightarrow{ws}} \\
\overleftarrow{\mathbf{x}_i} &= \mathbf{x}_i^c \oplus \mathbf{x}_i^{\overleftarrow{ws}} \\
\overrightarrow{\mathbf{h}_i} &= \overrightarrow{\mathrm{WC-LSTM}}(\overrightarrow{\mathbf{h}_{i-1}}, \overrightarrow{\mathbf{x}_i}) \\
\overleftarrow{\mathbf{h}_i} &= \overleftarrow{\mathrm{WC-LSTM}}(\overleftarrow{\mathbf{h}_{i+1}}, \overleftarrow{\mathbf{x}_i}) \\
\mathbf{h}_i &= \overrightarrow{\mathbf{h}_i} \oplus \overleftarrow{\mathbf{h}_i}
\end{aligned} \tag{11}$$

where $\overrightarrow{\mathbf{h}_i}$ and $\overleftarrow{\mathbf{h}_i}$ are hidden states at position i of forward and backward WC-LSTM respectively, and $\oplus$ denotes concatenation operation.

3.4 Decoding and Training

Considering the dependencies between successive labels, we use a CRF layer to make sequence tagging. We define matrix $\mathbf{O}$ to be scores calculated based on the output $\mathbf{H} = \{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n\}$:

$$\mathbf{O} = \mathbf{W}_o\mathbf{H} + \mathbf{b}_o \tag{12}$$

For a label sequence $\mathbf{y} = \{y_1, y_2, ..., y_n\}$, we define its probability to be:

$$p(\mathbf{y}|\mathbf{s}) = \frac{exp\left(\sum_i \left(\mathbf{O}_{i,y_i} + \mathbf{T}_{y_{i-1},y_i}\right)\right)}{\sum_{\tilde{\mathbf{y}}} exp\left(\sum_i \left(\mathbf{O}_{i,\tilde{y}_i} + \mathbf{T}_{\tilde{y}_{i-1},\tilde{y}_i}\right)\right)} \tag{13}$$

Where $\mathbf{W_o}$ and $\mathbf{b_o}$ are paramters to calculate $\mathbf{O}$; $\mathbf{T}$ is a transition score matrix and $\tilde{\mathbf{y}}$ denotes all possible tag sequences.

While decoding, we use the Viterbi algorithm to find the label sequences that obtained the highest score:

$$\mathbf{y}^* = arg \max_{\mathbf{y} \in \tilde{\mathbf{y}}} \sum_i \left(\mathbf{O}_{i,y_i} + \mathbf{T}_{y_{i-1},y_i}\right) \tag{14}$$

Given N manually labeled data $\{(\mathbf{s}_j, \mathbf{y}_j)\}|_{j=1}^N$, we minimize the sentence-level negative log-likelihood loss to train the model:

$$L = -\sum_j log(p(\mathbf{y}_j|\mathbf{s}_j)) \tag{15}$$

Dataset	Train sent	Dev sent	Test sent
OntoNotes	15724	4301	4346
MSRA	46364	-	4365
Weibo NER	1350	270	270
Chinese resume	3821	463	477

Table 1: Statistics of the datasets

4 Experiments

4.1 Experimental Settings

Dataset. We evaluate our model on four datasets, including OntoNotes4 (Weischedel et al., 2011), MSRA (Levow, 2006), Weibo NER (Peng and Dredze, 2015) and a Chinese resume dataset (Zhang and Yang, 2018). Both OntoNotes4 and MSRA datasets are news in simplified Chinese. Weibo NER dataset is social media data, which is drawn from the Sina Weibo. Chinese resume dataset consists of resumes of senior executives, which is annotated by (Zhang and Yang, 2018). For OntoNotes, we use the same training, development and test splits as (Che et al., 2013). For other datasets which have already been split, and we don't change them. We summarize the datasets in Table 1.

Implementation Details. We utilize the character and word embeddings used in (Zhang and Yang, 2018), both of which are pre-trained on Chinese Giga-Word using word2vec model. Following (Zhang and Yang, 2018), we use the word embedding dictionary as Lexicon $\mathbf{D}$ in our model. For characters and words that do not appear in the pretrained embeddings, we initialize them with a uniform distribution[3]. When training the model, character embeddings and word embeddings are updated along with other parameters.

For hyper-parameter configurations, we mostly refer to the settings in (Zhang and Yang, 2018). We set both character embedding size and word embedding size to 50. The dimensionality of each unidirectional multi-input LSTM hidden states is 100 for Weibo NER and Chinese Resume, and 200 for OntoNote 4 and MSRA. For self-attention strategy, we set the d_a to 50. To avoid overfitting, we apply dropout to both embeddings and LSTM with a rate of 0.5. We use SGD to optimize all the trainable parameters. Learning rate is set to 0.015 initially and decays during training at a rate

---

[3] The range is $\left[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}\right]$, where dim demotes the size of embedding.

of 0.05.

For evaluation, we use the Precision(P), Recall(R) and F1 score as metrics in our experiments.

4.2 Experimental Results

OntoNotes. Table 2 shows the experimental results on OntoNote 4 dataset. The ”Input” column shows the representation of input sentence, where ”Gold seg” means a sequence of words with gold-standard segmentation, and ”No seg” means a sequence of character without any segmentation.

The first block in Table 2 are the results of word-based models (Wang et al., 2013; Che et al., 2013; Yang et al., 2016). By using gold-standard segmentation and external labeled data, all of them achieve good performance. But the only resource used in our model are pretrained character and word embeddings.

The first two rows in the second block show the performance of the lattice model and character-based model. The character baseline denotes the original character-based BiLSTM-CRF model. Zhang and Yang (2018) propose a lattice LSTM to exploit word information in character sequence, giving the F1 score of 73.88%. Compared with the character baseline, lattice model gains 8.92% improvement in F1 score, which shows the importance of word information in character sequence.

In the last four rows, we list the results of our proposed model. The results show that all of our models outperform other character-based models, and the one with self-attention strategy achieves the best result. Without gold-standard segmentation and external labeled data, our model gives competitive results to the word-based models on this dataset. Compared with the character baseline, our model with self-attention obtains 9.48% improvement in F1 score, which proves the effectiveness of our way to integrating word information. Compared with lattice model, all of our models achieve better results, which shows that our approach to integrating word information is more reasonable than lattice model.

Models	P	R	F1
Zhang et al. (2006)	92.20	90.18	91.18
Zhou et al. (2013)	91.86	88.75	90.28
Dong et al. (2016)	91.28	90.62	90.95
Cao et al. (2018)	91.73	89.58	90.64
Lattice (Zhang and Yang, 2018)	93.57	92.79	93.18
Character baseline	89.61	86.98	88.37
WC-LSTM + shortest	93.97	92.59	**93.28**
WC-LSTM + longest	94.33	**93.11**	**93.71**
WC-LSTM + average	**94.58**	92.91	**93.74**
WC-LSTM + self-attention	94.36	92.38	**93.36**

Models	NE	NM	Overall
Peng and Dredze (2015)	51.96	61.05	56.05
Peng and Dredze (2016)	**55.28**	62.97	58.99
Sun and He (2017)	54.50	62.17	58.23
He and Sun (2017)	50.60	59.32	54.82
Cao et al. (2018)	54.34	57.35	58.70
Lattice (Zhang and Yang, 2018)	53.04	62.25	58.79
Character baseline	47.98	57.94	52.88
WC-LSTM + shortest	52.99	65.75	**59.20**
WC-LSTM + longest	52.55	**67.41**	**59.84**
WC-LSTM + average	**53.19**	64.17	58.67
WC-LSTM + self-attention	49.86	65.31	57.51

Table 4: Results on Weibo NER

MSRA. Table 3 shows the results on MSRA dataset. Zhang et al. (2006) and Zhou et al. (2013) use the statistical model with rich hand-crafted features. Dong et al. (2016) exploit radical features in Chinese character. Cao et al. (2018) joint train Chinese NER task with Chinese word segmentation, in which adversarial learning and self-attention mechanism are applied for better performance. We can observe that our proposed models outperformance the above models and the one with average strategy achieves new state-of-the-art performance.

Weibo. Table 4 shows the results[4] on Weibo dataset. The ”NE”, ”NM” and ”Overall” columns denote F1-score for named entities, nominal entities(excluding named entities) and both respectively. We can see that WC-LSTM model with longest word first strategy achieves new state-of-the-art performance. Multi-task learning (Peng and Dredze, 2015, 2016; Cao et al., 2018) and semi-supervised learning (Sun and He, 2017; He and Sun, 2017) are the most common methods

---

[4] The results of (Peng and Dredze, 2015, 2016) are taken from (Peng and Dredze, 2017)

Models	**P**	**R**	**F1**
Lattice (Zhang and Yang, 2018)	94.81	94.11	94.46

Table 5: Results on Chinese Resume

	Time(s)/epoch
Character baseline (*batch_size*=1)	880
Character baseline (*batch_size*=8)	253
Lattice	2245
WC-LSTM (*batch_size*=1)	980
WC-LSTM (*batch_size*=8)	350

Table 6: Time per epoch of models

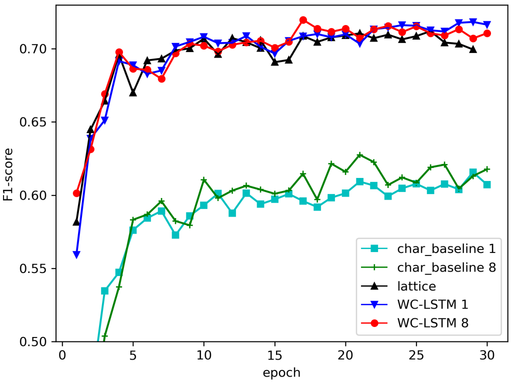

Figure 3: Convergence curve of models. Our model can converge within the same epochs as lattice model does. ”1” and ”8” denotes batch_size. Lattice model can only be trained with batch_size=1 due to its DAG structure.

for Weibo NER task due to the small amount of training data. All of the above models require additional cross-domain or semi-supervised data. Compared with those models, our model does not need additional labeled data; we only exploit pre-trained character and word embeddings.

Resume. Table 5 shows the results on Chinese Resume dataset. Consistent with the previous results, our models outperform lattice model (Zhang and Yang, 2018). The above experimental results strongly verify that our method to utilize word information is more effective than the lattice model.

Our proposed model has achieved state-of-the-art results on **various domains** such as news, social media, and Chinese resume.

4.3 Efficiency

To further explore the efficiency of our model, we conduct some comparative experiments on training time and convergence speed. The lattice model proposed in (Zhang and Yang, 2018) is our principal comparison object, since it also utilizes the word information in character sequence. Our model is an extension of the character-based model, so we also report the results on character-based model as character baseline. We only conduct our experiments on OnteNotes dataset due to space limitation. And we choose the model with the self-attention strategy for the comparative experiments, as it outperforms other strategies on OntoNotes dataset.

The training time of each epoch for all models is shown in Table 6. The lattice model needs the most training time for each epoch, since it can only be trained with batch_size=1 due to its complex DAG structure. Compared with it, our model with batch_size=1 only need half of the training time. Which shows that our model is more efficient. With batch_size=8, our model is nearly 6 times faster than the lattice model, which further demonstrates the efficiency of our model. Compared with the character baseline, our model only adds a small amount of training time but greatly improves the performance. All the experiments are conducted on a single GPU with NVIDIA Tesla K40m.

Figure 3 shows the learning curve of the models in Table 6. As we can see from the figure, whether with batch_size=1 or 8, our model can converge within the same epochs as lattice model does. But compared with the lattice model, our model with batch_size=8 only takes about 1/7 of their training time per epoch. Besides, we can observe from Figure 3, both our model and lattice model significantly outperform the character baseline, which shows the importance of the word information again.

4.4 Detailed Analysis

Case Study. Word information is very useful for Chinese NER task, since it can provide rich word boundary information. To verify that our model can better utilize the boundary information, we analyze an example from OntoNotes dataset. As shown in Table 7, the character-based model cannot detect the existence of the entity ”东北亚(Northeast Asia)” without word information. The lattice model incorrectly recognizes ”东北亚

Sentence (truncated)	新的 New		东北亚 Northeast Asian			大陆桥 Continental Bridge		
Latent words	东北, 东北亚, 北亚, 亚大, 亚大陆, 大陆, 大陆桥, 陆桥 Northest, Northeast Asia, North Asia, Second largest, Subcontinent, Continent, Continental bridge, Land bridge							
Gold labels	新 O	的 O	东 B-LOC	北 M-LOC	亚 E-LOC	大 O	陆 O	桥 O
Character	新 O	的 O	东 O	北 O	亚 O	大 O	陆 O	桥 O
Lattice	新 O	的 O	东 B-LOC	北 M-LOC	亚 M-LOC	大 M-LOC	陆 M-LOC	桥 E-LOC
Shortest	新 O	的 O	东 B-LOC	北 M-LOC	亚 E-LOC	大 O	陆 O	桥 O
Longest	新 O	的 O	东 B-LOC	北 M-LOC	亚 E-LOC	大 O	陆 O	桥 O
Average	新 O	的 O	东 B-LOC	北 M-LOC	亚 E-LOC	大 O	陆 O	桥 O
Self-attention	新 O	的 O	东 B-LOC	北 M-LOC	亚 E-LOC	大 O	陆 O	桥 O

Table 7: An example of that our models can mitigate the influence of wrong boundary information while utilizing word information. ”Latent words” denotes all words in character sequences; ”Character” denotes the character-based model; ”Lattice” denotes lattice model and the last four rows are our models with different encoding strategies.

大陆桥(Northeast Asian Continental Bridge)” as an entity, which is caused by the wrong selection of paths. Different from the lattice model, our models are not disturbed by the wrong boundary information and make the correct predictions.

Strategies Analysis. In this part, we analyze the difference between strategies. The application scenarios of shortest word first and longest word first can be explained by Nested Name Entity Recognition (Ju et al., 2018; Sohrab and Miwa, 2018). Short word first is good at identifying inner nested entities due to the short word information, while longest word first tends to identify flat entities with the help of long word information. Taking ”长江三角洲(Yangtze River Delta)” as an example, shortest word first recognizes ”长江(Yangtze)” and ”三角洲(Delta)” as entities, but longest word first tend to think that they are part of the entity ”长江三角洲(Yangtze River Delta)”. Both results are reasonable, but the right result depends on specific needs.

The average and self-attention strategies are the combination of all words information and can use more information. Intuitively, they should outperform the shortest word first and the longest word first. But results on Weibo NER(Table 4) and Resume(Table 5) show the opposite effect. We conjecture that this is caused by the small amount of training data since more word information but small dataset will lead to overfitting. The average strategy is a special case of the self-attention strategy where all weights are the same, so we would like to see the latter outperforms the former when training data is sufficient. Surprisingly, the average strategy achieves higher F1 score than the self-attention strategy in MSRA dataset(Table 3). We carefully analyze the experimental results and find that there are a large number of informal texts in the MSRA test set. Specifically, the MSRA test set contains some very long sentences, in which there are a series of Chinese person name without delimiter. As shown in Table 8, when applied to such informal text, the self-attention strategy fails to determine the entity boundary sometimes while the average strategy correctly recognizes the entities. And we conjecture that, with more trainable parameters, the self-attention strategy can better fit the formal text in the training set but cannot adapt well to the informal data in the test set, so it performs worse than the average strategy.

Sentence (truncated)	房维中经叔平 Fang Weizhong and Jing Shuping					
Latent words	房维, 中经, 经叔平, 经叔, 叔平 Fang Wei, Zhongjing, Jing Shuping, Jingshu, Shuping					
Gold labels	房 B-PER	维 M-PER	中 E-PER	经 B-PER	叔 M-PER	平 E-PER
Average	房 B-PER	维 M-PER	中 E-PER	经 B-PER	叔 M-PER	平 E-PER
Self-attention	房 B-PER	维 M-PER	中 M-PER	经 E-PER	叔 B-PER	平 E-PER

Table 8: An example of our model applied to informal text using the average strategy and self-attention strategy. ”Latent words” denotes all words in character sequences.

Finally, the application scenarios of different strategies can be summarized as followings. If the training data is sufficient, we recommend using self-attention for formal texts and average strategy for informal texts. If there is only a very small amount of annotated data, we recommend using the shortest words first for inner nested entities and longest word first strategy for flat entities.

Lexicon and Embeddings. To further analyze the contribution from word lexicon and pretrained word embeddings, we conduct some comparative experiments by using the same word lexicon with and without pretrained embeddings. We choose the strategy that achieving the best performance for each dataset. We estimate the contribution of the lexicon by replacing pretrained word embeddings with randomly initialized embeddings[5]. As shown in Table 9, both lexicon

---

[5] Same initialization strategy as in ”Implement Details”.

	OntoNotes	**Resume**	**MSRA**	**Weibo**
Character baseline	64.95	93.35	88.37	52.88
WC-LSTM + init	67.81(+2.86)	94.51(+1.16)	90.68(+2.31)	54.94(+2.06)
WC-LSTM + pretrain	74.43(+9.48)	95.21(+1.86)	93.74(+5.37)	59.84(+6.96)

Table 9: Comparison F1 scores between our proposed model with and without pretrained word embeddings. Where ”init” and ”pretrain” denote without and with pretrained embeddings respectively. ”+” denotes the boost value to baseline.

and pretrained word embeddings are useful to our model. However, different from the result in lattice model(Yang et al., 2018), pretrained word embeddings contribute more than lexicon to our model. Taking the result on Ontonote for example, the contribution of pretrained embeddings can be estimated as $(9.48\% - 2.86\%) = 6.62\%$, which is higher than the contribution of lexicon 2.86%. The results show that our model relies more on pretrained embeddings instead of the lexicon, which explains the excellent performance of our model in different domains.

5 Conclusion and Future Work

In this paper, we propose a novel method to utilize word information in character sequence for Chinese NER. Four encoding strategies are introduced to extract fixed-sized but different information for batch training. By using WC-LSTM to extract features from the character vector and word vector, our model can effectively exploit word boundary information and mitigate the influence of word segmentation errors. Experiments on datasets in different domains show that our model is more efficient and faster than the lattice model and also outperforms other state-of-the-art models.

In the future, we plan to further improve and perfect the proposed method, such as exploring some strategies to handle OOV words. Also, the proposed methods can be further extended to other Chinese NLP tasks, such as CWS, Text Classification, and Sentiment Analysis.

Acknowledgments

The research work is supported by the No. BHKX-17-07 project of Hefei Innovation Research Institute, Beihang University. We would like to thank Jie Yang for his open-source toolkit ”NCRF++” (Yang and Zhang, 2018). Moreover, we sincerely thank all anonymous reviewers for their valuable comments.

Abstract

Arabic text is typically written without short vowels (or diacritics). However, their presence is required for properly verbalizing Arabic and is hence essential for applications such as text to speech. There are two types of diacritics, namely core-word diacritics and case-endings. Most previous works on automatic Arabic diacritic recovery rely on a large number of manually engineered features, particularly for case-endings. In this work, we present a unified character level sequence-to-sequence deep learning model that recovers both types of diacritics without the use of explicit feature engineering. Specifically, we employ a standard neural machine translation setup on overlapping windows of words (broken down into characters), and then we use voting to select the most likely diacritized form of a word. The proposed model outperforms all previous state-of-the-art systems. Our best settings achieve a word error rate (WER) of 4.49% compared to the state-of-the-art of 12.25% on a standard dataset.

1 Introduction

Arabic uses two types of vowels, namely long vowels, which are explicitly placed in the text, and short vowels, which are diacritic marks that are typically omitted during writing. In order to read Arabic words properly, readers need to reintroduce the missing diacritics. Therefore, accurate diacritic recovery is essential for some applications such as text-to-speech. There are, in turn, two types of Arabic diacritics, namely core-word diacritics (CW), which specify lexical selection, and case endings (CE), which typically indicate syntactic role. For example, the word “AlElm”[1] can accept many possible core-word diacritics depending on the intended meaning such as: “AaloEalam” (the flag) and “AaloEilom” (the knowledge/science). In our training corpus, 17.1% of the word-cores have more than one valid diacritized form. In the sentence “Zahara AaloEalam**u**” (the flag appeared), “AaloEalam**u**” is the subject and takes the case ending “**u**”, and in the sentence “ra>ayotu AaloEalam**a**” (I saw the flag), “AaloEalam**a**” is the object and takes the case ending “**a**”. Aside from function words, past tense and accusative verb forms, and foreign names, most words can accept different case-endings depending on context.

In this paper, we introduce a unified model for both diacritic types while improving upon the state-of-the-art. Specifically, we approached the task as a sequence-to-sequence (seq2seq) problem (Cho et al., 2014); taking advantage of the recent advancements in Neural Machine Translation (NMT) (Britz et al., 2017; Kuchaiev et al., 2018) among other applications where seq2seq models made a breakthrough (Yu et al., 2016; Witten et al., 2016; Abadi et al., 2016). Using the analogy of translation which employs a sequential encoder and a sequential decoder, the input undiacritized text will be encoded and then decoded into diacritized form.

As we show later, directly applying a seq2seq model at sentence level using word or character representations produces nearly unusable results that are much worse than the state-of-the-art due to word insertions, omissions, and substitutions. Such problems are exaggerated when using word-based models due to Out-Of-Vocabulary words (OOVs). Conversely, character-based models suffer from not learning long-term dependencies. To avoid these problems, we train a seq2seq model on a sliding window of words that are represented using characters, and we employ voting to pick the best most likely diacritized form from different windows. In doing so, we provide suffi-

Proceedings of NAACL-HLT 2019, pages 2390–2395
Minneapolis, Minnesota, June 2 - June 7, 2019.

cient context to properly guess proper diacritized forms, while stinting the aforementioned undesirable word operations. Further, the use of voting has the effect of picking the most frequent diacritized form obtained from applying the model on different contexts. The resultant system makes full use of NMT machinery to achieve error rates that are 63.3% lower than the best state-of-the-art system[2].

The contributions in this paper are:

- Adaptation of neural machine translation for Arabic diacritic recovery with voting.
- Unified model to handle both core-diacritics and case-endings.
- Substantial improvement over state-of-the-art with 4.49% word error rate compared to 12.25%.

2 Background

One of the first approaches to Arabic diacritization used a Hidden Markov Model (Gal, 2002; Elshafei et al., 2006) that was applied to the Qur'an achieving double digit word error rates (WER). Vergyri and Kirchhoff (2004) used acoustic features in conjunction with morphological and contextual constrains to train a diacritizer and reported a 9% and 28% diacritics error rate (DER) without and with CEs. Since words are composed of multiple letters with corresponding diacritics, DER values are typically lower than WER values. Nelken and Shieber (2005) used a cascade of word-level, character-level, and morphological models finite state transducers to attain a Word Error Rate (WER) of 7.33% without CE and and 23.61% WER with CE. Zitouni et al. (2006) trained a maximum entropy model for sequence classification using the LDCs Arabic Treebank (ATB) and attained a WER of 18% (with CE) on 600 articles from An-Nahar Newspaper.

Habash and Rambow (2005); Rashwan et al. (2011); Bebah et al. (2014); Pasha et al. (2014); Metwally et al. (2016); Darwish et al. (2017) combined morphological features along with POS tagging information and n-gram language models. MADA-D system (Habash and Rambow, 2007) achieved a 5.5% and 14.9% WER respectively without and with CE. MADAMIRA (Pasha et al., 2014) ranks a list of candidate analyses from the Buckwalter analyzer (Buckwalter, 2004) using an SVM classifier and achieves 19.0% and 6.7% WER with and without CE respectively. Similarly, Microsoft Arabic Toolkit Services (ATKS) diacritizer (Said et al., 2013) uses a rule-based morphological analyzer that produces possible analyses and an HMM in conjunction with rules to guess the most likely analysis. They report WER of 11.4% and 4.4% with and without CE. Darwish et al. (2017) used a Viterbi decoder to guess core word diacritics and SVM-rank to guess case-endings and their system achieves a WER of 3.29% and 12.77% for words without and with CE. They trained their system using a large corpus of roughly 4.5 million words.

More recent work employed different neural architectures to model the diacritization problem. Abandah et al. (2015) used a biLSTM-based recurrent neural network trained on the same dataset as (Zitouni et al., 2006), and they report a WER of 9.1% including CE on ATB. Similar architectures were explored but with lower results (Rashwan et al., 2015; Belinkov and Glass, 2015). Azmi and Almajed (2015); Osama Hamed (2017) survey recent work on Arabic diacritization. They concluded that: reported results are often incomparable due to the usage of different test sets; a large unigram LM for CW diacritic recovery is competitive with many of the systems in the literature. In this paper, we compare our results to those of Said et al. (2013); Pasha et al. (2014); Rashwan et al. (2015); Belinkov and Glass (2015); Darwish et al. (2017) on standard test set.

3 Methodology

Representation Unit. The diacritization of Arabic is a word-internal property dependent on both character and word-level contexts. Therefore, we consider characters as units of representation. We represent source sentences as a sequence of characters by adding a space after every character and a word boundary "_" between words. The target side, which is fully diacritized, is split into a sequence of subword units each consisting of a letter and its diacritic(s). For example, source word "AlElm" would be represented as "A/l/E/l/m" and its diacritized target "AaloEalamu" as "Aa/lo/Ea/la/mu".

The character-level representation has several benefits, such as reducing the vocabulary size and avoiding OOV words. The splitting of diacritized

---

[2] Patent pending.

words into subword units simplifies the problem as there will be identical number of source and target tokens in a parallel sentence. Later, we support our design decisions with results in the experiments section. Subwords (BPE (Sennrich et al., 2016)) have been used as a defacto standard in building NMT systems. They are a natural choice to handle unknown words. However, BPE does not fit in our scenario as it may create source and target segments of different lengths. In the Arabic diacritization problem, both source and target words and characters are strictly tied to each other and loosening it would result in sub-optimal performance and may generate unexpected errors.

Context Window. The diacritization of Arabic words is highly sensitive to context. Character representations significantly increase the size of the source and target sequences. This leads to a well known limitation of character-based LSTM-based models, namely poor handling of long range dependencies (Sennrich, 2017). An easy fix is to split sentences greater than a certain length into multiple lines. However, boundary words may loose context in the newly created sequences. To handle this, we propose to keep a fixed size context window c for every word. Given a sentence, we use a sliding context window to split it into segments of overlapping windows of size c as in Table 1. This fixes the problems of both long range dependencies and context of neighboring words. We are further aided by the fact that local context can conclusively determine the correct diacritization in the vast majority of cases.

Voting. As shown in Table 1, the sliding window approach replicates a word present in a sentence c times. At test time, a word may get different diacritized forms from different contexts. We use voting to choose the most frequent diacritized form from the c predictions. In case of a tie, we favor the context where the word appears in the middle.

Sentence	w_1	w_2	w_3	w_4	w_5
c=3	w_1	w_2	w_3		
		w_2	w_3	w_4	
			w_3	w_4	w_5

Table 1: Example sentence: w_1 w_2 w_3 w_4 w_5 with context window c of size 3.

	Train		Test		
	Total	Uniq	Total	Uniq	OOV
Diacritized	4.5M	333k	18.3k	7.9k	5.0%
Undiacritized		209k		6.8k	3.3%

Table 2: Number of tokens in training and test data.

Seq2Seq Model. We use a seq2seq model consisting of three main components: i) Encoder, ii) Decoder, and iii) Attention. Given a source sentence $s = w_1, ..., w_N$ and a target sentence $t = v_1, ..., v_N$, the encoder models the source sentence and computes a set of hidden states $h = h_1, ..., h_N$. The attention mechanism (Bahdanau et al., 2014) computes a weighted average of these hidden states from the previous decoder state, known as the context vector c_i, while decoder models the target sentence. The seq2seq model is trained jointly on a large parallel corpus by maximizing the log-likelihood of the data:

$$log\ p(t|s) = \sum_{i} \sum_{j=1}^{|t^i|} log\ p(v_j^i | v_1^i, ..., v_{j-1}^i, s^i) \tag{1}$$

where s^i and t^i are the i^{th} source and target sentences. In addition, we experiment with a Transformer model (Vaswani et al., 2017), which is an attention based architecture without LSTM, and compare its results to the aforementioned seq2seq model with attention.

4 Experimental Setup and Results

Data. We used a modern diacritized corpus of 4.5 million tokens that covers a wide range of topics such as politics, religion, sport, health, and economics. For testing, we used the freely available WikiNews corpus (18,300 words) (Darwish et al., 2017) as a test set, which covers a variety of genres. Table 2 reports the size of the training and test sets including the unique diacritized and undiacritized tokens and the percentage of OOVs in the test set that don't appear in the training set. We randomly used 10% of the train data for validation and the rest for training. We used a sequence length of 100, 500 and 7 tokens for word-, character-, and window-based systems respectively. The vocabulary is restricted to 100k words types and 1,000 character units.

System Settings. The settings for LSTM-based Seq2Seq model were: word embeddings and LSTM states = 512; 2 layer unidirectional LSTM;

Exp	Description	Core WER%	CE WER%	WER%	DER%	OOV%
01	Baseline Word	44.29	54.95	54.31	41.62	13.03
02	Baseline Char	41.29	41.95	48.31	36.62	0.00
03	Word 7g	14.83	19.01	20.69	18.92	11.04
04	Char 7g	2.78	6.11	8.32	2.19	0.00
05	Word 7g+overlap	14.50	16.57	18.05	18.14	10.97
06	Char 7g+overlap	2.04	3.23	4.94	1.34	0.00
07	Char 3g+overlap+voting	2.31	5.97	7.79	2.01	0.00
08	Char 5g+overlap+voting	2.37	3.57	5.49	1.49	0.00

10	Char 11g+overlap+voting	3.03	3.93	6.40	1.78	0.00
†11	Char 7g+overlap+voting (Transformer)	2.05	3.04	4.77	1.29	0.00
12	Combination *09 +† 11	**1.89**	**2.89**	**4.49**	**1.21**	0.00

Table 3: Diacritization results: *g represents ngram size e.g. 7g means 7-gram context. Experiment 09 and 11 are comparing NMT models – LSTM-based architecture with attention mechanism and Transformer model

and dropout rate = 0.3. The setting for the Transformer were: 6 encoder and 6 decoder layers each of size 512; number of attention heads = 8; feed forward dimension = 2048; and dropout = 0.1. We used the OpenNMT (Klein et al., 2017) implementation with tensorflow for all experiments.

System Runs. We conducted a variety of experiments as follows, namely: **Word-level experiments** where the input is a sequence of words and the output is a sequence of diacritized words:
– Baseline Word: uses the full sentences and shows the deficiency of using NMT directly.
– Word 7g: uses non-overlapping windows of 7 words to compare to our best character-level model, which also uses a window of length 7.
– Word 7g+overlap: uses a sliding window of 7 words.
Character-level experiments where the input is represented as a sequence of character and the output as a sequence of diacritized characters:
– Baseline Char: uses the full sentence.
– Char 7g: uses non-overlapping sequences of 7 words.
– Char 7g+overlap: uses a sliding window of 7 words without voting.
– Char ng-overlap+voting: uses a sliding window of n words with voting, where we varied n to equal 3, 5, 7, and 11. When $n = 7$, we experimented with a seq2seq model with attention, a Transformer model, and a combination of both.

Results. Table 3 summarizes the results of our experiments. As the results clearly show, using an NMT model at word or character level produced unusable results. Both Baselines suffer also from excessive repetition of characters that are often meaningless hallucination (e.g. "AalofaA}iti AaloHaAdiy waAlt∼awaAliy Aaloayoiy AloanohaAti AaloanohaAti"). When we limited the context to 7 words, the results improved dramatically, nonetheless, the output still suffered from a high ratio of OOVs. Using characters instead alleviated the OOV problem. The results improved dramatically with contexts of length 7 yielding the best results. Using voting lowered WER rate further, leading to a 4.77% WER. Using a Transformer model led to nearly identical WER to using our NMT model with attention. However their results are somewhat complimentary. Thus, voting on the predictions across both systems improved the results further with a 4.49% WER. Table 4 compares our best system with other systems. The WER of our best system is 63.3% lower than the state-of-the-art.

Setup	WER%
Our System	**04.49**
Microsoft ATKS (Said et al., 2013)	12.25
Farasa (Darwish et al., 2017)	12.76
RDI (Rashwan et al., 2015)	15.95
MADAMIRA (Pasha et al., 2014)	19.02
MIT (Belinkov and Glass, 2015)	30.50

Table 4: Comparison to other systems for full diacritization (Darwish et al., 2017).

Error Analysis. we randomly selected 100 errors word-core and 100 case-ending errors we ascertain the most common error types. For case-ending, the top 4 error types were: long-distance dependency (e.g. coordination or verb subj/obj), which is an artifact of using limited context – 24%

of errors; confusion between different syntactic functions (e.g. N N vs. N ADJ or V Subj vs. V Obj) – 22%; wrong selection of morphological analysis (e.g. present tense vs. past tense) – 20%; and named entities (NEs) – 16%. For long distance dependencies, increasing context size may help in some case, but may introduce additional errors (see Table 3). Perhaps combining multiple context sizes may help. As for word-core, the top 4 errors were: incorrect selection for ambiguous words, where most of these errors were related to active vs. passive voice – 60%; NEs – 32%; borrowed words – 4%; and words with multiple valid diacritized words – 4%.

5 Conclusion

In this paper, we adapted a seq2seq model to build a unified model for Arabic diacritic recovery. We trained the model on a fixed length sliding window of n words that are represented using their characters. We further employed voting to pick the most common diacritized form of a word in different contexts. The adaptation yielded a word error rate of 4.49%, which is 63.3% lower than the best state-of-the-art system. One possible future direction is to use a system combination with varying context sizes with a weighted voting scheme. Further, the explicit inclusion of a large gazetteer of diacritized NEs in the training set would help diacritize them properly. We also want to examine the effect of training data size to determine if more data would yield better results.

Abstract

Multi-task learning (MTL) has been studied recently for sequence labeling. Typically, auxiliary tasks are selected specifically in order to improve the performance of a target task. Jointly learning multiple tasks in a way that benefit all of them simultaneously can increase the utility of MTL. In order to do so, we propose a new LSTM cell which contains both shared parameters that can learn from all tasks, and task-specific parameters that can learn task specific information. We name it a Shared-Cell Long-Short Term Memory (SC-LSTM). Experimental results on three sequence labeling benchmarks (named-entity recognition, text chunking, and part-of-speech tagging) demonstrate the effectiveness of our SC-LSTM cell.

1 Introduction

As one of the fundamental tasks in NLP, sequence labeling has been studied for years. Before the blooming of neural network methods, handcrafted features were widely used in traditional approaches like CRFs, HMMs, and maximum entropy classifiers (Lafferty et al., 2001; McCallum et al., 2000; McCallum and Li, 2003; Florian et al., 2003). However, applying them to different tasks or domains is hard. Recently, instead of using handcrafted features, end-to-end neural network based systems have been developed for sequence labeling tasks, such as LSTM-CNN (Chiu and Nichols, 2015), LSTM-CRF (Huang et al., 2015; Lample et al., 2016), and LSTM-CNN-CRF (Ma and Hovy, 2016). These models utilize LSTM to encode the global information of a sentence into a word-level representation of its tokens, which avoids manual feature engineering. Moreover, by incorporating a character-level representation of tokens, these models further improve.

In many such studies, though, neural network models are trained toward a single task in a supervised way by making use of relatively small annotated training material. Jointly learning multiple tasks can reduce the risk of over-fitting to one task, and many attempts have been made at doing so for sequence labeling tasks (Caruana, 1997; Collobert and Weston, 2008; Collobert et al., 2011). Results so far are not conclusive.

Some works have reported negative results overall. For instance in their pioneering work, Collobert et al. (2011) observed that training their model on NER, POS tagging and chunking altogether led to slight decrease in performance compared to a similar model trained on each task separately. Søgaard and Goldberg (2016) study chunking and CCG super tagging, coupled with an additional POS tagging task. They do report gains on both target tasks over single task models, but results varied depending where the additional task was taken care of in their architecture. The authors actually reported a failure to leverage other labelling tasks, and concluded that combined tasks should be sufficiently similar to the target one, for significant gains to be observed. Similarly, Alonso and Plank (2017) achieved significant improvements for only 1 out of 5 tasks considered. Also of interest is the work of (Changpinyo et al., 2018) where the authors investigate the classical shared encoder-based MTL framework (Collobert et al., 2011; Collobert and Weston, 2008) on 11 sequence labeling datasets including POS, NER, and chunking. They report that chunking is beneficial to NER, while POS tagging can be harmful.

We present in Section 2 the two major approaches proposed for multi-task learning and discuss their limitations. We describe our approach in Section 3, and present our experimental settings and results in Section 4 and 5 respectively. We further analyze our approach in Section 6, discuss

related works in Section 7 and conclude in Section 8.

2 Multi-task Learning

2.1 Problem Statement

We are given a set of K tasks (in our case named-entity recognition, text chunking and part of speech tagging) that we want to train jointly in an end-to-end fashion. Each task k has an associated training set $S_k = \{(x_i^k, y_i^k)_{i \in [1,n_k]}\}$ of n_k examples, where x_i^k and y_i^k are sequences of size m_i of tokens and tags respectively. We wish to learn a single function $\mathcal{F}$ which maps any token input sequence x_i to its task-specific labels, where the mapping defines a probabilistic distribution for each involved task: $p(y_i^1, \ldots, y_i^K) = \mathcal{F}(x_i)$.

2.2 Existing Shared Encoder Methods

There are two kinds of neural-based MTL methods. The first one — LSTM-s hereafter — uses an identical representation for all tasks, as proposed in (Collobert et al., 2011). This is illustrated in Figure 1 (left), where 3 layers of LSTMs are being stacked.[1] While different tasks directly interact with all parameters of the model, this increases the risk of optimization conflicts when gold-standard labels from different tasks have no significant correlation.

The second class of multi-task architectures is depicted in the middle part of Figure 1, and is named LSTM-d hereafter. In this configuration, each LSTM layer feeds a task-specific classifier and serves as input to the next stacked LSTM layer (Søgaard and Goldberg, 2016). The underlying assumption is that tasks may be ordered in such a way that easier tasks are learned first, the target tasks being the latest one considered, thus benefiting the hidden state of the lower layers. One drawback, however, is that one must decide which task to consider first, a decision which may impact the overall performance. Furthermore, using the hidden state of lower layers increases the limitation of learning representation for that task.

We believe that one reason for the lack of consistent benefits of MTL in the labelling literature is that the proposed models share all or part of parameters for extracting hidden states, which leads to optimization conflicts when different tasks require different features. We believe it would be helpful if we make the model have ability to learn a task-specific representation (Ammar et al., 2016; Östling and Tiedemann, 2016; Kiperwasser and Ballesteros, 2018) at the same time. This observation led us to design a new LSTM cell which allows at almost no additional computation cost to efficiently train a single RNN-based model, where task-specific labelers clearly outperform their singly-tasked counterparts. Actually, by training our model on NER, chunking and POS tagging, we report state-of-the-art (or highly competitive) results on each task, without using external knowledge (such as gazetteers that has been shown to be important for NER), or hand-picking tasks to combine.

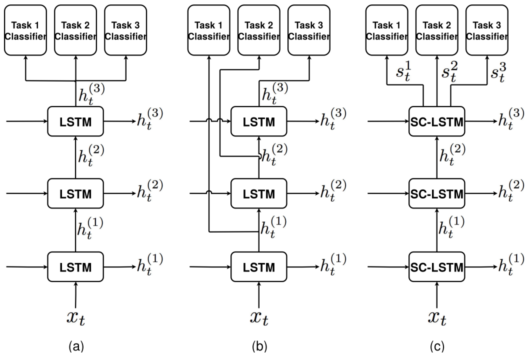

Figure 1: Overview of three shared encoder MTL tagging system: (a) LSTM-s (b) LSTM-d (c) our SC-LSTM based system.

3 Proposed Method

Our solution is depicted in the right part of Figure 1 and detailed in the next section. It is actually very similar to the LSTM-s one, except that each LSTM layer passes on task-specific hidden representations that learn the peculiarities of individual tasks. In the last layer, each classifier is fed with a concatenation of a global representation (as in LSTM-s) and the task-specific one. By doing so, we keep the advantages of both aforementioned approaches, where one task can have its task-specific representation as in LSTM-d, while not enforcing any task order, further giving the freedom to the model to learn specificities of each task. For this architecture to work, we need to modify the classical LSTM cell, which is described in the next section.

---

[1] This typically delivers better performance than having just one. In practice also, LSTM layers are replaced by bi-LSTM ones.

3.1 LSTM Cell

An LSTM cell (Hochreiter and Schmidhuber, 1997) is made up of four functional gates which control the input and output of the memory state $\mathbf{c_t}$: a forget gate $\mathbf{f_t}$ controls what information to remove from the memory state of the last time step, an input gate $\mathbf{i_t}$ controls the information to add to the current memory, and an output gate $\mathbf{o_t}$ controls what information to release from the current memory state. This mechanism is formalized in Equation 1 where $\mathbf{x}_t$, $\mathbf{h}_t$ is the input vector and hidden vector at time step t, σ is the sigmoid function, $\hat{\mathbf{c}}$ is the new candidate state, $\mathbf{c}_t$ is the memory state, which encodes information of the current input and history information, and $*$ indicates the element-wise product. $\mathbf{W}_f, \mathbf{U}_f, \mathbf{W}_i, \mathbf{U}_i, \mathbf{W}_o, \mathbf{U}_o, \mathbf{W}_c, \mathbf{U}_c$ are weight matrices that are being learned.

$$
\begin{aligned}
\mathbf{f}_t &= \sigma(\mathbf{W}_f \mathbf{h}_{t-1} + \mathbf{U}_f \mathbf{x}_t), \\
\mathbf{i}_t &= \sigma(\mathbf{W}_i \mathbf{h}_{t-1} + \mathbf{U}_i \mathbf{x}_t), \\
\mathbf{o}_t &= \sigma(\mathbf{W}_o \mathbf{h}_{t-1} + \mathbf{U}_o \mathbf{x}_t), \\
\hat{\mathbf{c}} &= \tanh(\mathbf{W}_c \mathbf{h}_{t-1} + \mathbf{U}_c \mathbf{x}_t), \\
\mathbf{c}_t &= \mathbf{i}_t * \hat{\mathbf{c}} + \mathbf{f}_t * \mathbf{c}_{t-1}, \\
\mathbf{h}_t &= \mathbf{o}_t * \tanh(\mathbf{c}_t),
\end{aligned}
\tag{1}
$$

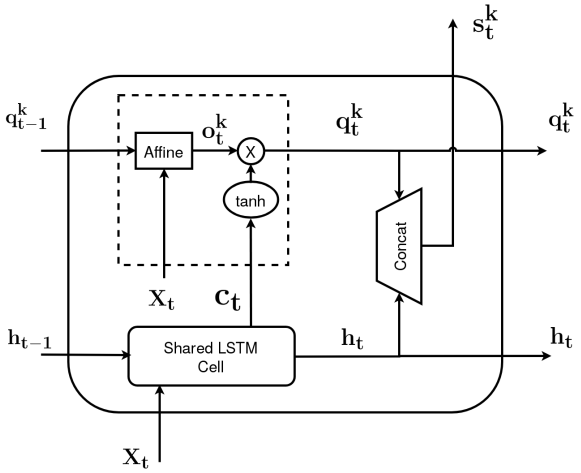

Figure 2: Structure of an SC-LSTM cell. The dashed delimited box depicts the task-specific cell. For clarity reasons, we only show one such cell, while in practice there is one task-specific cell for each task.

3.2 SC-LSTM Cell

The overall structure of our cell is depicted in Figure 2. On top of a standard LSTM cell, we add one cell per task with its own parameters. The standard LSTM cell is thus shared among the K task-specific cells, therefore the name we choose for this new cell, which stands for Shared-Cell LSTM. Task-specific cells are each parametrized by an output gate $\mathbf{o}_t^k$ which learns to select the useful information from the shared memory cell $\mathbf{c}_t$ and outputs $\mathbf{q}_t^k$. This is formally described in Equation 2, where $\mathbf{W}_k$ and $\mathbf{U}_k$ are two extra weight matrices that parametrize the kth task, and $\mathbf{q}_t^k$ has to be understood as a task-specific hidden representation since parameters of kth task-specific cell are only updated by supervision from task k.

$$
\begin{aligned}
\mathbf{o}_t^k &= \sigma(\mathbf{W}_k \mathbf{q}_{t-1}^k + \mathbf{U}_k \mathbf{x}_t^k) \\
\mathbf{q}_t^k &= \mathbf{o}_t^k * \tanh(\mathbf{c}_t)
\end{aligned}
\tag{2}
$$

In order to make use of both shared and task-specific information (Kim et al., 2016; Peng et al., 2017; Hershcovich et al., 2018), for the kth task, we concatenate the output of the shared cell $\mathbf{h}_t$ and of the task-specific one $\mathbf{q}_t^k$ to generate the final latent representation, as noted in Equation 3, where $\oplus$ is the concatenation operation. In practice, we stack SC-LSTM layers. The top-most layer uses $\mathbf{s}_t^k$ as a representation of the current input, while cells in lower layers pass the current shared hidden state $\mathbf{h}_t$ to the upper SC-LSTM cell. The use of s in the topmost layer only is arbitrary and should be investigated.

$$
\mathbf{s}_t^k = \mathbf{q}_t^k \oplus \mathbf{h}_t \tag{3}
$$

3.3 Training procedure

The training material available may be gathered from different datasets S_k which means that input sequences differ from one task to another. Therefore in practice, we build K dataloaders, and the training is achieved in a stochastic manner by looping over the tasks at each epoch, as detailed in Algorithm 1.

The loss function ϵ we minimize is a linear combination of task-specific loss functions, where the weighting coefficients (λ^k in Equation 4) are hyper-parameters.

$$
\epsilon = \sum_{k=1}^{K} \lambda^k L(\mathbf{y}^k, \hat{\mathbf{y}}^k) \tag{4}
$$

Algorithm 1 Stochastic training procedure

```
1: procedure TRAINING
2:     for each epoch do
3:         Randomly choose a task $k$.
4:         Randomly choose a training example not yet considered in the dataset $S_k$
5:         Update the parameters for this task by taking a gradient step based on this example.
6:         Go to step 3 until using all examples.
```

We seek to minimize cross-entropy of the predicted and true distributions, therefore task-specific loss functions are defined according to Equation 5.

$$L(\mathbf{y}^k, \hat{\mathbf{y}}^k) = -\sum_{i=1}^{n_k} \sum_{j=1}^{m_i} \mathbf{y}_{i,j}^k \log \hat{\mathbf{y}}_{i,j}^k \qquad (5)$$

where $\hat{\mathbf{y}}_{i,j}^k$ is the prediction of the kth softmax classifier parametrized by a projection matrix $\mathbf{W}^k$ and a bias vector $\mathbf{b}^k$:

$$\hat{\mathbf{y}}_{i,j}^k = softmax(\mathbf{W}^k \mathbf{s}_{\mathbf{i,j}}^{\mathbf{k}} + \mathbf{b}^k) \qquad (6)$$

where $\mathbf{s}_{\mathbf{i,j}}^{\mathbf{k}}$ stands for jth token of the ith sequence for task k. In an SC-LSTM cell with k tasks, we will add k matrices and k bias vectors, compared with a vanilla LSTM cell, which increases the capacity of the resulting model. This extra calculation is conducted in parallel with the original LSTM computations.

4 Experimental Setting

4.1 Benchmarks

We test several baseline systems and our SC-LSTM model on three well-established sequence labeling benchmarks: CoNLL2003 (Tjong Kim Sang and De Meulder, 2003) for named-entity recognition, CoNLL2000 (Tjong Kim Sang and Buchholz, 2000) for chunking, and the more recent Universal Dependency dataset (Nivre et al., 2016) for part-of-speech tagging,[2] and on which recent MTL investigations have been conducted (Alonso and Plank, 2017; Changpinyo et al., 2018).

We conformed to the pre-defined splits into train/dev/test except for chunking that does not contain a validation set. For this dataset, following recent works (Peters et al., 2017; Liu et al., 2017), sections 15-18 of the Wall Street Journal are used for training, and we randomly sampled 1000 sentences in the training set as the development set. Section 20 is used for tests. Table 1 presents the main characteristics of the training, development and test sets we used.

	Train	Dev	Test
NER			**#tags** = 4
#sentences	14,987	3,644	3,486
#tokens	205k	52k	47k
#entities	23,523	5,943	5,654
Chunking			**#tags** = 10
#sentencies	8,936	-	2,012
#tokens	212k	-	47k
#chunks	107k	-	24k
POS			**#tags** = 17
#sentences	12,543	2,002	2,077
#tokens	204k	25k	25

Table 1: Main characteristics of the datasets used.

4.2 Architectural Choices

We used bidirectional LSTM or SC-LSTM as our encoders for the vector representation of words. Bidirectional LSTM can capture global information of the whole sentence, thanks to the encoding of a sequence in a recurrent way. The vector representation of words consists of three parts: word embedding, character-level representation and contextual representation:

- previous works have proven that pre-trained word embeddings like Word2vec (Mikolov et al., 2013), SENNA (Collobert et al., 2011), or Glove (Pennington et al., 2014) have a positive impact on sequence labeling tasks. We used Glove embeddings[3] of dimension 100, that are fine-tuned during training;

- character-level information has been proven useful for three sequence labeling tasks (Santos and Zadrozny, 2014; Ma and Hovy, 2016; Lample et al., 2016) and Some works further show its effectiveness (Reimers and Gurevych, 2017; Yang et al., 2018). In order to encode character sequences, we used a CNN. The character embedding look-up table is initialized by randomly sampling from

---

[2] We used UD English POS v1.3.

[3] The embedding file `glove6B` are available `https://nlp.stanford.edu/projects/glove/`

the uniform distribution in the range [-0.1, 0.1];

- the third part of the input vector is contextual embedding. Most of the recent works found that contextualized features such as ELMo or BERT (Peters et al., 2018; Devlin et al., 2018) can greatly boost performance. We incorporate ELMo into our input vector by using the ELMo implementation of Gardner et al. (2018).

Conditional random field (CRF) classifiers can consider the dependency of output tags and has been proven useful for tasks like NER or chunking. We consider CRF layers in our models.

To compare the effectiveness of three MTL models, we first test our SC-LSTM and other vanilla LSTM based models without CNN based character-level information extractor and contextual embeddings. In this case, the input will be a concatenation of word embedding and capitalization features[4]. To compare with the state-of-art models, we further implemented three more variants: SC-LSTM-CNN-CRF which makes use of CNN-based character level features with a CRF layer on top, very similar to (Ma and Hovy, 2016), and SC-LSTM-LM-CNN, a variant which considers contextualized word embeddings as in (Peters et al., 2018).

4.3 Implementation

For SC-LSTM-LM-CNN, we used mainly the configuration advocated in (Peters et al., 2018) except for the hidden size of SC-LSTM, which we report in Table 2. We further weighted the NER task in the objective function of Equation 4 to 3 (λ_{NER}), the weights of the other tasks where set to 1.[5] We trained this model SC-LSTM-LM-CNN using the Adam optimizer (Kingma and Ba, 2014) with default setting. Such a model spends typically less than 30 epochs to converge. We choose the mini-batch size of 10 and used the gradient clipping threshold 5. All models are implemented using the Pytorch library (Paszke et al., 2017).

Several tagging schemas have been proposed for conducting chunking and NER tasks. We used the most common BIO one in this work.

Layers	Parameters	
Char-level Embedding	dimension	16
Character-CNN	kernel size	3
	padding	1
	stride	1
	channel	128
Word Embedding	dimension	100
SC-LSTM	hidden size	256∗3
	layer	3
ELMo	dimension	1024
Dropout	rate	0.5

Table 2: Hyper-parameters used for training the SC-LSTM-LM-CNN model.

5 Experiments

In this section, we start by comparing MTL approaches based on LSTM and SC-LSTM cells. We then report the performance of variants of our approach we implemented and compare it to state-of-the-art models.

5.1 biLSTM versus biSC-LSTM

We compare bidirectional LSTM (STL), SC-LSTM, and baseline MTL models. The results are shown in Table 3. Training Bi-LSTM models on each task separately (STL) was first conducted as a point of comparison (line 1).

For LSTM-s and LSTM-d, we regard one task as the main task and the others as auxiliary tasks; a setting consistent with Søgaard and Goldberg (2016). Because LSTM-s and LSTM-d always fail to achieve stable and competitive results on the three tasks we considered at the same time, we report the best performance we could obtain for each task (line 2 and 3) specifically. On the contrary, our SC-LSTM model is trained once jointly on all tasks, and only one model is being tested in the end, which is much easier and more realistic of a real deployment (line 4).

The results show that our SC-LSTM model improves the performance of the three tasks simultaneously compared with LSTM (STL), and outperforms the other two MTL methods. By joint learning three tasks, both LSTM-s and LSTM-d can boost the chunking task significantly, but both fail to improve NER and POS tasks. This is consistent with observations made in (Collobert et al., 2011; Søgaard and Goldberg, 2016). We also observe that our SC-LSTM model also benefits the chunking task the most. We will analyze this fur-

---

[4] Eight features encode capitalization patterns, such as AllUpper, InitialUpper, etc.

[5] We found the loss of the NER task to be around 1/3 of the loss of the chunking and POS tasks.

ther in Section 6.

	POS	chunking	NER
LSTM (STL)	95.46	94.44	89.39
LSTM-s	95.45	95.12	89.35
LSTM-d	95.44	95.24	89.37
SC-LSTM	**95.51**	**96.04**	**89.96**

Table 3: Results of models being trained in STL or MTL mode. For all MTL models, we report the best performance via a small grid search over combinations of the hidden size [100, 200, 300, 400] and the number of layers [1, 2, 3]. The best performance of each MTL model was obtained with hidden size 300 and 3 layers.

5.2 SC-LSTM versus state-of-the-art

To further demonstrate the effectiveness of our SC-LSTM model, we compared different variants with state-of-the-art approaches, that we classify into three broad categories:

- **Single sequence labeling** where models are trained without the supervision of other tasks. Specifically, we compare our results to the LSTM-CRF model of Lample et al. (2016) and the LSTM-CNN-CRF of Ma and Hovy (2016), since those are state-of-the-art singly tasked sequence labelers.
- **Multi-tasked sequence labelers** where models leverage the supervision of other tasks. We compare our model with the representative approaches of Luo et al. (2015); Søgaard and Goldberg (2016); Collobert and Weston (2008); Collobert et al. (2011).
- **Models with language model.** Recently, several studies in using contextualized word embeddings achieved great success in a number of tasks. Some recent studies (Peters et al., 2017; Rei, 2017; Peters et al., 2018; Devlin et al., 2018) are particularly considered.

It is worth noting that we did not engineer tasks specific features or integrate external ressources such as gazetteers in our variants.

5.2.1 NER

Results for the CoNLL 2003 dataset are reported in Table 4. We observe that our SC-LSTM-LM-CNN model outperforms all approaches but Devlin et al. (2018) and Akbik et al. (2018). The latter work is using the development set as training material, which avoids a direct comparison. The former model (BERT) is achieving great success by leveraging a huge amount of unannotated data as well as a lot of computation resources we could not afford in this study. We are however pleased that our model is leveraging contextual embeddings with 0.38 absolute F1 improvement over the results of Peters et al. (2018). We leave as future work to investigate whether our MTL model can leverage BERT embeddings.

NER	F1-score
Collobert et al. (2011)	89.59
Chiu and Nichols (2015) ♣	91.62
Huang et al. (2015)	88.83
Luo et al. (2015)	91.20

SC-LSTM-LM-CNN	92.60

Table 4: F1-score on the CoNLL03 NER dataset. Models with ♣ use both train and dev splits for training.

5.2.2 Chunking

We compared a number of models on the CoNLL2000 chunking dataset. A few of them (Ma and Hovy, 2016; Lample et al., 2016; Peters et al., 2018) where not tested on this benchmark, and we reimplemented them. We also trained the companion toolkits of those models, but (as detailed in the next section) got slightly lower results for some reasons. Table 5 reports the performance of the many approaches we tested.

We observe that our SC-LSTM-LM-CNN architecture achieves a new state-of-the-art F1 score, with over 1 absolute point over the competitive approach of Peters et al. (2017), and an improvement of 0.4% over the current state-of-the-art method of Clark et al. (2018).

Chunking	F1-score
Collobert et al. (2011)	94.32
Huang et al. (2015)	94.13

SC-LSTM-LM-CNN	**97.40**

Table 5: F1-score on the CoNLL00 chunking dataset. Configurations with a † sign are approaches we reimplemented.

5.2.3 POS

We conducted experiments on the Universal Dependency POS English dataset and present the results in Table 6. The only study we found that reports results on the UD v1.3 benchmark we used here is (Bjerva et al., 2016), and we report the results they published. For Liu et al. (2017), Peters et al. (2018) we used the available companion toolkits[6] that we trained ourself with the default settings. We re-implemented the other approaches.

Again, we observe that SC-LSTM-LM-CNN outperforms all other approaches we tested. The absolute improvement in F1 score over the current state-of-the-art of Peters et al. (2018) is 0.21%.

In order to further validate our implementations, we also ran the toolkits of Ma and Hovy (2016) and Lample et al. (2016) and obtained slightly lower results[7].

POS	Accuracy
Collobert et al. (2011)	95.41†

6 Analysis

We conducted a number of investigations in order to understand better why our multi-task learning model is effective.

6.1 Convergence Analysis

We report in Figure 3 the convergence of different MTL models on the development set. To obtain those curves, we collected the F1-score on the NER and chunking tasks as well as the accuracy of the POS task, and averaged them after each epoch.

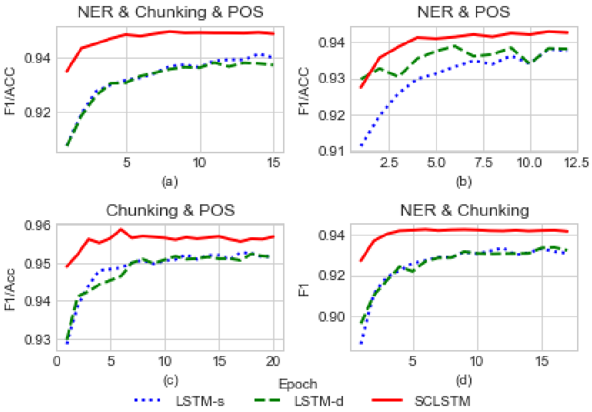

Figure 3: The change of F1-score/Accuracy on the development datasets at different epochs for SC-LSTM (red solid line), LSTM-s (blue dotted line) and LSTM-d (green dashed line) baselines. (a) reports results with NER, chunking and POS; (b) results with NER and POS; (c) results with chunking and POS; and (d) results with NER and chunking. All models were trained using the Adam optimizer with the same setting, and the mini-batch size was set to 10.

We clearly see that the SC-LSTM model converges faster than other ones. It achieves higher

---

[6] `https://github.com/LiyuanLucasLiu/LM-LSTM-CRF` and `https://github.com/allenai/allennlp`

[7] We obtained 95.7% for the toolkit we took from `https://github.com/XuezheMax/NeuroNLP2` and 95.6% for the one at `https://github.com/glample/tagger`.

performance after the first epoch, and after about ten epochs, it shows a smooth performance curve, while LSTM-s and LSTM-d models still fluctuate. This indicates that our model can learn the hidden representation of multiple tasks in a faster and smoother way than the other two methods.

Besides, we observe in Figure 3c and 3d that combinations of tasks involving chunking typically show a smooth training curve, on the contrary to Figure 3b where NER and POS tasks are combined. The fact that the training regimen fluctuates in the latter case for both LSTM-s and LSTM-d suggests that conflicts with those two tasks happen during optimisation, which we do not observe for our model. Also, Figure 3a illustrates that combining the three tasks altogether leads to comparably better performance of our model over LSTM-s and LSTM-d.

6.2 Effect of Different Task Combinations

We analyzed which task is benefited or harmed by others under the three MTL settings we considered and present results in Figure 4.

We find that it leads to better performance for all MTL models by jointly learning chunking with NER or POS(see in Figure 4b). This is in particular the case of our SC-LSTM model which records the largest gain, especially when all tasks are being trained on.

Figure 4c shows results obtained on POS. Only our SC-LSTM model achieves a meaningful improvement. We however observe that the NER task tends to hurt the performance of POS, since in most cases, the performance of POS+NER is lower than the one obtained with POS+chunking.

For NER, Figure 4 shows that POS hurts LSTM-s and LSTM-d models, while the chunking task is beneficial for all MTL methods.

Clearly, the combination of different tasks has a different effect on the final performance of each task. The chunking task seems compatible with NER and POS tasks, and it boosts the other two tasks in all three MTL settings, which is consistent with the results of Changpinyo et al. (2018). Directly jointly training on POS and NER datasets tends to reduce the performance in LSTM-s and LSTM-d, which is also consistent with the conclusion in (Changpinyo et al., 2018). In conclusion, all of the results show that our SC-LSTM model is effective at capturing the mutual benefits of all combined tasks. Since it performs consistently better in various settings, we believe our model to be more robust.

7 Related Work

There are many works that use extra knowledge to improve the performance of sequence labeling tasks.

Many works have focussed on jointly learning two tasks, often with one being considered as the main task, the other being the auxiliary one (Søgaard and Goldberg, 2016; Bjerva et al., 2016; Alonso and Plank, 2017). For instance, chunking, combinatory categorical grammar supertagging, NER, super senses (SemCor), or multiword expression + supersense will be taken as the main task, while POS is the auxiliary task in (Søgaard and Goldberg, 2016). Exceptions to this line of work include (Collobert et al., 2011) that evaluates four tasks: POS, chunking, NER and semantic role labeling; (Kiperwasser and Ballesteros, 2018) that considers a machine translation task with POS and dependency parsing. And Niehues and Cho (2017) considers machine translation with POS and NER tasks; Zhang and Weiss (2016) show that jointly learning a POS tagger and a dependency parser is effective. Miwa and Bansal (2016) jointly trained models for entity detection and relation extraction in the field of relation extraction.

Other works are also trying to leverage language models to empower the performance of sequence labeling tasks. Notably, Liu et al. (2017) propose a model which uses a neural language model to learn character-level knowledge, and conducts sequence labeling to guide the language model towards specific tasks. Others (Peters et al., 2017, 2018; Devlin et al., 2018) use neural language models pre-trained on a large unlabeled corpus to learn context-sensitive representations of words, and leverage this representation into the sequence labeling model.

More related to the present work are studies that analyze the effectiveness of different combinations of sequence labeling tasks in a multi-task learning. In particular, Changpinyo et al. (2018) conduct an investigation on 11 sequence labeling tasks, while Alonso and Plank (2017) evaluate 5 tasks but report signifiant gains for only one task.

8 Conclusion

In this paper, we propose a simple yet powerful LSTM cell that leverage both shared and task-

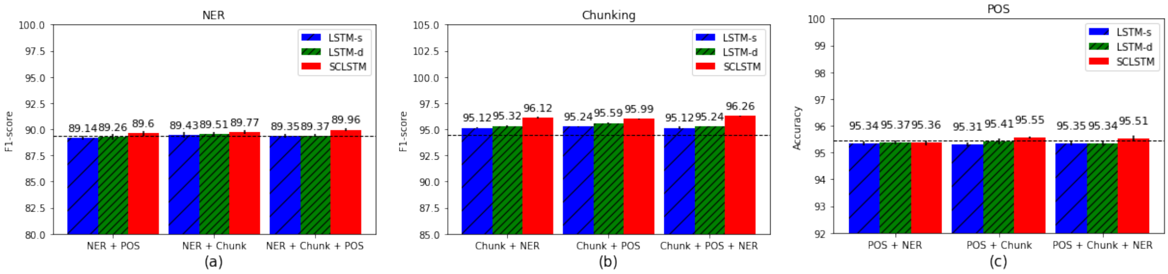

Figure 4: Results of different task groups on each test set: (a) NER, (b) chunking, and (c) POS. Horizontal lines show results for single-task models(NER: 89.39, Chunking: 94.44 and POS: 95.46).

specific parameters in a multi-task setting designed for sequence labelling. We conduct extensive experiments to compare both single-task learning and multi-task learning models. We analyzed the influence of grouping different tasks under various multi-task settings. Experiments demonstrate the effectiveness of our model for sequence labeling tasks. We report new state-of-the-art results on both POS and chunking tasks, and close to state-of-the-art performance on NER, without exploiting external ressources, neither diving into dedicated feature engineering.

Despite those positive outcomes, several issues with multi-task learning for sequence labeling remain open. In particular, we only considered 3 tasks here, and therefore plan to test our approach on more tasks, perhaps understanding better why some tasks are less useful to others. Also, there are several ways we could have used our SC-LSTM cell into our models which we would like to investigate further. In particular, in this work, we only used the specific-task hidden states in the last layer of the model, which can obviously be revisited.

Learning to Denoise Distantly-Labeled Data for Entity Typing

Yasumasa Onoe and **Greg Durrett**
Department of Computer Science
The University of Texas at Austin
{yasumasa, gdurrett}@cs.utexas.edu

Abstract

Distantly-labeled data can be used to scale up training of statistical models, but it is typically noisy and that noise can vary with the distant labeling technique. In this work, we propose a two-stage procedure for handling this type of data: denoise it with a learned model, then train our final model on clean and denoised distant data with standard supervised training. Our denoising approach consists of two parts. First, a filtering function discards examples from the distantly labeled data that are wholly unusable. Second, a relabeling function repairs noisy labels for the retained examples. Each of these components is a model trained on synthetically-noised examples generated from a small manually-labeled set. We investigate this approach on the ultra-fine entity typing task of Choi et al. (2018). Our baseline model is an extension of their model with pre-trained ELMo representations, which already achieves state-of-the-art performance. Adding distant data that has been denoised with our learned models gives further performance gains over this base model, outperforming models trained on raw distant data or heuristically-denoised distant data.

1 Introduction

With the rise of data-hungry neural network models, system designers have turned increasingly to unlabeled and weakly-labeled data in order to scale up model training. For information extraction tasks such as relation extraction and entity typing, distant supervision (Mintz et al., 2009) is a powerful approach for adding more data, using a knowledge base (Del Corro et al., 2015; Rabinovich and Klein, 2017) or heuristics (Ratner et al., 2016; Hancock et al., 2018) to automatically label instances. One can treat this data just like any other supervised data, but it is noisy; more effective approaches employ specialized probabilistic models (Riedel et al., 2010; Ratner et al., 2018a), capturing its interaction with other supervision (Wang and Poon, 2018) or breaking down aspects of a task on which it is reliable (Ratner et al., 2018b). However, these approaches often require sophisticated probabilistic inference for training of the final model. Ideally, we want a technique that handles distant data just like supervised data, so we can treat our final model and its training procedure as black boxes.

This paper tackles the problem of exploiting weakly-labeled data in a structured setting with a two-stage denoising approach. We can view a distant instance's label as a noisy version of a true underlying label. We therefore learn a model to turn a noisy label into a more accurate label, then apply it to each distant example and add the resulting denoised examples to the supervised training set. Critically, the denoising model can condition on both the example and its noisy label, allowing it to fully leverage the noisy labels, the structure of the label space, and easily learnable correspondences between the instance and the label.

Concretely, we implement our approach for the task of fine-grained entity typing, where a single entity may be assigned many labels. We learn two denoising functions: a *relabeling* function takes an entity mention with a noisy set of types and returns a cleaner set of types, closer to what manually labeled data has. A *filtering* function discards examples which are deemed too noisy to be useful. These functions are learned by taking manually-labeled training data, synthetically adding noise to it, and learning to denoise, similar to a conditional variant of a denoising autoencoder (Vincent et al., 2008). Our denoising models embed both entities and labels to make their predictions, mirroring the structure of the final entity typing model itself.

We evaluate our model following Choi et al. (2018). We chiefly focus on their ultra-fine en-

tity typing scenario and use the same two distant supervision sources as them, based on entity linking and head words. On top of an adapted model from Choi et al. (2018) incorporating ELMo (Peters et al., 2018), naïvely adding distant data actually hurts performance. However, when our learned denoising model is applied to the data, performance improves, and it improves more than heuristic denoising approaches tailored to this dataset. Our strongest denoising model gives a gain of 3 F_1 absolute over the ELMo baseline, and a 4.4 F_1 improvement over naive incorporation of distant data. This establishes a new state-of-the-art on the test set, outperforming concurrently published work (Xiong et al., 2019) and matching the performance of a BERT model (Devlin et al., 2018) on this task. Finally, we show that denoising helps even when the label set is projected onto the OntoNotes label set (Hovy et al., 2006; Gillick et al., 2014), outperforming the method of Choi et al. (2018) in that setting as well.

2 Setup

We consider the task of predicting a structured target y associated with an input x. Suppose we have high-quality labeled data of n (input, target) pairs $\mathcal{D} = \{(x^{(1)}, y^{(1)}), \dots, (x^{(n)}, y^{(n)})\}$, and noisily labeled data of n' (input, target) pairs $\mathcal{D}' = \{(x^{(1)}, y^{(1)}_{\text{noisy}}), \dots, (x^{(n')}, y^{(n')}_{\text{noisy}})\}$. For our tasks, $\mathcal{D}$ is collected through manual annotation and $\mathcal{D}'$ is collected by distant supervision. We use two models to denoise data from $\mathcal{D}'$: a filtering function f disposes of unusable data (e.g., mislabeled examples) and a relabeling function g transforms the noisy target labels y_{noisy} to look more like true labels. This transformation improves the noisy data so that we can use it to $\mathcal{D}$ without introducing damaging amounts of noise. In the second stage, a classification model is trained on the augmented data ($\mathcal{D}$ combined with denoised $\mathcal{D}'$) and predicts y given x in the inference phase.

2.1 Case Study: Ultra-Fine Entity Typing

The primary task we address here is the fine-grained entity typing task of Choi et al. (2018). Instances in the corpus are assigned types from a vocabulary of more than 10,000 types, which are divided into three classes: 9 *general* types, 121 *fine-grained* types, and $10,201$ *ultra-fine* types. This dataset consists of 6K manually annotated examples and approximately 25M distantly-labeled examples. 5M examples are collected using entity linking (EL) to link mentions to Wikipedia and gather types from information on the linked pages. 20M examples (HEAD) are generated by extracting nominal head words from raw text and treating these as singular type labels.

Figure 1 shows examples from these datasets which illustrate the challenges in automatic annotation using distant supervision. The manually-annotated example in (a) shows how numerous the gold-standard labeled types are. By contrast, the HEAD example (b) shows that simply treating the head word as the type label, while correct in this case, misses many valid types, including more general types. The EL example (c) is incorrectly annotated as `region`, whereas the correct coarse type is actually `person`. This error is characteristic of entity linking-based distant supervision since identifying the correct link is a challenging problem in and of itself (Milne and Witten, 2008): in this case, *Gascoyne* is also the name of a region in Western Australia. The EL example in (d) has reasonable types; however, human annotators could choose more types (grayed out) to describe the mention more precisely. The average number of types annotated by humans is 5.4 per example while the two distant supervision techniques combined yields 1.5 types per example on average.

In summary, distant supervision can (1) produce

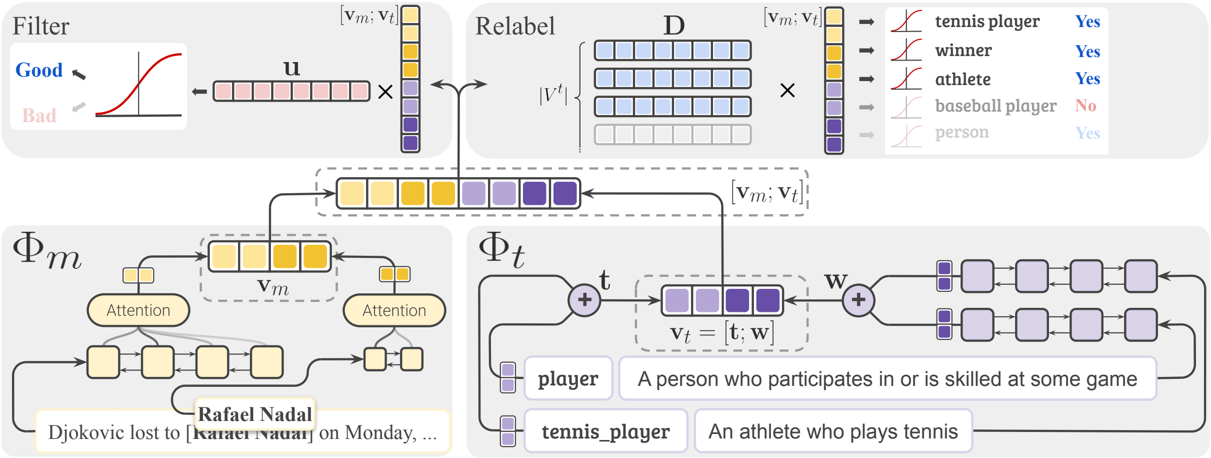

Figure 2: Denoising models. The *Filter* model predicts whether the example should be kept at all; if it is kept, the *Relabel* model attempts to automatically expand the label set. Φ_m is a mention encoder, which can be a state-of-the-art entity typing model. Φ_t encodes noisy types from distant supervision.

completely incorrect types, and (2) systematically miss certain types.

3 Denoising Model

To handle the noisy data, we propose to learn a denoising model as shown in Figure 2. This denoising model consists of filtering and relabeling functions to discard and relabel examples, respectively; these rely on a shared mention encoder and type encoder, which we describe in the following sections. The filtering function is a binary classifier that takes these encoded representations and predicts whether the example is good or bad. The relabeling function predicts a new set of labels for the given example.

We learn these functions in a supervised fashion. Training data for each is created through synthetic noising processes applied to the manually-labeled data, as described in Sections 3.3 and 3.4.

For the entity typing task, each example (x, y) takes the form $((s, m), t)$, where s is the sentence, m is the mention span, and t is the set of types (either clean or noisy).

3.1 Mention Encoder

This encoder is a function $\Phi_m(s, m)$ which maps a sentence s and mention m to a real-valued vector $\mathbf{v}_m$. This allows the filtering and relabeling function to recognize inconsistencies between the given example and the provided types. Note that these inputs s and m are the same as the inputs for the supervised version of this task; we can therefore share an encoder architecture between our denoising model and our final typing model. We use an encoder following Choi et al. (2018) with a few key differences, which are described in Section 4.

3.2 Type Encoder

The second component of our model is a module which produces a vector $\mathbf{v}_t = \Phi_t(t)$. This is an encoder of an unordered bag of types. Our basic type encoder uses trainable vectors as embeddings for each type and combines these with summing. That is, the noisy types $t_1, \ldots, t_m$ are embedded into type vectors $\{\mathbf{t}_1, \ldots, \mathbf{t}_m\}$. The final embedding of the type set $\mathbf{t} = \sum_j \mathbf{t}_j$.

Type Definition Encoder Using trainable type embeddings exposes the denoising model to potential data sparsity issues, as some types appear only a few or zero times in the training data. Therefore, we also assign each type a vector based on its definition in WordNet (Miller, 1995). Even low-frequent types are therefore assigned a plausible embedding.[1]

Let w_i^j denote the ith word of the jth type's most common WordNet definition. Each w_i^j is embedded using GloVe (Pennington et al., 2014). The resulting word embedding vectors $\mathbf{w}_i^j$ are fed into a bi-LSTM (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005), and a concatenation of the last hidden states in both directions is used as the definition representation $\mathbf{w}^j$. The final representation of the definitions is the sum over these vectors for each type: $\mathbf{w}$ =

---

[1] We found this technique to be more effective than using pretrained vectors from GloVe or ELMo. It gave small improvements on an intrinsic evaluation over not incorporating it; results are omitted due to space constraints.

$\sum_k \mathbf{w}^k$.

Our final $\mathbf{v}_t = [\mathbf{t}; \mathbf{w}]$, the concatenation of the type and definition embedding vectors.

3.3 Filtering Function

The filtering function f is a binary classifier designed to detect examples that are completely mislabeled. Formally, f is a function mapping a labeled example (s, m, t) to a binary indicator z of whether this example should be discarded or not.

In the forward computation, the feature vectors $\mathbf{v}_m$ and $\mathbf{v}_t$ are computed using the mention and type encoders. The model prediction is defined as $P(\text{error}) = \sigma\left(\mathbf{u}^\top \text{Highway}\left([\mathbf{v}_m; \mathbf{v}_t]\right)\right)$, where σ is a sigmoid function, $\mathbf{u}$ is a parameter vector, and $\text{Highway}(\cdot)$ is a 1-layer highway network (Srivastava et al., 2015). We can apply f to each distant pair in our distant dataset $\mathcal{D}'$ and discard any example predicted to be erroneous ($P(\text{error}) > 0.5$).

Training data We do not know a priori which examples in the distant data should be discarded, and labeling these is expensive. We therefore construct synthetic training data $\mathcal{D}_{\text{error}}$ for f based on the manually labeled data $\mathcal{D}$. For 30% of the examples in $\mathcal{D}$, we replace the gold types for that example with *non-overlapping* types taken from another example. The intuition for this procedure follows Figure 1: we want to learn to detect examples in the distant data like *Gascoyne* where heuristics like entity resolution have misfired and given a totally wrong label set.

Formally, for each selected example $((s, m), t)$, we repeatedly draw another example $((s', m'), t')$ from $\mathcal{D}$ until we find t'_{error} that does not have any common types with t. We then create a positive training example $((s, m, t'_{\text{error}}), z = 1)$. We create a negative training example $((s, m, t), z = 0)$ using the remaining 70% of examples. f is trained on $\mathcal{D}_{\text{error}}$ using binary cross-entropy loss.

3.4 Relabeling Function

The relabeling function g is designed to repair examples that make it through the filter but which still have errors in their type sets, such as missing types as shown in Figure 1b and 1d. g is a function from a labeled example (s, m, t) to an improved type set $\tilde{t}$ for the example.

Our model computes feature vectors $\mathbf{v}_m$ and $\mathbf{v}_t$ by the same procedure as the filtering function f. The decoder is a linear layer with parameters $\mathbf{D} \in \mathbb{R}^{|V^t| \times (d_m + d_t)}$. We compute $\mathbf{e} = \sigma\left(\mathbf{D}\left[\mathbf{v}_m; \mathbf{v}_t\right]\right)$, where σ is an element-wise sigmoid operation designed to give binary probabilities for each type.

Once g is trained, we make a prediction $\tilde{t}$ for each $(s, m, t) \in \mathcal{D}'$ and replace t by $\tilde{t}$ to create the denoised data $\mathcal{D}'_{\text{denoise}} = \{(s, m, \tilde{t}), \dots\}$. For the final prediction, we choose all types t_ℓ where $e_\ell > 0.5$, requiring at least two types to be present or else we discard the example.

Training data We train the relabeling function g on another synthetically-noised dataset $\mathcal{D}_{\text{drop}}$ generated from the manually-labeled data $\mathcal{D}$. To mimic the type distribution of the distantly-labeled examples, we take each example (s, m, t) and randomly drop each type with a fixed rate 0.7 independent of other types to produce a new type set t'. We perform this process for all examples in $\mathcal{D}$ and create a noised training set $\mathcal{D}_{\text{drop}}$, where a single training example is $((s, m, t'), t)$. g is trained on $\mathcal{D}'_{\text{drop}}$ with a binary classification loss function over types used in Choi et al. (2018), described in the next section.

One can think of g as a type of denoising autoencoder (Vincent et al., 2008) whose reconstructed types $\tilde{t}$ are conditioned on $\mathbf{v}$ as well as t.

4 Typing Model

In this section, we define the sentence and mention encoder Φ_m, which is use both in the denoising model as well as in the final prediction task. We extend previous attention-based models for this task (Shimaoka et al., 2017; Choi et al., 2018). At a high level, we have an instance encoder Φ_m that returns a vector $\mathbf{v}_m \in \mathbb{R}^{d_\Phi}$, then multiply the output of this encoding by a matrix and apply a sigmoid to get a binary prediction for each type as a probability of that type applying.

Figure 3 outlines the overall architecture of our typing model. The encoder Φ_m consists of four vectors: a sentence representation $\mathbf{s}$, a word-level mention representation $\mathbf{m}^{\text{word}}$, a character-level mention representation $\mathbf{m}^{\text{char}}$, and a head-word mention vector $\mathbf{m}^{\text{head}}$. The first three of these were employed by Choi et al. (2018). We have modified the mention encoder with an additional bi-LSTM to better encode long mentions, and additionally used the headword embedding directly in order to focus on the most critical word. These pieces use pretrained contextualized word embeddings (ELMo) (Peters et al., 2018) as input.

Pretrained Embeddings Tokens in the sentence s are converted into contextualized word vectors

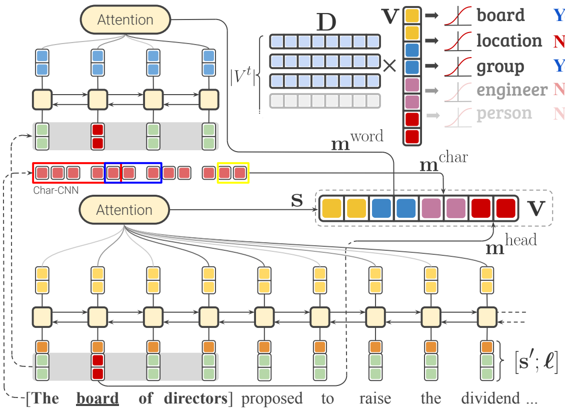

Figure 3: Sentence and mention encoder used to predict types. We compute attention over LSTM encodings of the sentence and mention, as well as using character-level and head-word representations to capture additional mention properties. These combine to form an encoding which is used to predict types.

using ELMo; let $\mathbf{s}'_i \in \mathbb{R}^{d_{ELMo}}$ denote the embedding of the ith word. As suggested in Peters et al. (2018), we learn task specific parameters $\gamma^{\text{task}} \in \mathbb{R}$ and $\mathbf{s}^{\text{task}} \in \mathbb{R}^3$ governing these embeddings. We do not fine-tune the parameters of the ELMo LSTMs themselves.

Sentence Encoder Following Choi et al. (2018), we concatenate the mth word vector $\mathbf{s}_m$ in the sentence with a corresponding location embedding $\boldsymbol{\ell}_m \in \mathbb{R}^{d_{\text{loc}}}$. Each word is assigned one of four location tokens, based on whether (1) the word is in the left context, (2) the word is the first word of the mention span, (3) the word is in the mention span (but not first), and (4) the word is in the right context. The input vectors $[\mathbf{s}'; \boldsymbol{\ell}]$ are fed into a bi-LSTM encoder, with hidden dimension is d_{hid}, followed by a span attention layer (Lee et al., 2017; Choi et al., 2018): $\mathbf{s} = \text{Attention}(\text{bi-LSTM}([\mathbf{s}'; \mathbf{l}]))$, where $\mathbf{s}$ is the final representation of the sentence s.

Mention Encoder To obtain a mention representation, we use both word and character information. For the word-level representation, the mention's contextualized word vectors $\mathbf{m}'$ are fed into a bi-LSTM with hidden dimension is d_{hid}. The concatenated hidden states of both directions are summed by a span attention layer to form the word-level mention representation: $\mathbf{m}^{\text{word}} = \text{Attention}(\text{bi-LSTM}(\mathbf{m}'))$.

Second, a character-level representation is computed for the mention. Each character is embedded and then a 1-D convolution (Collobert et al., 2011) is applied over the characters of the mention. This gives a character vector $\mathbf{m}^{\text{char}}$.

Finally, we take the contextualized word vector of the headword $\mathbf{m}^{\text{head}}$ as a third component of our representation. This can be seen as a residual connection (He et al., 2016) specific to the mention head word. We find the headwords in the mention spans by parsing those spans in isolation using the spaCy dependency parser (Honnibal and Johnson, 2015). Empirically, we found this to be useful on long spans, when the span attention would often focus on incorrect tokens.

The final representation of the input x is a concatenation of the sentence, the word- & character-level mention, and the mention headword representations, $\mathbf{v} = \left[\mathbf{s}; \mathbf{m}^{\text{word}}; \mathbf{m}^{\text{char}}; \mathbf{m}^{\text{head}}\right] \in \mathbb{R}^{d_\Phi}$.

Decoder We treat each label prediction as an independent binary classification problem. Thus, we compute a score for each type in the type vocabulary V^t. Similar to the decoder of the relabeling function g, we compute $\mathbf{e} = \sigma(\mathbf{E}\mathbf{v})$, where $\mathbf{E} \in \mathbb{R}^{|V^t| \times d_\Phi}$ and $\mathbf{e} \in \mathbb{R}^{|V^t|}$. For the final prediction, we choose all types t_ℓ where $e_\ell > 0.5$. If none of e_ℓ is greater than 0.5, we choose $t_\ell = \arg\max \mathbf{e}$ (the single most probable type).

Loss Function We use the same loss function as Choi et al. (2018) for training. This loss partitions the labels in general, fine, and ultra-fine classes, and only treats an instance as an example for types of the class in question if it contains a label for that class. More precisely:

$$\begin{aligned}\mathcal{L} =& \mathcal{L}_{\text{general}} \mathbb{1}_{\text{general}}(t) + \mathcal{L}_{\text{fine}} \mathbb{1}_{\text{fine}}(t) \\ &+ \mathcal{L}_{\text{ultra-fine}} \mathbb{1}_{\text{ultra-fine}}(t),\end{aligned} \tag{1}$$

where $\mathcal{L}_{\dots}$ is a loss function for a specific type class: general, fine-grained, or ultra-fine, and $\mathbb{1}_{\dots}(t)$ is an indicator function that is active when one of the types t is in the type class. Each $\mathcal{L}_{\dots}$ is a sum of binary cross-entropy losses over all types in that category. That is, the typing problem is viewed as independent classification for each type.

Note that this loss function already partially repairs the noise in distant examples from missing labels: for example, it means that examples from HEAD do not count as negative examples for general types when these are not present. However, we show in the next section that this is not sufficient for denoising.

Implementation Details The settings of hyperparameters in our model largely follows Choi et al. (2018) and recommendations for using the pre-trained ELMo-Small model.[2] The word embedding size d_{ELMo} is 1024. The type embedding size and the type definition embedding size are set to 1024. For most of other model hyperparameters, we use the same settings as Choi et al. (2018): $d_{\text{loc}} = 50$, $d_{\text{hid}} = 100$, $d_{\text{char}} = 100$. The number of filters in the 1-d convolutional layer is 50. Dropout is applied with $p = 0.2$ for the pretrained embeddings, and $p = 0.5$ for the mention representations. We limit sentences to 50 words and mention spans to 20 words for computational reasons. The character CNN input is limited to 25 characters; most mentions are short, so this still captures subword information in most cases. The batch size is set to 100. For all experiments, we use the Adam optimizer (Kingma and Ba, 2014). The initial learning rate is set to 2e-03. We implement all models[3] using PyTorch. To use ELMo, we consult the AllenNLP source code.

5 Experiments

Ultra-Fine Entity Typing We evaluate our approach on the ultra-fine entity typing dataset from Choi et al. (2018). The 6K manually-annotated English examples are equally split into the training, development, and test examples by the authors of the dataset. We generate synthetically-noised data, $\mathcal{D}_{\text{error}}$ and $\mathcal{D}_{\text{drop}}$, using the 2K training set to train the filtering and relabeling functions, f and h. We randomly select 1M EL and 1M HEAD examples and use them as the noisy data $\mathcal{D}'$. Our augmented training data is a combination of the manually-annotated data $\mathcal{D}$ and $\mathcal{D}'_{\text{denoised}}$.

OntoNotes In addition, we investigate if denoising leads to better performance on another dataset. We use the English OntoNotes dataset (Gillick et al., 2014), which is a widely used benchmark for fine-grained entity typing systems. The original training, development, and test splits contain 250K, 2K, and 9K examples respectively. Choi et al. (2018) created an augmented training set that has 3.4M examples. We also construct our own augmented training sets with/without denoising using our noisy data $\mathcal{D}'$, using the same label mapping from ultra-fine types to OntoNotes types described in Choi et al. (2018).

5.1 Ultra-Fine Typing Results

We first compare the performance of our approach to several benchmark systems, then break down the improvements in more detail. We use the model architecture described in Section 4 and train it on the different amounts of data: manually labeled only, naive augmentation (adding in the raw distant data), and denoised augmentation. We compare our model to Choi et al. (2018) as well as to BERT (Devlin et al., 2018), which we fine-tuned for this task. We adapt our task to BERT by forming an input sequence "`[CLS] sentence [SEP] mention [SEP]`" and assign the segment embedding A to the sentence and B to the mention span.[4] Then, we take the output vector at the position of the `[CLS]` token (i.e., the first token) as the feature vector **v**, analogous to the usage for sentence pair classification tasks. The BERT model is fine-tuned on the 2K manually annotated examples. We use the pretrained BERT-Base, uncased model[5] with a step size of 2e-05 and batch size 32.

Results Table 1 compares the performance of these systems on the development set. Our model with no augmentation already matches the system of Choi et al. (2018) with augmentation, and incorporating ELMo gives further gains on both precision and recall. On top of this model, adding the distantly-annotated data lowers the performance; the loss function-based approach of (Choi et al., 2018) does not sufficiently mitigate the noise in this data. However, denoising makes the distantly-annotated data useful, improving recall by a substantial margin especially in the general class. A possible reason for this is that the relabeling function tends to add more general types given finer types. BERT performs similarly to ELMo with denoised distant data. As can be seen in the performance breakdown, BERT gains from improvements in recall in the fine class.

Table 2 shows the performance of all settings on the test set, with the same trend as the performance on the development set. Our approach outperforms the concurrently-published Xiong et al. (2019); however, that work does not use ELMo. Their improved model could be used for both de-

---

Table 1: Macro-averaged P/R/F1 on the dev set for the entity typing task of Choi et al. (2018) comparing various systems. ELMo gives a substantial improvement over baselines. Over an ELMo-equipped model, data augmentation using the method of Choi et al. (2018) gives no benefit. However, our denoising technique allow us to effectively incorporate distant data, matching the results of a BERT model on this task (Devlin et al., 2018).

noising as well as prediction in our setting, and we believe this would stack with our approach.

Usage of Pretrained Representations Our model with ELMo trained on denoised data matches the performance of the BERT model. We experimented with incorporating distant data (raw and denoised) in BERT, but the fragility of BERT made it hard to incorporate: training for longer generally caused performance to go down after a while, so the model cannot exploit large external data as effectively. Devlin et al. (2018) prescribe training with a small batch size and very specific step sizes, and we found the model very sensitive to these hyperparameters, with only 2e-05 giving strong results. The ELMo paradigm of incorporating these as features is much more flexible and modular in this setting. Finally, we note that our approach could use BERT for denoising as well, but this did not work better than our current approach. Adapting BERT to leverage distant data effectively is left for future work.

5.1.1 Comparing Denoising Models

We now explicitly compare our denoising approach to several baselines. For each denoising method, we create the denoised EL, HEAD, and EL & HEAD dataset and investigate performance on these datasets. Any denoised dataset is combined with the 2K manually-annotated examples and used to train the final model.

Heuristic Baselines These heuristics target the same factors as our filtering and relabeling functions in a non-learned way.

Synonyms and Hypernyms For each type observed in the distant data, we add its synonyms and hypernyms using WordNet (Miller, 1995). This is motivated by the data construction process in Choi et al. (2018).

Model	P	R	F1
Ours + GloVe w/o augmentation	47.6	23.3	31.3
Ours + ELMo w/o augmentation	**55.8**	27.7	37.0
Ours + ELMo w augmentation	55.5	26.3	35.7
Ours + ELMo w augmentation + filter & relabel	51.5	**33.0**	**40.2**
BERT-Base, Uncased	51.6	**33.0**	**40.2**
Choi et al. (2018) w augmentation	47.1	24.2	32.0
LabelGCN (Xiong et al., 2019)	50.3	29.2	36.9

Table 2: Macro-averaged P/R/F1 on the test set for the entity typing task of Choi et al. (2018). Our denoising approach gives substantial gains over naive augmentation and matches the performance of a BERT model.

Common Type Pairs We use type pair statistics in the manually labeled training data. For each base type that we observe in a distant example, we add any type which is seen more than 90% of the time the base type occurs. For instance, the type `art` is given at least 90% of the times the `film` type is present, so we automatically add `art` whenever `film` is observed.

Overlap We train a model on the manually-labeled data only, then run it on the distantly-labeled data. If there is an intersection between the noisy types t and the predicted type $\hat{t}$, we combine them and use as the expanded type $\tilde{t}$. Inspired by tri-training (Zhou and Li, 2005), this approach adds "obvious" types but avoids doing so in cases where the model has likely made an error.

Results Table 3 compares the results on the development set. We report the performance on each of the EL & HEAD, EL, and HEAD dataset. On top of the baseline Original, adding synonyms and hypernyms by consulting external knowledge does not improve the performance. Expanding labels with the Pair technique results in small gains over Original. Overlap is the most ef-

Type	Denoising Method	EL & HEAD			EL			HEAD		
		P	R	F1	P	R	F1	P	R	F1
Heuristic Baselines	Raw Data	**55.2**	26.4	35.7	52.3	26.1	34.8	**52.8**	28.4	36.9
	Synonyms & Hypernyms	43.0	30.0	35.3	47.5	26.3	33.9	44.8	31.7	37.1
	Pair	50.2	29.0	36.8	49.6	27.0	35.0	50.6	31.2	38.6
	Overlap	50.0	32.3	39.2	49.5	**30.8**	38.0	50.6	31.4	38.7
Proposed Approach	Filter	53.1	28.2	36.8	51.9	26.5	35.1	51.2	31.2	38.7
	Relabel	52.1	32.2	39.8	50.2	31.4	38.6	50.2	31.8	38.9
	Filter & Relabel	50.7	**33.1**	**40.1**	**52.7**	30.5	**38.7**	50.7	**32.1**	**39.3**
	Choi et al. (2018)	48.1	23.2	31.3	50.3	19.6	28.2	48.4	22.3	30.6

Table 3: Macro-averaged P/R/F1 on the dev set for the entity typing task of Choi et al. (2018) with various types of augmentation added. The customized loss from Choi et al. (2018) actually causes a decrease in performance from adding any of the datasets. Heuristics can improve incorporation of this data: a relabeling heuristic (Pair) helps on HEAD and a filtering heuristic (Overlap) is helpful in both settings. However, our trainable filtering and relabeling models outperform both of these techniques.

fective heuristic technique. This simple filtering and expansion heuristic improves recall on EL. Filter, our model-based example selector, gives similar improvements to Pair and Overlap on the HEAD setting, where filtering noisy data appears to be somewhat important.[6] Relabel and Overlap both improve performance on both EL and HEAD while other methods do poorly on EL. Combining the two model-based denoising techniques, Filter & Relabel outperforms all the baselines.

5.2 OntoNotes Results

We compare our different augmentation schemes for deriving data for the OntoNotes standard as well. Table 4 lists the results on the OntoNotes test set following the adaptation setting of Choi et al. (2018). Even on this dataset, denoising significantly improves over naive incorporation of distant data, showing that the denoising approach is not just learning quirks of the ultra-fine dataset. Our augmented set is constructed from 2M seed examples while Choi et al. (2018) have a more complex procedure for deriving augmented data from 25M examples. Ours (total size of 2.1M) is on par with their larger data (total size of 3.4M), despite having 40% fewer examples. In this setting, BERT still performs well but not as well as our model with augmented training data.

One source of our improvements from data augmentation comes from additional data that is able to be used because *some* OntoNotes type can be derived. This is due to denoising doing a better job of providing correct general types. In the EL setting, this yields 730k usable examples out of 1M (vs 540K for no denoising), and in HEAD, 640K out of 1M (vs. 73K).

Model	Acc.	Ma-F1	Mi-F1
Ours + ELMo w/o augmentation	42.7	72.7	66.7
Ours + ELMo w augmentation	59.3	76.5	70.7
Ours + ELMo w augmentation + filter & relabel	63.9	**84.5**	78.9
Ours + ELMo w augmentation by Choi et al. (2018)	**64.9**	**84.5**	**79.2**
BERT-Base, Uncased	51.8	76.6	69.1
Shimaoka et al. (2017)	51.7	70.9	64.9
AFET (Ren et al., 2016a)	55.1	71.1	64.7
PLE (Ren et al., 2016b)	57.2	71.5	66.1
Choi et al. (2018)	59.5	76.8	71.8
LabelGCN (Xiong et al., 2019)	59.6	77.8	72.2

Table 4: Test results on OntoNotes. Denoising helps substantially even in this reduced setting. Using fewer distant examples, we nearly match the performance using the data from Choi et al. (2018) (see text).

5.3 Analysis of Denoised Labels

To understand what our denoising approach does to the distant data, we analyze the behavior of our filtering and relabeling functions. Table 5 reports the average numbers of types added/deleted by the relabeling function and the ratio of examples discarded by the filtering function.

Overall, the relabeling function tends to add more and delete fewer number of types. The HEAD examples have more general types added than the EL examples since the noisy HEAD labels are typically finer. Fine-grained types are added to both EL and HEAD examples less frequently. Ultra-fine examples are frequently added to both datasets, with more added to EL; the noisy EL labels are mostly extracted from Wikipedia defini-

---

[6] One possible reason for this is identifying stray word senses; *film* can refer to the physical photosensitive object, among other things.

	General		Fine		Ultra-Fine		
Data	Add	Del	Add	Del	Add	Del	Filter (%)
EL	0.87	0.01	0.36	0.17	2.03	0.12	9.4
HEAD	1.18	0.00	0.51	0.01	1.15	0.16	10.0

Table 5: The average number of types added or deleted by the relabeling function per example. The right-most column shows that the rate of examples discarded by the filtering function.

tions, so those labels often do not include ultra-fine types. The filtering function discards similar numbers of examples for the EL and HEAD data: 9.4% and 10% respectively.

Figure 4 shows examples of the original noisy labels and the denoised labels produced by the relabeling function. In example (a), taken from the EL data, the original labels, {`location, city`}, are correct, but human annotators might choose more types for the mention span, **Minneapolis**. The relabeling function retains the original types about the geography and adds ultra-fine types about administrative units such as {`township, municipality`}. In example (b), from the HEAD data, the original label, {`dollar`}, is not so expressive by itself since it is a name of a currency. The labeling function adds coarse types, {`object, currency`}, as well as specific types such as {`medium of exchange, monetary unit`}. In another EL example (c), the relabeling function tries to add coarse and fine types but struggles to assign multiple diverse *ultra-fine* types to the mention span **Michelangelo**, possibly because some of these types rarely cooccur (`painter` and `poet`).

6 Related Work

Past work on denoising data for entity typing has used multi-instance multi-label learning (Yaghoobzadeh and Schütze, 2015, 2017; Murty et al., 2018). One view of these approaches is that they delete noisily-introduced labels, but they cannot add them, or filter bad examples. Other work focuses on learning type embeddings (Yogatama et al., 2015; Ren et al., 2016a,b); our approach goes beyond this in treating the label set in a structured way. The label set of Choi et al. (2018) is distinct in not being explicitly hierarchical, making past hierarchical approaches difficult to apply.

Denoising techniques for distant supervision have been applied extensively to relation extraction. Here, multi-instance learning and probabilistic graphical modeling approaches have been used (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Takamatsu et al., 2012) as well as deep models (Lin et al., 2016; Feng et al., 2017; Luo et al., 2017; Lei et al., 2018; Han et al., 2018), though these often focus on incorporating signals from other sources as opposed to manually labeled data.

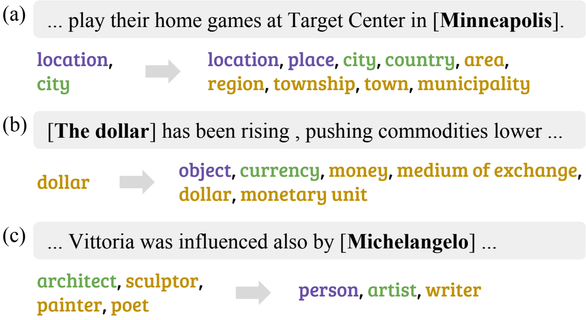

Figure 4: Examples of the noisy labels (left) and the denoised labels (right) for mentions (bold). The colors correspond to type classes: *general* (purple), *fine-grained* (green), and *ultra-fine* (yellow).

7 Conclusion

In this work, we investigated the problem of denoising distant data for entity typing tasks. We trained a filtering function that discards examples from the distantly labeled data that are wholly unusable and a relabeling function that repairs noisy labels for the retained examples. When distant data is processed with our best denoising model, our final trained model achieves state-of-the-art performance on an ultra-fine entity typing task.

Abstract

While rule-based detection of subject–verb agreement (SVA) errors is sensitive to syntactic parsing errors and irregularities and exceptions to the main rules, neural sequential labelers have a tendency to overfit their training data. We observe that rule-based *error generation* is less sensitive to syntactic parsing errors and irregularities than error detection and explore a simple, yet efficient approach to getting the best of both worlds: We train neural sequential labelers on the combination of large volumes of silver standard data, obtained through rule-based error generation, and gold standard data. We show that our simple protocol leads to more robust detection of SVA errors on both in-domain and out-of-domain data, as well as in the context of other errors and long-distance dependencies; and across four standard benchmarks, the induced model on average achieves a new state of the art.

1 Introduction

Grammatical Error Detection. Grammatical Error Detection (GED, Leacock et al., 2010) is the task of detecting grammatical errors in text. It is used in various real-world applications, such as writing assistance tools, self-assessment frameworks and language tutoring systems, facilitating incremental and/or exploratory editing of one's writing. Accurate error detection systems also have potential applications for language generation and machine translation systems, guiding automatically generated output towards grammatically correct sequences.

The problem of detecting subject–verb agreement (SVA) errors is an important subtask of GED. In this work, we focus on detecting subject–verb agreement errors in the English as a Second Language (ESL) domain. Most SVA errors occur at the third-person present tense when determining whether the subject describes a singular or a plural concept. The following examples demonstrate subject–verb agreement errors (bold):

(1) a. *They all **knows** where the conference is.
    b. *The Hotel **are** very close to Town Hall.

The task can be formulated as a sequence labeling problem, with the goal of labeling subject–verb pairs as being in agreement or not.

Approaches. Sequence labeling problems in NLP, including GED and the subtask of identifying SVA errors, have, in recent years, been handled with Recurrent Neural Networks (RNNs) trained on large amounts of data (Rei and Yannakoudakis, 2016, 2017). However, most publicly available datasets for GED are relatively small, making it difficult to learn a general grammar representation and potentially leading to over-fitting. Previous work has also shown that neural language models with a similar architecture have difficulty learning subject–verb agreement patterns in the presence of agreement attractors (Linzen et al., 2016).

Rule-based approaches (Andersen et al., 2013) are still considered a strong alternative to end-to-end neural networks, with many industry solutions still relying on rules defined over syntactic trees. The rule-based approach has the advantage of not requiring manual annotation, while also allowing easy access to adding and removing individual rules. On the other hand, language is continuously evolving, and there are exceptions to most grammar rules we know. Additionally, rule-based matching typically relies on syntactic pre-processing, which is error-prone, leading to compounding errors that hurt the downstream GED performance.

Our contributions. In this work, we compare the performance of rule-based approaches and

Proceedings of NAACL-HLT 2019, pages 2418–2427

end-to-end neural models for the detection of SVA errors. We show that rule-based systems are vulnerable to errors in the underlying syntactic parsers, while also failing to capture irregularities and exceptions. In contrast, end-to-end neural architectures are limited by the available labeled examples and sensitive to the variance in these datasets. We then make the following observation: while rule-based error *detection* is severely affected by errors and irregularities in syntactic parsing, rule-based error *generation* is more robust. SVA errors can be generated without identifying subject dependency relations in advance, and changing the number of a verb almost always leads to an error. This generated data can be used as a silver standard for optimizing neural sequence labeling models. We demonstrate that a system trained on a combination of available labeled data and large volumes of silver standard data outperforms both neural and rule-based baselines by a margin on three out of four standard benchmarks, and on average achieves a new state-of-the-art on detecting SVA errors.

2 Related work

Neural approaches. Recent neural approaches to GED include Rei and Yannakoudakis (2016) who argue that bidirectional (bi-) LSTMs, in particular, are superior to other RNNs when evaluated on standard ESL benchmarks for GED and give state-of-the-art results. Rei and Yannakoudakis (2017) show even better performance using a multi-task learning architecture for training bi-LSTMs that additionally predicts linguistic properties of words, such as their part of speech (PoS).

Recent studies (Linzen et al., 2016; Gulordava et al., 2018; Kuncoro et al., 2018) have specifically analyzed the performance of LSTMs in learning syntax-sensitive dependencies such as SVA.

Rule-based approaches. Cai et al. (2009) use a combination of dependency parsing and sentence simplification, as well as special handling of *wh*-elements, to detect SVA errors. Once the subject–verb relation is identified, after parsing the simplified input sentence, a PoS tagger is used to check agreement. This is similar in spirit to the rule-based baseline system used in our experiments below. Wang et al. (2015) use a similar approach, distinguishing between four different sentence types and using slightly different rules for each type. Their rules are, again, defined over the outputs of a dependency parser and a PoS tagger. Sun et al. (2007) use labeled data to derive rules based on dependency tree patterns.

Automatic error generation. Because of the scarcity of annotated datasets in GED, research has been carried out on creating artificial errors, where errors are injected into otherwise correct text using deterministic rules or probabilistic approaches using linguistic information (Felice and Yuan, 2014; Kasewa et al., 2018). Studies focusing on detecting specific error types such as determiners and prepositions (Rozovskaya and Roth, 2011) or noun number (Brockett et al., 2006) are mainly developed within the framework of automatic error generation. Recent work, expanding the detection (Rei et al., 2017) and the correction (Xie et al., 2018) tasks to all types of errors, improves the performance of neural models by training on additional artificial error data generated via machine translation methods.

Miscellaneous. Recent work has also led to good performance in correcting grammatical errors (Yannakoudakis et al., 2017; Bryant and Briscoe, 2018; Chollampatt and Ng, 2018). However, in this paper, we are interested in the task of grammatical error *detection* and we therefore compare our work to current state-of-the-art approaches to detecting errors and do not report the performance of correction systems.

3 Subject–verb agreement detection

Following recent work on GED (Rei and Yannakoudakis, 2016), we define SVA error detection as a sequence labeling task, where each token is simply labeled as correct or incorrect. For a given SVA error, only the verb is labeled as incorrect. Error types other than SVA are ignored, i.e., we do not correct the errors in the text and we do not attempt to predict them as incorrect.

In this paper, we only study SVA in English. We note that even for English, there is some controversy about what constitutes an SVA error. Manaster-Ramer (1987), cites this example, which has been used by some as an argument for English exhibiting cross-serial dependencies:

(2) The man and the women dance and sing, respectively.

We also note that subject–verb agreement can be more or less pervasive across languages, depending on how rich the morphology is, whether the given language exhibits *pro-drop*, and how far apart subjects and verbs are likely to occur.

4 Systems

4.1 Rule-based system

Typically, building a GED rule-based system is time-consuming and requires specific knowledge to deal with the multiple exceptions and irregularities of languages. Difficult cases (such as long distance subject–verb relations) are often ignored in order to ensure high precision, at the expense of the recall of the system. However, our rule-based system is not limited to the detection of simple cases of SVA errors. It relies on PoS tags and dependency relations to identify all types of SVA errors. Specifically, our rule-based system operates as follows: (i) it identifies the candidate verbs based on PoS tags;[1] (ii) for a given verb, it uses the dependency relations to find its subject;[2] (iii) the PoS tag of the verb and its subject are used to check whether they agree in number and person. We use predicted Penn Treebank PoS tags and dependency relations provided by the Stanford Log-linear PoS Tagger (Toutanova et al., 2003) and the Stanford Neural Network Dependency Parser (Chen and Manning, 2014) respectively.

4.2 Neural system

We use the state-of-the-art neural sequence labeling architecture for error detection (Rei and Yannakoudakis, 2016). The model receives a sequence of tokens $(w_1, ..., w_T)$ as input and outputs a sequence of labels $(l_1, ..., l_T)$, i.e., one for each token, indicating whether a token is grammatically correct (in agreement) or not, in the given context. All tokens are first mapped to distributed word representations, pre-trained using word2vec (Mikolov et al., 2013) on the Google News corpus. Following Lample et al. (2016), character-based representations are also built for every word using a bi-LSTM (Hochreiter and Schmidhuber, 1997) and then concatenated onto the word embedding.

The combined embeddings are then given as input to a word-level bi-LSTM, creating representations that are conditioned on the context from both sides of the target word. These representations are then passed through an additional feed-forward layer, in order to combine the extracted features and map them to a more suitable space. A softmax output layer returns the probability distribution over the two possible labels (*correct* or *incorrect*) for each word. We also include the language modeling objective proposed by Rei (2017), which encourages the model to learn better representations via multi-tasking and predicting surrounding words in the sentence. Dropout (Srivastava et al., 2014) with probability 0.5 is applied to word representations and to the output from the word-level bi-LSTM. The model is optimised using categorical cross-entropy with AdaDelta (Zeiler, 2012).

5 Data

5.1 Data preprocessing

As the public datasets either have their own taxonomy or they are not annotated with error types at all, we apply the error type extraction tool of Bryant, Felice, and Briscoe (2017) to automatically get error types mapped to the same taxonomy for all datasets. The tool automatically annotates parallel original and corrected sentences with error type information. When evaluated by human raters, the predicted error types were rated as "good" or "acceptable" in at least 95% of the cases. We use their publicly available tool[3] to automatically get error types for all public datasets mapped to the same taxonomy of 25 error types in total. We then set SVA errors as our target class.

5.2 Test data

We compare the rule-based and neural approaches for the task of SVA error detection on four benchmarks in the ESL domain.

- **FCE**. The Cambridge Learner Corpus of First Certificate in English (FCE) exam scripts consists of texts produced by ESL learners taking the FCE exam, which assesses English at the upper-intermediate proficiency level (Yannakoudakis et al., 2011). We use the publicly available test set.

- **AESW**. The dataset from the Automated Evaluation of Scientific Writing Shared Task

---

[1] Present tense verbs + "was" and "were".

[2] The subject can be direct – attached with a `nsubj` relation – or indirect, such as when the syntactic subject is a relative pronoun, e.g., *who*, or an expletive, e.g., *there*.

[3] https://github.com/chrisjbryant/errant

2016 (AESW) is a collection of text extracts from published journal articles (mostly in physics and mathematics) along with their (sentence-aligned) corrected counterparts (Daudaravicius et al., 2016). We test on the combined trained, development and test set.[4]

- **JFLEG**. The JHU Fluency-Extended GUG corpus (JFLEG) represents a cross-section of ungrammatical data, consisting of sentences written by ESL learners with different proficiency levels and L1s (Napoles et al., 2017). We evaluate our models on the public test set.
- **CoNLL14**. The test dataset from the CoNLL 2014 shared task consists of (mostly argumentative) essays written by advanced undergraduate students from the National University of Singapore, and are annotated for grammatical errors by two native speakers of English (Ng et al., 2014).

5.3 Training data

ESL writings. We use the following ESL datasets as training data:

- **Lang8** is a parallel corpus of sentences with errors and their corrected versions created by scraping the Lang-8 website[5], which is an open platform where language learners can write texts and native speakers of that language can provide feedback via error correction (Mizumoto et al., 2011). It contains $1,047,393$ sentences.
- **NUCLE** comprises around $1,400$ essays written by students from the National University of Singapore. It is annotated for error tags and corrections by professional English instructors (Dahlmeier et al., 2013). It contains $57,151$ sentences.
- **FCE train set**. We use the publicly available FCE training set, containing $25,748$ sentences. A subset of $5,000$ sentences was separated and used for development experiments.

Artificial errors. We generate artificial subject–verb agreement errors from large amounts of data. Specifically, we use the British National Corpus (BNC, BNC-Consortium et al., 2007), a collection of British English sentences that includes samples from different media such as newspapers, journals, letters or essays. Subject–verb agreement in English merely consists of inflecting 3rd person singular verbs in the present tense (and *be* in the past), which makes any text in English fairly easy to corrupt with SVA errors. We assume that the BNC data is written in correct British English. Using predicted PoS tags provided by the Stanford Log-linear PoS Tagger, we identify verbs in present tense, as well as *was* and *were* for the past tense, and flip them to their respective opposite version using the list of inflected English words (annotated with morphological features) from the Unimorph project (Kirov et al., 2016). The final artificial training set includes the sentences with injected errors ($265,742$ sentences), their original counterpart, and sentences where SVA errors could not be injected due to not containing candidate verbs that could be flipped ($241,295$ sentences).

6 Experiments

The models. We compare our neural model trained on both artificially generated errors and ESL data (LSTM$_{ESL+art}$) to three baselines: a neural model trained only on ESL data (LSTM$_{ESL}$) (i.e., reflecting the performance of current state-of-the-art approaches for GED), a language model based method (BERT-LM) and our rule-based system.

In order to measure the real performance of a language model (LM) on the detection of SVA errors, we choose to use the BERT system (Devlin et al., 2018) to assign probabilities to different versions of the test sentences. Specifically, we use the pre-trained uncased BERT-Base model. We duplicate the sentences each time a corruptible verb occurs (flipping its number). The LM assigns a probability to both possible versions of the verbs. We select the version which has the highest probability, if this probability is at least 0.1[6] higher than the probability of the verb in the original sentence.

---

[4] Sentences containing special placeholders for mathematical equations, dates, etc. are filtered out.

Table 1: Performance of our systems (rule-based and LSTMs) and baselines. BERT-LM is the language model baseline.

Hyper-parameters. We tune the model hyper-parameters on the FCE development set, according to the $F_{0.5}$ score. Training is stopped when $F_{0.5}$ on the FCE development set does not improve over 7 epochs. Word representations have size 300, while character representations have size 100. The word-level LSTM hidden layers have size 300 for each direction, and the character-level LSTM hidden layers have size 100 for each direction.

Evaluation. Existing approaches are typically optimised for high precision at the cost of recall, as a system's utility depends strongly on the ratio of true to false positives, which has been found to be more important in terms of learning effect. A high number of false positives would mean that the system often flags correct language as incorrect, and may therefore end up doing more harm than good (Nagata and Nakatani, 2010). Because of this, $F_{0.5}$ is preferred to F_1 in the GED domain as it puts more weight on precision than recall. For each experiment, we report the token-level precision (P), the recall (R), and the $F_{0.5}$ scores.

7 Results

The main results are summarized in Table 1. Looking at the performance of the LSTM$_{ESL+art}$ system, we see that on 3 out of 4 benchmarks, our neural model trained on artificially generated errors outperforms the LSTM$_{ESL}$ system with respect to $F_{0.5}$. On average, over the four benchmarks, its $F_{0.5}$ score is 2.43 points higher than the best performing baseline. Both neural models obtain higher $F_{0.5}$ scores than the rule-based baseline, on average and across the board, i.e., $+10.6$ for LSTM$_{ESL}$ and $+15.7$ for LSTM$_{ESL+Art}$. The BERT-LM outperforms the LSTM$_{ESL}$ (mostly due to its higher recall, i.e., $+18.66$) but still does not reach the $F_{0.5}$ score of the LSTM$_{ESL+Art}$ system which gets higher precision and recall overall ($+2.62$ and $+1.51$ respectively).

Furthermore, we observe a trend that the two LSTM systems trade off precision and recall, with the LSTM$_{ESL}$ system yielding the highest precision across most datasets, but also yielding significantly lower recall than LSTM$_{ESL+Art}$. It is also evident that the performance varies over domains: all models struggle with AESW. This is likely due to the complexity of the scientific writing genre where, for example, sentences contain parentheses interposed between a verb and its subject. We also note errors are far less frequent in this genre, leading to moderate recall and very low precision. For the rest of the datasets, system performance is generally better.

8 Analysis

We analyze the effect of adding artificial errors to the training data. In particular, we focus on the robustness of our models by looking at how sensitive they are to grammatical errors in the surrounding context; and by looking at how good the models are at predicting agreement relative to the distance between the subject and verb. This set of experiments is similar in spirit to Linzen et al. (2016). We also analyze our rule-based baseline: so far, we know our rule-based baseline was sensitive to parser errors and irregularities. We inspect the quality of the underlying parser by evaluating it on data that resembles the data used in our experiments, to see whether errors seem to result more from parser errors or irregularities. Finally, we also look at the sensitivity of our systems to other linguistic phenomena such as relative clauses or conjunctions.

8.1 Sensitivity to other errors in the surrounding context

In ESL writings, multiple errors can occur in the same sentence. This means more variable contexts, which can lead to degradation in the performance of both syntactic parsers / rule-based systems and GED models.

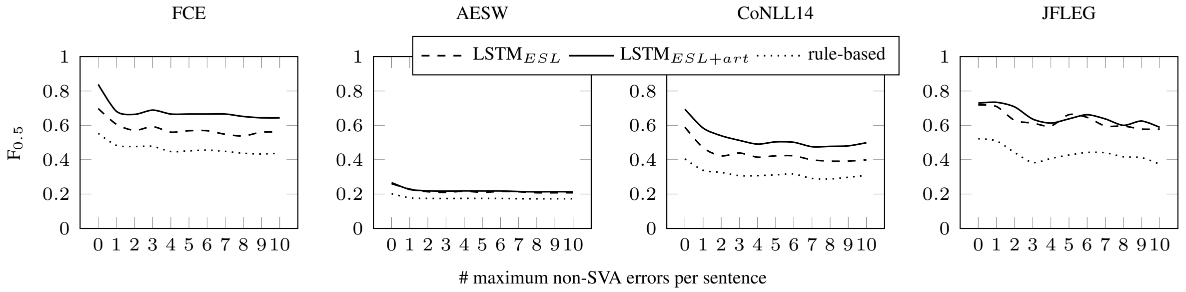

Figure 1: Performance ($F_{0.5}$ scores) of the systems with respect to the noise in test data (i.e., the number of additional non-SVA errors in sentences).

Testing on noisy contexts We first evaluate how our systems are impacted by additional non-SVA errors in the surrounding context of SVA errors in our test data. For each of the test datasets, we create multiple versions, allowing for n non-SVA errors per sentence (we correct the extra non-SVA errors). This way we can create datasets with different levels of complexity with respect to the grammatical errors within them.

In Figure 1, the $F_{0.5}$ scores of the models are shown for different numbers of grammatical errors per sentence. It is evident that all of the models are negatively affected by the presence of other errors in the same sentence. Using more data for training – i.e., our artificial training data which does not include context errors – generally boosts performance on data with and without grammatical errors in the context. In other words, training with additional artificially generated errors seems, overall, to be making our model more robust. We also note that our rule-based baseline is affected by errors to roughly the same extent as our baseline neural model is. One might have thought the rule-based baseline would suffer more, because of it being sensitive to errors in the underlying syntactic parser. We return to this issue below.

Training on non-noisy contexts In order to assess the benefit of training on non-erroneous contexts, we create a new dataset from our ESL training data (see §5.3). Based on the annotations in the data, we apply the corrections of error types other than SVA, thereby only leaving SVA errors in the data. We experiment with how adding this 'clean' dataset to the training set of our existing systems affects performance. The resulting $F_{0.5}$ scores are listed in Table 2. Using 'clean' sentences in addition to our original ESL data for training always positively affects performance. In this regard, as experimented in (Rei and Yannakoudakis, 2016), training on more data in the same domain is a valid solution for improving the performance of LSTM models. However, when also adding artificially generated data to the training set, we reach higher scores only on 2 out of the 4 benchmarks. It greatly improves the average recall (+11.03), without hurting the precision on FCE and CoNLL14 but affects negatively the precision on AESW and JFLEG.

	FCE	**AESW**	**CoNLL14**	**JFLEG**
System	$F_{0.5}$	$F_{0.5}$	$F_{0.5}$	$F_{0.5}$
LSTM$_{ESL}$	53.49	20.75	38.46	57.82
LSTM$_{ESL+art}$	66.04	21.31	46.27	57.29
LSTM$_{ESL+cor}$	65.08	**27.16**	46.26	**59.52**
LSTM$_{ESL+art+cor}$	**67.16**	21.12	**52.28**	54.64

Table 2: Performance ($F_{0.5}$ scores) of the LSTM models when trained using an additional set of 'clean' sentences (*cor*) where non-SVA errors have been corrected.

8.2 Sensitivity to long-distance dependencies

Next, we want to study how well our models perform when the subjects and verbs are far apart, i.e., when the agreement relation is defined over a long-distance dependency. In order to see how our systems are affected by the distance between the subject and verb, we split the test sets based on different subject–verb distances.

Note, however, that our benchmarks are not annotated with PoS tags and dependency relations. If we binned our test data based on predicted dependencies, the inductive bias of our syntactic parser and the errors it made would bias our evaluation. Instead, we perform our analyses on section 22 and 23 of the Penn Treebank (PTB) dataset (Marcus et al., 1993). The PTB however is not annotated with grammatical errors. We therefore corrupt the sentences by injecting SVA errors, in the same way we corrupted the BNC (§5.3) to create additional training data.

For each sentence in the PTB, we identify a subject–verb pair, and group the sentences by the subject–verb distance. We then run our models on two versions of each sentence: an unaltered version and a corrupted one, where we have generated an SVA error by corrupting the verb, using the method described earlier (§5.3). This way we can compute the performance of our models as $F_{0.5}$ scores over this dataset. The results are displayed in Figure 2. We can see that the LSTM trained with artificial data performs significantly better on long-distance subject–verb pairs than the LSTM trained only on ESL data. This suggests that training on artificially generated errors also makes our models more robust to this potential source of error.

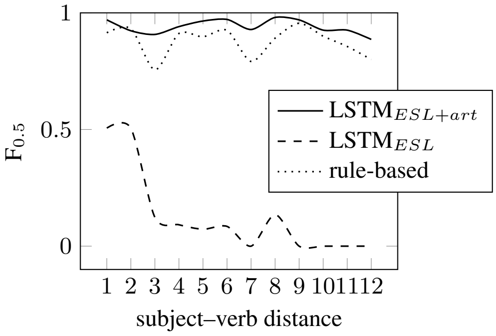

Figure 2: $F_{0.5}$ scores of the systems on the PTB as a function of subject–verb distance.

Note that, in general, there is a substantial gap between the performance of the two LSTM models. This is because one is trained on artificial data – similar to the data we use in our analysis. However, the conclusions are based on the relative differences in performance over long-distance dependencies, and these differences should still be comparable across the two models.

8.3 Sources of error for our rule-based baseline

There are two obvious potential sources of error for our rule-based baseline: sensitivity to errors in the underlying syntactic parsers, and sensitivity to the irregularities of language, e.g., when collective nouns or named entities are subjects, subject–verb agreement cannot always be determined by the PoS tags. We show that the main source of error seems to be irregularities by showing that the underlying syntactic parsers perform relatively well, even in the ESL domain.

Table 3 lists the parsing and tagging performance of our underlying syntactic parsers across three domains: learner data (ESL) and web data (EWT) from the Universal Dependencies (UD) project (Nivre et al., 2017), as well as the newswire data it was trained on (PTB). We only evaluate subject–verb relations, since these are the only ones of interest in this paper. We see that while there is a noticeable out-of-domain drop going from newswire to learner language or web data, the parser is still able to detect subject–verb relations with high precision and recall. This suggests that the vulnerability of our rule-based baseline is primarily a result of linguistic irregularities and exceptions to the implemented rules.

	UD-ESL	UD-EWT	PTB 23
Subject–verb precision	88.47	88.86	91.31
Subject–verb recall	89.37	85.11	89.84
PoS tags accuracy	96.36	93.20	97.79

Table 3: The Stanford PoS Tagger and Dependency Parser's performance on different treebanks. Subject–verb precision/recall relates to subject–verb relations. PoS tag accuracy is only for PoS tags of the subjects and verbs.

8.4 Sensitivity to other linguistic phenomena

Finally, manually reviewing the errors made by the rule-based system, we identified frequent linguistic sources of errors, including relative clauses, conjunctions, ambiguous PoS tags, and collective nouns. We therefore analyze how the LSTMs and the rule-based system are globally sensitive to these potential sources of error. Since our benchmarks are not annotated with PoS and dependency relations, we again use the corrupted PTB sentences (see §8.2).

Many of the examples in which our rule-based baseline fails include *relative clauses* (when the verb is the root of a relative clause) and *conjunctions* (when the subject is a conjunction). A second major cause of failure is ambiguous verbs, i.e., verb forms that can also be nouns (*ambiguous PoS*, e.g., "need", "stop", "point", etc.), and subjects which are singular nouns describing groups of people or things (*collective nouns*, e.g., "team", "family", "staff", etc.). The following examples illustrate these cases (underlined):

(3) a. The church and the cathedral **are** very interesting [. . .] (*conjunction*)

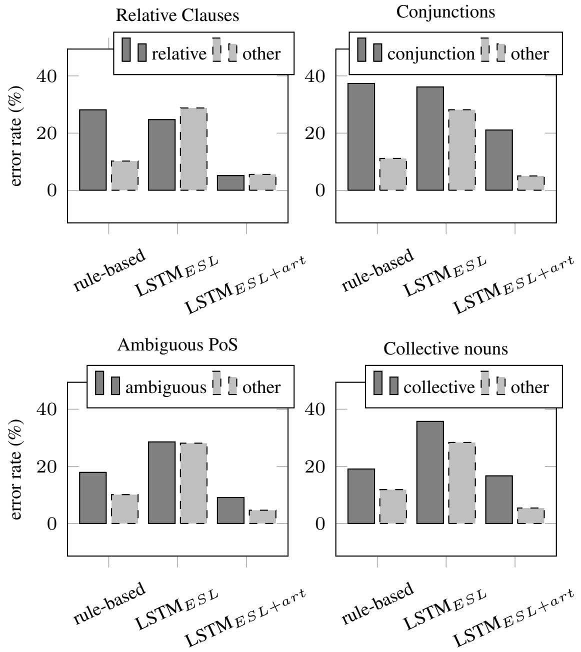

Figure 3: SVA error rates on the PTB data for complex syntactic structures and ambiguous cases.

b. If there is someone who **doesn't** agree with me, he or she [. . .] (*relative clause*)

c. It is said that the majority of the citizens **has** got a car [. . .] (*collective noun*)

d. [. . .] and police officer **walk** around the building as well. (*ambiguous PoS*)

We evaluate our models on the PTB data and report the error rate (the lower the better) on present tense verbs (Figure 3). Overall, results show that all models are negatively affected when they encounter complex syntactic structures and ambiguous cases. Figure 3 also confirms that the rule-based baseline is the most sensitive one to complex structures. Especially in comparison with the LSTM$_{ESL+art}$ model, the rule-based system achieves good scores on verbs which are not part of complex structures, but performs significantly worse on difficult cases. The LSTM$_{ESL}$ model is the worst across almost all cases, while the LSTM$_{ESL+art}$ shows significant improvements over the baselines, in particular for the difficult cases.

9 Conclusion

In this paper, we argue for artificial error generation as an effective approach to learning more robust neural models for subject–verb agreement detection. We demonstrate that error generation is much less sensitive to parsing errors and irregularities than rule-based systems for detecting subject–verb agreement. On the other hand, artificial error generation enables us to utilise much more training data, and therefore can develop more robust neural models for SVA error detection that do not overfit the available, manually annotated training data. Our simple approach to detecting subject–verb agreements achieves a new state of the art on three out of four available benchmarks, and, on average, is better than previous approaches on the task. We show that, in particular, models trained on large volumes of artificially generated errors become more robust to other errors in the surrounding context of SVA, long-distance dependencies, and other challenging linguistic phenomena.

Abstract

Unsupervised part of speech (POS) tagging is often framed as a clustering problem, but practical taggers need to *ground* their clusters as well. Grounding generally requires reference labeled data, a luxury a low-resource language might not have. In this work, we describe an approach for low-resource unsupervised POS tagging that yields fully grounded output and requires no labeled training data. We find the classic method of Brown et al. (1992) clusters well in our use case and employ a decipherment-based approach to grounding. This approach presumes a sequence of cluster IDs is a 'ciphertext' and seeks a POS tag-to-cluster ID mapping that will reveal the POS sequence. We show intrinsically that, despite the difficulty of the task, we obtain reasonable performance across a variety of languages. We also show extrinsically that incorporating our POS tagger into a name tagger leads to state-of-the-art tagging performance in Sinhalese and Kinyarwanda, two languages with nearly no labeled POS data available. We further demonstrate our tagger's utility by incorporating it into a true 'zero-resource' variant of the MALOPA (Ammar et al., 2016) dependency parser model that removes the current reliance on multilingual resources and gold POS tags for new languages. Experiments show that including our tagger makes up much of the accuracy lost when gold POS tags are unavailable.

1 Introduction

While cellular, satellite, and hardware advances have ensured that sophisticated NLP technology can reach all corners of the earth, the language barrier upon reaching remote locales still remains. As an example, when international aid organizations respond to new disasters, they are often unable to deploy technology to understand local reports detailing specific events (Munro and Manning, 2012; Lewis et al., 2011). An inability to communicate with partner governments or civilian populations in a timely manner leads to preventable casualties.

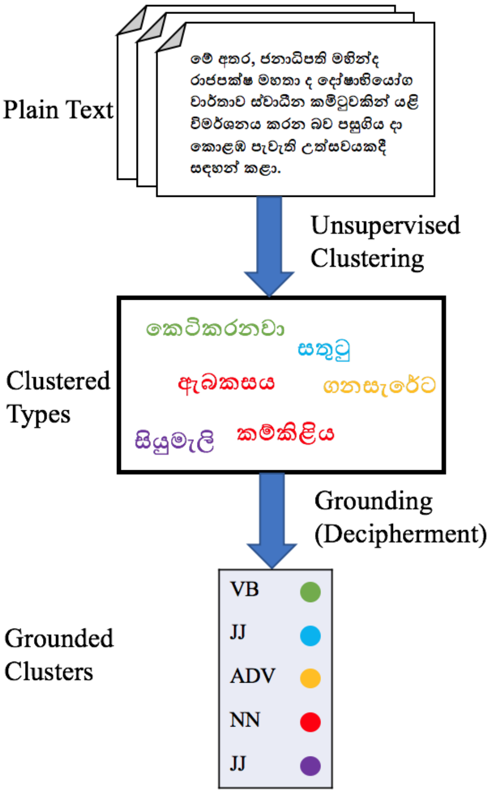

Figure 1: Overview of our approach to grounded POS tagging. We use an unsupervised clustering method (Section 3.2) then reduce and ground the clusters using a decipherment approach informed by POS tag sequence data from many languages (Section 3.3).

The lack of adequate labeled training data has been the major obstacle to expanding NLP's outreach more multilingually. Developments in unsupervised techniques that require only monolingual corpora (Lample et al., 2018a; Artetxe et al., 2018) and the ability to leverage labeled resources in other languages have been proposed to address this issue (Das and Petrov, 2011; Duong et al., 2014; Ammar et al., 2016). Unfortunately, these

Proceedings of NAACL-HLT 2019, pages 2428–2439
Minneapolis, Minnesota, June 2 - June 7, 2019.

methods either do not work in practice on true low-resource cases or unrealistically assume the availability of some amount of supervision.

Consider syntactic parsing as a prime example. Past editions of the CoNLL Shared Task on Multilingual Parsing (Zeman et al., 2017, 2018) featured a category of target languages for which either little or no training data was provided. However, even in the 'no-resource' scenario that most closely matches our use case, gold part-of-speech (POS) tags for test data were provided for the participants to use. Prior to these shared tasks, Ammar et al. (2016) proposed a variant of their main model, MALOPA, that was meant to produce reasonable parses for languages under "zero-resource" conditions. In order to function, however, the model requires users to provide gold POS tags and word mappings from these languages into a common semantic space, using approaches that require parallel data (Guo et al., 2015).

Indeed, the compulsion to use POS tag-labeled data in zero-resource circumstances extends to the vast, varied lines of research in unsupervised POS tagging itself! Every approach explored so far ultimately requires POS-annotated resources for the language being studied in order to produce a final, grounded output. Even the most conservative strategies (Goldwater and Griffiths, 2007; Berg-Kirkpatrick et al., 2010; Stratos et al., 2016) that do not require any supervised signal during training still ultimately produce only ungrounded clusters, and require a reference annotated corpus to map the inferred clusters or states to actual POS tags.

Making matters worse, evaluation is generally offered in terms of the 'many-to-one' or 'one-to-one' analyses Johnson (2007). These metrics use a reference corpus to determine the *optimal* mapping of clusters to tags. While this evaluation approach is intuitively sensible for measuring cluster purity, to actually *use* such an output, an entire annotated training corpus is required.[1] It is not enough to simply rely on ungrounded clusters in real-world systems; grounded labels offer a sort of universal API between other resources such as rule-based modules that operate on certain word types or between resources built from other annotated high-resource language data.

Since POS tag and parallel data resources for new languages are often unavailable or unreliable, we make the following contributions to ensure the surprise of a new language does not immobilize us:

- We introduce a decipherment-based approach to POS grounding, which yields fully grounded output and does not require any annotated data or parallel corpora in the language to be analyzed. The approach uses pre-existing human-labeled POS tag sequences from high-resource *parent languages* (PL) but no labeled data or sequences for the target, or *child language* (CL). An overview of the approach is shown in Figure 1.
- We demonstrate our approach by evaluating over a variety of languages spanning 4 families and 8 genera (Germanic, Romance, Slavic, Japanese, Semitic, Iranian, Indic, and Bantoid), and show across-the-board reasonable intrinsic performance, given the difficulty of the task and the stringency (straightforward accuracy) in comparison to other unsupervised evaluation strategies.
- We test the utility of our grounded tags in a name tagging task, obtaining state-of-the-art performance for Sinhalese and Kiryarwanda, two languages with nearly no labeled POS or named entity resources.
- We further pare down the annotated resources required in an existing 'zero-resource' dependency parser model and show that our unsupervised and grounded tags are helpful at closing the gap between a nihilistic tag-free setting and an unrealistic gold tag setting.
- We release our code so that others may create zero-resource syntactic analysis and information extraction systems at the onset of the next new emergency.[2]

2 POS Grounding as Decipherment

We consider the task of POS induction as a two-step pipeline: from word sequence w to POS tag sequence p via cluster sequence c. Formally, our conditional probability model is

---

[1] Additionally, Headden III et al. (2008) demonstrated that these metrics are not indicative of downstream performance.

[2] `https://github.com/isi-nlp/universal-cipher-pos-tagging.git`

$$\begin{aligned}&\underset{p}{\operatorname{argmax}} P_\theta(p|w)\\&\qquad= \underset{p}{\operatorname{argmax}} \sum_{c\in C^{|w|}} P_\theta(p,c|w)\\&\qquad= \underset{p}{\operatorname{argmax}} \sum_{c\in C^{|w|}} P_\theta(p|c,w)P_\theta(c|w)\end{aligned}$$

where C is the cluster vocabulary and θ parameterizes our probability model. If we assume a deterministic pipelined clustering of words and a tag labeling model that does not depend on words, then for chosen $\hat{c}$, this becomes

$$\begin{aligned}&\underset{p}{\operatorname{argmax}} \sum_{c\in C^{|w|}} P_\theta(p|c,w)P_\theta(c|w)\\&\qquad= \underset{p}{\operatorname{argmax}}\, P_\theta(p|\hat{c})\\&\qquad= \underset{p}{\operatorname{argmax}}\, P_\theta(\hat{c}|p)P_\theta(p) \qquad (1)\end{aligned}$$

We call this model the *cipher grounder*. As presented it requires an estimate for $P_\theta(p)$ for the CL, which requires POS training data. Under the zero-resource scenario, we instead approximate $P_\theta(p)$ by the tag distribution of a PL. Then, the *cipher table* $P_\theta(\hat{c}|p)$ can be trained using a noisy-channel, expectation-maximization (EM)-based approach as in Ravi and Knight (2011).

3 POS Tagger construction

We approach the search for optimal components in the two-step pipeline outlined in Section 2 in a cascaded manner. First, an optimal word clustering is determined by means of the many-to-one evaluation method. This method is explained well by Johnson (2007):

> “ ...deterministically map each hidden state to the POS tag it co-occurs most frequently with, and return the proportion of the resulting POS tags that are the same as the POS tags of the gold-standard corpus.”

While unrealistic for POS tagger performance purposes, many-to-one is a good choice for determining cluster ‘purity’ and provides a reasonable grounding upper bound. As the calculation of many-to-one does require labeled data, we constrain the use of these labels for development and will evaluate extrinsically using languages for which we do not have any training data; see Section 5.2.

Secondly, we search for the best approach to ground the chosen clusters, given several possible PL options.

After the optimal components and parameters are determined, we validate POS tag quality intrinsically via tag accuracy on reference data where it exists, and then extrinsically on two downstream tasks. We investigate a simulated no-resource scenarios in the task of dependency parsing, and a real low-resource scenario in name tagging.

3.1 Datasets

For intrinsic evaluation and optimization of the tagging pipeline, including all preliminary experiments, we use annotated corpora from Universal Dependencies (UD) v2.2[3] for the following languages: English (en), German (de), French (fr), Italian (it), Spanish (es), Japanese (ja), Czech (cs), Russian (ru), Arabic (ar), and Farsi (fa). For Swahili (sw), we use the Helsinki Corpus of Swahili 2.0.[4] Overall in these experiments we cover 11 languages and 4 language families.

In our dependency parsing experiments, we use the Universal Treebank v2.0 (McDonald et al., 2013) for en, de, fr, es, it, Portuguese (pt), and Swedish (sv). This set of treebanks is chosen instead of UD in order to obtain results comparable to those of previous work on simulated zero-resource parsing scenarios (Ammar et al., 2016; Zhang and Barzilay, 2015; Rasooli and Collins, 2015).

In our name tagging experiments, we use monolingual texts for Sinhalese (si) and Kinyarwanda (rw) provided by DARPA’s Low Resource Languages for Emergent Incidents (LORELEI) Program during the 2018 Low Resource Human Languages Technologies (LoReHLT) evaluation.

3.2 Unsupervised Clustering

In this step we compare two approaches to unsupervised ungrounded labeling. The first strategy is to cluster by word types and thus label each token with its cluster ID independently of its context.[5] We consider Brown’s hierarchical clustering algo-

---

[3] `http://universaldependencies.org/`

[4] `http://urn.fi/urn:nbn:fi:lb-2016011301`

[5] We refer to ungrounded POS tag labels as ‘clusters’ even though not all methods induce a clustering.

rithm, (Brown et al., 1992)[6] BROWN; Brown's exchange algorithm,[7] (Martin et al., 1998) MARLIN; and k-means clustering of monolingual word embeddings of dimension size 100, trained using *fastText* (Joulin et al., 2016), E-KMEANS. The second labeling strategy is context-sensitive; it uses the Bayesian HMM tagger proposed by Stratos et al. (2016), which we call A-HMM. As noted previously, we evaluate unsupervised labeling extrinsically, via the many-to-one approach, and use the best performing labeling in the complete two-step grounded tagging pipeline.

In preliminary experiments, we vary the number of clusters and hidden states ($|C|$) between 17 and 500. We initially sought to create one cluster per UD POS tag and then choose the proper 1:1 assignment of cluster to tag, following the approach of Stratos et al. (2016). However, cluster purity is low when only 17 clusters are allowed (i.e. each cluster has words with a variety of POS tags). Naturally, as the number of clusters is raised, the purity of each cluster improves. We ultimately fix the cluster limit at 500, which gives a good trade-off between overall cluster quality for all the ungrounded tagging methods, and size small enough to allow EM-based decipherment to be tractable.

Given this setting, we evaluate our four labeling strategies using the many-to-one approach, as presented in Table 1. Due to the larger number of clusters, the results presented here are higher than and not comparable to the original literature describing the methods.[8] We can, nevertheless, make relative judgements. In all cases, clustering by type with Brown-based algorithms works better than using a sophisticated tagger such as A-HMM. Since BROWN and MARLIN obtain similar results, with no consistently dominant model, in all subsequent experiments we use the BROWN labeler with 500 clusters.

3.3 Grounding via Decipherment

We now seek an appropriate method for grounding the clusters generated in Section 3.2. We experiment with en, fr, fa, and sw as CLs. For each CL t, we instantiate our model following Equation 1, using the Carmel toolkit (Graehl, 1997) and forming the cipher table as a one-state transducer. We train these models using EM for 500 iterations or until convergence, and we select the model with the lowest perplexity from among 70 random restarts.

Yet unspecified is the nature of the POS language model $P_\theta(p)$. We begin by training bigram models of POS tag sequences with additive smoothing using the SRILM toolkit (Stolcke, 2002) for each PL $s \in \mathcal{S}$ = {en, de, fr, it, es, ja, ar, cs, ru, sw}. But which PL's POS tag data to use for each CL? We explore two initial criteria for choosing a single suitable PL s: confidence of the model during decoding (perplexity, PPL), and typological similarity. For the first criterion, the PL whose cipher grounder s-t yields the better performance is chosen. For the second criterion, the most similar language to CL t is chosen according to the cosine similarity between typological features vectors. We employ 102 features obtained from WALS[9] related to word order and morphosyntactic alignment, further reduced to 50 dimensions using PCA. However, none these criteria correlates significantly to tagging accuracy, as we elaborate in Section 5.1. We instead try a combined approach.

The likelihood of cluster ID replacement, $P_\theta(\hat{c}_i|p_j), \forall \hat{c}_i \in C, \forall p_j$ in the tagset, is replaced by

$$P_{avg}(\hat{c}_i|p_j) \sim \frac{\sum_{s \in \mathcal{S}, s \neq t} P_\theta(\hat{c}_i|p_j^s)}{|S| - 1}$$

where $P_\theta(\hat{c}_i|p_j^s)$ is the likelihood of POS tag p_j being represented by cluster $\hat{c}_i$ after training with the language s tag distribution. Note that the CL is excluded from $\mathcal{S}$ for the combination. The combined cipher grounder is then defined by

$$\underset{p}{\operatorname{argmax}}\, P_{all}(p) P_{avg}(\hat{c}|p) \qquad (2)$$

where $P_{all}(p)$ is a language model trained over the concatenation of POS sequences of all parent languages in $\mathcal{S}$. We call this approach CIPHER-AVG.

4 Downstream Tasks

4.1 Name Tagging

We experiment with the LSTM-CNN model proposed by Chiu and Nichols (2016), one of the

---

state-of-the-art name tagging models, as our baseline model. To incorporate POS features, we extend the token representation (word and character embeddings) with a one-hot vector representation of the POS tag. Figure 2 presents an outline of the architecture.

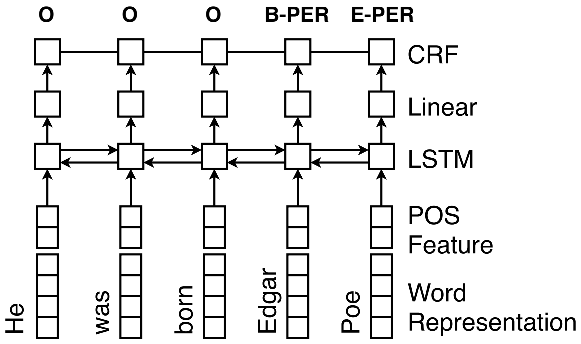

Figure 2: Name tagging model evaluated in Section 5.2. This is an extension of the model of Chiu and Nichols (2016) with POS tag features added.

4.2 Multilingual Dependency Parsing

We base our experiments on the no-treebank setup of MALOPA (Ammar et al., 2016), but change the underlying transition-based parser to the graph-based parser proposed by Dozat and Manning (2017) for implementation convenience. Following this setup, for each CL except en, we train the parser on the concatenation of treebanks of the other 6 languages as PLs.

The original MALOPA work enriches the input representation by concatenating pretrained multilingual word embeddings (Guo et al., 2016), multilingual Brown cluster IDs, and POS tag information. However, these representations are obtained using parallel corpora and gold POS tags are required for parsing at test time.

In contrast, we are interested in the realistic scenario in which no resource is available in the child language but raw text. It is important to note, however, that our objective is not to beat the state-of-the-art on this benchmark but to investigate parsing performance fluctuation when cross-lingual components (gold POS annotations and supervised multilingual embeddings) are replaced by those obtained in an unsupervised manner.

We investigate the following variations to each component of the input representation.

- **Multilingual word and cluster embeddings.** The original work of Ammar et al. (2016) uses 'robustly projected' pre-trained embeddings (Guo et al., 2015) for word embeddings and embeddings learned from English Brown cluster IDs projected through word alignments (Guo et al., 2016) for cluster embeddings; both of these rely on parallel data and we refer to them collectively as GUO. We replace these with monolingual *fastText* embeddings (Bojanowski et al., 2017) projected to a common space using MUSE, the unsupervised method of Lample et al. (2018b). For cluster embeddings we start with *fastText* monolingual embeddings trained over Brown cluster ID sequences instead of word tokens ($|C| = 256$, the same as in Guo et al. (2016)). Then, unsupervised multilingual embeddings are derived, again using MUSE.[10] Note that this approach, which we refer to collectively as MUSE, requires no parallel data. We compare both MUSE and GUO approaches in Section 5.2 and Table 5.
- **POS tag scheme.** The original work uses gold POS tag data at both train and test time. While realistic to have gold POS info from PLs for training, it is unrealistic to have this data available for new CLs at test time. We thus compare the original GOLD scenario with the realistic CIPHER scenario, where the training data is still gold, but the test POS tags use the method presented in this work. Another realistic scenario dispenses

---

[10] Both cluster and word MUSE embeddings are projected to the corresponding English space.

with POS disambiguation except for the trivial distinction of punctuation; for compatibility purposes this is done in both train and test data and is labeled NONE.

We investigate all combinations of {GUO, MUSE}-{GOLD, CIPHER, NONE}.

5 Results and Discussion

5.1 Labeling and Cipher Grounding

The results in Table 1 are somewhat at odds with those presented in Stratos et al. (2016), but these are done at different operating points; we use different data, the UD-17 tag set instead of the Universal Treebank 12 tag set, and, perhaps most importantly, generate more clusters. We further note that to some degree, choosing Brown clusters based on the results in Table 1 compromises claims of our approach being fully ‘unsupervised’ for those six languages, however our subsequent experiments on additional languages are truly unsupervised.
