  - **Consecutive**: Sentences that have a coordinate structure consisting of more than two conjuncts.
  - **Multiple**: Sentences that have multiple coordinate structures.

Sentences categorized as "All" are the union of the mutually exclusive sets of Simple and Complex.

Table 4 shows complete match rates on the PTB. Both on the development and test sets, our system records significant gain, in comparison to Teranishi+17:+ext, on Simple coordination sentences. It might be because the inner and outer-boundary scoring models learn to predict four boundaries of two spans, whereas the baseline model predicts only two outer boundaries on Simple coordination sentences. Since an appositive or adverbial phrase can appear between a coordinator and its conjunct, the assumption that two conjuncts must be next to

---

[5] *Consecutive* and *Multiple* both contain sentences that are Consecutive and Multiple.

Model	Sentence	Development	Test
Ours	All	489 / 673 = **72.65**	619 / 873 = **70.90**
	- Simple	378 / 481 = **78.58**	476 / 609 = **78.16**
	- Complex	111 / 192 = **57.81**	143 / 264 = **54.16**
	- Consecutive	41 / 66 = **62.12**	56 / 96 = **58.33**
	- Multiple	79 / 146 = **54.10**	96 / 197 = **48.73**
Teranishi+17 :+ext	All	468 / 673 = 69.53	577 / 873 = 66.09
	- Simple	358 / 481 = 74.42	444 / 609 = 72.90
	- Complex	110 / 192 = 57.29	133 / 264 = 50.37
	- Consecutive	40 / 66 = 60.60	48 / 96 = 50.00
	- Multiple	78 / 146 = 53.42	92 / 197 = 46.70

Table 4: Complete match rates of coordinations per sentence.

	All (exact)			All (inner)
	P	R	F	F
default	76.95	76.76	76.85	79.10
-POS tags	71.59	71.34	71.47	74.42
-CharCNNs	76.41	76.41	76.41	78.53
-GloVe	75.05	75.23	75.14	77.03
+ELMo	76.35	76.17	76.26	78.15
concat feature	74.85	74.41	74.63	76.64

Table 5: Performance comparison between different settings of the proposed models.

a coordinator fails and causes errors. Our system also outperforms Teranishi+17:+ext on Consecutive and Multiple coordination sentences. Teranishi+17:+ext predicts a coordination span, and then splits it into conjunct spans. Therefore, it can mistakenly segment coordinations when false sub-coordinators appear in a sentence. In contrast, our approach ascertains whether sub-coordinating words are true sub-coordinators; thus, it can lead to more robust production of Consecutive sentences.

What helps for Coordination Parsing?

We conduct an ablation study for our model. Table 5 shows the results. Without the POS tags, the model performs poorly. It is worthy of note that the pretrained word embedding is beneficial information for the task. On the other hand, the use of contextual embedding, ELMo, does not improve performance. We deduce that POS tags and morphological information, and not contextual word senses, are clues for shorter and similar coordinations such as NP coordinations. For the feature extraction function of the outer-boundary scoring model, the *concat* function that performs the same function as the inner-boundary scoring model does not achieve competitive advantage. The feature function described as Eq. 12 is designed to capture the similarity and replaceability of two spans; while the *concat* function has only the contextual information of the outer boundaries of a pair.

5 Related Work

5.1 Similarity-based Approaches

For the coordination identification task in Japanese, Kurohashi and Nagao (1994) used a chart to find the highest similarity pair of conjuncts using dynamic programming. Hogan (2007) developed a generative parsing model for coordinated noun phrases, incorporating symmetry in conjunct structures and head words. Shimbo and Hara (2007) proposed a discriminative model that computes scores based on the syntactic and morphological features assigned to edges and nodes in a sequence alignment. While their method focused on non-nested coordinations, Hara et al. (2009) extended their work to accommodate nested coordinations using CFG rules. A consistent global structure of coordinations is produced using discriminative functions based on the similarity of conjuncts with dynamic programming. Our concept of the CKY parsing is borrowed from their work; however, a key difference of our approach lies in how it computes the score of conjuncts and trains the score function. Hanamoto et al. (2012) used dual decomposition to combine HPSG parsing with the discriminative model developed by Hara et al. (2009).

5.2 Non Similarity-based Approaches

Kawahara and Kurohashi (2008) focused on resolving the ambiguities of coordinate structures without the use of any similarities. Their method relied on the dependency relations surrounding the conjuncts and the generative probabilities of phrases. Yoshimoto et al. (2015) extended the Eisner algorithm by adding new rules to accommodate coordinations during dependency parsing.

5.3 Coordination Boundary Identification using Neural Networks

Ficler and Goldberg (2016b) used neural networks for the coordination boundary identification task. They incorporated the replaceability property between conjuncts, in addition to the similarity property, in the computation of a score for a pair of conjuncts. They first used a binary classifier for coordinating words; then, they extracted probable candidate pairs of conjuncts using the Berkeley Parser (Petrov et al., 2006); afterward, they assigned scores to the pairs using neural networks. However, the shortcoming of their work is that it is highly dependent on the external parser. The work of Teranishi et al. (2017) developed an end-to-end model, as opposed to the pipeline approach of Ficler and Goldberg (2016b). They also used similarity and replaceability feature representations without information from a syntactic parser. While Ficler and Goldberg (2016b) cut off improbable pairs of conjuncts ahead of training, Teranishi et al. (2017) calculated scores for all possible pairs of the beginning and the end of coordinate structures instead of conjuncts. We apply the same strategy to the inner-boundary pairs and the outer-boundary pairs because assigning low probabilities to improbable inner and outer pairs makes the model robust for the CKY parsing.

6 Conclusion

We proposed a simple and accurate model for coordination boundary identification. Our system decomposes this task into three subtasks, and uses three different neural networks to tackle them. For inference, the CKY algorithm is applied using the CFG rules in order to produce globally consistent coordinate structures in a sentence. Experimental results demonstrated that our locally-trained models interoperate to obtain the optimal combination of coordinate structures and outperform existing systems and the strong baseline. Through empirical analysis, we found that our system performs better than the baseline in complete matches of sentences that contain more than two conjuncts and/or multiple coordinations.

Multi-task Learning for Japanese Predicate Argument Structure Analysis

Hikaru Omori

komachi@tmu.ac.jp

Abstract

An *event-noun* is a noun that has an argument structure similar to a predicate. Recent works, including those considered state-of-the-art, ignore event-nouns or build a single model for solving both Japanese predicate argument structure analysis (PASA) and event-noun argument structure analysis (ENASA). However, because there are interactions between predicates and event-nouns, it is not sufficient to target only predicates. To address this problem, we present a multi-task learning method for PASA and ENASA. Our multi-task models improved the performance of both tasks compared to a single-task model by sharing knowledge from each task. Moreover, in PASA, our models achieved state-of-the-art results in overall F1 scores on the NAIST Text Corpus. In addition, this is the first work to employ neural networks in ENASA.

1 Introduction

Japanese predicate argument structure analysis (PASA) examines semantic structures between the predicate and its arguments in a text. The identification of the argument structure such as "who did what to whom?" is useful for natural language processing that requires deep analysis of complicated sentences such as machine translation and recognizing textual entailment. PASA is a task targeted at predicates such as verbs and adjectives. However, there are also many nouns that have event-related arguments in a sentence. We call these nouns that refer to events *event-nouns*, for example, a verbal noun (*sahen* nouns) such as *houkoku* "report" or a deverbal noun (nominalized forms of verbs) such as *sukui* "rescue."

Figure 1 shows examples of PASA and event-noun argument structure analysis (ENASA). In the NAIST Text Corpus (Iida et al., 2007), both predicates and event-nouns have one of three core case roles, *nominative* (NOM), *accusative* (ACC), and *dative* (DAT) as an argument. According to Iida et al. (2007), predicates have almost no argument in the same *bunsetsu*[1] phrase. However, in the case of event-nouns, approximately half of the accusative and dative arguments appear in the same bunsetsu phrase. Accordingly, although PASA and ENASA are semantically highly related, they are syntactically different tasks. However, most previous studies focused on predicates only; hence, there are few studies that focus

---

[1] Functional chunk in Japanese. It consists of one or more content words (noun, verb, adjective, etc.) followed by zero or more function words (postposition, auxiliary verb, etc.). A verb phrase in Japanese thus cannot bear noun arguments in the same bunsetsu.

Proceedings of NAACL-HLT 2019, pages 3404–3414
Minneapolis, Minnesota, June 2 - June 7, 2019.

on event-nouns (Komachi et al., 2007; Taira et al., 2008). To identify the semantic units of a sentence and to correctly understand syntactic relations, it is not sufficient to target only PASA.

Thus, we propose a multi-task learning model that effectively leverages ENASA and improves PASA. Our proposed model is based on an end-to-end multilayer bi-directional recurrent neural network (RNN) used in recent works, and the model has networks that distinguish task-independent information and task-specific information.

In summary, the main contributions of this work are the following:

1. This is the first attempt to design a multi-task learning framework for PASA and ENASA, and we show that our models improve the performance of both tasks.
2. Although our model is a simple model that does not consider the interactions between multiple predicates, it achieves a state-of-the-art result on the NAIST Text Corpus (NTC) in PASA by combining syntactic information as one of the features.
3. For ENASA, this is the first work to employ neural networks to effectively incorporate PASA.

2 Related Work

2.1 Japanese PASA and ENASA Approaches

Many machine learning-based methods have been studied in Japanese PASA. Traditional models take pointwise approaches that construct independent models for each core case role (NOM, ACC, DAT). Taira et al. (2008) proposed a supervised model that learns features of each case using decision lists and support vector machines. Imamura et al. (2009) proposed a model that combines a maximum entropy model with a language model trained from large-scale newspaper articles. Hayashibe et al. (2011) designed three models exploiting argument position and type and determined the maximum likelihood output using pairwise comparison.

However, the joint approach that optimizes the scores of all predicate-argument pairs in a sentence simultaneously showed better results than the pointwise approach. Yoshikawa et al. (2011) proposed a model that considers dependency between multiple predicate-argument relations using Markov logic networks. Ouchi et al. (2015) jointly optimized the combinations among multiple predicates and arguments in a sentence using a bipartite graph.

Except for (Taira et al., 2008), these studies focused on the analysis of predicates while there are few studies that focus on event-nouns. Komachi et al. (2007) decomposed ENASA into two tasks: *event-hood* determination and argument identification; they proposed a supervised method using lexico-syntactic patterns. Event-hood determination is the most important characteristic that semantically differentiates ENASA from PASA. It is a task to determine whether a noun refers to an event (e.g., *houkoku* can refer to either “to report” or the outcome of reporting action, “a report”). Since the previous ENASA models adopted the pointwise approach with a single model, they did not explore the effective features in each task. In contrast, our models simultaneously optimize three core case roles. Moreover, the proposed models allow us to distinguish between task-shared and task-specific features using multi-task learning.

2.2 PASA using neural networks

Some neural models have achieved higher performance than traditional machine learning models in Japanese PASA. Shibata et al. (2016) replaced Ouchi et al. (2015)’s scoring function with feed forward neural networks. Matsubayashi and Inui (2017) represented a dependency path between a predicate and its argument with path embeddings and showed that even the local model without multiple predicates can outperform a global model.

Moreover, some end-to-end models have been proposed in Japanese PASA. Ouchi et al. (2017) proposed an end-to-end model based on the model using eight-layer bi-directional long short-term memory (LSTM) proposed by Zhou and Xu (2015) and considered the interaction of multiple predicates simultaneously using a Grid RNN. Matsubayashi and Inui (2018) combined self-attention with Ouchi et al. (2017)’s model to directly capture interaction among multiple predicate-arguments. In particular, the model improved the performance of arguments that have no syntactic dependency with predicates and achieved a state-of-the-art result on Japanese PASA.

2.3 Semantic Role Labeling

Semantic role labeling (SRL) is a similar task to Japanese PASA. Recently, several end-to-end models using neural networks showed high performance in English SRL (Zhou and Xu, 2015; He et al., 2017; Tan et al., 2018). Strubell et al. (2018) proposed a multi-task learning model that jointly learned dependency parsing, part-of-speech tagging, predicate detection, and SRL based on multi-head self-attention. Ouchi et al. (2018) proposed a span-based SRL model using bi-directional LSTMs and achieved state-of-the-art results. The authors scored all possible spans for each label and selected correct spans satisfying constraints when decoding. In terms of the event-noun research, Gerber and Chai (2010) used pointwise mutual information (PMI) as a feature for 10 event-nouns with high frequency and identified semantic roles using a logistic regression model.

There were several LSTM models that also achieved high accuracy gains in Chinese SRL (Wang et al., 2015; Roth and Lapata, 2016; Sha et al., 2016; Marcheggiani et al., 2017; Qian et al., 2017). For event-nouns, Li et al. (2009) showed that combining effective features in verbal SRL with nominal SRL can improve results. Although the authors did not demonstrate that verbal SRL also improves performance in combination with nominal SRL, we show that our model improves performance in both PASA and ENASA.

3 Japanese PASA and ENASA

3.1 Task Description

Japanese predicate (event-noun) argument structure analysis is a task to extract arguments for certain predicates (event-nouns) and assign three case labels, NOM, ACC and DAT (Iida et al., 2007). Arguments are divided into four categories (Taira et al., 2008) according to the positions with their predicates (event-nouns).

Dep Arguments depend on their predicate (event-noun), or a predicate (event-noun) depends on its arguments.

Zero Arguments and their predicate (event-noun) are in the same sentence, but the arguments are omitted by zero anaphora. Therefore, they have no direct dependency.

Inter-zero Zero anaphoric arguments and their predicate (event-noun) are not in the same sentence.

Bunsetsu Arguments and their event-noun are in the same bunsetsu.

A sentence $w = w_1, w_2, \cdots, w_T$ and a predicate (event-noun) $p = p_1, p_2, \cdots, p_q$ are given as input. Iida et al. (2006), Imamura et al. (2009), and Sasano and Kurohashi (2011) also analyze Inter-zero, which is a difficult task because the whole document must be searched. Following existing research (Ouchi et al., 2015, 2017; Matsubayashi and Inui, 2017, 2018; Taira et al., 2008), we only focus on three categories where arguments and their predicate (event-noun) are in the same sentence. In addition, we exclude the Bunsetsu category from the PASA evaluation following Ouchi et al. (2017) and Matsubayashi and Inui (2018).

3.2 End-to-end Single Model

Our single model is based on an end-to-end approach (Zhou and Xu, 2015; Ouchi et al., 2017; Matsubayashi and Inui, 2018). Additionally, we add new features. Figure 2 shows the network architecture of our base model.

3.2.1 Input Layer

Each word $w_t \in [w_1, \cdots, w_T]$ is converted to a feature representation $\mathbf{x}_t \in [\mathbf{x}_1, \cdots, \mathbf{x}_T]$ at the input layer. We use six types of features. The feature representation $\mathbf{x}_t$ is defined as follows:

$$\mathbf{x}_t = \mathbf{x}_t^{\mathrm{as}} \oplus \mathbf{x}_t^{\mathrm{posi}} \oplus \mathbf{x}_t^{\mathrm{dep}} \oplus \mathbf{x}_t^{\mathrm{type}} \oplus \mathbf{x}_p^{\mathrm{task}} \quad (1)$$

where ($\oplus$) indicates concatenation of vectors.

Argument Structure Predicate (event-noun) w_p and argument candidates w_t are converted to the vectors $\mathbf{x}_t^{\mathrm{as}} \in \mathbb{R}^{2d_{\mathrm{w}}}$ by the word embedding matrix.

Position This is a feature that represents the positional relation between w_p and w_t. The feature is calculated by subtracting the word index of argument candidates from the word index of predicates (event-nouns). We use two types of units to represent relative position: word unit p_t^{word} and bunsetsu unit p_t^{bunsetsu}, which are converted to the word positional vector $\mathbf{p}_t^{\mathrm{word}} \in \mathbb{R}^{d_{\mathrm{p}}}$ and the bunsetsu positional vector $\mathbf{p}_t^{\mathrm{bunsetsu}} \in \mathbb{R}^{d_{\mathrm{p}}}$, respectively, by the word and bunsetsu positional embed-

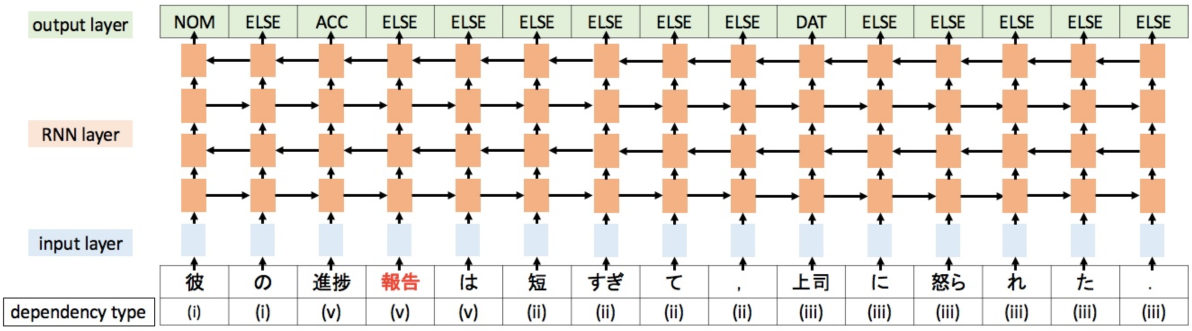

Figure 2: End-to-end single model.

ding matrices. We concatenate these two vectors and obtain the positional vectors $\mathbf{x}_t^{\text{posi}} \in \mathbb{R}^{2d_\text{p}}$.

Dependency This is a feature that represents the dependency relation between w_p and w_t. We set five types of dependency relations:

i). Argument candidates depend on the predicate (event-noun).

ii). The predicate (event-noun) depends on the argument candidates.

iii). No dependency relations between the predicate (event-noun) and argument candidates.

iv). The predicate and candidate arguments are in the same bunsetsu.

v). The event-noun and candidate arguments are in the same bunsetsu.

The dependency relation d_t is converted to the dependency vector $\mathbf{x}_t^{\text{dep}} \in \mathbb{R}^{d_\text{d}}$ by the dependency relation embedding matrix. The dependency type in Figure 2 shows how to make dependency features in Figure 1b as an example. We define the dependency type from the syntactic information annotated in the NTC.

In previous work, dependency features are used differently from our study. Imamura et al. (2009) used a binary feature that represents whether or not there is a dependency relation between the predicate and its arguments. We employ more fine-grained relation types to adapt to event-nouns. Matsubayashi and Inui (2017) represented the interactions between a predicate and its arguments using path embedding. In contrast, we define different types for a predicate and event-noun to distinguish event-nouns from predicates and learn embeddings to find the associated latent structures.

Event-hood Type This is a binary feature to flag all predicates (event-nouns) in a sentence inspired by Matsubayashi and Inui (2018). The purpose of this feature is to prevent predicates from becoming arguments and to help some event-nouns become arguments. The event-hood type vector $\mathbf{x}_t^{\text{type}} \in \mathbb{R}^2$ of a candidate indicates [0,1] if the candidate is a predicate, [1,0] if the candidate is an event-noun, and [0,0] otherwise. The predicate and event-noun are annotated in the NTC.

Task Label This is a binary feature vector $\mathbf{x}_p^{\text{task}} \in \mathbb{R}^1$ that indicates 1 if the task is predicate argument structure analysis; otherwise, 0.

3.2.2 RNN Layer

We use the gated recurrent unit (GRU) (Cho et al., 2014) for RNN. The RNN layers are made up of L layers of stacked bi-directional GRU. Additionally, we apply the residual connections (He et al., 2016) following Ouchi et al. (2017); Matsubayashi and Inui (2018). At each time step t, the hidden state $\mathbf{h}_t^l \in \mathbb{R}^{d_\text{h}}$ in the $l \in [1, \cdots, L]$-th layer is calculated as follows:

$$\mathbf{h}_t^l = \begin{cases} g^l(\mathbf{h}_t^{l-1}, \mathbf{h}_{t-1}^l) & (l = \text{odd}) \\ g^l(\mathbf{h}_t^{l-1}, \mathbf{h}_{t+1}^l) & (l = \text{even}) \end{cases} \quad (2)$$

where $g^l(\cdot)$ denotes the l-th layer GRU function. In addition, $\mathbf{h}_t^0 = \mathbf{x}_t$.

3.2.3 Output Layer

In the output layer, we input each hidden state $\mathbf{h}_t^L$. Then, we obtain the output vector $\mathbf{o}_t$ using the softmax function:

$$\mathbf{o}_t = \text{softmax}(\mathbf{W}_\text{o}\mathbf{h}_t^L + \mathbf{b}_\text{o}) \quad (3)$$

where $\mathbf{W}_\text{o} \in \mathbb{R}^{4 \times d_\text{h}}$ is the parameter matrix, and $\mathbf{b}_\text{o} \in \mathbb{R}^4$ is the bias term. The output vector represents the probability for each argument candidate

over four labels, [NOM, ACC, DAT, ELSE]. ELSE denotes that the candidate argument does not have a case label. In testing, the maximum probability label is selected as the output label. We train the model using the cross-entropy loss function.

4 Multi-task Model

Multi-task learning has been successfully applied to various natural language processing tasks (Collobert et al., 2011; Søgaard and Goldberg, 2016; Luong et al., 2016; Hashimoto et al., 2017; Liu et al., 2017; Stoyanov et al., 2018; Marasovic and Frank, 2018; Strubell et al., 2018). One of the advantages of multi-task learning is that it learns better representation, which is robust against task-dependent noise by increasing training data. In this paper, we introduce multi-task learning to PASA and ENASA for the first time. We propose three methods to extend the end-to-end single model to the multi-task learning model in the input layer, RNN layer, and output layer. Figure 3 shows the proposed models. Our final model combines all three methods (Figure 3e).

4.1 Multi Input Layer

Even if the surface form is the same, the contexts are different for predicates and event-nouns. For example, the event-noun *houkoku* "report" in Figure 1b has an argument in the same bunsetsu unlike predicates. Moreover, the event-noun also has a nominative argument role for the predicate *mijikai* "short". Therefore, given this, we prepare a task-specific word embedding matrix that addresses the task-specific distribution of words. The predicate is converted to PASA-specific vectors $\mathbf{x}_t^{\mathrm{p}} \in \mathbb{R}^{d'_{\mathrm{w}}}$ by the PASA-specific predicate embedding matrix. Similarly, the event-noun is converted to ENASA-specific vectors $\mathbf{x}_t^{\mathrm{n}} \in \mathbb{R}^{d'_{\mathrm{w}}}$ by the ENASA-specific event-noun embedding matrix. These matrices are randomly initialized and can be learned during training.

The feature vector $\overline{\mathbf{x}}_t$ is defined as follows:

$$\overline{\mathbf{x}}_t = \begin{cases} \mathbf{x}_t \oplus \mathbf{x}_t^{\mathrm{p}} & (\mathrm{PASA}) \\ \mathbf{x}_t \oplus \mathbf{x}_t^{\mathrm{n}} & (\mathrm{ENASA}) \end{cases} \tag{4}$$

4.2 Multi RNN Layer

Previous work (Søgaard and Goldberg, 2016; Hashimoto et al., 2017) proposed hierarchical multi-task learning models that exploited features obtained from easy tasks for difficult tasks. These studies showed that performance improves when low-layer RNN representations are trained in easy tasks and high-layer RNN are leveraged for difficult tasks. Therefore, we construct a network that hierarchically overlaps a task-specific RNN on a task-independent RNN. Lower RNN layers learn task-independent knowledge representations. Then, the task-specific RNN adjusts the representations for each task. At each time step t, the hidden state $\mathbf{m}_t^{l'} \in \mathbb{R}^{d'_\mathrm{h}}$ in the $l' \in [1, \cdots, L']$-th layer is calculated as follows:

$$\mathbf{m}_t^{l'} = \begin{cases} g^{l'}(\mathbf{m}_t^{l'-1}, \mathbf{m}_{t-1}^{l'}) & (l' = \mathrm{odd}) \\ g^{l'}(\mathbf{m}_t^{l'-1}, \mathbf{m}_{t+1}^{l'}) & (l' = \mathrm{even}) \end{cases} \quad (5)$$

$$g^{l'}(\cdot) = \begin{cases} g_\mathrm{p}^{l'}(\cdot) & (\mathrm{PASA}) \\ g_\mathrm{n}^{l'}(\cdot) & (\mathrm{ENASA}) \end{cases} \quad (6)$$

where $g^{l'}(\cdot)$, $g_\mathrm{p}^{l'}(\cdot)$, and $g_\mathrm{n}^{l'}(\cdot)$ denote the l'-th layer GRU functions. In addition, $\mathbf{m}_t^0 = \mathbf{h}_t^L$.

4.3 Multi Output Layer

The position of arguments is different with respect to predicates and event-nouns. For example, predicates seldom have arguments in the same bunsetsu. In contrast, event-nouns often have arguments in the same bunsetsu, compound nouns, for example. Therefore, it is intuitive and natural to divide the output layer into task-independent and task-specific layers. The task-specific output vectors are calculated as follows:

$$\mathbf{o}_t^\mathrm{p} = \mathbf{W}_\mathrm{o}^\mathrm{p}\mathbf{h}_t + \mathbf{b}_\mathrm{o}^\mathrm{p} \quad (7)$$

$$\mathbf{o}_t^\mathrm{n} = \mathbf{W}_\mathrm{o}^\mathrm{n}\mathbf{h}_t + \mathbf{b}_\mathrm{o}^\mathrm{n} \quad (8)$$

$$\mathbf{g}_t = \sigma(\mathbf{W}_\mathrm{g}\mathbf{h}_t + \mathbf{b}_\mathrm{g}) \quad (9)$$

where $\mathbf{W}_\mathrm{o}^\mathrm{p}, \mathbf{W}_\mathrm{o}^\mathrm{n}, \mathbf{W}_\mathrm{g} \in \mathbb{R}^{4 \times d_\mathrm{h}}$ are the parameter matrices, and $\mathbf{b}_\mathrm{o}^\mathrm{p}, \mathbf{b}_\mathrm{o}^\mathrm{n}, \mathbf{b}_\mathrm{g} \in \mathbb{R}^4$ are the bias terms. $\mathbf{h}_t$ is the hidden state of the last layer. We combine task-specific output vectors $\mathbf{o}_t^\mathrm{p}, \mathbf{o}_t^\mathrm{n}$ with task-independent output vector $\mathbf{o}_t$ by the gate $\mathbf{g}_t$.

$$\mathbf{c}_t = \begin{cases} \mathbf{g}_t \odot \mathbf{o}_t + (1 - \mathbf{g}_t) \odot \mathbf{o}_t^\mathrm{p} & (\mathrm{PASA}) \\ \mathbf{g}_t \odot \mathbf{o}_t + (1 - \mathbf{g}_t) \odot \mathbf{o}_t^\mathrm{n} & (\mathrm{ENASA}) \end{cases} \quad (10)$$

$$\overline{\mathbf{o}}_t = \mathrm{softmax}(\mathbf{c}_t) \quad (11)$$

where $(\odot)$ denotes the element-wise product. The output vector $\overline{\mathbf{o}}_t$ represents the probability of [NOM, ACC, DAT, ELSE].

5 Experiments

5.1 Dataset and Setting

We use NTC 1.5 for our experiments. We divide the dataset into training, development, and test sets in the same way as Taira et al. (2008). We use morphological and syntactic information, such as the word boundaries, the bunsetsu boundaries and the dependency relations provided in the NTC.

For the development and test sets, if there are two or more arguments annotated with the same case label in a sentence, we set an argument that only has a dependency relation with a predicate as a correct answer and assign the ELSE label to other arguments. If there is no dependency relation, we set an argument with the shortest distance $|w_p - w_t|$ as a correct answer. If the distance is equal, an argument on the left side of a predicate is considered a correct answer.

In NTC 1.5, if there is a predicate phrase, such as "verbal noun + *suru*," *suru* is annotated as a predicate word. We consider the verbal noun as the predicate word at the preprocessing step to match the surface of a predicate with that of an event-noun. Take the predicate *houkoku-suru* "to report" and an event-noun *houkoku* "report" as an example. Although w_p before preprocessing are *suru* and *houkoku*, w_p are unified to *houkoku* after preprocessing.

dropout rate	0.4
batch size	8
gradient clipping	4

Table 1: Hyperparameters.

5.2 Hyperparameters

We use pre-trained embeddings[2] for the initial values of the word embedding matrix. The initial values of the other embedding matrices are sampled according to a uniform distribution of [-0.25,0.25]. We convert words appearing more than once in the training set into word vectors and the remaining words into the unknown word vector. We adopt AdaDelta ($\epsilon = 10^{-6}, \ \rho = 0.95$) as the optimization method. We set the number of epochs to 20 and evaluate the model with the highest F1 scores on the development set. Table 1 shows the hyperparameters.

5.3 Results

We evaluate each model with the NTC 1.5 test. The experimental results for the argument structure analysis of predicates and event-nouns are shown in Tables 2 and 3.

Table 3: F1 scores on the ENASA test set.

Predicate Argument Structure Analysis The first set of rows in Table 2 shows the results of previous models. Ouchi+ 17 is the model from the Multi-Seq model in (Ouchi et al., 2017). M&I 17 is the model in (Matsubayashi and Inui, 2017). M&I 18 is the model from the MP-POOL-SELFATT model in (Matsubayashi and Inui, 2018).

The second set of rows in Table 2 shows the results of the proposed models. These models do not use the dependency feature. Compared with the single model, all multi-task learning models improved the overall F1 scores. Among them, Multi-RNN improved the overall F1 score from the single model by 0.29 points. In previous work, Ouchi et al. (2017); Matsubayashi and Inui (2018) see improvements of 0.27 and 0.55 F1 points in their baseline models by considering multiple predicate-argument interactions. Therefore, we show that multi-task learning with ENASA achieved comparable effects as these studies in PASA.

The third set of rows shows the results of proposed models using all features including the dependency feature. Multi-ALL+`DEP` achieved the best F1 score among all the models including previous state-of-the-art models. In particular, the dependency feature was effective for Dep arguments. On the other hand, the performance for Zero arguments was poor. This result suggests that the dependency feature causes the model to optimize mainly for Dep arguments since Dep arguments are more numerous than Zero arguments.

The fourth set of rows shows the results of ensemble models. Overall, our proposed model outperformed the previous ensemble model by 0.67 points in the overall F1 score. Moreover, our models are simple models that independently analyze each predicate in a sentence. Nevertheless, our models achieved higher results than Ouchi et al. (2017); Matsubayashi and Inui (2018). Although recent works have researched the method whereby multiple predicate-argument interactions are considered simultaneously, how to use syntactic in-

Figure 4: Examples of analysis errors on the PASA test set

formation in the end-to-end model is a subject for future work.

Event-noun Argument Structure Analysis The first set of rows in Table 3 shows the results of a previous model in event-noun argument structure analysis. Taira+ 08 is the model from (Taira et al., 2008). Since its scores are from NTC 1.4, the model cannot be directly compared to our models. Compared with the single model, all multi-task models improved the overall F1 scores. However, Multi-ALL+DEP compared unfavorably with Multi-ALL even though it was the best PASA architecture. Therefore, this implies that the dependency type feature between the predicate and its argument is not effective in ENASA.

5.4 Analysis

In Figure 4, we compare the PASA results from test sets for each model. In Examples (a), (b) and (d), the single model failed to predict correct arguments but the Multi-RNN model correctly predicted arguments. In Example (a), the single model incorrectly predicted that arguments do not exist in this sentence. Comparing the training set of each task, although the number of event-nouns is approximately one-third of the number of predicates, the number of *kessei* 結成 “organize (event-nouns)” is approximately twice the number of *kessei* 結成 “organize (predicates).” Accordingly, we showed that the Multi-RNN model effectively leverages the information of event-nouns using multi-task learning.

In Example (b), the single model incorrectly predicted that the NOM argument does not exist, but the multi-RNN predicted the correct arguments. Comparing the training set, there is *sayuu* 左右 "determine (predicate)" but not *sayuu* 左右 "determine (event-noun)." However, there are some *kagi* カギ "key (arguments of predicates)" in the PASA training set, and there is one *kagi* カギ "key (argument of event-noun)" in the ENASA training set (Example (c)). Moreover, in Example (c), *dakai* 打開 "break (event-noun)" depends on *kagi* カギ "key" like *sayuu* 左右 "determine (predicate)" in Example (b); however, no predicate depends on *kagi* カギ "key" in the training set. Accordingly, the Multi-RNN model also leverages the arguments of event-nouns and the positional relations between event-nouns and their arguments.

Example (d) is an interesting case in which a predicate *kaihi* 回避 "avoid" and its argument *sekinin* 責任 "responsibility" are located in the same bunsetsu. Although this argument type (Bunsetsu) is excluded from the evaluation target in PASA, it is common as a compound noun in ENASA. Therefore, the single model wrongly predicted that the ACC argument does not exist, but multi-RNN was able to predict the answer using the specific knowledge of event-nouns.

In contrast, in Example (e), the single model correctly predicted the answer, but the multi-RNN model failed to predict the correct arguments. Multi-RNN incorrectly predicted that the DAT argument does not exist in this sentence. However, *ni* に, a postpositional particle located after an argument, often indicates a dative case. Nevertheless, multi-RNN often predicted a wrong DAT argument by ignoring *ni* に. Therefore, for DAT analysis, the information of event-nouns adversely affects PASA.

In Example (f), the Multi-ALL+`DEP` model correctly predicted the answer, but the Multi-ALL model failed. Specifically, Multi-ALL+`DEP` correctly predicted that the ACC argument is *yakuwari* 役割 "role," which is dependent on *hatasu* 果たす "play." However, the Multi-ALL incorrectly predicted that the ACC argument is *kaimei* 解明 "solution." Similarly, Multi-ALL without syntactic information made many mistakes, including attributive modification, such as Figure 1c. Table 4 shows the results of the two PASA models for attributive modification instances. Multi-ALL+`DEP` considerably outperformed Multi-ALL for all cases using dependency features. Therefore, these results suggest that the dependency type feature is effective for PASA with respect to attributive modifications.

	ALL	NOM	ACC	DAT
Multi-ALL	80.31	83.37	72.16	19.48
Multi-ALL+`DEP`	81.83	84.67	74.41	28.31

Table 4: F1 scores on the PASA test set with respect to attributive modifications.

6 Conclusion

We design a multi-task learning model for predicate and event-noun argument structure analysis. The experiment results show that the multi-task models outperform the single-task model on the NAIST Test Corpus for both tasks. Moreover, our model achieves a state-of-the-art result for PASA. In addition, this is the first work to employ neural networks for ENASA. In future work, we plan to consider multiple predicates and event-nouns.

Domain adaptation for part-of-speech tagging of noisy user-generated text

Luisa März and **Dietrich Trautmann** and **Benjamin Roth**
CIS, University of Munich (LMU) Munich, Germany
`{luisa.maerz, dietrich, beroth}@cis.lmu.de`

Abstract

The performance of a Part-of-speech (POS) tagger is highly dependent on the domain of the processed text, and for many domains there is no or only very little training data available. This work addresses the problem of POS tagging noisy user-generated text using a neural network. We propose an architecture that trains an out-of-domain model on a large newswire corpus, and transfers those weights by using them as a prior for a model trained on the target domain (a data-set of German Tweets) for which there is very little annotations available. The neural network has two standard bidirectional LSTMs at its core. However, we find it crucial to also encode a set of task-specific features, and to obtain reliable (source-domain and target-domain) word representations. Experiments with different regularization techniques such as early stopping, dropout and fine-tuning the domain adaptation prior weights are conducted. Our best model uses external weights from the out-of-domain model, as well as feature embeddings, pretrained word and sub-word embeddings and achieves a tagging accuracy of slightly over 90%, improving on the previous state of the art for this task.

1 Introduction

Part-of-speech (POS) tagging is a prerequisite for many applications and necessary for a wide range of tools for computational linguists. The state-of-the art method to implement a tagger is to use neural networks (Ma and Hovy, 2016; Yang et al., 2018). The performance of a POS tagger is highly dependent on the domain of the processed text and the availability of sufficient training data (Schnabel and Schütze, 2014). Existing POS taggers for canonical German text already achieve very good results around 97% accuracy, e.g. (Schmid, 1999; Plank et al., 2016). When applying these trained models to out-of-domain data the performance decreases drastically.

One of the domains where there is not enough data is online conversational text in platforms such as Twitter, where the very informal language exhibits many phenomena that differ significantly from canonical written language.

In this work, we propose a neural network that combines a character-based encoder and embeddings of features from previous non-neural approaches (that can be interpreted as an inductive bias to guide the learning task). We further show that the performance of this already effective tagger can be improved significantly by incorporating external weights using a mechanism of domain-specific L2-regularization during the training on in-domain data. This approach establishes state-of-the-art results of 90.3% accuracy on the German Twitter corpus of Rehbein (2013).

2 Related Work

The first POS tagging approach for German Twitter data was conducted by Rehbein (2013) and reaches an accuracy of 88.8% on the test set using a CRF. They use a feature set with eleven different features and an extended version of the STTS (Schiller et al., 1999) as a tagset. Gimpel et al. (2011) developed a tagset for English Twitter data and report results of 89.37% on their test set using a CRF with different features as well. POS tagging for different languages using a neural architecture was successfully applied by Plank et al. (2016). The data comes from the Universal Dependencies project[1] and mainly contains German newspaper texts and Wikipedia articles.

The work of Barone et al. (2017) investigates different regularization mechanisms in the field of domain adaptation. They use the same L2 regularization mechanism for neural machine translation, as we do for POS tagging.

3 Data

3.1 Tagset

The Stuttgart-Tübingen-TagSet (STTS, Schiller et al. (1999)) is widely used as the state-of-the-art tagset for POS tagging of German. Bartz et al. (2013) show that the STTS is not sufficient when working with textual data from online social platforms, as online texts do not have the same characteristics as formal-style texts, nor are identical to spoken language. Online conversational text often contains contracted forms, graphic reproductions of spoken language such as prolongations, interjections and grammatical inconsistencies as well as a high rate of misspellings, omission of words etc.

For POS tagging we use the tagset of Rehbein (2013), where (following Gimpel et al. (2011)) additional tags are provided to capture peculiarities of the Twitter corpus. This tagset provides tags for @-mentions, hashtags and URLs. They also provide a tag for non-verbal comments such as ***Trommelwirbel*** (drum-roll). Additional, complex tags for amalgamated word forms were used (see Gimpel et al. (2011)). Overall the tagset used in our target domain contains 15 tags more than the original STTS.

3.2 Corpora

Two corpora with different domains are used in this work. One of them is the TIGER corpus and the other is a collection of German Twitter data.

The texts in the TIGER corpus (Brants et al., 2004) are taken from the Frankfurter Rundschau newspaper and date from 1995 over a period of two weeks. The annotation of the corpus was created semi automatically. The basis for the annotation of POS tags is the STTS. The TIGER corpus is one of the standard corpora for German in NLP and contains 888.505 tokens.

The Twitter data was collected by Rehbein (2013) within eight months in 2012 and 2013. The complete collection includes 12.782.097 distinct tweets, from which 1.426 tweets were randomly selected for manual annotation with POS tags. The training set is comparably small and holds 420 tweets, whereas the development and test set hold around 500 tweets each (overall 20.877 tokens). Since this is the only available German annotated Twitter corpus, we use it for this work.

3.3 Pretrained word vectors

The usage of pretrained word embeddings can be seen as a standard procedure in NLP to improve the results with neural networks (see Ma and Hovy (2016).

3.4 FastText

FastText[2] provides pretrained sub-word embeddings for 158 different languages and allows to obtain word vectors for out-of-vocabulary words. The pretrained vectors for German are based on Wikipedia articles and data from Common Crawl[3]. We obtain 97.988 different embeddings for the tokens in TIGER and the Twitter corpus of which 75.819 were already contained in Common Crawl and 22.171 were inferred from sub-word units.

3.5 Word2Vec

Spinningbytes[4] is a platform for different applications in NLP and provides several solutions and resources for research. They provide word embeddings for different text types and languages, including Word2Vec (Mikolov et al., 2013) vectors pretrained on 200 million German Tweets. Overall 17.030 word embeddings form the Spinningbytes vectors are used (other words are initialized all-zero).

3.6 Character level encoder

Lample et al. (2016) show that the usage of a character level encoder is expedient when using bidirectional LSTMs. Our implementation of this encoder follows Hiroki Nakayama (2017)[5], where character embeddings are passed to a bidirectional LSTM and the output is concatenated to the word embeddings.

4 Experiments

This section describes the proposed architecture of the neural network and the conditional random field used in the experiments. For comparison of the results we also experiment with jointly training on a merged training set, which contains the Twitter and the TIGER training sets.

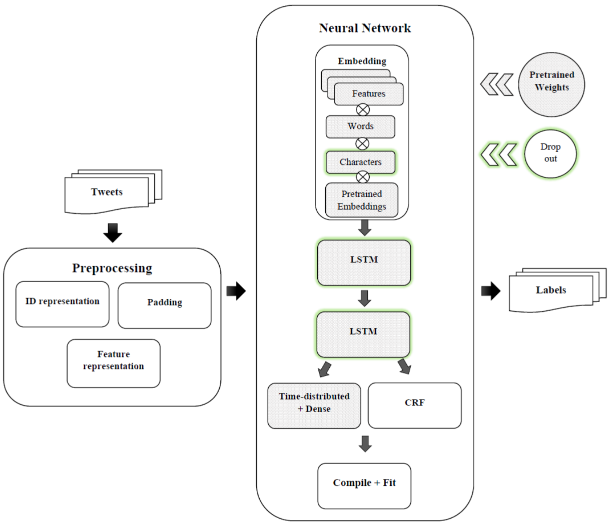

Figure 1: Final architecture of the neural model. Layers that are passed pretrained weights are hatched in gray. Dropout affected layers are highlighted in green.

4.1 Methods

4.1.1 Conditional random field baseline

The baseline CRF of Rehbein (2013) achieves an accuracy of 82.49%. To be comparable with their work we implement a CRF equivalent to their baseline model. Each word in the data is represented by a feature dictionary. We use the same features as Rehbein proposed for the classification of each word. These are the lowercased word form, word length, number of uppercase letters, number of digits and occurrence of a hashtag, URL, @-mention or symbol.

4.1.2 Neural network baseline

The first layer in the model is an embedding layer. The next layers are two bidirectional LSTMs. The baseline model uses softmax for each position in the final layer and is optimized using Adam core with a learning rate of 0.001 and the categorical crossentropy as the loss function.

4.1.3 Extensions of the neural network

The non neural CRF model benefits from different features extracted from the data. Those features are not explicitely modeled in the neural baseline model, and we apply a feature function for the extended neural network. We include the features used in the non-neural CRF for hashtags and @-mentions. In addition, we capture orthographic features, e.g., whether a word starts with a digit or an upper case letter. Typically, manually defined features like these are not used in neural networks, as a neural network should take over feature engineering completely. Since this does not work optimally, especially for smaller data sets, we have decided to give the neural network this type of information as well. Thus we combine the advantages of classical feature engineering and neural networks. This also goes along with the observations of Plank et al. (2018) and Sagot and Martínez Alonso (2017), who both show that adding conventional lexical information improves the performance of a neural POS tagger. All words are represented by their features and for each feature type an embedding layer is set up within the neural network in order to learn vectors for the different feature expressions. Afterwards all the feature embeddings are added together. As the next step we use the character level layer mentioned in section 3.6 (Lample et al., 2016). The following vector sequences are concatenated at each position and form the input to the bidirectional LSTMs:

- Feature embedding vector
- character-level encoder
- FastText vectors
- Word2Vec vectors

4.1.4 Domain Adaptation and regularization

We train the model with the optimal setting on the TIGER corpus, i.e., we prepare the TIGER data just like the Twitter data and extract features, include a character level layer and use pretrained embeddings. We extract the weights $\hat{W}$ that were optimized with TIGER. The prior weights $\hat{W}$ are used during optimization as a regularizer for the weights W used in the final model (trained on the Twitter data). This is achieved by adding the penalty term R_W, as shown in Equation 1, to the objective function (cross-entropy loss).

$$R_W = \lambda||W - \hat{W}||_2^2 \qquad (1)$$

The regularization is applied to the weights of the two LSTMs, the character LSTM, to all of the embedding layers and to the output layer.

As a second regularization mechanism we include dropout for the forward and the backward LSTM layers. We also add 1 to the bias of the forget gate at initialization, since this is recommended in Jozefowicz et al. (2015). Additionally, we use early stopping. Since the usage of different regularization techniques worked well in the experiments of Barone et al. (2017), we also tried the combination of different regularizers in this work. Figure 1 shows the final architecture of our model.

4.2 NCRF++

We also report results obtained by training the sequence labelling tagger of Yang and Zhang (2018), NCRF++. They showed that their architecture produces state-of-the-art models across a wide range of data sets (Yang et al., 2018) so we used this standardized framework to compare it with our model.

5 Results

5.1 Experimental Results

Table 1 shows the results on the Twitter test set. The feature-based baseline CRF outperforms the baseline of the neural net with more than 20 percentage points. After adding the feature information, the performance of the neural baseline is improved by 13 percentage points, which is understandable, because many German POS tags are case sensitive.

experiment	**accuracy**
baseline crf	0.831
baseline neural model	0.634
neural model	
+features	0.768
+character embeddings	0.796
+pretrained word vectors	0.845
+l2 domain adaptation	0.896
+dropout	**0.903**
neural model joint training	0.894
final CRF of Rehbein 2013	0.888
NCRF++ system	0.887

Table 1: Results on the test set using the time-distributed layer.

The model's performance increases by another 3 percentage points if the character level layer is used. Including the pretrained embeddings, FastText and Word2Vec vectors, the accuracy is 84.5%, which outperforms the CRF baseline.

Figure 2 shows the impact of domain adaptation and fine-tuning the prior weight. The value of the λ parameter in the regularization formula 1 can control the degree of impact of the weights on the training. Excluding the pretrained weights means that λ is 0. We observe an optimal benefit from the out-of-domain weights by using a λ value of 0.001. This is in line with the observations of Barone et al. (2017) for transfer-learning for machine translation.

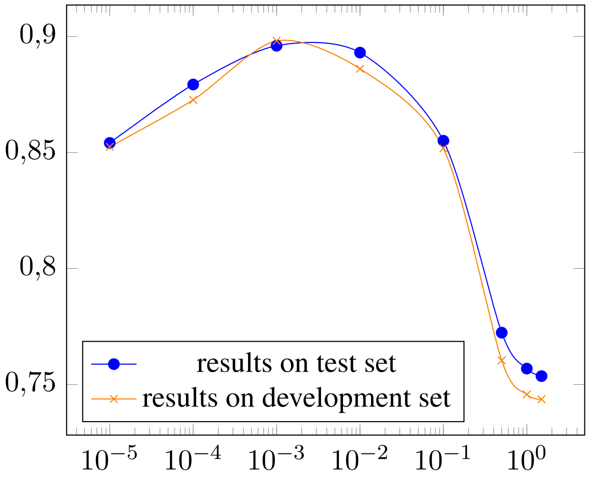

Figure 2: Influence of fine-tuning on the results on dev and test set in accuracy (y-axis). The x-axis corresponds to the different λ values.

Overall the addition of the L2 fine-tuning can improve the tagging outcome by 5 percentage points, compared to not doing domain adaptation. A binomial test shows that this improvement is significant. This result confirms the intuition that the tagger can benefit from the pretrained weights. On top of fine-tuning different dropout rates were added to both directions of the LSTMs for the character level layer and the joint embeddings. A dropout rate of 75% is optimal in our scenario, and it increases the accuracy by 0.7 percentage points.

The final 90.3% on the test set outperform the results of Rehbein (2013) by 1.5 percentage points.Our best score also outperforms the accuracy obtained with the NCRF++ model. This shows that for classifying noisy user-generated text, explicit feature engineering is beneficial, and that the usage of domain adaptation is expedient in this context. Joint training, using all data (out-of-domain and target domain), can obtain an accuracy score of 89.4%, which is about 1 percentage point worse than using the same data with domain adaptation. The training setup for the joint training is the same as for the other experiments and includes all extensions except for the domain adaptation.

5.2 Error Analysis

The most frequent error types in all our systems were nouns, proper nouns, articles, verbs, adjec-

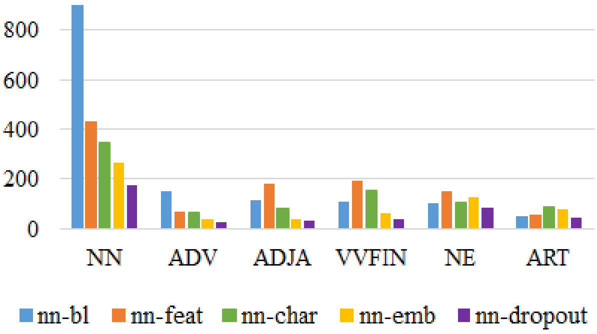

Figure 3: Total number of errors for the six most frequent POS-tags and different experimental settings

tives and adverbs as pictured in figure 3. By including the features the number of errors can be reduced drastically for nouns. Since we included a feature that captures upper and lower case, and nouns as well as proper nouns are written upper case in German, the model can benefit from that information. The pretrained word embeddings also help classifying nouns, articles, verbs, adjectives and adverbs. Only the errors with proper nouns increase slightly. Compared to only including the features, the model can benefit from adding both, the character level layer and the pretrained word vectors, while the results for tagging proper nouns and articles are still slightly worse than the baseline. In contrast the final experimental setup can optimize the results for every POS tag compared to the baseline, see figure 3. Slightly in case of articles and proper nouns, but markedly for the other tags. A comparison of the baseline errors and the errors of the final system shows that Twitter specific errors, e.g. with @-mentions or URLs, can be reduced drastically. Only hashtags still pose a challenge for the tagger. In the gold standard words with hashtags are not always tagged as such, but sometimes are classified as proper nouns. This is due to the fact that the function of the token in the sentence is the one of a proper noun. Thus the tagger has decision problems with these hashtags. Other types of errors, such as confusion of articles or nouns, are not Twitter-specific issues, but are often a problem with POS tagging and can only be fixed by general improvement of the tagger.

6 Conclusion

We present a deep learning based fine-grained POS tagger for German Twitter data using both domain adaptation and regularization techniques. On top of an efficient POS tagger we implemented domain adaptation by using a L2-norm regularization mechanism, which improved the model's performance by 5 percentage points. Since this performance is significant we conclude that fine-tuning and domain adaptation techniques can successfully be used to improve the performance when training on a small target-domain corpus.

Our experiments show that the combination of different regularization techniques is recommendable and can further optimize already efficient systems.

The advantage of our approach is that we do not need a large annotated target-domain corpus, but only pretrained weights. Using a pretrained model as a prior for training on a small amount of data is done within minutes and therefore very practicable in real world scenarios.

Abstract

This paper introduces a new task – Chinese address parsing – the task of mapping Chinese addresses into semantically meaningful chunks. While it is possible to model this problem using a conventional sequence labelling approach, our observation is that there exist complex dependencies between labels that cannot be readily captured by a simple linear-chain structure. We investigate neural structured prediction models with latent variables to capture such rich structural information within Chinese addresses. We create and publicly release a new dataset consisting of 15,000 Chinese addresses, and conduct extensive experiments on the dataset to investigate the model effectiveness and robustness. We release our code and data at http://statnlp.org/research/sp.

Figure 1: Two example Chinese addresses and the expected structures after parsing. Each chunk is underlined with its corresponding label in blue.

1 Introduction

Addresses play an important role in modern society. They are typically used as identifiers to locations and entities in the world that can be used to facilitate various social activities, such as business correspondences, meetings and events. Recent research efforts show that systems that perform *address parsing*, the task of automatically parsing addresses into semantically meaningful structures, can be useful for tasks such as building e-commerce or product recommendation systems (Jia et al., 2017; Avvenuti et al., 2018). Due to historical reasons, the English addresses come with a standardized format, mostly written in order from most specific to most general. Meaningful chunks in an English address are also separated by punctuation or the new-line symbols. Such characteristics make parsing English addresses a relatively easy task.

However, addresses written in eastern Asian languages such as Chinese present several unique challenges. Unlike English addresses, Chinese addresses are typically written in the form of a consecutive sequence of Chinese characters (possibly intermixed with digits and English letters). Figure 1 presents two example Chinese addresses and their desired output structures after parsing – chunks annotated with their labels indicating semantics (such as province, road, etc). The Chinese addressing system is also different from that of English. Though it is generally believed that the system uses the opposite ordering – starting from most general (e.g., province) and ending with most specific (e.g., room no.), in practice it can be observed that the format is far less rigorous than expected. The lack of rigor also leads to other issues – the addresses may come with incomplete, redundant or even inaccurate information, as we can see from the second example listed in Figure 1. Such unique challenges make the design of an effective Chinese address parser non-trivial.

Table 1: Statistics of different labels in our *Chinese Address* corpus.

Parsing a Chinese address into semantically meaningful structures can be regarded as a special type of chunking task (Abney, 1991), where we need to perform address-specific Chinese word segmentation (Xue, 2003; Peng et al., 2004; Zhao et al., 2006) while assigning a semantic label to each chunk. However, existing models designed for chunking may not be readily applicable in this task. Our observations show that there are a few characteristics associated with the task. We found that while generally there exists certain ordering information among the chunks of different labels in the addresses, such ordering information is better preserved among the chunks that appear at the beginning of the addresses. For the chunks appearing towards the end of the addresses, chunks of different types often appear in more flexible order.

On top of the above observations, we propose a specific model based on neural networks for the task of Chinese address parsing. The model is able to encode the regular patterns among chunks that appear at the beginning of a Chinese address, while flexibly capturing the irregular patterns and rich dependencies among the chunks of different types that appear towards the end of the address. This is achieved by designing a novel structured representation integrating both a linear structure and a latent-variable tree structure.

Our main contributions in this work can be summarized as follows:

- We create and publicly release a new corpus consisting of 15K Chinese address entries fully annotated with chunk boundaries and address labels. To the best of our knowledge, this is the first and largest annotated Chinese address corpus.
- We introduce a novel neural approach to Chinese address parsing with latent variables to flexibly capture both prior ordering information and rich dependencies among labels.
- Through extensive experiments, we demonstrate the effectiveness of our approach. The experimental results show that our approach outperforms several baselines significantly.

2 Data

In this work, we created a *Chinese Address* corpus. To do so, we crawled a large number of publicly available addresses from the Chinese websites including online business directory websites (e.g., `b2b.huangye88.com`), social media websites (e.g., `www.dianping.com`), and an online API service translating a geo-location to a Chinese address (`lbs.amap.com`). In order to protect privacy, we discarded sensitive addresses (such as those involving military locations) and randomly altered the digits in the collected addresses.

Due to the lack of Chinese address standard format as well as complicated and different writing preferences in different regions (e.g., people living in southern China prefer the word “弄” as the suffix of the name of a lane or sub-road over the word “胡同” which is widely used in northern China), we create an annotation guideline[1] by summarizing different writing preferences. We proposed 21 chunk labels listed in Table 1. The meaning

---

[1] The annotation guideline can be found at `http://statnlp.org/research/sp`.

of most labels can be inferred from their names. We hire 3 annotators to annotate chunk boundaries and chunk labels for each Chinese address following the annotation guideline. In order to maintain high annotation quality, we also hire 2 additional quality controllers to sample 20 sentences from each batch of 1,000 annotated sentences for human evaluation. Re-annotation for that batch will be performed should the accuracy of human evaluation fall below 95%.

We randomly split the annotated data into 3 portions following the ratio of 60%, 20%, and 20%, yielding training, development, and test sets. The complete statistics of our data can be found in Table 1. From the table we can observe that the chunk label POI (point of interest) occurs most frequently. Indeed, such a label has a high level of importance. This is because location-based information can be extracted from such chunks, which is crucial for recommendation services (Gao et al., 2015; Xie et al., 2016). In addition, we report the number of distinctive chunks (unique#) that appear in the data for each label, from which we can see our corpus has a good coverage on PROVINCE, CITY, and DISTRICT[2].

We empirically assign each label a order ID indicating its level of specificity. For example, the label COUNTRY is used for describing a country, and is the most general concept. It is thus assigned the order ID 20, which is the highest among all labels. As another example, the label PERSON gets assigned an order ID 3, as it is used to describe one of the most specific concepts. Such order ID information will be useful later when designing our models for Chinese address parsing.

3 Approach

Our objective is to design a model for parsing Chinese addresses into semantically meaningful structures in the form of consecutive chunks, where each chunk is assigned a label as described in the previous section. As we have mentioned before, we believe there exist Chinese address-specific characteristics associated with address texts that can be exploited in designing a parsing model. Specifically, we argue there are two types of structured information within Chinese addresses that can be exploited when designing our parser – the *latent tree structures* and the *regular chain structures*. The former is used for capturing rich dependencies among chunks that appear towards the end of each address. The latter is used for capturing the structural patterns associated with chunks appearing at the beginning of each address.

3.1 Latent Tree Structures

We focus our discussions on the latent tree structures first. Given a consecutive sequence of labeled chunks, we can construct a binary tree structure whose yield exactly corresponds to the sequence of labeled chunks. We build the latent tree structures to capture complex dependencies based on the observation that chunks appearing towards the end of a given address do not follow a rigorous order. For instance, as we can see in the second example in Figure 1, chunks towards the end of the address consist of some labels related to numbers as well as the label REDUNDANT. These labels are either optional or do not follow some regular patterns in terms of order, which makes capturing dependencies among labels challenging.

We first introduce *auxiliary labels* based on the set of *original labels* we defined in the previous section. Such auxiliary labels are assigned to the internal nodes within a parse tree. Specifically, for each original label X, we introduce the auxiliary label $\overline{\text{X}}$. For example, the auxiliary label for ROAD would be $\overline{\text{ROAD}}$.

We now illustrate how a latent tree is constructed from a sequence of labeled chunks. These chunks will be regarded as a sequence of leaf nodes, each of which contains the corresponding chunk boundary and chunk type information. To simplify the construction process, we focus on building a specific type of binary trees with each non-leaf node containing at least 1 leaf node as one of its child.[3] We start the process by selecting any chunk first as one leaf node. Next we take a chunk that is either on the left or on the right of the selected chunk as its binary sibling node, and create a parent node by assigning the two selected leaf nodes as child nodes. To determine the label of the newly created parent node, we choose the auxiliary label based on the label with a higher order ID between the two of the child nodes. The newly created parent node will replace the 2 child nodes in the sequence and now the parent node becomes a selected node. We repeat this construction pro-

---

[2] We found these numbers are comparable with statistics on `www.stats.gov.cn`.

[3] Preliminary results show that considering arbitrary binary trees would lead to slightly worse results for our task.

cess until there is only 1 node left in the sequence. Note that the construction process makes use of the label order information.

Figure 2 shows an example tree that the gold chunks correspond to. From the example we can see that the non-leaf node label $\overline{\text{POI}}$ that appears twice has connections to other non-leaf node labels such as $\overline{\text{ROADNO}}$ and $\overline{\text{POI}}$. Such tree structures will allow us to capture rich Chinese address-specific structural information among labels. Since there are many latent trees corresponding to the given address consisting of consecutive labeled chunks, the model is facilitated to learn such complicated patterns, which is potentially beneficial for the address parsing task.

3.2 Regular Chain Structures

The latent tree structures allow complex dependencies between different chunks to be captured within a Chinese address. Such dependencies would be helpful when there exist irregular patterns within an address. However, if we believe there are regular patterns among the labeled chunks, using an alternative assumption on the dependencies to properly capture such patterns may be more desirable. For instance, the first example in Figure 1 illustrates a common regular pattern at the beginning of the address, which is the order of (PROVINCE, CITY, DISTRICT). This motivates us to employ an alternative representation for capturing dependencies within chunks that appear at the beginning of the addresses, which are believed to exhibit more regular patterns.

Specifically, we employ a chain structure to capture the dependencies between adjacent labeled chunks. For example, given a sequence of chunks, we may always consider a right-branching tree structure to connect all these chunks. The resulting structure will be able to capture first-order dependencies between adjacent labeled chunks, which allows the regular orders among the labels to be learned. For example, consider the first two chunks that appear within the address as illustrated in Figure 2. The first two chunks form a right-branching tree structure. The construction process for such chain structures is similar to that of the latent trees, except that there is a single fixed (right-branching tree) structure for given labeled chunks.

Based on the observation that regular patterns appear mostly at the beginning of an address, we define the space $\mathcal{H}(x, y, sp)$ that consists of all latent tree structures that are consistent with the input character sequence x, the gold labeled chunks y and sp which determines the split point. Formally, we define the split point of a given address as specified by sp as the left boundary of the rightmost chunk whose label order ID is larger than or equal to sp. The split point divides the chunks into two groups – those appearing on the left of sp will form a chain structure while those on the right will form a tree structure where the correct construction is latent. Both structures are then merged to form a single representation, which is used for building our address parsing model.

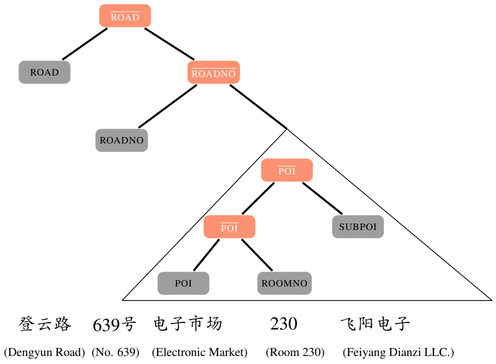

Figure 2: An example latent tree for given gold chunks where $sp = \text{POI}$. The English translation is listed below each chunk. Leaf nodes are in gray, and the internal nodes are in pink (labeled with white auxiliary labels). The tree structure within the triangle is latent – we show one of the many possible structures for illustration only.

Notice that when sp is set to -1 (denoted as $sp = \text{LAST}$), the split point is on the right of the last chunk. In this case the latent structured space $\mathcal{H}(x, y, sp)$ consists of only one single right-branching tree. On the other hand, when sp is set to its maximal value 20, the label order ID of COUNTRY (denoted as $sp = \text{COUNTRY}$), the latent structured space does not contain any structure that involves a partial regular chain component. Different values of sp leads to different interpolations between the two types of structural assumptions, resulting in different variants of our models. We will discuss the effect of different sp values in the experiments section.

3.3 Chunk Representation

A parse tree corresponds to a collection of labeled chunks as leaves. We adopt a bi-directional LSTM over a given input to compute the span-level representation. At each position i in the original input consisting of a sequence of characters, we use $\mathbf{f}_i$ and $\mathbf{b}_i$ to denote the outputs of forward LSTM and backward LSTM respectively. We use $\mathbf{c}_{i,j} = [\mathbf{f}_j - \mathbf{f}_i; \mathbf{b}_i - \mathbf{b}_j]$ to denote the vector representation of the span covering characters from position i to position j (Wang and Chang, 2016). Motivated by Stern et al. (2017), we define the label score as follows:

$$\mathbf{s}(i,j) = F(\mathbf{c}_{i,j})$$

where F is a 2-layer feed-forward neural network with output dimension being the number of chunk labels. In addition, we denote the score of the span with a specific label l as the value of the l-th element in the vector $\mathbf{s}(i,j)$:

$$s(i,j,l) = [\mathbf{s}(i,j)]_l \tag{1}$$

3.4 Model

Inspired by Stern et al. (2017), we build a chart-based parsing model. Unlike that work, however, our model involves latent structures as mentioned in Section 3.1. For a given sequence of labeled chunks, our model considers all possible constituent trees whose yield are exactly the labeled chunks.

Consider a tree $\mathbf{t}$ that can be represented by a set of labeled spans, where each span is uniquely defined by the boundary (i,j) and the label l:

$$\mathbf{t} := \{(i_n, j_n, l_n) : n = 1, \ldots, |\mathbf{t}|\}. \tag{2}$$

The score of the tree $\mathbf{t}$ can be defined as follows:

$$\mathcal{S}(\mathbf{t}) = \sum_{(i,j,l)\in\mathbf{t}} [s(i,j,l)] \tag{3}$$

Similar to (Stern et al., 2017), we use a CKY-style algorithm to calculate the score of the optimal sub-tree that spans the interval (i,j) recursive using the following formula:

$$\begin{aligned}\pi(i,j) = \max_l[s(i,j,l)] + \\ \max_k \Big\{ \max_l[s(i,k,l)] + \pi(k,j), \\ \pi(i,k) + \max_l[s(k,j,l)]\Big\}\end{aligned} \tag{4}$$

The base case is when the text span (i,j) corresponds to a leaf node (a chunk) in the tree; in this case we have: $\pi(i,j) = \max_l[s(i,j,l)]$.

3.5 Training and Decoding

Inspired by the structural support vector machines with latent variables (Yu and Joachims, 2009), we employ a (per instance) hinge loss during training:

$$L = \max_{\mathbf{t}\in\mathcal{H}(x)}[0, \boldsymbol{\Delta}(\mathbf{t},\mathbf{t}^*) + \mathcal{S}(\mathbf{t}) - \mathcal{S}(\mathbf{t}^*)] \tag{5}$$

where $\mathcal{H}(x)$ refers to the set of all possible trees for the given input x, and $\mathbf{t}^*$ denotes the best tree in the latent space $\mathcal{H}(x, y, sp)$:

$$\mathbf{t}^* = \max_{\mathbf{t}'\in\mathcal{H}(x,y,c)} \mathcal{S}(\mathbf{t}') \tag{6}$$

Here $\boldsymbol{\Delta}(\mathbf{t},\mathbf{t}^*)$ represents the Hamming loss on labeled spans, measuring the similarity between the predicted tree and the best latent tree that corresponds to the gold chunks.

During decoding, we aim to obtain the best tree as the prediction $\hat{\mathbf{t}}$ for a new address x' among all the possible trees:

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}\in\mathcal{H}(x')}[\mathcal{S}(\mathbf{t})] \tag{7}$$

The yield of the predicted tree $\hat{\mathbf{t}}$ gives us the list of labeled chunks.[4]

4 Experimental Setup

We call our model Address Parser with Latent Trees (**APLT**). We conducted experiments based on different settings of the sp values, leading to many model variants. We describe baselines, model hyperparameters as well as evaluation metrics in this section.

Baselines To understand the effectiveness of our models, we build the following baselines:

- **ℓCRF** is the standard first-order linear CRF model (Lafferty et al., 2001) with discrete features for sequence labeling tasks.
- **sCRF** is based on the standard semi-Markov CRF (Sarawagi and Cohen, 2004) with discrete features[5].
- **LSTM** is the standard bi-directional LSTM model for sequence labeling tasks.

---

[4] In some cases, it is possible to predict a tree with one or more leaf chunks labeled with auxiliary labels (e.g., $\overline{\text{ROAD}}$). We have a post-processing step that converts such labels into their corresponding original labels (e.g., ROAD).

[5] See the supplementary material for details on the features for **ℓCRF** and **sCRF**. For **sCRF** (and **LSTM-sCRF**), maximal chunk length is set to 36, which is the length of the longest chunk appearing in the training set.

- **LSTM-ℓCRF** is proposed by Lample et al. (2016) which is the state-of-the-art for many sequence labeling tasks
- **LSTM-sCRF** is based on segmental recurrent neural network (Kong et al., 2016) which is the neural network version of semi-Markov CRF (Sarawagi and Cohen, 2004).
- **TP** is a transition-based parser for chunking based on Lample et al. (2016), which makes use of the *stack LSTM* (Dyer et al., 2015) to encode the representation of the stack.

Hyperparameters We conducted all the experiments based on our *Chinese Address* corpus. We pre-trained Chinese character embeddings based on the Chinese Gigaword corpus (Graff and Chen, 2005), using the skip-gram model with hierarchical softmax implemented within the *word2vec* toolkit (Mikolov et al., 2013) where we set the sample rate to 10^{-5} and embedding size to 100.

We use a 2-layer LSTM (for both directions) with a hidden dimension of 200. For optimization, we adopt the Adam (Kingma and Ba, 2014) optimizer to optimize the model with batch size 1 and dropout rate 0.4. We randomly replace the low frequency words with the *UNK* token and normalize all numbers by replacing each digit (including Chinese characters representing numbers from 0-9) to 0. We train our model for a maximal of 30 epochs and select the model parameters based on the F_1 score after each epoch on the development set. The selected model is then applied to the test set for evaluation. Our model, as well as the baseline neural models, are implemented using DyNet (Neubig et al., 2017). All the neural weights are initialized following the default initialization method used in DyNet.

Evaluation Metrics We use the standard evaluation metrics from the CoNLL-2000 shared task (Tjong Kim Sang and Buchholz, 2000), reporting precision ($P.$), recall ($R.$) and F_1 percentage scores.

5 Result and Discussion

5.1 Main Results

We present our main results in Table 2, where we report the overall performance as well as specific results on the POI label. For our model, we report results for sp=20, -1 as two special cases – the former learns latent tree structures only and the latter assumes a single right-branching tree. We also report results for sp=7 which is selected based on the optimal results on the development set.

Model	POI			OVERALL		
	$P.$	$R.$	F_1	$P.$	$R.$	F_1
ℓCRF	69.76	72.68	71.19	87.78	85.33	86.53
sCRF	74.95	77.14	76.03	88.64	87.36	87.99
LSTM	70.11	76.90	73.35	85.63	88.11	86.85
LSTM-ℓCRF	77.94	75.62	76.76	88.83	88.88	88.86

TP	77.61	75.67	76.63	88.80	88.75	88.77
APLT $sp = 20$ (COUNTRY)	**80.36**	78.46	79.40	90.10	88.64	89.37
APLT $sp = -1$ (LAST)	79.64	78.89	79.26	90.06	89.07	89.56
APLT $sp = 7$ (HOUSENO)	79.75	**79.26**	**79.51**	**90.65**	**89.21**	**89.93**

Table 2: Main results.

Among all the baselines, **LSTM-ℓCRF** performs better than **LSTM** and **TP**, which is consistent with the finding reported in (Lample et al., 2016). The two models **LSTM-ℓCRF** and **LSTM-sCRF** both achieve similar results, which is also consistent with the finding reported in (Liu et al., 2016). The two non-neural models **ℓCRF** and **sCRF** perform substantially worse than their neural counterparts, which we believe is mainly due to the use of only handcrafted features in such systems. All these baseline models are capable of encoding transition patterns between neighboring chunks, which can partially capture certain structural information. However, certain Chinese address-specific structural information is not explicitly captured in such models.

Our model **APLT** (sp=7) achieves the best overall results, as well as the best results when evaluated on POI only. Compared with the strongest baselines **LSTM-ℓCRF** and **LSTM-sCRF**, **APLT** (sp=7) outperforms them significantly by more than 1 F_1 point overall ($p < 10^{-5}$)[6]. Furthermore, the **APLT** (sp=7) model obtains the best F_1 scores among all the models on POI. Note that our **APLT** model is able to learn richer dependencies among labels including label order information, regular patterns and irregular patterns among labels. Overall, the model **APLT** (sp=7) also outperforms both **APLT** (sp=-1) ($p < 0.05$) and **APLT** (sp=20) ($p < 0.005$) significantly. Such a result implies the importance of capturing the various Chinese address-specific structural information mentioned above within our model.

To understand the results better, we conduct detailed analysis of our results. Table 3 shows the F_1 scores of each label as well as the percentage of each label in the test data among four

---

[6] We perform the bootstrap resampling significant test.

OTHERINFO	0.02	0.00	0.00	0.00	0.00

Table 3: F_1 score comparison on test data for each label among 4 models as well as the percentage of each label in the gold data.

models **LSTM-ℓCRF**, **LSTM-sCRF**, **APLT** (sp=-1) and **APLT** (sp=7). Note that the results for the top 4 labels POI, DISTRICT, ROAD and CITY, which take up 45% of total chunks, all get improved when using our **APLT** models. Moreover, it achieves better or comparable $F1$ scores on 15 labels in the table among the total 21 labels, especially on POI, DISTRICT, REDUNDANT, COMMUNITY and PERSON with at least 1 point improvement in F_1. Interestingly, our models perform worse than **LSTM-ℓCRF** on labels such as ROADNO, ROOMNO, and FLOORNO, which are mostly related to numbers. We note that, however, chunks with such labels do not constitute a large proportion of all chunks. Results suggest that our models somehow learned to focus on optimization performance for chunks with more prominent labels such as POI and DISTRICT.

5.2 Effectiveness of Structural Information

In order to investigate how tree structures affect the final performance, we also conducted experiments with different values for sp, which is used for determining the split point. Figure 3 shows the moving-averaged F_1 scores on the test set obtained when choosing sp around specific values (a similar distribution can be observed on the development set). From the bottom (COUNTRY,20) to the top (LAST,-1) along y axis, the lower the sp is, the more constraints are applied to the latent space $\mathcal{H}(x, y, sp)$. Note that when sp=-1 (LAST), the gold input only corresponds to a single right-branching tree. We exclude the following labels: REDUNDANT, ASSIST and OTHERINFO, because we found these labels may appear at any place within a given address, which make them unsuitable for determining the split point.

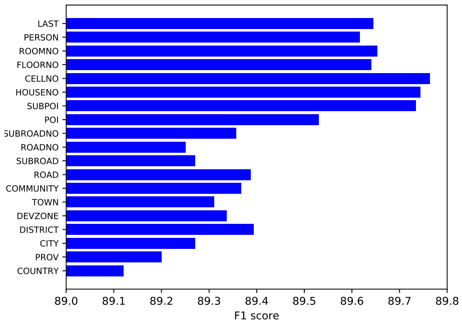

Figure 3: Effect of sp.

From Figure 3 we can observe that the F_1 score generally increases as we decrease sp, starting from COUNTRY(with order ID 20). The performance reaches the maximum when the sp is set to a value within the range [SUBPOI, CELLNO]. This observation implies that there does exist ordering information among labels, and introducing more constraints on the latent space will have the benefit of modeling the regular patterns around the beginning part of a given address. After reaching the best value, as we further decrease sp, the performance drops slightly and oscillates around the range [FLOORNO, LAST]. From here we can observe that the latent trees are able to help capture irregular patterns within labels that appear towards the end of the address. Overall, these results suggest the importance of designing a model like ours that is capable of capturing Chinese address-specific characteristics.

5.3 Error Analysis

We conduct error analysis on two strongest baselines **LSTM-ℓCRF** and **LSTM-sCRF** as well as two best-performing **APLT** models respectively. We examined the list of top-10 labels with most errors for each model, and found most of the errors come from labels such as POI, SUBPOI and REDUNDANT – this implies they are the most challenging labels for this task. We also found labels such as ROOMNO appear in the list for **APLT** models, but not for the **LSTM-ℓCRF** model, showing that **APLT** models are still not good at handling numbers as we discussed above.

There are two major types of errors. The type-

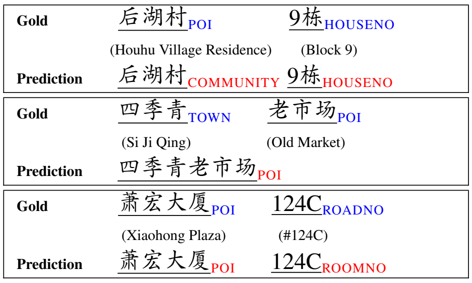

Figure 4: Example outputs from **APLT**(*sp*=7).

Length	%	LSTM ℓCRF	LSTM *s*CRF	APLT *sp*=−1	APLT *sp*=7
1	9.39	**92.16**	92.14	91.65	91.77
2	**23.73**	86.69	86.13	87.16	**87.77**
3	**44.60**	92.26	92.04	93.03	**93.51**
4	**13.31**	86.49	87.48	88.05	**88.18**
5	3.70	74.57	76.41	77.55	**79.43**
6	2.14	68.88	70.19	70.87	**73.73**
7	1.16	64.61	68.14	67.59	**68.22**
≥8	1.97	63.31	62.57	**63.33**	60.19

Table 4: Results for different chunk lengths.

I error refers to the case where the boundary of a chunk is predicted correctly but not its label. The type-II error is the case where even the boundary of a predicted chunk is incorrect. We found that **APLT** (*sp*=−1) and **APLT** (*sp*=7) produce less type-I errors (45.04% and 42.95% respectively) than **LSTM-ℓCRF** and **LSTM-*s*CRF** (49.87% and 47.26% respectively). Moreover, we find that **APLT** (*sp*=7) model produces the least number of type-I errors as well as type-II errors.

Looking into the type-I errors of both two **APLT** models, we find chunks with label POI are often incorrectly labeled as COMMUNITY, which is a major source of errors (9% of total errors). As a typical example, we show a partial prediction in Figure 4, where our model fails to recognize "后湖村"(Houhu Village Residence) as a POI. Here the character "村"(Village) is a common suffix for the name of either a village or a residence, hence the confusion.

The second example in Figure 4 demonstrates another typical kind of errors produced by our models around the POI labels. Here, "四季青(Si Ji Qing)" is actually the name of a town. However, as most names of towns end with "镇(Town)" as the suffix, our models as well as baseline models all fail to identify the correct chunk boundaries.

We also investigate the errors around the number labels. We choose to look into the results on ROADNO because it is the fifth most popular label in the test data. Based on the error analysis, we found that many chunks of label ROADNO were incorrectly assigned other types of number labels. As we can see from the third example in Figure 4, the ROADNO "124C" is incorrectly predicted as a ROOMNO. Indeed, this chunk does look like a room number, though in fact it refers to a road within a "plaza" (大厦) rather than an office within a "building" (another interpretation of 大厦). From these examples we can observe that many ambiguities may not be easily resolved without further background knowledge.

5.4 Robustness Analysis

We analyze the model robustness by assessing the performance on chunks of different lengths for each of the four models discussed above. We group chunks into 8 categories based on their lengths and present the results in Table 4 where the distribution information is also included. As we can see, all the models achieve at least a F_1 score of 86 when considering chunks whose lengths are less than 5. As the length increases, the performance of all models drop gradually. For chunks whose lengths are at least 8, the F_1 score is around 60-63 for all models. Considering chunks whose lengths are either 2, 3, or 4 only (such chunks constitute over 80% of total chunks), we can observe that **APLT** (*sp*=7) outperforms two baselines significantly by more than 1 point for each category. These results demonstrate the robustness of our model when handling chunks of different lengths.

Comparing the two **APLT** models, we can see the model **APLT** (*sp*=7) outperforms **APLT** (*sp*=−1) for each chunk category, except for chunks whose lengths are greater than or equal to 8. These two models differ in their latent spaces. **APLT** (*sp*=7) with a richer latent space appears to be better at handling chunks with short or medium lengths.

In addition, we conducted a further experiment to understand how each model is able to handle new chunks – the chunks that appear in the test set (according to the gold labels) but do not appear in the training set. We found empirically there are 31% of the chunks in the test set that are new chunks. Such an experiment allows us to assess the robustness of each model when new data is available. We report the accuracy for the new chunks in Table 5. As we can see, two **APLT** models outperform two baselines, indicating our **APLT** models appear to be better at handling new chunks. We believe this is due to the tree models

LSTM	**LSTM**	**APLT**	**APLT**
ℓ**CRF**	s**CRF**	$sp{=}-1$	$sp{=}7$

that we used, which are capable of capturing complex dependencies among chunks.

6 Related Work

While the Chinese address parsing task is new, it is related to the following traditional tasks within the field of natural language processing (NLP) – chunking, named entity recognition, word segmentation and parsing. We briefly survey research efforts which are most related to our task below.

Chunking as a fundamental task in NLP has been investigated for decades (Abney, 1991). Chunking for Chinese can typically be regarded as a sequence labeling problem solvable by models such as conditional random fields (Chen et al., 2006; Tan et al., 2005; Zhou et al., 2012), hidden Markov models (Li et al., 2003), support vector machines (Tan et al., 2004) and the maximum entropy model (Wu et al., 2005). Our task can also be regarded as a chunking task where we need to assign an address-specific label to each chunk.

Named entity recognition (NER) is another fundamental task close to chunking within the field of NLP, which focuses on the extraction of semantically meaningful entities from the text. The state-of-the-art approach by Lample et al. (2016) employs a LSTM-CRF model. Ma and Hovy (2016) proposed a LSTM-CNNs-CRF model that utilizes convolutional neural networks (CNNs) to extract character-level features besides word-level features. Zhai et al. (2017) suggested a neural chunking model based on pointer networks (Vinyals et al., 2015) to resolve the issue of being difficult to use chunk-level features such as the length of the chunk for segmentation. Zhang and Yang (2018) tackled the problem of Chinese NER by deploying a lattice LSTM leveraging lexicons.

Another task closely related to our task is the Chinese word segmentation task which at least dates back to the 1990s (Sproat et al., 1994). The segmentation task is typically casted as a character-based sequence labeling problem (Xue, 2003) which can be solved by CRF based models (Peng et al., 2004; Zhao et al., 2006), their latent-variable variants (Sun et al., 2009), or max-margin based models (Zhang and Clark, 2007). Recently, Zhang et al. (2016) proposed a neural transition-based segmentation approach by encoding both words and characters as well as the history action sequence. Yang et al. (2017) suggested to perform segmentation with a neural transition-based method with rich pre-training.

Constituent parsing is another line of work that is related to our task. The state-of-the-art approaches to parsing include transition-based models (Dyer et al., 2016) and chart-based models (Stern et al., 2017; Kitaev and Klein, 2018).Our model is motivated by the latter approaches, where we additionally introduce latent variables for capturing complex dependencies among chunks.

7 Conclusion

In this work, we introduce a new task – *Chinese address parsing*, which is to segment a given Chinese address text into chunks while assigning each chunk a semantically meaningful label. We create and publish a *Chinese address* corpus that consists of 15K fully labeled Chinese addresses. We identify interesting characteristics associated with the task and design a novel neural parsing model with latent variables for this task, which is able to capture Chinese address-specific structural information. We conduct extensive experiments and compare our approach with strong baselines through detailed analysis. We show that our proposed model outperforms baseline approaches significantly, due to its ability in capturing rich structural information present in the Chinese addresses.

Future work includes leveraging external knowledge bases to disambiguate chunks and entities that appear within Chinese addresses, as well as designing algorithms that are able to capture longer-range dependencies among chunks using alternative structures.

Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments on this work. This work is done under a collaborative agreement between SUTD and Alibaba on an Alibaba Innovative Research (AIR) Program funded by Alibaba, where Alibaba provided data. We appreciate Alibaba's generosity in the agreement that makes it possible for us to make all data and code in this research publicly available upon acceptance of this paper. This work is also partially supported by SUTD project PIE-SGP-AI-2018-01.

Abstract

On the one hand, nowadays, fake news articles are easily propagated through various online media platforms and have become a grand threat to the trustworthiness of information. On the other hand, our understanding of the language of fake news is still minimal. Incorporating hierarchical discourse-level structure of fake and real news articles is one crucial step toward a better understanding of how these articles are structured. Nevertheless, this has rarely been investigated in the fake news detection domain and faces tremendous challenges. First, existing methods for capturing discourse-level structure rely on annotated corpora which are not available for fake news datasets. Second, how to extract out useful information from such discovered structures is another challenge. To address these challenges, we propose **H**ierarchical **D**iscourse-level **S**tructure for **F**ake news detection. HDSF learns and constructs a discourse-level structure for fake/real news articles in an automated and data-driven manner. Moreover, we identify insightful structure-related properties, which can explain the discovered structures and boost our understating of fake news. Conducted experiments show the effectiveness of the proposed approach. Further structural analysis suggests that real and fake news present substantial differences in the hierarchical discourse-level structures.

1 Introduction

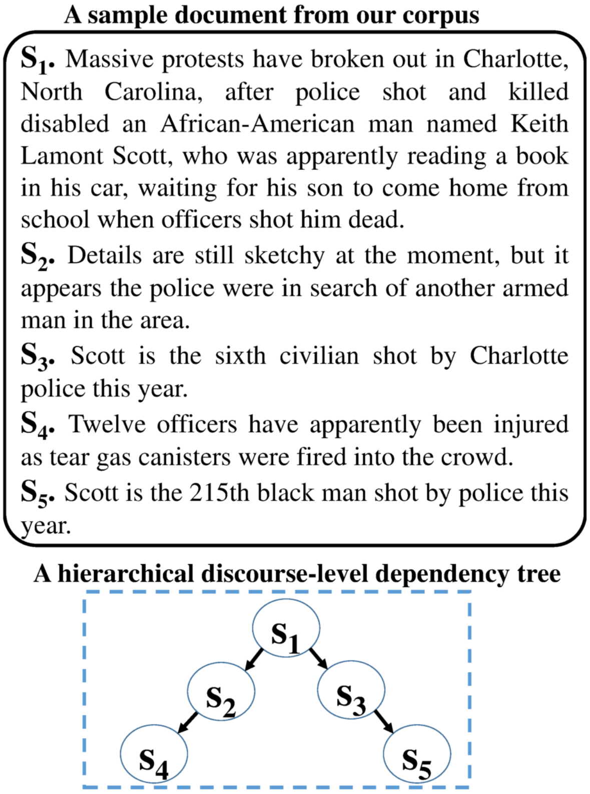
In this work, we focus on detecting fake news articles (hereafter referred to as *documents*) based on their contents. Many existing linguistic approaches for fake news detection (Feng et al., 2012; Pennebaker et al., 2015; Ott et al., 2011) overlook a crucial linguistic aspect of fake/real news documents i.e., the hierarchical discourse-level structure. Usually, in a document, discourse units (e.g., sentences) are organized in a hierarchical structure e.g., a tree. The importance of considering the hierarchical discourse-level structure for fake news detection is three-fold. First, previous studies (Bachenko et al., 2008; Rubin and Lukoianova, 2015) explored discourse-level structure in fake news detection and discovered that the way two discourse units of a document are connected could be quite revealing and insightful about its truthfulness. For instance, (Rubin and Lukoianova, 2015) applied Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) and noted that fake stories lack "evidence" as a defined inter-discourse relation. Second, fake news is typically produced by connecting disjoint pieces of news and unlike well-established journalism (e.g., New York Times) fake news production lacks a meticulous editorial board. Therefore, by incorporating the hierarchical discourse-level structure, we can investigate the coherence of fake/real news documents (we will show this later). Third, a substantial number of studies have shown that using hierarchical structures yields a better document representation in various downstream tasks whose predictions depend on the entire text (Bhatia et al., 2015; Morey et al., 2018; Li et al., 2014b). Since typically fake news detection is considered as a classification problem based on the entire text, applying discourse analysis has the potential to advance fake news detection (this will be verified later).

On the other hand, incorporating the hierarchical structure at the discourse level for fake news detection faces tremendous challenges. First, many existing methods incorporating structural discourse (Li et al., 2014a; Bhatia et al., 2015) (not for fake news detection though) rely on annotated corpora such as Penn Discourse Treebank (Prasad et al., 2007). Constructing and annotating such corpora is an arduous and costly process. Incor-

Proceedings of NAACL-HLT 2019, pages 3432–3442
Minneapolis, Minnesota, June 2 - June 7, 2019.

porating hierarchical structure is even more difficult for fake news detection as there exists virtually no available annotated discourse corpus in this domain. Therefore, we need to learn the discourse-level structure in a data-driven and automated manner. Second, how to use the hierarchical discourse-level structure and extract insightful information that can boost our understanding of fake news is another challenge.

In this study, we embrace the opportunities and challenges and propose **H**ierarchical **D**iscourse-level **S**tructure for **F**ake news detection (HDSF) framework. HDSF in an automated manner learns a hierarchical structure for a given document through an approach based on the dependency parsing at the sentence level (i.e., sentences are discourse units). As an example, Figure 1 illustrates a hierarchical structure of a document i.e., a dependency tree of sentences. Sentences represent discourse units and two sentences are connected by a directed link where a sentence at the *head* of the link *semantically depends* on a sentence at the *tail* of the link e.g., in Figure 1, the sentence s_4 depends on the sentence s_2.



A sample document from our corpus

S_1. Massive protests have broken out in Charlotte, North Carolina, after police shot and killed disabled an African-American man named Keith Lamont Scott, who was apparently reading a book in his car, waiting for his son to come home from school when officers shot him dead.

S_2. Details are still sketchy at the moment, but it appears the police were in search of another armed man in the area.

S_3. Scott is the sixth civilian shot by Charlotte police this year.

S_4. Twelve officers have apparently been injured as tear gas canisters were fired into the crowd.

S_5. Scott is the 215th black man shot by police this year.

A hierarchical discourse-level dependency tree

Figure 1: An illustration of the hierarchical discourse-level structure of a document using a dependency tree

Our key contributions are summarized as follow.

- To the best of our knowledge, we are the first to study automatic document structure learning for fake news detection.
- We propose the framework HDSF that automatically and in an end-to-end manner learns structurally rich representations for fake and real news documents.
- We identify a set of structure-related properties delineating meaningful structural differences between fake and real news documents.

The rest of the paper is organized as follows. In Section 2, we formally define the problem. Section 3 describes the proposed framework. In Section 4, we introduce several structure-related properties to analyze the hierarchical structures. Section 5 presents the experiments and discussions followed by an overview of the related work in Section 6. We conclude the paper in Section 7 and shed light on a few future directions.

2 Notations and Problem Statement

Following the previous work (Allcott and Gentzkow, 2017; Shu et al., 2017), we define the fake news as follows.

Definition. We define a news document *fake* if its content is verified to be false and *real* otherwise.

Let's briefly introduce some notations. Suppose we have a corpus $\mathcal{D}$ of fake and real news documents. Let a document $d \in \mathcal{D}$ contain k sentences $s_1, s_2, \cdots s_k$. Suppose a sentence $s_j \in d$ ($1 \leq j \leq k$) includes words $W_j = \{w_1, w_2, \cdots, w_{T_j}\}$ where T_j denotes the number of words in sentence s_j. Additionally, binary labels Y (i.e., *fake* or *real* labels) hold ground-truth labels associated with documents in $\mathcal{D}$.

Given the corpus of fake/real news documents (i.e., $\mathcal{D}$), we aim to learn model $\mathcal{M}$ that can automatically learn hierarchical and structurally rich representations for documents in $\mathcal{D}$. Meanwhile, given binary labels Y, the model $\mathcal{M}$ uses the hierarchical representations to automatically predict the labels of unseen news documents.

3 The Proposed Framework

To incorporate the discourse-level structure for fake news detection, we propose the framework HDSF illustrated in Figure 2. It provides three components: the *Hierarchical Discourse-level*

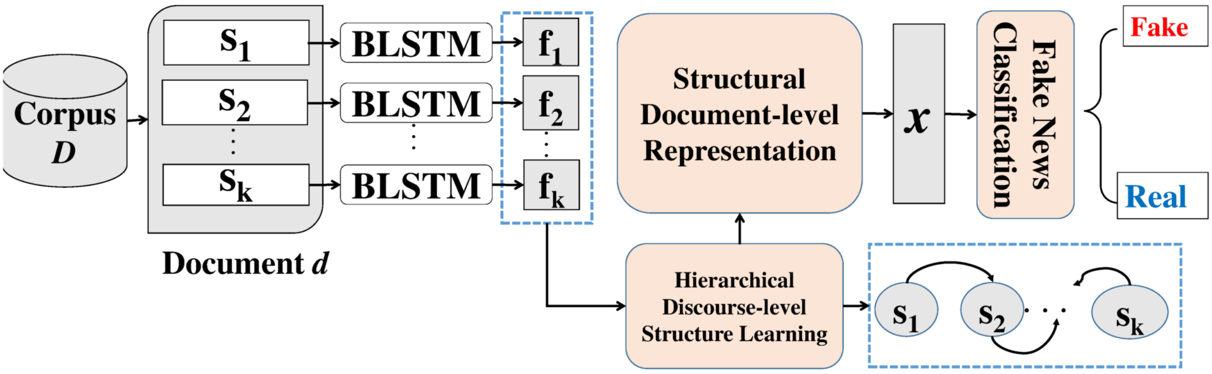


Figure 2: The proposed framework Hierarchical Discourse-level Structure for Fake news detection (HDSF)

Structure Learning automatically learns a proper structure for a given document, the *Structural Document-level Representation* yields a numerical and unified representation for the entire document, which is used by the *Fake News Classification* component to predict the label of a document.

3.1 Hierarchical Discourse-level Structure Learning

In this component, we aim to construct a hierarchical structure between discourse units (i.e., sentences) without relying on an annotated corpus. To achieve this, we use a dependency parsing approach (Liu and Lapata, 2018; Li et al., 2014a; Kim et al., 2017) and represent the hierarchical structure of a document as a dependency tree (see Figure 1 for an example of a dependency tree). In dependency parsing of discourse units, we mainly need to identify if a discourse unit semantically depends on another one. If so, a *parent-child* (or *tail-head*) link in the dependency tree can be established. Therefore, as long as the semantic dependencies between discourse units are identified, we can construct a discourse-level dependency tree without an annotated corpus. In Section 3.1.1, we describe a method to discover the semantic dependencies between discourse units in an automated manner. Afterward, in Section 3.1.2, we utilize these dependencies to construct the dependency tree of a document.

3.1.1 Learning Inter-Discourse Dependencies

Since discourse units are defined as sentences, we first need to get a fixed representation for each sentence. To this end, we utilize Bi-directional Long Short-Term Memory (BLSTM) network (Schuster and Paliwal, 1997). We represent each word in a sentence s_j by a fixed-size word embedding, and further the BLSTM network at each time step $t \in [1, T_j]$ executes the following functions[1]:

$$\begin{aligned} \overrightarrow{h}_t &= \mathcal{F}(\overrightarrow{h}_{t-1}; w_{t-1}) \\ \overleftarrow{h}_t &= \mathcal{F}(\overleftarrow{h}_{t-1}; w_{T_j-t+1}) \end{aligned} \qquad (1)$$

where $\mathcal{F}$ is the LSTM function (Hochreiter and Schmidhuber, 1997), and $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ are outputs of the forward and backward LSTM networks at time step t, respectively. Then, a fixed representation for a sentence s_j, denoted as f_j, is defined as the average of the last output of forward and backward LSTM networks:

$$f_j = \frac{[\overrightarrow{h}_{T_j} + \overleftarrow{h}_{T_j}]}{2} \qquad (2)$$

Similarly, we apply the BLSTM network to all sentences of a document and obtain a sequence of sentential representations i.e., $f_1, f_2, \cdots, f_k$ (see Figure 2).

As mentioned before, in dependency parsing, we need to identify the dependency between two discourse units in an automated manner. To do this, the HDSF framework learns and optimizes an inter-sentential attention matrix $\mathbf{A} \in \mathbb{R}^{k \times k}$. The entry (m, n) of $\mathbf{A}$ holds the probability of the sentence s_m being the parent of the sentence s_n where $1 \leq m, n \leq k$ and $m \neq n$. In other words, $\mathbf{A}$ contains parent-child probabilities and is computed as follows.

$$\begin{aligned} u_m &= \mathcal{G}(\mathbf{W} \times f_m + \mathbf{b}) \\ u_n &= \mathcal{G}(\mathbf{W} \times f_n + \mathbf{b}) \\ \mathbf{A}[m, n] &= \frac{e^{(u_m \odot u_n)}}{\sum_{i=1}^{k} e^{\sum (u_i \odot u_n)}} \end{aligned} \qquad (3)$$

---

[1] Note that the backward LSTM (i.e., the lower part of Eq. 1) takes a sequence of words in a reverse order.

where $\mathcal{G}$ is a non-linear activation function, $\mathbf{W}$ is some weight matrix, $\mathbf{b}$ is a bias vector, and $\odot$ denotes the dot product operator. Further, since we need a root node in a dependency tree, we compute the probability of a sentence s_j being the root node, denoted as r_j, as follows.

$$\begin{aligned} u_j &= \mathcal{G}(\mathbf{W} \times f_j + \mathbf{b}) \\ r_j &= \frac{e^{\sum_{\forall y} u_j[y]}}{\sum_{i=1}^{k} e^{\sum_{\forall y} u_i[y]}} \end{aligned} \tag{4}$$

where $u_j[y]$ is the y-th element of vector u_j. Similarly, we calculate the root probabilities for all sentences and obtain the array of root probabilities denoted as $\mathbf{r} = \{r_1, r_2, \cdots, r_k\}$ where $0 \leq r_j \in \mathbf{r} \leq 1$.

3.1.2 Discourse Dependency Tree Construction

We use the learned matrix of inter-sentential parent-child probabilities i.e., $\mathbf{A}$ (Eq. 3) as well as the array of root probabilities i.e., $\mathbf{r}$ (Eq. 4) and propose a greedy algorithm, illustrated in Algorithm 1, to construct the discourse dependency tree of a document. A sentence with the maximum value in $\mathbf{r}$ is considered the root node and is inserted into the tree (line 5). Then, at each iteration, the algorithm finds the maximum entry in a block of the matrix $\mathbf{A}$ whose rows correspond to the rows of current nodes added to the tree (i.e., nodes V in line 7) and its columns correspond to columns of the rest of nodes (i.e., nodes $N \backslash V$ in line 7). Note that the columns of the current nodes are excluded because their parents have already been identified and also each node should have exactly one parent (except the root which has no parent). Assume the search in line 7 results in the entry (p, c) of $\mathbf{A}$ where $1 \leq p, c \leq k$ and $p \neq c$. Then, the sentence s_c is added as the child node of the sentence s_p (line 8). Algorithm 1 continues until all sentences of a document are added to the tree $\mathcal{T}$.

To fix the idea of discourse dependency tree construction algorithm, we present a step-by-step execution of this algorithm demonstrated in Figure 3. In Step 0, the sentence s_1 is added as the root of the tree $\mathcal{T}$ since it has the maximum value in the array of the root probabilities. Next in Step 1, the algorithm searches for the maximum probability value in the row s_1 while the column s_1 is excluded. The maximum value is this block is 0.4 and corresponds to entry (s_1,s_2). Therefore, the sentence s_2 is added as the child node of the sentence s_1. In a similar fashion, the algorithm continues until all 6 sentences are added to the tree.

Algorithm 1: The proposed algorithm for discourse dependency tree construction

```
    Input: $\mathbf{A}$; $\mathbf{r}$
    Output: Discourse dependency tree $\mathcal{T}$
 1  $\mathcal{T} = empty$
 2  $N = \{s_1, s_2, \cdots, s_k\}$ // All nodes
 3  $V = \{\}$ // Set of current nodes
 4  Add $N[argmax(\mathbf{r})]$ to $V$
 5  $\mathcal{T}.root = N[argmax(\mathbf{r})]$ // Adding the root
 6  while $|V| \neq k$ do
 7      $p, c = argmax(\mathbf{A}[V, N \backslash V])$ // Search block
 8      $\mathcal{T}.link(N[c], N[p])$ // Child-parent link
 9      $V.add(N[c])$ // Adding the child node
10  end
11  return $\mathcal{T}$
```

3.2 Structural Document-level Representation

We use a similar method presented in (Liu and Lapata, 2018) to extract a structurally rich representation for the entire document. First, for each sentence (i.e., a discourse unit), we obtain a structurally-aware representation. To achieve this, we take into account the parent-child probabilities as well as the root probabilities as follows.

$$\begin{aligned} \mathbf{p}_j &= r_j \times \mathbf{e}_{root} + \sum_{z=1}^{k} \mathbf{A}[z, j] \times f_z \\ \mathbf{c}_j &= \sum_{z=1}^{k} \mathbf{A}[j, z] \times f_j \\ \mathbf{g}_j &= \mathcal{G}(\mathbf{W}[\mathbf{p}_j || \mathbf{c}_j || f_j] + \mathbf{b}) \end{aligned} \tag{5}$$

where $\mathbf{p}_j$ and $\mathbf{c}_j$ are two context vectors taking into account possible parents and children of a sentence s_j, respectively, $\mathbf{e}_{root}$ denotes a special root embedding vector, $||$ denotes vector concatenation operator, and $\mathbf{g}_j$ is a *structurally-aware representation for sentence* s_j. Finally, to extract a structurally rich representation for the entire doc-

ument, we average all of its $\mathbf{g}_j$ vectors:

$$x = \frac{1}{k}\sum_{j=1}^{k}\mathbf{g}_j \tag{6}$$

where x denotes *the structurally rich document-level representation*.

3.3 Fake News Classification

We hypothesize that the document-level structurally rich representations (Eq. 6) offer a discriminatory power to detect fake news documents. Therefore, as shown in Figure 2, we employ a binary classification for fake news detection formulated as follows.

$$\begin{aligned} c_i &= -\big(y_i log(p^i_f) + (1-y_i)log(p^i_r)\big) \\ \mathcal{L}(\theta) &= \sum_{\forall d_i \in \mathcal{D}} c_i \end{aligned} \tag{7}$$

where y_i is the ground-truth label of a document $d_i \in \mathcal{D}$, c_i is the cross-entropy loss value, p^i_f and p^i_r are probabilities of d_i being fake or real, respectively. p^i_f and p^i_r are obtained from the representation x (Eq. 6) fed to a fully connected layer followed by the softamx function. In Eq. 7, θ denotes the framework’s parameters and $\mathcal{L}$ is the total loss of the model. Since the entire framework (Eq. 1 to 7) is fully differentiable, we utilize the error backpropagation (Hecht-Nielsen, 1992) to calculate the gradients followed by the stochastic gradient descent (Bottou, 2010) to update and optimize the parameters. Note that the discourse dependency tree construction algorithm presented in Section 3.1.2 is employed post hoc. Hence, the gradient calculation over $argmax$ operator (line 7 of Algorithm 1) is not performed.

4 Structure-related Properties

Incorporating discourse-level structure offer a discriminatory power distinguishing fake and real documents, which will be verified in Section 5.3. We expect more than this discriminatory power. We expect to identify insightful and interpretable information from extracted structures which can delineate intrinsic differences between fake and real news documents. To meet this expectation, we define three fundamental properties of constructed discourse dependency trees. Note that we leave the definitions of more advanced properties as one future work. We seek to fulfill two goals by defining the structure-related properties. First, we intend to highlight the way that fake and real news documents are different. Second, we intend to leverage these properties to shed light on the *coherence* of fake and real news documents. Coherence has been the subject of many studies (Barzilay and Lapata, 2008; Lin et al., 2011; Guinaudeau and Strube, 2013; Li and Hovy, 2014) and is concerned with how constituents of a document (e.g., discourse units) are linked together in a way that the entire text creates a clear mental picture to the readers (Storrer, 2002). Notwithstanding its importance, coherence has not been investigated in the fake news domain in a large-scale and systematic fashion. Aiming at filling this gap, we naturally connect the defined structure-related properties with the coherence of news documents.

Property 1 (Number of Leaf Nodes) *This property, denoted as* P_l*, defines the normalized number of leaf nodes in a discourse dependency tree:*

$$\mathsf{P}_l = \frac{l}{log(k)} \tag{8}$$

where l is the number of leaf nodes (i.e., sentences) in the discourse dependency tree of a document. Recall that k is the total number of sentences in a document.

The intuition behind defining Property 1 is as follows. According to the description of the dependency tree in Section 3.1, leaf nodes are isolated discourse units and no other discourse units depend on them. Thus, the more the number of leaf nodes is, the less inter-linked the discourse units will be, and vice versa. Therefore, Property 1 is likely to indicate the coherence of a document – the higher P_l, the more isolated sentences and the less coherent the document. Also, for a document with k sentences $\mathsf{P}_l \in [\frac{1}{log(k)}, \frac{k-1}{log(k)}]$.

Property 2 (Preorder Difference) *This property, denoted as* P_t*, defines the normalized positional difference between the preorder traversal of a document's discourse dependency tree and its original sentential sequential order:*

$$\mathsf{P}_t = \frac{\sum_{j=1}^{k} |s_j^{position} - j|}{log(k)} \tag{9}$$

where $s_j^{position}$ denotes the position of a sentence s_j in the preorder traversal[1] of dependency tree of a document e.g., $s_3^{position} = 4$ in Figure 1. The position of s_j in the original sequential order is simply j[2]. The preorder traversal of the tree in Figure 1 is the sequence $\{s_1, s_2, s_4, s_3, s_5\}$ and the sentential sequential order is $\{s_1, s_2, s_3, s_4, s_5\}$. Therefore, according to the definition of Property 2:
$\mathsf{P}_t = \frac{|1-1|+|2-2|+|4-3|+|3-4|+|5-5|}{log(5)} \approx 2.86.$

The preorder traversal of a document's discourse dependency tree takes into consideration the organization of a document respect to the dependencies between sentences. Then, the purpose of Property 2 is to measure how much the organization of a document, captured through the preorder traversal, deviates from its sentential sequential order. Sentence order is highly related to the coherence of a document where the displaced order of sentences in a document makes it less coherent (Li and Hovy, 2014). Thus, intuitively, the less the value of Property 2 for a document is, the more coherent that document should be. Also, for a document with k sentences $\mathsf{P}_t \in [\frac{k-1}{log(k)}, \frac{(k^2-1)}{2log(k)}]$ if k is odd and $\mathsf{P}_t \in [\frac{k-1}{log(k)}, \frac{k^2}{2log(k)}]$ if k is even.

Property 3 (Parent-Child Distance) *This property, denoted as* P_c*, defines the normalized sum of positional distances between child nodes and their parents when they are considered in the original sequential order:*

$$\mathsf{P}_c = \frac{\sum_{\forall c,p \in \mathcal{T}} |c_{position} - p_{position}|}{log(k)} \tag{10}$$

where $c_{position}$ and $p_{position}$ denote the positions of a child node c and a parent node p, respectively, in the original sentential sequential order. For instance, in our running example, the parent node s_3 has $p_{position} = 3$ (i.e., it is the third sentence) and its child node s_5 has $c_{position} = 5$. Therefore, their parent-child distance is $|5-3| = 2$. Following a similar calculation for other parent-child pairs, we have $\mathsf{P}_c = \frac{1+2+2+2}{log(5)} \approx 10$.

Similar to Property 2, Property 3 pertains to the organization of a document and takes into consideration the deviation from sentential sequential order. Intuitively speaking, usually, we expect that a child node and its parent to be close to each other in the original sequential order. Consequently, the less value of this property is, the more coherent a document is likely to be. The range of Property 3 in a document containing k sentences is $\mathsf{P}_c \in [\frac{k-1}{log(k)}, \frac{k(k-1)}{2log(k)}]$.

5 Experiments

To verify the performance of the proposed framework HDSF, we conduct a set of experiments. We seek to answer the following research questions:

1. How does the proposed framework perform on fake news detection?
2. How do the defined structure-related properties describe the fake and real news documents?

In this section, we first describe the datasets followed by presenting the experimental settings. Afterward, we evaluate the performance of HDSF compared to several representative baselines. Finally, we present a structural analysis of the fake/real news documents.

5.1 Datasets

We utilize five available fake news datasets in this study. The first two datasets are collected by (Shu

---

[1] The subtrees are ordered based on *when* they are added as the child nodes of a parent node in Algorithm 1. That is why we can compute preorder traversal.

[2] We assume that the sentences in the sequential order are numbered incrementally from 1 to k.

et al., 2017) and include online articles whose veracities have been identified by experts in BuzzFeed[1] and PolitiFact[2]. For the next two datasets, we utilize two available online fake news datasets provided by *kaggle.com*[3] [4]. Finally, we include the dataset constructed and shared by McIntire[5]. Since the proposed framework HDSF is a general-purpose framework investigating discourse-level structures of fake/real news documents based on their textual contents, we do not restrict HDSF to a particular source of data and therefore combine all datasets. Similar to the previous work (Shu et al., 2017), we balance the dataset to avoid a trivial solution as well as ensuring a fair performance comparison. In total, we have 3360 fake and 3360 real documents.

5.2 Experimental Settings

First, we pre-process the documents by removing numbers, non-English characters, stop-words (e.g., ‘with’), and converting all characters to lower case. We randomly select 134 documents as the development set, (67 from each class) and 134 documents (67 from each class) as the test set. The remaining 6452 documents are used for training. The development set is used for tuning the hyper-parameters. We initialize the word embeddings from the Google news pre-trained word2vec embeddings (Mikolov et al., 2013)[6]. LeakyReLU (Xu et al., 2015) is used as the non-linear activation function and the number of hidden units in the BLSTM network is set to 100. Each simulation is run for 200 steps with a random mini-batch size of 40 documents. The learning rate starts at 0.01 with the decay rate of 0.9 after every 50 steps. We use the ADAM optimizer (Kingma and Ba, 2014) to optimize the parameters. The PyTorch package[7] is utilized for the implementation and the code and data are publicly available in `https://github.com/hamidkarimi/HDSF`.

5.3 Comparison Results

To answer the research question (1), we compare the performance of HDSF with the following representative baselines.

N-grams. In this baseline method, we extract and combine unigrams, bigrams, and trigrams features and use SVM (Support Vector Machines) (Scholkopf and Smola, 2001) for classification.

LIWC (Pennebaker et al., 2015). LIWC (Linguistic Inquiry and Word Count) offers a set of rich psycholinguistic features for a written document. We extract 94 features for each document and use SVM for classification.

RST (Rubin and Lukoianova, 2015). We extract a set of RST relations (Mann and Thompson, 1988) using the implementation of the method proposed by (Ji and Eisenstein, 2014). Then, we vectorize the relations and employ SVM for classification. This baseline takes into account the hierarchical structure of documents via RST.

BiGRNN-CNN (Ren and Zhang, 2016). A CNN (Convolutional Neural Network) is applied at the sentence-level on word embeddings and a BiGRNN (Bi-Directional Gated Recurrent Neural Network) extracts features from a sequence of extracted sentential features. This baseline takes into consideration a two-level sequential structure for a document.

LSTM[w+s]. In this baseline, we apply an LSTM network on a sequence of word embeddings belonging to a sentence and then apply another LSTM on a sequence of extracted sentential features. LSTM[w+s] also considers a two-level sequential structure for a document.

LSTM[s]. This method is similar to LSTM[w+s] except that the mean of word embeddings in a sentence is used instead of applying an LSTM network. LSTM[s] considers a single sequential structure for a document.

We use accuracy as the metric of performance evaluation given that the dataset is fully balanced. Table 1 shows the comparison results on the test set and we make the following observations:

- N-grams achieve a better performance than LIWC. In line with the previous study (Ott et al., 2011), this shows that for fake news detection, taking into account the context of a document as n-grams do is more effective than employing the existing pre-defined dictionaries as LIWC does.

[6] Out-of-vocabulary words are initialized randomly.

[7] `https://pytorch.org/`

Method	Accuracy (%)
N-grams	72.37
LIWC	70.26
RST	67.68
BiGRNN-CNN	77.06
LSTM[w+s]	80.54
LSTM[s]	73.63
HDSF	**82.19**

Table 1: Comparison results

- Most of the time, methods wherein a document's structure is somehow taken into account outperform n-grams and LIWC. This observation shows that for fake news detection, the content's structure plays an important role.

- The poor performance of RST is because of the following reasons: a) using RST without an annotated corpus is not very effective, and b) RST relations are extracted using auxiliary tools optimized for other corpora which cannot be applied effectively to the fake news corpus in hand. Note that annotating RST for our corpus is extremely unscalable and time-consuming.

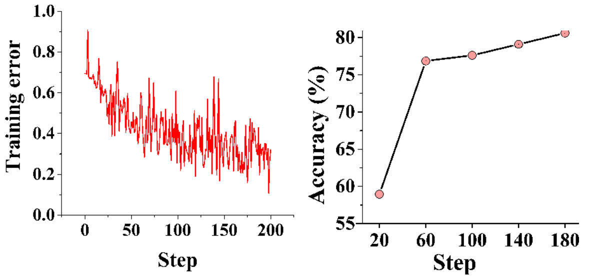
- The proposed framework HDSF significantly outperforms all other methods. This observation shows that hierarchical discourse-level representations are effectively rich for fake news prediction.

5.4 The Inspection of HDSF

To further verify the working of the HDSF framework, we inspect HDSF in more detail. Figure 4a demonstrates the training error during model optimization. As we can observe from this figure, the error is decreasing as the training process proceeds. Furthermore, Figure 4b demonstrates the accuracy on the development set during the training and it is monotonically increasing as the training goes on. Hence, based on these figures, we can ensure the framework is getting optimized and *learns* to classify fake news documents correctly.

5.5 Structural Analysis for Fake/Real Documents

In this section, we compute the average values of structure-related properties, presented in Section 4, for the fake/real news documents belonging to the test set. Figure 5 shows the results. We make the two key observations based on this figure:



(a) The training error (b) The accuracy on dev set

Figure 4: The Inspection of HDSF

- There is a significant difference in all three properties for fake news documents vs. real news documents. *This observation shows the fact that structures of fake news documents at the discourse-level are substantially different from those of real ones.*

- Noticeably, in all three properties, the real news documents show less value than the fake news documents. As described in Section 4, all three properties are closely connected to the coherence of a document. *Therefore, real news documents indicate more degree of coherence.*

6 Related Work

Content-based fake news detection has been the subject of many linguistic research endeavors. (DePaulo et al., 2003) investigated fake stories introduced insightful cues in fake stories and highlighted 'unusual' language in such stories. N-grams and Part-of-Speech (POS) tags are fundamental features of a text which have been utilized for fake news detection (Ahmed et al., 2017; Ott et al., 2013). Also, LIWC (Pennebaker et al., 2015) has been employed to investigate the role of individual words in a document for deception detection (Ott et al., 2011). Since POS tags, n-grams, and LIWC features are considered as 'shallow' and hand-crafted features, deep neural networks have been utilized for fake news detection where features are extracted automatically (Wang, 2017; Ren and Zhang, 2016; Volkova et al., 2017; Karimi et al., 2018). In this study, we also utilized an automated feature extraction instead of relying on hand-craft features.

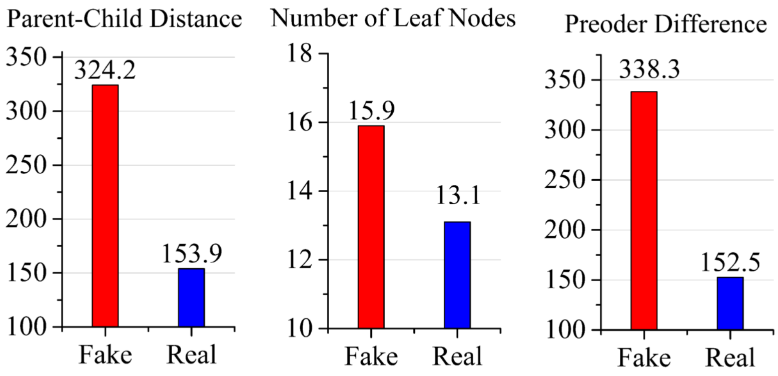


Figure 5: Average values of the proposed structure-related properties for fake and real news documents

Syntax-based approaches have been employed to take into account the hierarchical structure of textual documents for fake news detection (Feng et al., 2012; Pérez-Rosas and Mihalcea, 2015). One caveat of syntax-based approaches is their reliance on auxiliary parsing tools which might propagate error in later part of a developed model. Moreover, generating syntactic production rules in an automated manner is a complicated process.

Another way of incorporating structure is discourse-level parsing (Mann and Thompson, 1988; Li et al., 2014a; Ren and Zhang, 2016) which has seldom been explored for fake news detection. The noticeable exception is the approach developed by (Rubin and Lukoianova, 2015). They extracted a set of RST relations in fake and real documents and vectorized them using a Vector Space Model (VSM) method (Strehl and Ghosh, 2000). Unlike (Rubin and Lukoianova, 2015), in this work, we proposed an automated and data-driven discourse-level parsing approach which used neither any annotated corpus nor any external tool.

7 Conclusion and Future Work

In this work, we looked into fake news detection from a new perspective. We hypothesized that hierarchical discourse-level structure of news documents offers a discriminatory power for fake news detection. To investigate this hypothesis, we proposed a new framework HDSF, which can automatically extract discourse-level structures of real/fake news documents represented by dependency trees while does not rely on an annotated corpus. Moreover, we defined a set of insightful properties describing tree structures. Conducted experiments confirmed the power of our approach where it outperformed representative baselines. More importantly, we highlighted noticeable differences between structures of fake and real news documents. These differences also indicated less coherency in the fake news documents.

The new perspective pursued in this paper can be continued in several directions. First, we intend to define more advanced properties from the discourse dependency trees. Second, investigating the hierarchical structure at the word-level will be an exciting research inquiry. Finally, unsupervised discourse-level structure extraction of fake/real news documents is a worthwhile research topic.

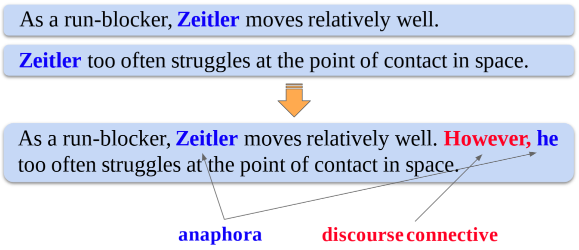
Abstract

Sentence fusion is the task of joining several independent sentences into a single coherent text. Current datasets for sentence fusion are small and insufficient for training modern neural models. In this paper, we propose a method for automatically-generating fusion examples from raw text and present DiscoFuse, a large scale dataset for discourse-based sentence fusion. We author a set of rules for identifying a diverse set of discourse phenomena in raw text, and decomposing the text into two independent sentences. We apply our approach on two document collections: Wikipedia and Sports articles, yielding 60 million fusion examples annotated with discourse information required to reconstruct the fused text. We develop a sequence-to-sequence model on DiscoFuse and thoroughly analyze its strengths and weaknesses with respect to the various discourse phenomena, using both automatic as well as human evaluation. Finally, we conduct transfer learning experiments with WebSplit, a recent dataset for text simplification. We show that pretraining on DiscoFuse substantially improves performance on WebSplit when viewed as a sentence fusion task.

1 Introduction

Sentence fusion is the task of combining several independent sentences into a single coherent text (Barzilay and McKeown, 2005). Sentence fusion is important in many NLP applications, including retrieval-based dialogue (Song et al., 2018; Yan and Zhao, 2018), text summarization (Barzilay and McKeown, 2005; Bing et al., 2015) and question answering (Li et al., 2018; Marsi and Krahmer, 2005). Such systems retrieve multiple sentences from different sources, documents or paragraphs, and use them to construct a coherent text.



As a run-blocker, **Zeitler** moves relatively well.

Zeitler too often struggles at the point of contact in space.

As a run-blocker, **Zeitler** moves relatively well. **However, he** too often struggles at the point of contact in space.

Figure 1: Example for two independent sentences, and their fusion. The modifications applied are pronominalization (blue) and connective insertion (red).

Sentence fusion is challenging because it requires understanding the discourse semantics between the input sentences. Consider the example in Figure 1: a coherent fusion of the sentences requires understanding that the second sentence *contrasts* the first one, in order to insert the discourse connective *"However"*. In addition, the gender and syntactic role of the entity *"Zeitler"* needs to be inferred to insert the pronoun *"he"*.

Prior work on sentence fusion (Barzilay and McKeown, 2005; Turner and Charniak, 2005; Filippova, 2010; Elsner and Santhanam, 2011; Thadani and McKeown, 2013; Bing et al., 2015; Chali et al., 2017) utilized very small amounts of labeled data, which are insufficient to train modern neural models. In this work, we propose a method for automatically generating sentence fusion examples at scale from raw text corpora.

To this end, we go over sentences and contiguous pairs of sentences in a corpus, and apply a set of manually-constructed rules, which identify the occurrence of prevalent fusion operations. The rules specify how to modify the sentences such that they are "unfused" into two independent sentences. E.g., in Figure 1 one rule will delete the discourse connective *"However"*, and another will replace the pronoun *"he"* with the named entity *"Zeitler"*.

In the generated examples, the original fused text becomes the target, and the unfused sentences (generated by rules) are the input. Importantly, sentence fusion models trained on our data cannot simply learn to invert rule application, because information is lost and can be recovered only by understanding the text semantics . As mentioned, learning to insert *"However"* in Figure 1 requires inferring that the sentences contrast. We cover a wide range of fusion phenomena such as inserting discourse connectives in various positions of the sentences, anaphora and cataphora identification, and sentence merging through coordination, relative clauses and apposition.

We applied our method on two large document collections, Wikipedia and sports articles from the Web, resulting in two datasets of 16 million and 44 million examples respectively. We call the combined dataset DISCOFUSE. We extensively analyze the quality of our dataset with crowdsourcing, and find that workers understand the text after splitting in 85% of the cases, and the other 15% are due to either the original text being unclear or errors in rule application.

We trained a state-of-the-art sequence-to-sequence model (Vaswani et al., 2017) and analyzed the fusion phenomena in which the model struggles. We found that the model succeeds in fusing sentences through structural constructions such as apposition or relative clauses, but performs badly when fusion involves inserting a particular discourse connective, or selecting pronominals.

Last, we performed transfer learning by training on DISCOFUSE and then fine-tuning on a smaller dataset from a different distribution. To this end, we utilize WEBSPLIT, a recent dataset for sentence splitting (Narayan et al., 2017; Aharoni and Goldberg, 2018), viewing WEBSPLIT as a sentence fusion task. We found that pre-training on DISCOFUSE substantially improves the performance of a fusion model in this setup.

To conclude, our contributions are:

1. DISCOFUSE: a dataset of 60 million sentence fusion examples from two different corpora.
2. A method for automatically generating sentence fusion examples from raw text.
3. Automatic and human evaluation of the Transformer model on the fusion task.
4. A transfer learning setting in which model performance improves when pre-trained with DISCOFUSE.

The DISCOFUSE dataset is publicly available at: `https://discofuse.page.link/data`.

2 Background

Existing fusion datasets are small, which is perhaps why only few works have explored the application of supervised models to sentence fusion (Elsner and Santhanam, 2011; Thadani and McKeown, 2013). McKeown et al. (2010) introduced a human-generated corpus of 3,000 examples. Elsner and Santhanam (2011) extracted around 300 fusion examples from pre- and post-editing news articles. Thadani and McKeown (2013) constructed 1,858 examples from summarization tasks. Such datasets are too small to train modern data-hungry neural models.

Related to sentence fusion is its "inverse" task of sentence splitting. Collados (2013) automatically constructed a Spanish simplification dataset by splitting single sentences into several simpler ones. Recently, two larger datasets for text splitting were released (Botha et al., 2018; Narayan et al., 2017; Aharoni and Goldberg, 2018). However, using these datasets for the "mirror" task of sentence fusion is problematic. First, sentence splitting often involves removing content from the original sentence for simplification, and this content is impossible to recover in the fusion direction. Second, these datasets do not focus on discourse and thus prominent discourse phenomena may be missed. Last, our new dataset is more than an order of magnitude larger than the above sentence splitting datasets.

Another related line of recent work focused on predicting discourse connectives between sentences and automatically generating examples from raw text (Liu et al., 2016; Malmi et al., 2018). We substantially expand over those works by handling more diverse linguistic phenomena, such as connectives in single sentences, generating anaphora and cataphora constructions, relative clauses, coordination and more, which are all represented in a single dataset. Moreover, our dataset is 20x larger compared to prior work, allowing us to examine in depth long-tail scenarios.

3 The DISCOFUSE Dataset

We next describe our process for building DISCOFUSE, which contains 60 million sentence fusion examples from two different document collections: Wikipedia and Web articles about sports.

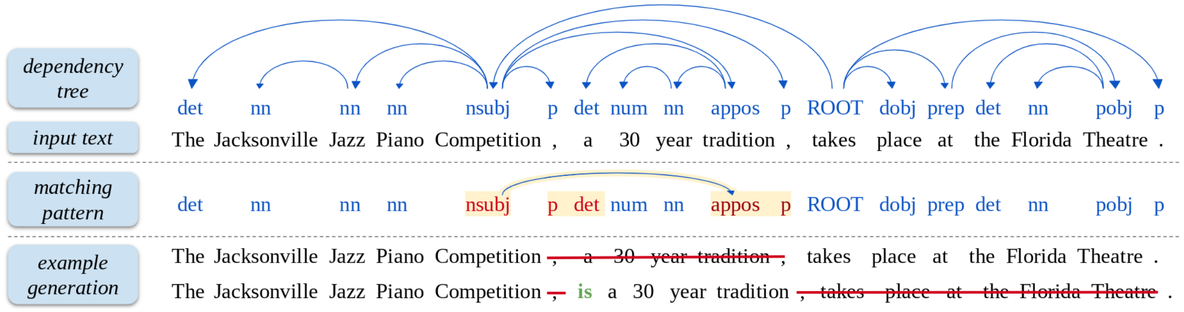

Figure 2: Example generation rule for apposition. Given an input text and its dependency tree, we check for a match with the apposition pattern. We then use the dependency tree to split the sentence and create a new example.

3.1 Example Generation

DiscoFuse contains union-fusion examples, *i.e.* fusing sentences without loss of content (Marsi and Krahmer, 2005). To automatically extract examples, we manually crafted a list of text splitting rules. Our rule-set covers 9 fusion phenomena, including handling discourse connectives, coordination and relative clauses, and entity resolution for anaphora and cataphora constructions. For entity resolution, both anaphoric pronouns (*"she"*, *"they"*, *"his"*) and anaphoric nominals (*"the team"*, *"the man"*) are considered, based on the output of a coreference system. The covered phenomena are summarized in Table 1 and a detailed description is given in Appendix A.1.

Given a text t consisting of one or two consecutive sentences, each of our rules addresses a specific discourse phenomenon and has two parts: (a) conditions for matching the phenomenon in t, and (b) operations over a dependency tree annotated with coreference resolution. Applying the operations generates a fusion example $(x = (s_1, s_2), t)$, in which (s_1, s_2) are two independent sentences originating from t, but stripped from the discourse phenomenon that tied them in t.

Figure 2 gives an example of a rule for the apposition structure. The rule is applied to the sentence *"The Jacksonville Jazz Piano Competition, a 30 year tradition, takes place at the Florida Theatre"*. First, the input is matched to the rule's condition. In this case, the condition is a single clause surrounded by two commas, which has a determiner as its first token and includes an apposition with incoming edge from a preceding token to the clause. Once matched, an example is generated. For this rule, the first sentence is created by removing the apposition clause, and the second sentence by removing the part after the clause and inserting the appropriate *"be"* verb (*"is"*). Generation examples for all 9 rule types are provided in Table 1.

As explained in Section 1, solving sentence fusion involves more than just reverse-engineering the generation rules. The model needs to decide whether to insert a discourse connective with the right semantics, whether to merge the input sentences, and what syntactic construction (relative clause, coordination, apposition) is most appropriate in the given context.

Last, often several discourse phenomena occur in a single text t. Thus, we allow combining anaphora rules with one of the following rule types: discourse connective, inner connective and sentence coordination, which cover frequent combinations in our texts.

3.2 Building the DiscoFuse Dataset

To create DiscoFuse we retrieved the latest Wikipedia release and crawled the Web for several million sports articles. Documents were annotated with dependency trees and coreference resolution using Google Cloud Natural Language.[1]

We considered each sentence and pair of consecutive sentences in each document as candidates, applying the example generation process described in Section 3.1. Additionally, we added as examples sentence pairs from the original corpus that did not match any rule, that is $(s_1, s_2) = t$, so that a trained model would also learn when not to change the input. We filtered out examples with sentence length $\leq$ 6 tokens, and examples with non-ASCII characters. This process resulted in $44,177,443$ sports examples and $16,642,323$ Wikipedia examples. We randomly split these examples into 98% train, 1% dev, and 1% test sets,

Phenomenon	**Example**
Discourse connective	(A) Hebden Bridge is a popular place to live .
	(B) **However ,** space is limited due to the steep valleys and lack of flat land .
	(a) Hebden Bridge is a popular place to live .
	(b) Space is limited due to the steep valleys and lack of flat land .
Anaphora	(A) **Rider** entered the weekend averaging 23.0 points , good for 10th in the league .
	(B) **He** said those numbers mean little because of the Hawks ' 11 - 18 record.
	(a) **Rider** entered the weekend averaging 23.0 points , good for 10th in the league .
	(b) **Rider** said those numbers mean little because of the Hawks ' 11 - 18 record.
Forward connective	(A) **Although** the friendship somewhat healed years later , it was a devastating loss to Croly .
	(a) The friendship somewhat healed years later .
	(b) It was a devastating loss to Croly .
Inner connective	(A) Open workouts are held every Sunday **unless** the gym is closed for a holiday or other special events .
	(a) Open workouts are held every Sunday .
	(b) The gym is closed for a holiday or other special events .
Cataphora	(A) **Stating** that the proponents were unlikely to succeed in this appeal , **Walker** rejected the stay request on October 23 .
	(a) **Walker stated** that the proponents were unlikely to succeed in this appeal .
	(b) **Walker** rejected the stay request on October 23 .
Sentence coordination	(A) The time of the autumn floods came **, and** the hundred streams poured into the Yellow River .
	(a) The time of the autumn floods came .
	(b) The hundred streams poured into the Yellow River .
Verb phrase coordination	(A) The Sharks **started** the year 0 - 4 **, yet recovered** to claim sixth spot .
	(a) The Sharks **started** the year 0 - 4 .
	(b) The Sharks **recovered** to claim sixth spot .
Relative clause	(A) Kubler **, who** retired from cycling in 1957 **,** remained a revered figure in the wealthy alpine nation .
	(a) Kubler remained a revered figure in the wealthy alpine nation .
	(b) Kubler retired from cycling in 1957 .
Apposition	(A) The frigidarium **,** the last stop in the bathhouse **,** was where guests would cool off in a large pool .
	(a) The frigidarium was where guests would cool off in a large pool .
	(b) The frigidarium is the last stop in the bathhouse .

Table 1: Generated fusion examples for different phenomena. The input text is marked in uppercase blue, and the generated sentence pair is marked in lowercase red. We show in **boldface** parts that allow us to detect the target phenomenon.

making sure that each document contributes examples to only one of the split sets.

Like prior work (Malmi et al., 2018), we observed a skewed distribution of discourse phenomena in the data. Specifically, examples with anaphora or the connectives *"and"* and *"but"* constitute 99.7% of Sports and 59% of Wikipedia examples. Such a skewed distribution is likely to bias models and will fail to elucidate the ability of models to capture a wide range of linguistic phenomena. Therefore, we constructed a version of DISCOFUSE by down-sampling examples containing *"and"* and *"but"* or anaphora. The down-sampled dataset contains 12,080,513 Sports examples and 4,581,352 Wikipedia examples.

The resulting distributions of discourse types and most common connectives in the two parts of DISCOFUSE are provided in Appendix A.2. We will release both the original and the down-sampled versions of DISCOFUSE.

Rater Selection	SPORTS (%)	WIKIPEDIA (%)
Yes	83.4	86.0
No majority	10.9	8.9
No	5.7	5.1

Table 2: Rater evaluation understandability of the text after splitting. For each example, the majority of 5 raters was taken as the final rater selection.

4 DISCOFUSE Quality Evaluation

To assess the quality of the generated fusion examples in DISCOFUSE, we randomly selected 500 examples from each of the development sets of the Wikipedia and the Sports parts. We then conducted a crowdsourcing experiment in which each example was rated by 5 proficient English speakers, limiting each rater to at most 6 items. Each rater was presented with the two independent sentences in the example and was asked to indicate whether the text is understandable. If the rater answered "yes", she was then asked to characterize the relation between the sentences and how she would fuse them. We next detail the results.

Reason	Example
Original text unclear	(A) UPDATE: Peat falls because footwork and quickness. (a) UPDATE: Peat falls. (b) Footwork and quickness.
Missing context	(A) We were right on the heels of Spurs, although Everton were closing in. (a) We were right on the heels of Spurs. (b) Everton were closing in.
Bad rule generation	(A) He told reporters after the game his reaction was because he missed a wide-open Randall Cobb in the end zone. (a) He told reporters after the game his reaction was. (b) He missed a wide-open Randall Cobb in the end zone.

Table 3: Examples for three possible reasons for not understanding the text. In each example, (A) is the original text and (a) and (b) are the two sentences generated by our rules.

Error	Generated sentence
Extra comma	The space behind the fence in right field is blocked off **,** .
Missing determiner	*My* internist sent me for a mammogram and sonogram .
Bad pronoun replacement	**Lions** have a 3 - 1 record overall against Lions .

Table 4: Examples of grammatical errors introduced by our rules. The **red boldface** text was incorrectly inserted and the *blue italic* text was incorrectly removed.

4.1 Example Text Clarity

Raters were asked whether they can understand the text after the example is split. Table 2 summarizes this evaluation. Most examples were marked as understandable by the raters ("yes") – 86% of Wikipedia examples and 83.4% of Sports examples. The rest either had no majority of rater votes or were marked as not understandable.

To shed light on the possible reasons for obscurity, we analyzed 70 random examples that were not marked as understandable by the majority of raters. In 29 examples (41%) the original text was unclear and for 17 examples a broader context was needed (24%). In the remaining 24 examples (34%), our rules generated sentences with grammatical or semantic errors. Examples for these cases are in Table 3.

Additionally, we analyzed 100 random examples for grammatical errors, and found that our rules did not introduce any errors in 79 examples. For 15 examples, the errors did not modify the meaning of the text nor caused semantic errors. The detected grammatical errors include extra commas, missing determiners and bad pronoun replacements, and are demonstrated in Table 4.

4.2 Fusion Evaluation

Next, we evaluated agreement on the fusion task for the 847 examples marked as understandable in Section 4.1. Because there are many ways in which sentences can be fused, one cannot expect raters to produce the original text t verbatim. Instead, we analyzed three central decisions and estimated whether people agree on those: (a) whether to merge the two sentences into a single one or keep them separate; (b) whether there are entities in the text that should be replaced with nominal or pronominal anaphors or cataphors; and (c) which discourse connective to add (if any).

For the last question, we presented raters with one connective from each of the four coarse-grained senses for discourse connectives defined by the PDTB (Prasad et al., 2008): *comparison*, *expansion*, *contingency* and *temporal*, as well as a *no-connective* option. If the original text in the example includes a connective, we provided it as one of the options.

We observed a strong bias among raters towards refraining from performing any changes. E.g., while only 38% of the examples did not contain a connective in t, the raters chose not to add a connective in 69.2% of the cases. Similarly, only in 29.1% of the examples the two sentences were not merged into a single one, while the raters chose not to merge in 53.1% of the examples. Similar behavior was also observed by Malmi et al. (2018) and Rohde et al. (2016).

We further looked at the agreement between the rater majority and the 'gold' fusion decision. This analysis is shown in Table 5. Agreement on merging the input sentences into one is almost random (52%), since usually both options are valid. Consensus on whether to add an anaphor is higher, but not very high (63%), especially in sentences when the anaphor in t is a nominal rather than a pronoun. Finally, there is higher agreement on selecting the connective category (57%), for which the random baseline is 20%.

As mentioned, raters tend to keep the sentences unchanged. But in cases where raters agree to add a connective, agreement figures increase substantially. Specifically, when it is clear that a connective is needed, there is also high agreement for picking the right one (76%), for deciding whether

Decision Type	All Examples (%)	Examples with connectives (%)
Single / pair	52.0	70.1
Anaphor	63.4	70.1
Connective category	57.0	76.4
# Examples	847	271

Table 5: Average agreement for each fusion decision between the gold annotation and rater majority on examples marked as understandable by the raters. The right column considers only examples in which both the 'gold' and rater majority agreed that a connective should be added.

Sports	Full		Sampled	
	SARI	*Exact*	*SARI*	*Exact*
DfSport	**81.9**	**42.3%**	**83.9**	**50.6%**

to add an anaphor (70%), and for deciding whether to merge the sentences or not (70%).

5 Supervised Neural Fusion Models

Using DiscoFuse, we trained a Transformer seq2seq model (Vaswani et al., 2017) that reads the input sentence pair and generates a fused text. We report model performance on the test-set using automatic metrics as well as human evaluation. We also provide detailed analysis of the different phenomena captured by this model.

5.1 Experimental Settings

We tokenized all texts using byte-pair-encoding (Sennrich et al., 2015) and compared the following three Transformer models :

- **DfSport** - trained on the sports portion of DiscoFuse after down-sampling.
- **DfWiki** - trained on the Wikipedia portion of DiscoFuse after down-sampling.
- **DfS+W** - trained on a 50%-50% mixture of the sports and Wikipedia portions of DiscoFuse after down-sampling.

All models share the same network architecture, based on the best practices discussed by Popel and Bojar (2018). We tuned parameters to select the best learning and dropout rates for each model with respect to the Exact Match objective (described in Section 5.2). Network architecture and hyper-parameters are in Appendix A.3. As a baseline, we also tested a model called Copy, which simply concatenates the two input sentences.

5.2 Automatic Evaluation Results

We evaluated model performance using two automatic metrics. The first is Exact Match (*Exact*) to see how often the model generates the exact same text as the gold fusion. The second is *SARI* (Xu et al., 2016), which computes the set of added, removed, and kept n-grams in the model output, comparing the output both with the gold text and the input text. Then it computes the F_1 scores for these three sets and averages the scores. We compute *SARI* on up to 4-grams, as in Xu et al. (2016). We refrained from using metrics like BLEU because in fusion there is large overlap between the input sentences and their fused version, and such metrics do not capture well fine-grained differences of only a single word.

We note that our definition of *SARI*[2] slightly differs from the one given by Xu et al. (2016) in

---

[2] Our *SARI* implementation is available at: `https://github.com/tensorflow/tensor2tensor/blob/master/tensor2tensor/utils/sari_hook.py`

two aspects: (i) We define $\frac{0}{0} = 1$ when computing precision and recall, otherwise *SARI* could be less than 1 even if the output matches the gold text exactly. (ii) Instead of considering only the precision of deleted n-grams, we use F_1 for all three sets. Otherwise, *SARI* will give high scores to models that merely copy everything in the input, without even trying to infer what to delete.

Table 6 summarizes the results. When training and testing on the same domain, either Sports or Wikipedia, *SARI* score is a little above 80 points for the full dataset. Yet *Exact* is not high, around 42% for Sports and 47% for Wikipedia, showing that in the majority of the examples the model's fusion differs from the gold. Tested on the down-sampled test-set, performance increases significantly for *Exact*, especially on Sports, where discourse phenomena is more skewed.

We next turn to cross-domain evaluation. When applying a model trained on one domain to the other domain performance drops. This shows that the discourse phenomena distribution differs between the domains, indicating that transfer learning is not trivial even with these large datasets. This is especially evident when applying DFWIKI to Sports, where *Exact* falls from 42% to 32% on the full dataset and from 50% to 40% on the down-sampled one. Interestingly, when learning on the mixed training set, performance on both domains is close to in-domain performance, showing that the model has the capacity to handle both domains.

Finally, we take advantage of the provided annotation of the different discourse phenomena within each example in DISCOFUSE. We conducted a detailed analysis of in-domain model performance by discourse type, presented in Table 7. Results show that structural discourse types, such as apposition and relative clause, are easier to learn with both high exact match and *SARI* scores. While differences with respect to *SARI* scores are not large between phenomena, exact match varies more. Anaphora and verb phrase coordination are more challenging, but still require matching of the same noun (the named entity or the subject). On the other hand, discourse types that involve connective prediction, such as sentence coordination and discourse connective, require semantic understanding, and performance is significantly lower. In addition, when two discourse types are required for fusion, performance drops dramatically.

		# Examples	Detection
SPORTS	output = gold	525	50%
	output != gold	475	65%
	total	1000	**57%**
WIKIPEDIA	output = gold	528	50%
	output != gold	472	61%
	total	1000	**55%**

Table 8: Human detection (*Detection*) percentage for DFSPORT and DFWIKI on 1000 samples from each of the Sports and Wikipedia development sets. We report *Detection* for cases when model output differed from the gold, and cases when they were identical.

5.3 Human Evaluation Results

As our second experiment we employed crowd-sourcing to test how distinguishable the fusion model outputs are from the gold fused texts. Concretely, we present raters an independent sentence pair from DISCOFUSE and two fused versions - the gold version and one generated by a model. Raters were asked to detect the gold version. For each example, we took the majority of 5 raters as the final choice. This experiment mitigates the difficulties of automatic text generation evaluation, where many outputs are valid for a single input.

We sampled 1000 random examples from each development set of the two domains and applied the in-domain model to both. The raters were presented only with examples where the model output was different from the gold fusion, and assumed 50% detection accuracy otherwise.

Table 8 depicts the results. Out of cases when model output differed from the gold, raters were able to identify the human version in 65% of Sports examples and 61% of Wikipedia examples. Looking at the entire set, humans were able to identify the human version in 57% (Sports) and 55% (Wikipedia) of the cases. This shows that our Transformer model, applied over a dataset of millions of examples, is able to learn good fusions in general. Nevertheless, models are still far from perfect – human accuracy is clearly better than random and this improvement is statistically significant at a level of $p < 10^{-5}$ for Sports and $p < 10^{-3}$ for Wikipedia.

5.4 Alignment-based Analysis

We next present an analysis of the types of errors our models produce. To this end, we sampled 40K examples of DFSPORT and DFWIKI outputs on Sports and Wikipedia development sets. We then automatically aligned predicted sequences to gold

Connective	DfSport accuracy	DfWiki accuracy	Top 3 connectives
and	50.9	53.7	and, but, ⟨other⟩
but	42.8	43.7	but, ⟨other⟩, and
because	61.5	60.7	because, ⟨other⟩, but
although	35.1	33.2	although, ⟨other⟩, but
so	50.6	50.2	so, but, and
or	70.5	72.1	or, and, ⟨other⟩
however	28.3	26.7	⟨other⟩, however, but
while	70.1	70.6	while, ⟨other⟩, but
so that	64.3	63.0	so that, ⟨other⟩, because
unless	68.9	67.0	unless, because, ⟨other⟩
for example	26.9	28.1	⟨other⟩, for example, however

Table 9: Alignment-based connective prediction accuracy for the most common connectives. When a model did not add a connective, the token ⟨other⟩ is used.

sequences and looked at the differences between aligned words. The trained models successfully learned to copy most of the input text, and thus errors due to alignment problems are rare.

We start by considering the semantic relation between the input sentences. Table 9 displays model accuracy in predicting the most common connectives in DiscoFuse, as well as the top connectives predicted in this slot. We observe that when the model predicts a wrong connective, that connective is often reasonable, e.g., predicting *"but"* instead of *"and"* or *"however"*. Moreover, a second source of error is not adding a connective at all. It is also clear that some connectives, like *"however"*, *"although"* and *"for example"*, are harder to learn.

We also analyzed the models' ability to correctly infer pronoun anaphors including gender, possessive and plurality. Figure 3 shows the pronoun confusion matrix for DfWiki,[3] where lines refer to gold pronouns and columns to the generated pronoun in the same position. The clear diagonal shows that in most cases, the model successfully outputs the correct pronoun. However, the ⟨other⟩ column indicates that occasionally the model tends not to replace the entity in the input with a pronoun anaphor. In addition, the model seems to struggle with possession and plural 3rd person (*"it"*, *"its"*, *"they"*, *"their"*, *"theirs"*).

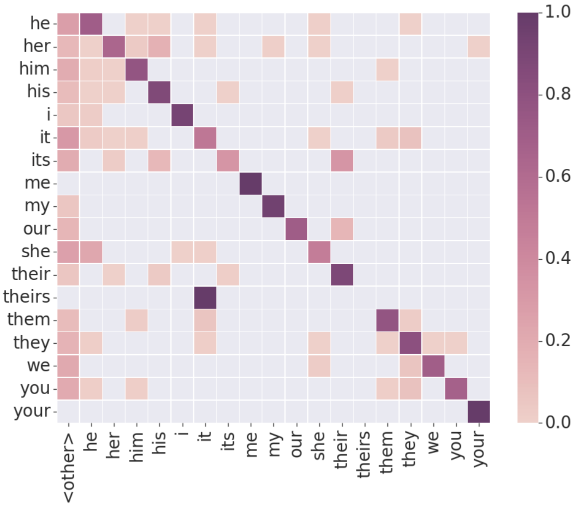

Figure 3: DfWiki outputs versus the gold pronouns. Rows refer to gold pronouns and columns refer to aligned model outputs at the gold pronoun position. Values in each row are normalized to 1. Column ⟨other⟩ refers to model outputs that are not pronouns.

6 Transfer Learning Experiment

With the DiscoFuse approach we can collect a large amount of examples automatically. Still, these examples only reflect the manual rules that identify discourse phenomena. We wanted to see if DiscoFuse covers enough cases such that a trained model would be helpful for testing on fusion datasets generated by different approaches.

6.1 Experimental Settings

In this experiment, we looked at the recently released WebSplit dataset 1.0 (Narayan et al., 2017). It consists of examples $(t, \{s_i\}_{i=1}^{n})$, where t is a sentence that verbalizes the same set of RDF triples as $\{s_i\}_{i=1}^{n}$. We note that WebSplit was originally developed for sentence splitting, from t to $\{s_i\}_{i=1}^{n}$, but here we view its examples for the reverse fusion task: from $\{s_i\}_{i=1}^{n}$ to t. We only considered examples where $\{s_i\}_{i=1}^{n}$ corresponds to exactly two simpler sentences ($n = 2$). This leaves us with 135K training, 8K validation, and 8K test samples.

We tokenized the data using byte-pair-encoding (Sennrich et al., 2015) and compared three models: (i) The Copy baseline that concatenates the two input sentences, (ii) a model trained on WebSplit alone, and (iii) a model pre-trained on DfWiki and fine-tuned on WebSplit.

For the last two models, we use the CopyNet architecture (Gu et al., 2016), which is similar

---

[3] Results for DfSport are very similar.

Training data	*SARI*	Keep	Add	Delete
COPY	18.1	52.9	0.5	0.9
WEBSPLIT	40.5	44.6	7.8	**69.3**
DFWIKI + WEBSPLIT	**44.2**	**54.8**	**10.4**	67.5

Table 10: Fusion results on WEBSPLIT, measured by *SARI* and the F1 scores that compose it.

to state-of-the-art models for the splitting task on WEBSPLIT (Narayan et al., 2017; Botha et al., 2018). While the Transformer outperformed this model on our main experiments, here it overfit on the small training set of WEBSPLIT. The training details are provided in Appendix A.3.

6.2 Results

Table 10 shows the results of the experiment. Similarly to Section 5, we measured the model performance using *SARI*. Pre-training with DFWIKI improves *SARI* score by 9% compared to using WEBSPLIT alone. In particular, the F1 of the 'kept' and 'added' n-grams is significantly higher, by 23% and 33% respectively. Specifically, 'added' tokens refer also to correctly choosing discourse connectives, to which the large-scale examples in DISCOFUSE were likely helpful.

We note that even with pre-training, the SARI 'add' score is only 10.4. This is probably due to the large amount of paraphrasing done in WEBSPLIT, which makes it problematic for fusion evaluation (see also Section 2). For example:

> **Sentence 1:** *Bolt , a comic character AKA Larry Bolatinsky , was created by Paris Cullins and Ernie Colon .*
>
> **Sentence 2:** *Paris Cullins is a United States national .*
>
> **Gold:** *Larry Bolatinsky is the alternative name for the comic book character Bolt , which was created by Ernie Colon and the American Paris Cullins .*

Correctly inferring the added terms (shown in red) requires paraphrasing knowledge that is outside the scope of DISCOFUSE.

7 Conclusions

We presented DISCOFUSE, a large-scale dataset for sentence fusion that was generated by applying a rule-based method. It contains millions of examples from two domains, annotated with multiple discourse phenomena.

We used DISCOFUSE to build supervised neural models for sentence fusion and conducted fine-grained analyses of the results. Currently, our models fuse only two sentences together. We would like to expand them to more input sentences in future work.

We also demonstrated DISCOFUSE's usefulness in a transfer learning setup on a different fusion test-set, hoping it would facilitate research on text fusion in data-scarce domains.

Acknowledgments

We thank Marta Recasens, Jan Botha, and Sascha Rothe from Google AI for helpful discussions. This research was supported by the Yandex Initiative in Machine Learning and by The Israel Science Foundation grant 942/16. This work was completed in partial fulfillment for the Ph.D degree of the first author.

A Supplemental Material

A.1 Generation Rules

In this section we provide technical details of the generation rules used to create DiscoFuse. For the sake of clarity, we provide a simplified version of the rules, that does not include edge cases and minor implementation details. The discourse connectives we considered in the rules were selected from the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) and are listed in Table 12.

Given an input text, it is encoded with 3 lists: Z is the token list, Z_t is a list of POS tags, Z_l is a list of dependency labels (see Table 11). In addition, all entities mentioned in the text are extracted and stored such that for two token lists Z, R, the set $m(Z, R)$ holds all the mention pairs of the same entity in the two lists. Each rule is designed for a specific discourse phenomenon and contains two parts. First, a set of conditions is applied to the input lists to detect whether the phenomenon occurs in the text. If a discourse pattern has been identified, a short sequence of simple operations is applied to the input, yielding a new sentence pair. Table 13 summarizes the operations in use, which allow insertion and deletion of tokens and splitting of the input text.

Table 14 provides the technicalities of each rule, i.e. the detection conditions of the discourse structure, and the sequence of operations for generating a new sentence pair from it. A detailed example for two-rule execution process is given in Table 15.

As mentioned, the rules are simplified for clarity. However, we note two special cases where morphological modifications are required to produce text without grammatical errors. First, in some cases of forward connective and cataphora, the tense change of a verb is required when splitting the input sentence. For instance, in the cataphora example in Table 1, we change the verb *“stating”* to have a past tense – *“stated”*. Likewise, occasionally a *“be”* verb needs to be inserted when splitting a single sentence, as demonstrated in Figure 2. In our rules, we choose which *“be”* verb to insert based on the tense and perspective of the rest of the sentence.

A.2 DiscoFuse Data Distribution

Figure 4 and Table 16 show the distributions of discourse types and most common connectives in the two parts of DiscoFuse.

Analyzing the dataset reveals significant differences in discourse phenomena between the two types of documents (Figure 4). E.g., coordination is very common in Wikipedia while anaphora is dominant in Sports. Likewise, the distribution of discourse connectives is quite different (Table 16).

A.3 Neural Models Parameters

The models DfSport, DfWiki, DfS+W share the same Transformer network architecture, that was originally proposed by Vaswani et al. (2017). During training, we split the samples to buckets

Notation	Definition
Token list Z	A list of tokens $\{z^{(1)}, \ldots, z^{(\lvert Z\rvert)}\}$
Z_t	The list of POS tags of Z, where $Z_t^{(i)}$ is the tag of $z^{(i)}$ for every $i = 1, \ldots, \lvert Z\rvert$.
Z_l	The list of dependency labels of Z, where $Z_l^{(i)}$ is the label of incoming edge of $z^{(i)}$ for every $i = 1, \ldots, \lvert Z\rvert$.
$m(Z, R)$	A set of mention pairs in $Z, R : \{\langle S_Z, S_R\rangle \mid S_R \prec R$ and $S_Z \prec Z$ are mentions of the same entity$\}$
$S \prec Z$	S is a span in Z, such that $\exists i \in 1, \ldots, \lvert Z\rvert - \lvert S\rvert + 1 : \forall j = 0, \ldots, \lvert S\rvert - 1 : s_{1+j} = z_{i+j}$
$S \sqsubset Z$	S is a prefix of Z, such that $\forall i = 1, \ldots, \lvert S\rvert : s_i = z_i$
$i \curvearrowright_U j$	There is an edge from the ith token to the jth token in the dependency tree of Z.
$\mathcal{C}_b$	A set of backward connectives.
$\mathcal{C}_s$	A set of intra-sentence connectives, which are either forward connectives or conjunctions.
$\mathcal{C}_f$	A set of forward connectives.
$\mathcal{C}_c$	A set of coordinating conjunctions.
$\mathcal{P}_r$	A set of relative pronouns.
$\mathcal{V}$	A set of POS tags for verbal phrases.

Table 11: Notation and definitions for Table 14 of generation rules. Z, R, S_Z, S_R are token lists and $1 \leq i, j \leq |Z|$ are indices. The full lists of connectives and POS tags are provided in Table 16.

Set	Values
$\mathcal{C}_b$	”accordingly”, ”additionally”, ”afterward”, ”alternatively”, ”although ,”, ”and”, ”as a result ,”, ”because of that”, ”because of this”, ”besides ,”, ”but”, ”by comparison ,”, ”by contrast ,”, ”by doing this ,”, ”by then”, ”consequently”, ”conversely”, ”else,”, ”finally ,”, ”for example”, ”for instance”, ”further ,”, ”furthermore”, ”hence ,”, ”however”, ”in contrast ,”, ”in fact ,”, ”in other words”, ”in particular ,”, ”in short ,”, ”in sum ,”, ”in the end ,”, ”in turn ,”, ”indeed ,”, ”instead ,”, ”lest”, ”likewise ,”, ”meantime ,”, ”in the meantime ,”, ”meanwhile ,”, ”moreover”, ”nevertheless”, ”next ,”, ”nonetheless”, ”on the contrary ,”, ”on the other hand”, ”or ,”, ”otherwise ,”, ”overall ,”, ”plus ,”, ”rather ,”, ”regardless ,”, ”similarly ,”, ”simultaneously”, ”specifically ,”, ”still ,”, ”then ,”, ”thereafter ,”, ”thereby ,”, ”therefore”, ”though ,”, ”thus ,”, ”ultimately ,”, ”whereas”, ”yet ,”, ”now ,”, ”second ,”, ”third ,”, ”basically ,”, ”this ,”, ”eventually ,”, ”obviously ,”, ”again ,”, ”fortunately ,”, ”luckily ,”, ”meaning ,”, ”interestingly ,”, ”anyway ,”, ”clearly ,”
$\mathcal{C}_s$	”because”, ”, because”, ”hence”, ”, while”, ”whereas”, ”, although”, ”although”, ”and although”, ”unless”, ”now that”, ”, now that”, ”so that”, ”, so that”, ”meaning”, ”, meaning”
$\mathcal{C}_f$	although, since, in addition to, aside from
$\mathcal{C}_c$	and, but, or, nor, yet, so, for
$\mathcal{P}_r$	who, which, whose, whom
$\mathcal{V}$	VB, VBD, VBG, VBN, VBP, VBZ

Table 12: Connectives and POS tags used in our detection rules. A preceding comma is allowed for conjunctions in $\mathcal{C}_c$. For the connectives *“although”* and *“since”* in $\mathcal{C}_f$, we do not allow a following comma.

Operation	Description
DELETE(X, i, n)	Delete a sequence of n tokens from X, starting from index i.
PREPEND(X, Y)	Attach the list Y at the beginning of X.
REPLACE(X, Y, Z)	Replace every occurrence of Y in X with Z, in a non-overlapping manner.
SPLIT(X, i)	Split X into two token lists $V = \{x_1, \ldots, x_{i-1}\}, W = \{x_i, \ldots, x_{\lvert X\rvert}\}$.
TRIM(X)	Delete all tokens in X after the first punctuation token, e.g. period, comma, etc.

Table 13: Operations upon token lists, which are used for generation of sentence pairs (Table 14). The arguments X, Y, Z are token lists and the arguments i, n are integers.

Phenomenon	**Input**	**Detection**	**Generation**
Discourse connective	(A,B)	$\exists S \in \mathcal{C}_b\,,\ i \in [1,5] : S \sqsubset \{b^{(i)}, \ldots, b^{(\lvert B\rvert)}\}$	$\textsc{Delete}(B, i, \lvert S\rvert)$
Anaphora	(A,B)	$m(B,A) \neq \emptyset$	$\textsc{Replace}(B, S_B, S_A)$ $\forall\langle S_B,\ S_A\rangle \in m(B,A)$

trained on WEBSPLIT alone, and a model pretrained on DFWIKI and finetuned on WEBSPLIT. The first model was trained for 200,000 steps on WEBSPLIT, whereas the second model was pretrained for 1 million steps on DFWIKI and then finetuned for 100,000 steps on WEBSPLIT. Again, the samples were split to buckets by their text length, with batch sizes between 25-125 for each bucket. The final test scores were computed with the parameters that maximize the validation *SARI* score during training. The network architecture and hyperparameters were shared between the models and not optimized during training. They are listed in Table 18.

Linguistically-Informed Specificity and Semantic Plausibility for Dialogue Generation

Wei-Jen Ko[1] **Greg Durrett**[1] **Junyi Jessy Li**[2]

Abstract

Sequence-to-sequence models for open-domain dialogue generation tend to favor generic, uninformative responses. Past work has focused on word frequency-based approaches to improving specificity, such as penalizing responses with only common words. In this work, we examine whether specificity is solely a frequency-related notion and find that more linguistically-driven specificity measures are better suited to improving response informativeness. However, we find that forcing a sequence-to-sequence model to be more specific can expose a host of other problems in the responses, including flawed discourse and implausible semantics. We rerank our model's outputs using externally-trained classifiers targeting each of these identified factors. Experiments show that our final model using linguistically motivated specificity and plausibility reranking improves the informativeness, reasonableness, and grammatically of responses.

1 Introduction

Since the pioneering work in machine translation (Sutskever et al., 2014), sequence-to-sequence (SEQ2SEQ) models have led much recent progress in open-domain dialogue generation, especially single-turn generation where the input is a prompt and the output is a response. However, SEQ2SEQ methods are known to favor universal responses, e.g., "I don't know what you are talking about" (Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a). These responses tend to be "safe" responses to many input queries, yet they usually fail to provide useful information.

One promising line of research tackling this issue is to improve the specificity of responses, building on the intuition that generic responses frequently appear in the training data or consist of frequent words (Yao et al., 2016; Zhang et al., 2018b; Liu et al., 2018). However, past work in sentence specificity—the "quality of belonging or relating uniquely to a particular subject"[1]—has shown that word frequency is only one aspect of specificity, and that specificity involves a wide range of phenomena including word usage, sentence structure (Louis and Nenkova, 2011; Li and Nenkova, 2015; Lugini and Litman, 2017) and discourse context (Dixon, 1987; Lassonde and O'Brien, 2009). Frequency-based specificity also does not exactly capture "the amount of information" as an information-theoretic concept. Hence, in dialogue generation, we can potentially make progress by incorporating more linguistically driven measures of specificity, as opposed to relying solely on frequency.

We present a sequence-to-sequence dialogue model that factors out specificity and explicitly conditions on it when generating a response. The decoder takes as input categorized values of several specificity metrics, embeds them, and uses them at each stage of decoding. During training, the model can learn to associate different specificity levels with different types of responses. At test time, we set the specificity level to its maximum value to force specific responses, which we found to be most beneficial. We integrate linguistic (Ko et al., 2019), information-theoretic, and frequency-based specificity metrics to better understand their roles in guiding response generation.

The second component of our model is designed to make the more specific responses more *semantically plausible*. In particular, we found that forcing a SEQ2SEQ model to be more specific exposes problems with plausibility as illustrated in Table 1. As sentences become more specific and contain more information, intra-response consistency

---

Proceedings of NAACL-HLT 2019, pages 3456–3466
Minneapolis, Minnesota, June 2 - June 7, 2019.

Conflicting	i understand. i am not sure if i can afford a babysitter, i am a millionaire
Wrong connective	i am an animal phobic, but i do not like animals
Wrong pronoun	my mom was a social worker, he was an osteopath.
Wrong noun	cool. i work at a non profit organization that sells the holocaust.
Repeating	my favorite food is italian, but i also love italian food, especially italian food.

Table 1: Examples of different types of implausible responses on the PersonaChat dataset generated from our system that maximizes specificity only.

problems become evident, making the overall response implausible or unreasonable in real life. Our inspection discovered that ∼30% of specific responses suffer from a range of problems from semantic incompatibility to flawed discourse. To improve the plausibility of responses, we propose a reranking method based on four external classifiers, each targeting a separate aspect of linguistic plausibility. These classifiers are learned on synthetically generated examples, and at test time their responses are used to rerank proposed responses and mitigate the targeted issues.

Using both automatic and human evaluation, we find that linguistic-based specificity is more suitable than frequency-based specificity for generating informative and topically relevant responses, and learning from different types of specificity metrics leads to further improvement. Our plausibility reranking method not only successfully improved the semantic plausibility of responses, but also improved their informativeness, relevance, and grammaticality.

Our system is available at `https://git.io/fjkDd`.

2 Related work

Generic responses is a recognized problem in dialogue generation. Li et al. (2016a) maximized mutual information in decoding or reranking, which practically looks like penalizing responses that are common under a language model. Zhou et al. (2017) promoted diversity by training latent embeddings to represent different response mechanisms. Shao et al. (2017) trained and reranked responses segment by segment with a glimpse model to inject diversity. Another angle is to promote prompt-response coherence using techniques such as LDA (Baheti et al., 2018; Xing et al., 2017). Cosine similarity between prompt and response has also been used for coherence (Xu et al., 2018b; Baheti et al., 2018). Wu et al. (2018) learn a small vocabulary of words that may be relevant during decoding and generates responses with this vocabulary.

Several works tackle the problem by directly controlling response specificity in terms of word and response frequency. IDF and response frequency have been used as rewards in reinforcement learning (Yao et al., 2016; Li et al., 2016d). Some methods adjusted sample weights in the training data, using a dual encoding model (Lison and Bibauw, 2017) or sentence length and frequency in the corpus (Liu et al., 2018). Zhang et al. (2018b) proposed a Gaussian mixture model using frequency-based specificity values. Their approach involves ensembling the context probability and a specificity probability, whereas our approach conditions on both in a single model.

Prediction of **sentence specificity** following the dictionary definition and pragmatically cast as "level of detail" was first proposed by Louis and Nenkova (2011), who related specificity to discourse relations. Sentence specificity predictors have since been developed (Louis and Nenkova, 2011; Li and Nenkova, 2015; Lugini and Litman, 2017; Ko et al., 2019). Insights from these feature-rich systems and hand-code analysis (Li et al., 2016e) showed that sentence specificity encompasses multiple phenomena, including referring expressions, concreteness of concepts, gradable adjectives, subjectivity and syntactic structure.

Researchers have noticed that distributional semantics largely fail to capture **semantic plausibility**, especially in terms of discrete properties (e.g., negation) (Kruszewski et al., 2016) and physical properties (Wang et al., 2018). Kruszewski et al. (2016) created a dataset building on synthetically generated sentences for negation plausibility.

Methodology-wise, Li et al. (2016b) trained embeddings for different speakers jointly with the dialogue context. Huang et al. (2018) learned embeddings of emotions; we learn embeddings of specificity metrics. Targeting multiple factors this way is broadly similar to the approach of Holtzman et al. (2018), who used multiple cooperative discriminators to model repetition, entailment, relevance, and lexical style in generation. Our approach additionally leverages synthetic synthetic sentences targeting a range of plausibility issues and trains discriminators for reranking.

3 Generating specific responses

Our main framework (Figure 1) is an attention-based SEQ2SEQ model (Section 3.1) augmented with the ability to jointly learn embeddings from a target metric (e.g., specificity) with the response (Section 3.2). We then integrate frequency-based, information-theoretic and linguistic notions of specificity (Section 3.3) as well as coherence (Section 3.4).

3.1 Base framework

Our model is based on a SEQ2SEQ model (Sutskever et al., 2014) consisting of an encoder and decoder, both of which are LSTMs (Hochreiter and Schmidhuber, 1997). We apply attention (Bahdanau et al., 2015) on the decoder. The encoder LSTM takes word embeddings x_i in the prompt sentence as input. The hidden layer and cell state of the decoder are initialized with the final encoder states. During training, the decoder takes the embedding of the previous word in the gold response as input; during testing, it uses the previous generated word. We denote both as y_{i-1}:

$$h_i^d, c_i^d = LSTM(y_{i-1}, [\hat{h}_i^d; c_{i-1}^d]) \qquad (1)$$

where $\hat{h}_i^d$ is the output of the attention mechanism, given the decoder hidden state.

During training, we minimize the negative log likelihood of responses Y given prompts X.

3.2 Conditioning on specificity

In the base model, uninformative responses are preferred partially because these are common in the training data. We want to be able to fit the training data while at the same time recognizing that we do not want to generate such responses at test time. Our approach, shown in Figure 1, involves conditioning on an explicit specificity level during both training and test time. This explicit conditioning allows us to model specificity orthogonally to response content, so we can control it at test time. We represent specificity as a collection of real valued metrics that can be estimated for each sentence independently of the dialogue system. To direct the model to generate more specific responses from multiple specificity metrics, we learn embeddings of various specificity levels for each metric jointly with the model.

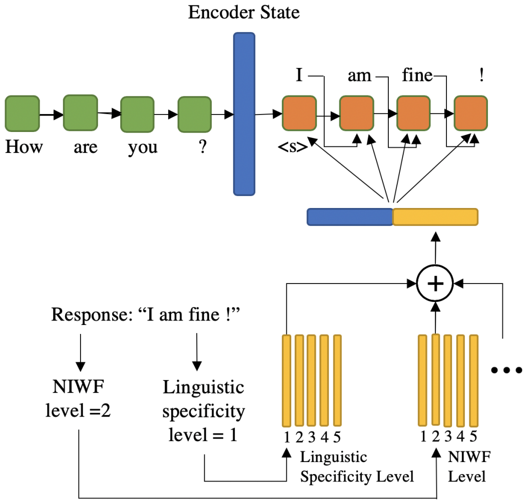

Figure 1: Structure of our model. The decoder explicitly conditions on embeddings of various specificity measures. At train time, these factor out specificity from generation; at test time, maxing these out encourages the model to generate specific responses. NIWF is defined in Section 3.3.

In particular, for each metric m, we rank the responses in the training data according to that metric and divide it into $K = 5$ levels of equal size. For each level, we learn an embedding e_k^m, $k \in \{1, 2, ...K\}$. During training, for each sentence pair in the training set, the response is classified to level l_m for metric m. We take the sum of embeddings across all metrics $e = \sum_{m=1}^{N} e_{l_m}^m$ and feed it into the decoder at every time step, where N is the number of metrics. The decoder becomes

$$h_i^d, c_i^d = LSTM(y_{i-1}, [\hat{h}_i^d; c_{i-1}^d; e]) \qquad (2)$$

During testing, we specify a level for each metric and calculate e based on those levels. In practice, the level of specificity varies with the larger context of dialogue discourse, however for the purpose of avoiding generic responses and improving specificity in single-turn dialogue generation, and examining various metrics of specificity, we use the level that maximizes specificity at test time (which we show in Section 5.3 is better the uninformative "median" level).[2]

---

[2] For the purposes of this work, we want an agent that is highly specific and keeps the conversation going. Learning the ideal specificity for a given response is something we leave for future work.

3.3 Specificity metrics

Normalized inverse word frequency (NIWF) Used in Zhang et al. (2018b), NIWF is the maximum of the Inverse Word Frequency (IWF) of all the words in a response, normalized to 0-1:

$$\max(IWF) = \max\left(\frac{\log(1+|Y|)}{f_w}\right) \quad (3)$$

where f_w denotes the number of responses in the corpus that contain the word w, and $|Y|$ is the number of responses in the corpus. Taking a maximum reflects the assumption that a response is specific as long as it has at least some infrequent word.

Perplexity per word (PPW) Perplexity is the exponentiation of the entropy, which estimates the expected number of bits required to encode the sentence (Brown et al., 1992; Goodman, 2001). Thus perplexity is a direct measure of the amount of information in the sentence in information theory; it has also been used as a measure of linguistic complexity (Gorin et al., 2000). To compute perplexity, we train a neural language model (Mikolov et al., 2011) on all gold responses and calculate cross-entropy of each sentence. To represent the amount of information per-token and to prevent the model to simply generate long sentences, we normalize perplexity by sentence length.

Linguistically-informed specificity We use the system developed by Ko et al. (2019), which estimates specificity as a real value. This system adopts a pragmatic notion of specificity—level of details in text—that is originally derived using sentence pairs connected via the INSTANTIATION discourse relation (Louis and Nenkova, 2011). With this relation, one sentence explains in further detail of the content in the other; the explanatory sentence is shown to demonstrate properties of specificity towards particular concepts, entities and objects, while the other sentence is much more general (Li and Nenkova, 2016). We use this particular system since other specificity predictors are trained on news with binary specificity labels (Li and Nenkova, 2015). Ko et al. (2019) is an unsupervised domain adaptation system that predicts continuous specificity values, and was evaluated to be close to human judgments across several domains. We retrain their system using the gold responses in our data as unlabeled sentences in the unsupervised domain adaptation component.

3.4 Coherence

Prior work has shown that the universal response problem can be mitigated by improving the coherence between prompt and response (Zhang et al., 2018a; Xu et al., 2018b; Baheti et al., 2018). We introduce two methods to improve coherence upon the base model, and analyze specificity on top.

For better interactions between decoder embeddings and the prompt, we feed the final encoder state into every time step of the decoder, instead of only the first token. Thus the decoder becomes

$$h_i^d, c_i^d = LSTM(y_{i-1}, [\hat{h}_i^d; c_{i-1}^d; e; h_f]). \quad (4)$$

Furthermore, Zhang et al. (2018a) showed that responses ranked higher by humans are more similar to the prompt sentence vector. Thus we compute the cosine similarity between input and response representations. This is computed by the weighted average of all word embeddings in the sentence, where the weight of each word is its inverse document frequency. Our model additionally conditions on an embedding of this measure so that coherence is factored out in our model as well as specificity. During testing, we condition on the highest level of our similarity metric in order to generate maximally coherent responses (Xu et al., 2018b).

4 Semantic plausibility

While injecting specificity encourages the model to generate more specific responses, we discovered that it exposes a series of issues that together, severely impact the semantic plausibility of generated responses. This is the case even when responses are considered independently without the prompt context. To have a better understanding of the problem, we first present manual analysis on generated responses with improved specificity. We then present a reranking method to improve the semantic plausibility of responses.

4.1 Data analysis

We manually inspected 200 responses generated from our full model on the PersonaChat dataset (Zhang et al., 2018c). We evaluated the responses independent of the input prompt and found that ∼33% of the sentences are semantically implausible; some of them shown in Table 1.

We found three major types of errors. The most common type is a wrong word that is not compatible with the context, making the phrase unreasonable (*cool . i work at a non profit organization that* *sells the* ***holocaust***), meaningless (*i like to* ***dance*** *battles*), or unnatural (*yeah , but i am more of a* ***game*** *worm . i am a pro ball player)*. These make up about 45% of the implausible cases.

About 30% of the problematic sentences contain incompatible phrases. Different phrases in the response are contradictory (*i understand. i am not sure if i can afford a babysitter, i am a millionaire*) or repetitive (*my favorite food is italian, but i also love italian food, especially italian food.*).

The third problem (∼15%) is that phrases are connected by a wrong discourse connective (*i am an animal phobic,* ***but*** *i do not like animals*). This and the previous problem reveal that even when the model generates sensible phrases, proper discourse relations between them are not captured.

Other notable errors include cohesion, such as wrong determiners or pronouns (*my mom was a social worker,* ***he*** *was an osteopath.*) and inappropriate prepositional phrases (*hello , i am winding down* ***to*** *the morning .*)

This semantic implausibility may come from two sources. First, since specific responses tend to be longer, it is easier to have internal consistency issues where parts of the sentence are incompatible with each other. Second, regardless of the specificity metric, word frequency in specific responses tend to be lower than that in generic responses. Learning meaningful representations for infrequent words is a known challenge (Gong et al., 2018) hence low-quality representations may increase the probability of the sentence being implausible.

4.2 Reranking

To mitigate semantic plausibility issues, we propose a reranking method so that more plausible sentences are ranked higher among the candidates. We use classifiers targeting various types of errors using synthetically generated data. Specifically, we train four classifiers that distinguish true response sentences from the dataset and negative sentences we create that reflect a specific type of semantic implausibility:

Phrase compatibility: We split all the training data into phrases by splitting sentences on punctuation or discourse connectives. To create a negative sentence given a gold response, we pick a random phrase in the true response and replace it with a random phrase in another random true response.

Content word plausibility: We replace a randomly selected content word (noun, verb, adjective, adverb) in the gold response with another random word with the same part-of-speech in the training set.

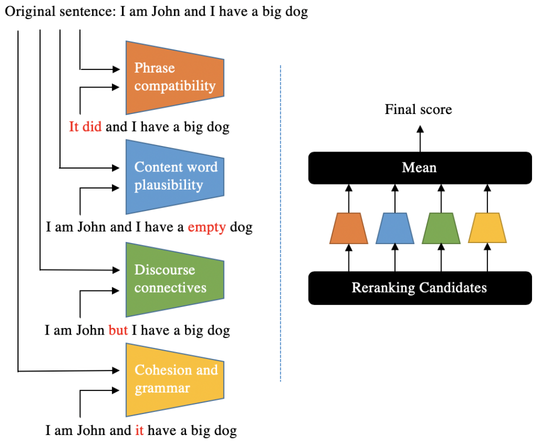

Figure 2: Reranking models to encourage plausibility. Four types of errors are synthetically applied to the data and classifiers are trained to differentiate each transformed sentence from the original. The mean score under these classifiers is then used as a feature to rerank system outputs.

Discourse connectives: We replace a discourse connective in the gold response (if one exists) with a random connective.

Cohesion and grammar: We replace a randomly selected function word in the gold response with another random function word of the same part-of-speech. For pronouns and determiners, these negative sentences would likely be incohesive; with other word categories such as prepositions, this will target grammatically.

One word or phrase is replaced in each synthetic sentence. We train one classifier $\theta_j, j \in \{1,2,3,4\}$ for each of the categories above.[3] The classifiers take word embeddings as input and predict if the response is real or generated. Each classifier consists of a bi-directional LSTM with a projection layer and max pooling (Conneau et al., 2017), followed by 3 fully connected layers. The posterior probabilities of these classifiers reflect how confident the classifiers are that the sentence is synthetic and prone to be implausible, hence we prefer sentences with lower posterior probabilities. During reranking, we feed each candidate sentence c into the classifiers and aggregate the posterior probabilities from these classifiers by taking the

---

[3] We compare with using one classifier lumping all negative sentences in the experiments.

mean $\frac{1}{4}\sum_{k=1}^{4} P(synthetic|c,\theta_k)$.

At test time, to encourage diversity, we repeat inference multiple times to generate different candidate sentences, and each time dropout is applied to different nodes in the network. Compared with diverse decoding (Li et al., 2016c), we observed during development that sentences generated by different dropouts tend to have diverse semantics (hence more likely to have different plausibility levels). On the contrary, sentences from diversity decoding often have similar structure and phrases across candidates. We also experimented with reinforcement learning, using policy gradient with the reranking scores as reward. However, during development, we observed that this method produced shorter, less informative sentences compared to reranking.

5 Experiments

5.1 Evaluation metrics

Automatic evaluation of dialogue generation systems is a known challenge. Prior work has shown that commonly used metrics for overall quality in other generation tasks such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005) and perplexity have poor correlations with human judgment (Liu et al., 2016; Tao et al., 2018)[4] or are model-dependent (Liu et al., 2016). Therefore, we adopt several metrics that evaluate multiple aspects of responses, and also conduct human evaluation for each result we present.

We use the following automatic evaluation metrics: (1) **distinct-1** and **distinct-2** (Li et al., 2016a), which evaluates response *diversity*. They respectively calculate the number of distinct unigrams and bigrams, divided by the total number of words in all responses; (2) linguistically-informed *specificity* (**spec**) (Ko et al., 2019); (3) **cosine similarity** between input and response representations, which captures *coherence* (Zhang et al., 2018a).

We follow standards from prior work for human evaluation (Li et al., 2017; Zhang et al., 2018a,b; Xu et al., 2018a). We select 250 prompt-response pairs, and asked 5 judges from MechanicalTurk to rate the responses for each prompt. We evaluate whether the responses are **informative** (Ko et al., 2019; Wu et al., 2018; Shao et al., 2017) and **on topic** with the prompt (Shen et al., 2018; Xu et al., 2018b; Xing et al., 2017), on a scale of 1-5. Average scores are reported. In addition, we evaluate **plausibility** by asking judges whether they think the given response sentence without the prompt can reasonably be uttered, following instructions from Kruszewski et al. (2016). The percentage of plausible ratings are reported.

5.2 Experiment setup

Data We use two datasets in this work: (1) *OpenSubtitles* (Tiedemann, 2009), a collection of movie subtitles widely used in open-domain dialogue generation. We sample 4,173,678 pairs for training and 5,000 pairs for testing from the movie subtitles dataset. Following Li et al. (2017), we remove all pairs with responses shorter than 5 words to improve the quality of the generated responses. (2) *PersonaChat* (Zhang et al., 2018c), a chit-chat dataset collected via crowdsourcing. This is a multi-turn dataset, but we only consider single turn generation in this work. We don't use the personas and false candidate replies. There are 122,458 prompt-response pairs for training and 14,602 pairs for testing. For validation, for reasons described in Section 5.1, we opt for human evaluation of overall response quality on a validation set of 60 prompt-response pairs from PersonaChat.

Settings We use LSTMs with hidden layers of size 500, Adam optimizer (Kingma and Ba, 2015) with learning rate 0.001, $\beta_1 = 0.9, \beta_2 = 0.999$, dropout rate 0.2 for both training and testing, metric embedding dimension 300 and 5 training epochs. We train randomly initialized word embeddings of size 500 for the dialog model and use 300 dimentional GloVe (Pennington et al., 2014) embeddings for reranking classifiers. We generate 15 candidates for reranking per input sentence. To train the 4 reranking classifiers, we use 375,996 positive sentences on Opensubtitles and 110,221 on PersonaChat. We generate one negative sentence per word or phrase in the positive sentences.

Since specificity is the focus of this study, during testing, we use the embedding of the highest specificity level (5) for NIWF and the linguistically informed specificity predictor. For PPW, we observe that the perplexity of generated sentences does not increase beyond the median level (3) during development, hence we use the median level. For comparison, we also report results when all metric levels are set to be the median (level 3).

---

[4] Although Tao et al. (2018) proposed an unsupervised metric, their code is not available.

Table 2: Results for the base SEQ2SEQ model and each component. (*) denotes significant improvement ($p < 0.05$ with paired bootstrap resampling) over our three baselines and benchmarks (*Seq2seq, MMI-Anti, Zhang*) according to paired bootstrap resampling. Our full reranking model performed the best in informativeness and topic relevance. A drop in plausibility is unavoidable as responses become more specific; the reranking model mitigates this.

Prompt (PersonaChat) thank you . also , the food is amazing . fries are the best thing ever .
Seq2seq yes it is . do you have a favorite color ? mine is blue .
Ours(Spec) yes , i am a vegetarian so i eat a lot of meat and bread puffs .
Ours(Spec+Plaus) i love italian food , but i am a vegan so i eat a lot of curries
MMI-Anti i agree . i am a vegetarian .
Zhang i agree . i love to eat and eat .

Prompt (PersonaChat) i work as kindergarten teacher at a school so pretty busy
Seq2seq what do you do for a living ? i work in a factory
Ours(Spec) i work at a grocery store and i work for a pharmaceutical company
Ours(Spec+Plaus) i work as a medical file clerk at a local hospital .
MMI-Anti what do you do for work ?
Zhang that is cool . i am a teacher and i love to be able to write .

Prompt (Opensubtitles) The countryside in spring Appears to the lovers in a new light . The air is already warm .
Seq2seq The snow is in the air .
Ours(Spec) It is the night of the dawn of the sunset .
Ours(Spec+Plaus) The light is rising from the skies , and the sun is shining .
MMI-Anti The light of the sun is rising .
Zhang The weather in the sky is a , .

Table 3: Example responses.

5.3 Results

We will first discuss results for the overall architecture, then dive into specificity and plausibility.

Overall architecture We evaluate our model against the base SEQ2SEQ for each component: coherence, specificity embeddings, and plausibility reranking (using the mean of all four classifiers). We also benchmark with the MMI-Anti model using mutual information (Li et al., 2016a), as well as Zhang et al. (2018b)'s model that incorproates a Gaussian kernel layer to control for specificity. We ran Zhang's code on our data and set $s = 1$ for PersonaChat and $s = 0.8$ for Opensubtitles when testing.[5] Significance tests are done via Paired Bootstrap Resampling (Berg-Kirkpatrick et al., 2012).

Table 2 shows that for both datasets, our full model with plausibility reranking (according to average posterior of the four classifiers) generates the most informative, relevant and plausible responses. Examples from our full model and the baselines are shown in Table 3.

Incorporating specificity led to more interesting responses, with 6-10% improvement in informativeness and 3-7% improvement in topic relevance. Since the system is trained without any semantics or common sense knowledge, this led to a drop in semantic plausibility. Plausibility reranking successfully mitigates this issue by improving plausibility by 3.6-6.5%. Although responses from MMI-Anti tend to be more plausible than directly using specificity, these responses are not useful if they are even less informative or relevant than the SEQ2SEQ baseline. Zhang et al. (2018b)'s model performed reasonably on PersonaChat but failed on OpenSubtitles.[6] One reason may be that OpenSubtitles is much more diverse in terms of topic and vocabulary, which makes their approach of estimating specificity independent of dialogue

---

[5] We observed that a higher s on Opensubtitles will result in many grammatical errors.

[6] Their original evaluation was on Chinese Weibo data.

Model	Informative		On topic	
Ours(Spec)	3.31		2.92	
-Linguistic	**3.11***	(-0.20)	**3.10***	(+0.18)
-NIWF	3.23	(-0.08)	3.20*	(+0.28)
-PPW	3.19*	(-0.12)	3.35*	(+0.43)

Table 4: Effect of excluding each specificity metric on PersonaChat. Delta against *Ours(Spec)* are included in parenthesis and (*) denotes significant delta ($p < 0.05$). Excluding linguistically informed specificity led to the greatest drop in informativeness and the slightest increase in topic relevance.

Model	Reranking	Inform.	Topic	Plaus.
Ours(Spec)	—	3.31	2.92	65.2
Ours(Spec +Plausibility)	1-classifier	3.26	3.36*	68.0*
	Max	**3.58***	3.35*	70.0*
	Mean	3.39	**3.45***	**71.7***
	+CoLA	3.45*	3.22*	68.5*
	CoLA	3.36	3.20*	58.0

Table 5: Comparison of different reranking methods on PersonaChat: training a single classifier, using max/mean posterior from four classifiers, and using CoLA. (*) denotes significant improvement over *Ours(Spec)* ($p < 0.05$). Learning multiple classifiers from synthetic data is the most effective.

context less effective. Indeed, we observe unstable word specificity learned across different training rounds and notable grammatical issues on OpenSubtitles. On the contrary, our joint approach gave stable performance on both datasets.

On PersonaChat, our coherence component led to improvements in topic relevance and cosine similarity, while specificity improved topic relevance and diversity, which is an intuitive result. On OpenSubtitles, coherence led to increased diversity while specificity led to a decrease. We looked into this and found that length trade-off is at play since the Distinct measures normalize by length of all generated responses: coherence led to diverse but short responses while specificity increased length. On human evaluation, they complement each other and using both gave better overall results. While reranking clearly did improve plausibility, there is also notable improvement in informativeness. This shows that informativeness is not only a frequency-only issue, or even a specificity-only issue, and that semantic plausibility plays an important role. Since the automatic metrics do not capture plausibility information in the sentence, it is unsurprising that they did not improve with plausibility added in.

We also study the effect of maxing out specificity and coherence levels at test time vs. using an uninformative level (median). Using median significantly improved informativeness and diversity (distinct-2) on PersonaChat by 0.90 and 0.53, and did not improve topic relevance. Similar but insignificant improvements are observed on OpenSubtitles. On the other hand, using the maximum levels led to significant improvements over the baseline or the median level on all metrics.

Specificity We now dive into a more detailed analysis for each specificity metric on PersonaChat. Table 4 shows human evaluation of informativeness, topic relevance and plausibility for the non-reranking model minus one specificity metric. Notably, excluding the linguistic based metric resulted in the largest drop in informativeness and relevance. Frequency based NIWF has the least impact on informativeness, indicating that specificity in dialogue is a multi-faceted issue and that the linguistically-informed notion is the most suitable. If none of the specificity metrics are included, topic relevance scores improve. This is because increasing specificity leads to fewer generic responses, yet they are more likely to be judged "on topic" by humans.

Plausibility We compare several different settings for plausibility reranking. Table 5 shows three ways of using the synthetically generated sentences discussed in Section 4: (1) **1-classifier**, which trains one classifier to distinguish true responses vs. all generated ones; (2) **Max**, which trains separate classifiers and take the maximum posterior probability (recall that higher posterior means less plausible responses); (3) **Mean**, which trains separate classifiers and averages the posterior probability. For all classifiers, at least 72% of the responses ranked top 50% on a balanced test set are true responses.

All three reranking methods helped, however, using one classifier is less effective than training and aggregating separate classifiers for each type of semantic implausibility. The latter not only improved plausibility but also informativeness and topic relevance. Using Max vs Mean yields comparable results in terms of plausibility, although Max improves informativeness more while Mean improves topic relevance more.

We also experimented with training an additional classifier (of the same architecture) on

Seq2seq	Ours(Spec)	Ours(Spec +Plausibility)	MMI -Anti	Zhang
82.4	78.7	82.6	90.0	61.5

Table 6: Percentage of sentences judged grammatical on OpenSubtitles.

the Corpus of Linguistic Acceptability (Warstadt et al., 2018), a dataset consisting of linguistically acceptable vs. unacceptable sentences. However, looking at results from PersonaChat, reranking using CoLA did not improve plausibility although is of slight help for informativeness and topic relevance. Combining CoLA with the other four classifiers decreased plausibility.

Grammaticality Finally, since the function word substitution aspect of our synthetic sentences is related to grammar, we also conduct human evaluation of grammaticality on OpenSubtitles. We did not evaluate on PersonaChat because almost all generate responses of our model we inspected are grammatically correct. Here annotators are asked to judge whether a sentence is grammatical vs. not. Results are shown in Table 6.

Informative and interesting responses that are the result of increasing specificity also made the model more prone to grammatical errors, but adding reranking completely mitigated this issue and grammaticality results are the same as the base model that generates much shorter, canned universal responses. MMI gave the best grammaticality; however, these response are not useful if they are even less informative or relevant than the SEQ2SEQ baseline. Zhang et al. (2018b)'s model generated more complicated sentences, but has worse grammar. Again we suspect that this is because of the lack of interaction between specificity estimates and dialogue context in their model.

6 Conclusion

We presented a new method to incorporate specificity information and semantic plausibility in SEQ2SEQ models. We showed that apart from frequency-based specificity metrics explored in prior work, information-theoretic and linguistically informed specificity improve the specificity of the responses. We proposed a reranking method aimed at improving the semantic plausibility of specific responses. Results showed that our method improved human ratings on informativeness, plausibility and grammaticality on both open domain and chit-chat datasets.

Abstract

When reading a text, it is common to become stuck on unfamiliar words and phrases, such as polysemous words with novel senses, rarely used idioms, internet slang, or emerging entities. If we humans cannot figure out the meaning of those expressions from the immediate *local* context, we consult dictionaries for definitions or search documents or the web to find other *global* context to help in interpretation. Can machines help us do this work? Which type of context is more important for machines to solve the problem? To answer these questions, we undertake a task of describing a given phrase in natural language based on its local and global contexts. To solve this task, we propose a neural description model that consists of two context encoders and a description decoder. In contrast to the existing methods for non-standard English explanation (Ni and Wang, 2017) and definition generation (Noraset et al., 2017; Gadetsky et al., 2018), our model appropriately takes important clues from *both* local and global contexts. Experimental results on three existing datasets (including WordNet, Oxford and Urban Dictionaries) and a dataset newly created from Wikipedia demonstrate the effectiveness of our method over previous work.

1 Introduction

When we read news text with emerging entities, text in unfamiliar domains, or text in foreign languages, we often encounter expressions (words or phrases) whose senses we do not understand. In such cases, we may first try to figure out the meanings of those expressions by reading the surrounding words (*local* context) carefully. Failing to do so, we may consult dictionaries, and in the case of polysemous words, choose an appropriate meaning based on the context. Learning novel word senses via dictionary definitions is known to be more effective than contextual guessing (Fraser, 1998; Chen, 2012). However, very often, hand-crafted dictionaries do not contain definitions of expressions that are rarely used or newly created. Ultimately, we may need to read through the entire document or even search the web to find other occurances of the expression (*global* context) so that we can guess its meaning.

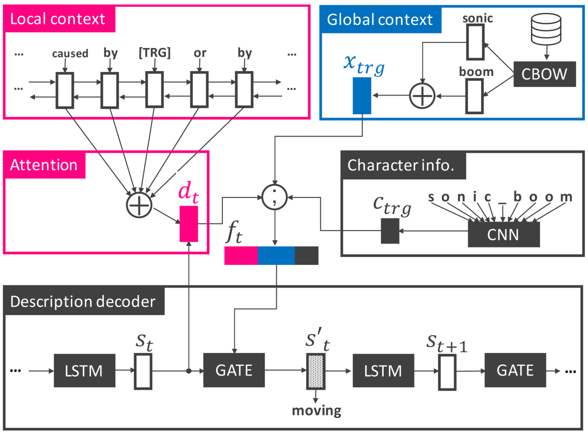

Figure 1: **Lo**cal & **G**lobal **C**ontext-**a**ware **D**escription generator (**LOG-CaD**).

Can machines help us do this work? Ni and Wang (2017) have proposed a task of generating a definition for a phrase given its local context. However, they follow the strict assumption that the target phrase is newly emerged and there is only a single local context available for the phrase, which makes the task of generating an accurate and coherent definition difficult (perhaps as difficult as a human comprehending the phrase itself). On the other hand, Noraset et al. (2017) attempted to generate a definition of a word from an embedding induced from massive text (which can be seen as global context). This is followed by Gadetsky et al. (2018) that refers to a local context to disambiguate polysemous words by choosing relevant dimensions of their word embeddings. Al-

though these research efforts revealed that both local and global contexts are useful in generating definitions, none of these studies exploited both contexts directly to describe unknown phrases.

In this study, we tackle the task of describing (defining) a phrase when given its local and global contexts. We present **LOG-CaD**, a neural description generator (Figure 1) to directly solve this task. Given an unknown phrase without sense definitions, our model obtains a phrase embedding as its global context by composing word embeddings while also encoding the local context. The model therefore combines both pieces of information to generate a natural language description.

Considering various applications where we need definitions of expressions, we evaluated our method with four datasets including WordNet (Noraset et al., 2017) for general words, the Oxford dictionary (Gadetsky et al., 2018) for polysemous words, Urban Dictionary (Ni and Wang, 2017) for rare idioms or slang, and a newly-created Wikipedia dataset for entities.

Our contributions are as follows:

- We propose **a general task of defining unknown phrases given their contexts**. This task is a generalization of three related tasks (Noraset et al., 2017; Ni and Wang, 2017; Gadetsky et al., 2018) and involves various situations where we need definitions of unknown phrases (§ 2).
- We propose a method for **generating natural language descriptions for unknown phrases with local and global contexts** (§ 3).
- As a benchmark to evaluate the ability of the models to describe entities, we **build a large-scale dataset** from Wikipedia and Wikidata for the proposed task. We release our dataset and the code[1] to promote the reproducibility of the experiments (§ 4).
- The proposed method achieves **the state-of-the-art performance** on our new dataset and the three existing datasets used in the related studies (Noraset et al., 2017; Ni and Wang, 2017; Gadetsky et al., 2018) (§ 5).

2 Context-aware Phrase Description Generation

In this section, we define our task of describing a phrase in a specific context. Given an undefined phrase $X_{trg} = \{x_j, \cdots, x_k\}$ with its context $X = \{x_1, \cdots, x_I\}$ $(1 \leq j \leq k \leq I)$, our task is to output a description $Y = \{y_1, \cdots, y_T\}$. Here, X_{trg} can be a word or a short phrase and is included in X. Y is a definition-like concrete and concise sentence that describes the X_{trg}.

For example, given a phrase "sonic boom" with its context "the shock wave may be caused by *sonic boom* or by explosion," the task is to generate a description such as "sound created by an object moving fast." If the given context has been changed to "this is the first official tour to support the band's latest studio effort, 2009's *Sonic Boom*," then the appropriate output would be "album by Kiss."

The process of description generation can be modeled with a conditional language model as

$$p(Y|X, X_{trg}) = \prod_{t=1}^{T} p(y_t|y_{<t}, X, X_{trg}). \quad (1)$$

3 LOG-CaD: Local & Global Context-aware Description Generator

In this section, we describe our idea of utilizing local and global contexts in the description generation task, and present the details of our model.

3.1 Local & global contexts

When we find an unfamiliar phrase in text and it is not defined in dictionaries, how can we humans come up with its meaning? As discussed in Section 1, we may first try to figure out the meaning of the phrase from the immediate context, and then read through the entire document or search the web to understand implicit information behind the text.

In this paper, we refer to the explicit contextual information included in a given sentence with the target phrase (i.e., the X in Eq. (1)) as "local context," and the implicit contextual information in massive text as "global context." While both local and global contexts are crucial for humans to understand unfamiliar phrases, are they also useful for machines to generate descriptions? To verify this idea, we propose to incorporate both local and global contexts to describe an unknown phrase.

3.2 Proposed model

Figure 1 shows an illustration of our **LOG-CaD** model. Similarly to the standard encoder-decoder model with attention (Bahdanau et al., 2015; Luong and Manning, 2016), it has a context encoder and a description decoder. The challenge here is that the decoder needs to be conditioned not only on the local context, but also on its global context. To incorporate the different types of contexts, we propose to use a gate function similar to Noraset et al. (2017) to dynamically control how the global and local contexts influence the description.

Local & global context encoders We first describe how to model local and global contexts. Given a sentence X and a phrase X_{trg}, a bi-directional LSTM (Gers et al., 1999) encoder generates a sequence of continuous vectors $\boldsymbol{H} = \{\boldsymbol{h}_1 \cdots, \boldsymbol{h}_I\}$ as

$$\boldsymbol{h}_i = \text{Bi-LSTM}(\boldsymbol{h}_{i-1}, \boldsymbol{h}_{i+1}, \boldsymbol{x}_i), \quad (2)$$

where $\boldsymbol{x}_i$ is the word embedding of word x_i. In addition to the local context, we also utilize the global context obtained from massive text. This can be achieved by feeding a phrase embedding $\boldsymbol{x}_{trg}$ to initialize the decoder (Noraset et al., 2017) as

$$\boldsymbol{y}_0 = \boldsymbol{x}_{trg}. \quad (3)$$

Here, the phrase embedding $\boldsymbol{x}_{trg}$ is calculated by simply summing up all the embeddings of words that consistute the phrase X_{trg}. Note that we use a randomly-initialized vector if no pre-trained embedding is available for the words in X_{trg}.

Description decoder Using the local and global contexts, a description decoder computes the conditional probability of a description Y with Eq. (1), which can be approximated with another LSTM as

$$\begin{aligned} \boldsymbol{s}_t &= \text{LSTM}(\boldsymbol{y}_{t-1}, \boldsymbol{s}'_{t-1}), && (4)\\ \boldsymbol{d}_t &= \text{ATTENTION}(\boldsymbol{H}, \boldsymbol{s}_t), && (5)\\ \boldsymbol{c}_{trg} &= \text{CNN}(X_{trg}), && (6)\\ \boldsymbol{s}'_t &= \text{GATE}(\boldsymbol{s}_t, \boldsymbol{x}_{trg}, \boldsymbol{c}_{trg}, \boldsymbol{d}_t), && (7)\\ p(y_t|y_{<t}, X_{trg}) &= \text{softmax}(\boldsymbol{W}_{s'}\boldsymbol{s}'_t + \boldsymbol{b}_{s'}), && (8) \end{aligned}$$

where $\boldsymbol{s}_t$ is a hidden state of the decoder LSTM ($\boldsymbol{s}_0 = \vec{0}$), and $\boldsymbol{y}_{t-1}$ is a jointly-trained word embedding of the previous output word y_{t-1}. In what follows, we explain each equation in detail.

Attention on *local* context Considering the fact that the local context can be relatively long (e.g., around 20 words on average in our Wikipedia dataset introduced in Section 4), it is hard for the decoder to focus on important words in local contexts. In order to deal with this problem, the ATTENTION$(\cdot)$ function in Eq. (5) decides which words in the local context X to focus on at each time step. $\boldsymbol{d}_t$ is computed with an attention mechanism (Luong and Manning, 2016) as

$$\begin{aligned} \boldsymbol{d}_t &= \sum_{i=1}^{T} \alpha_i \boldsymbol{h}_i, && (9)\\ \alpha_i &= \text{softmax}(\boldsymbol{U}_h \boldsymbol{h}_i^{\mathrm{T}} \boldsymbol{U}_s \boldsymbol{s}_t), && (10) \end{aligned}$$

where $\boldsymbol{U}_h$ and $\boldsymbol{U}_s$ are matrices that map the encoder and decoder hidden states into a common space, respectively.

Use of character information In order to capture the surface information of X_{trg}, we construct character-level CNNs (Eq. (6)) following (Noraset et al., 2017). Note that the input to the CNNs is a sequence of words in X_{trg}, which are concatenated with special character "_," such as "sonic_boom." Following Noraset et al. (2017), we set the CNN kernels of length 2-6 and size $10, 30, 40, 40, 40$ respectively with a stride of 1 to obtain a 160-dimensional vector $\boldsymbol{c}_{trg}$.

Gate function to control local & global contexts In order to capture the interaction between the local and global contexts, we adopt a GATE$(\cdot)$ function (Eq. (7)) which is similar to Noraset et al. (2017). The GATE$(\cdot)$ function updates the LSTM output $\boldsymbol{s}_t$ to $\boldsymbol{s}'_t$ depending on the global context $\boldsymbol{x}_{trg}$, local context $\boldsymbol{d}_t$, and character-level information $\boldsymbol{c}_{trg}$ as

$$\begin{aligned} \boldsymbol{f}_t &= [\boldsymbol{x}_{trg}; \boldsymbol{d}_t; \boldsymbol{c}_{trg}] && (11)\\ \boldsymbol{z}_t &= \sigma(\boldsymbol{W}_z[\boldsymbol{f}_t; \boldsymbol{s}_t] + \boldsymbol{b}_z), && (12)\\ \boldsymbol{r}_t &= \sigma(\boldsymbol{W}_r[\boldsymbol{f}_t; \boldsymbol{s}_t] + \boldsymbol{b}_r), && (13)\\ \tilde{\boldsymbol{s}}_t &= \tanh(\boldsymbol{W}_s[(\boldsymbol{r}_t \odot \boldsymbol{f}_t); \boldsymbol{s}_t] + \boldsymbol{b}_s), && (14)\\ \boldsymbol{s}'_t &= (1 - \boldsymbol{z}_t) \odot \boldsymbol{s}_t + z_t \odot \tilde{\boldsymbol{s}}_t, && (15) \end{aligned}$$

where $\sigma(\cdot)$, $\odot$ and ; denote the sigmoid function, element-wise multiplication, and vector concatenation, respectively. $\boldsymbol{W}_*$ and $\boldsymbol{b}_*$ are weight matrices and bias terms, respectively. Here, the update gate $\boldsymbol{z}_t$ controls how much the original hidden state $\boldsymbol{s}_t$ is to be changed, and the reset gate $\boldsymbol{r}_t$ controls how much the information from $\boldsymbol{f}_t$ contributes to word generation at each time step.

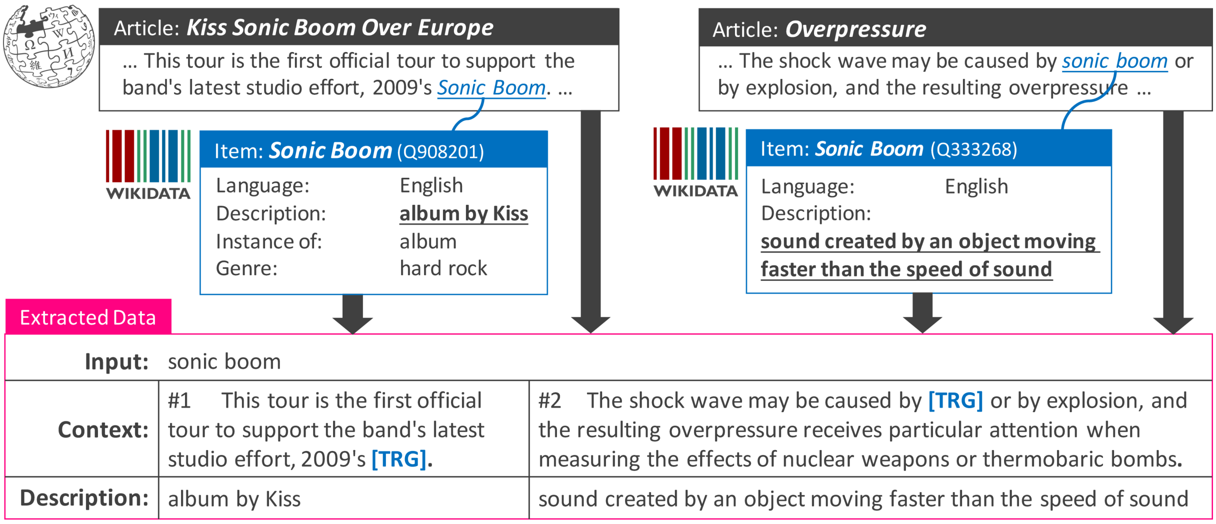

Figure 2: Context-aware description dataset extracted from Wikipedia and Wikidata.

4 Wikipedia Dataset

Our goal is to let machines describe unfamiliar words and phrases, such as polysemous words, rarely used idioms, or emerging entities. Among the three existing datasets, WordNet and Oxford dictionary mainly target the words but not phrases, thus are not perfect test beds for this goal. On the other hand, although the Urban Dictionary dataset contains descriptions of rarely-used phrases, the domain of its targeted words and phrases is limited to Internet slang.

In order to confirm that our model can generate the description of entities as well as polysemous words and slang, we constructed a new dataset for context-aware phrase description generation from Wikipedia[2] and Wikidata[3] which contain a wide variety of entity descriptions with contexts. The overview of the data extraction process is shown in Figure 2. Each entry in the dataset consists of (1) a phrase, (2) its description, and (3) context (a sentence).

For preprocessing, we applied Stanford Tokenizer[4] to the descriptions of Wikidata items and the articles in Wikipedia. Next, we removed phrases in parentheses from the Wikipedia articles, since they tend to be paraphrasing in other languages and work as noise. To obtain the contexts of each item in Wikidata, we extracted the sentence which has a link referring to the item through all the first paragraphs of Wikipedia articles and replaced the phrase of the links with a special token **[TRG]**. Wikidata items with no description or no contexts are ignored. This utilization of links makes it possible to resolve the ambiguity of words and phrases in a sentence without human annotations, which is a major advantage of using Wikipedia. Note that we used only links whose anchor texts are identical to the title of the Wikipedia articles, since the users of Wikipedia sometimes link mentions to related articles.

5 Experiments

We evaluate our method by applying it to describe words in WordNet[5] (Miller, 1995) and Oxford Dictionary,[6] phrases in Urban Dictionary[7] and Wikipedia/Wikidata.[8] For all of these datasets, a given word or phrase has an inventory of senses with corresponding definitions and usage examples. These definitions are regarded as ground-truth descriptions.

Datasets To evaluate our model on the word description task on WordNet, we followed Noraset et al. (2017) and extracted data from WordNet using the `dict-definition`[9] toolkit. Each entry in the data consists of three elements: (1) a word, (2) its definition, and (3) a usage example of the

word. We split this dataset to obtain Train, Validation, and Test sets. If a word has multiple definitions/examples, we treat them as different entries. Note that the words are mutually exclusive across the three sets. The only difference between our dataset and theirs is that we extract the tuples only if the words have their usage examples in WordNet. Since not all entries in WordNet have usage examples, our dataset is a small subset of Noraset et al. (2017).

In addition to WordNet, we use the Oxford Dictionary following Gadetsky et al. (2018), the Urban Dictionary following Ni and Wang (2017) and our Wikipedia dataset described in the previous section. Table 1 and Table 2 show the properties and statistics of the four datasets, respectively.

To simulate a situation in a real application where we might not have access to global context for the target phrases, we did not train domain-specific word embeddings on each dataset. Instead, for all of the four datasets, we use the same pre-trained CBOW[10] vectors trained on Google news corpus as global context following previous work (Noraset et al., 2017; Gadetsky et al., 2018). If the expression to be described consists of multiple words, its phrase embedding is calculated by simply summing up all the CBOW vectors of words in the phrase, such as "sonic" and "boom." (See Figure 1). If pre-trained CBOW embeddings are unavailable, we instead use a special **[UNK]** vector (which is randomly initialized with a uniform distribution) as word embeddings. Note that our pre-trained embeddings only cover 26.79% of the words in the expressions to be described in our Wikipedia dataset, while it covers all words in WordNet dataset (See Table 2). Even if no reliable word embeddings are available, all models can capture the character information through character-level CNNs (See Figure 1).

Models We implemented four methods: (1) **Global** (Noraset et al., 2017), (2) **Local** (Ni and Wang, 2017) with CNN, (3) **I-Attention** (Gadetsky et al., 2018), and our proposed model, (4) **LOG-CaD**. The **Global** model is our reimplementation of the best model (S + G + CH) in Noraset et al. (2017). It can access the global context of a phrase to be described, but has no ability to read the local context. The **Local** model is the reimplementation of the best model (dual encoder) in Ni and Wang(2017). In order to make a fair comparison of the effectiveness of local and global contexts, we slightly modify the original implementation by Ni and Wang(2017); as the character-level encoder in the **Local** model, we adopt CNNs that are exactly the same as the other two models instead of the original LSTMs.

The **I-Attention** is our reimplementation of the best model (S + I-Attention) in Gadetsky

Table 5: Averaged human annotated scores on Wikipedia dataset.

et al.(2018). Similar to our model, it uses both local and global contexts. Unlike our model, however, it does not use character information to predict descriptions. Also, it cannot directly use the local context to predict the words in descriptions. This is because the **I-Attention** model indirectly uses the local context only to disambiguate the phrase embedding $\boldsymbol{x}_{trg}$ as

$$\boldsymbol{x}'_{trg} = \boldsymbol{x}_{trg} \odot \boldsymbol{m}, \tag{16}$$

$$\boldsymbol{m} = \sigma(\boldsymbol{W}_m \frac{\sum_{i=1}^{I} \mathrm{FFNN}(\boldsymbol{h}_i)}{I} + \boldsymbol{b}_m). \tag{17}$$

Here, the $\mathrm{FFNN}(\cdot)$ function is a feed-forward neural network that maps the encoded local contexts $\boldsymbol{h}_i$ to another space. The mapped local contexts are then averaged over the length of the sentence X to obtain a representation of the local context. This is followed by a linear layer and a sigmoid function to obtain the soft binary mask $\boldsymbol{m}$ which can filter out the unrelated information included in global context. Finally, the disambiguated phrase embedding $\boldsymbol{x}'_{trg}$ is then used to update the decoder hidden state as

$$\boldsymbol{s}_t = \mathrm{LSTM}([\boldsymbol{y}_{t-1}; \boldsymbol{x}'_{trg}], \boldsymbol{s}_{t-1}). \tag{18}$$

All four models (Table 3) are implemented with the PyTorch framework (Ver. 1.0.0).[11]

Automatic Evaluation Table 4 shows the BLEU (Papineni et al., 2002) scores of the output descriptions. We can see that the **LOG-CaD** model consistently outperforms the three baselines in all four datasets. This result indicates that using both local and global contexts helps describe the unknown words/phrases correctly. While the **I-Attention** model also uses local and global contexts, its performance was always lower than the **LOG-CaD** model. This result shows that using local context to predict description is more effective than using it to disambiguate the meanings in global context.

Table 7: Descriptions for a phrase in Wikipedia.

In particular, the low BLEU scores of **Global** and **I-Attention** models on Wikipedia dataset suggest that it is necessary to learn to ignore the noisy information in global context if the coverage of pre-trained word embeddings is extremely low (see the third and fourth rows in Table 2). We suspect that the Urban Dictionary task is too difficult and the results are unreliable considering its extremely low BLEU scores and high ratio of unknown tokens in generated descriptions.

Table 8: Descriptions for a word in Wikipedia.

Manual Evaluation To compare the proposed model and the strongest baseline in Table 4 (i.e., the **Local** model), we performed a human evaluation on our dataset. We randomly selected 100 samples from the test set of the Wikipedia dataset and asked three native English speakers to rate the output descriptions from 1 to 5 points as: 1) completely wrong or self-definition, 2) correct topic with wrong information, 3) correct but incomplete, 4) small details missing, 5) correct. The averaged scores are reported in Table 5. Pair-wise bootstrap resampling test (Koehn, 2004) for the annotated scores has shown that the superiority of **LOG-CaD** over the **Local** model is statistically significant ($p < 0.01$).

Qualitative Analysis Table 6 shows a word in the WordNet, while Table 7 and Table 8 show the examples of the entities in Wikipedia as examples. When comparing the two datasets, the quality of generated descriptions of Wikipedia dataset is significantly better than that of WordNet dataset. The main reason for this result is that the size of training data of the Wikipedia dataset is 64x larger than the WordNet dataset (See Table 1).

For all examples in the three tables, the **Global** model can only generate a single description for each input word/phrase because it cannot access any local context. In the Wordnet dataset, only the **I-Attention** and **LOG-CaD** models can successfully generate the concept of "remove" given the context #2. This result suggests that considering both local and global contexts are essential to generate correct descriptions. In our Wikipedia dataset, both the **Local** and **LOG-CaD** models can describe the word/phrase considering its local context. For example, both the **Local** and **LOG-CaD** models could generate "american" in the description for "daniel o'neill" given "united states" in context #1, while they could generate "british" given "belfast" in context #2. A similar trend can also be observed in Table 8, where **LOG-CaD** could generate the locational expressions such as "philippines" and "british" given the different contexts. On the other hand, the **I-Attention** model could not describe the two phrases, taking into account the local contexts. We will present an analysis of this phenomenon in the next section.

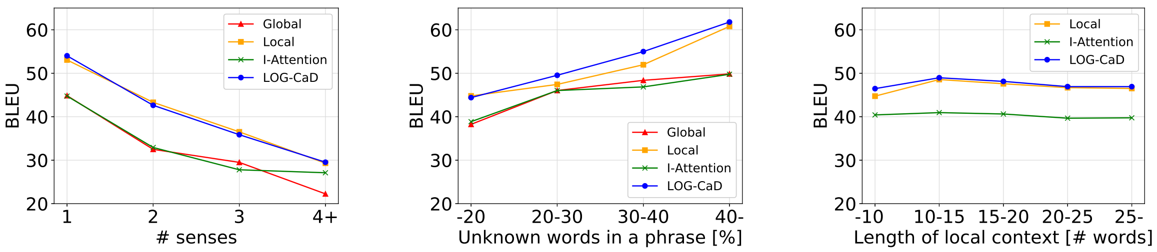
6 Discussion

In this section, we present analyses on how the local and global contexts contribute to the description generation task. First, we discuss how the local context helps the models to describe a phrase. Then, we analyze the impact of global context under the situation where local context is unreliable.

6.1 How do the models utilize *local* contexts?

Local context helps us (1) disambiguate polysemous words and (2) infer the meanings of unknown expressions. Can machines also utilize the local context? In this section, we discuss the two roles of local context in description generation.

Considering that the pre-trained word embeddings are obtained from word-level co-occurrences in massive text, more information is mixed up into a single vector as the more senses the word has. While Gadetsky et al. (2018) de-



(a) Number of senses of the phrase.

(c) Length of the local context.

Figure 3: Impact of various parameters of a phrase to be described on BLEU scores of the generated descriptions.

signed the **I-Attention** model to filter out unrelated meanings in the global context given local context, they did not discuss the impact of the number of senses has on the performance of definition generation. To understand the influence of the ambiguity of phrases to be defined on the generation performance, we did an analysis on our Wikipedia dataset. Figure 3(a) shows that the description generation task becomes harder as the phrases to be described become more ambiguous. In particular, when a phrase has an extremely large number of senses, (i.e., #senses ≥ 4), the **Global** model drops its performance significantly. This result indicates that the local context is necessary to disambiguate the meanings in global context.

As shown in Table 2, a large proportion of the phrases in our Wikipedia dataset includes unknown words (i.e., only 26.79% of words in the phrases have their pre-trained embeddings). This fact indicates that the global context in this dataset is not fully reliable. Then our next question is, how does the lack of information from global context affect the performance of phrase description? Figure 3(b) shows the impact of unknown words in the phrases to be described on the performance. As we can see from the result, the advantage of **LOG-CaD** and **Local** models over **Global** and **I-Attention** models becomes larger as the unknown words increases. This result suggests that we need to fully utilize local contexts especially in practical applications where the phrases to be defined have many unknown words. Here, Figure 3(b) also shows a counterintuitive phenomenon that BLEU scores increase as the ratio of unknown words in a phrase increase. This is mainly because unknown phrases tend to be person names such as writers, actors, or movie directors. Since these entities have fewer ambiguities in categories, they can be described in extremely short sentences that are easy for all four models to decode (e.g., "finnish writer" or "american television producer").

6.2 How do the models utilize *global* contexts?

As discussed earlier, local contexts are important to describe unknown expressions, but how about global contexts? Assuming a situation where we cannot obtain much information from local contexts (*e.g.*, infer the meaning of "boswellia" from a short local context "Here is a boswellia"), global contexts should be essential to understand the meaning. To confirm this hypothesis, we analyzed the impact of the length of local contexts on BLEU scores. Figure 3(c) shows that when the length of local context is extremely short ($l \leq 10$), the **LOG-CaD** model becomes much stronger than the **Local** model. This result indicates that not only local context but also global context help models describe the meanings of phrases.

7 Related Work

In this study, we address a task of describing a given phrase with its context. In what follows, we explain existing tasks that are related to our work.

Our task is closely related to word sense disambiguation (WSD) (Navigli, 2009), which identifies a pre-defined sense for the target word with its context. Although we can use it to solve our task by retrieving the definition sentence for the sense identified by WSD, it requires a substantial amount of training data to handle a different set of meanings of each word, and cannot handle words (or senses) which are not registered in the dictionary. Although some studies have attempted to detect novel senses of words for given contexts (Erk, 2006; Lau et al., 2014), they do not provide definition sentences. Our task avoids these difficulties in WSD by directly generating descriptions for phrases or words. It also allows us to flexibly tailor a fine-grained definition for the specific context.

Paraphrasing (Androutsopoulos and Malakasiotis, 2010; Madnani and Dorr, 2010) (or text simplification (Siddharthan, 2014)) can be used to rephrase words with unknown senses. However, the target of paraphrase acquisition are words/phrases with no specified context. Although a few studies (Connor and Roth, 2007; Max, 2009; Max et al., 2012) consider subsentential (context-sensitive) paraphrases, they do not intend to obtain a definition-like description as a paraphrase of a word.

Recently, Noraset et al. (2017) introduced a task of generating a definition sentence of a word from its pre-trained embedding. Since their task does not take local contexts of words as inputs, their method cannot generate an appropriate definition for a polysemous word for a specific context. To cope with this problem, Gadetsky et al. (2018) proposed a definition generation method that works with polysemous words in dictionaries. They presented a model that utilizes local context to filter out the unrelated meanings from a pre-trained word embedding in a specific context. While their method use local context for disambiguating the meanings that are mixed up in word embeddings, the information from local contexts cannot be utilized if the pre-trained embeddings are unavailable or unreliable. On the other hand, our method can fully utilize the local context through an attentional mechanism, even if the reliable word embeddings are unavailable.

The most related work to this paper is Ni and Wang (2017). Focusing on non-standard English phrases, they proposed a model to generate the explanations solely from local context. They followed the strict assumption that the target phrase was newly emerged and there was only a single local context available, which made the task of generating an accurate and coherent definition difficult. Our proposed task and model are more general and practical than Ni and Wang (2017); where (1) we use Wikipedia, which includes expressions from various domains, and (2) our model takes advantage of global contexts if available.

Our task of describing phrases with its context is a generalization of the three tasks (Noraset et al., 2017; Ni and Wang, 2017; Gadetsky et al., 2018), and the proposed method utilizes both local and global contexts of an expression in question.

8 Conclusions

This paper sets up a task of generating a natural language description for an unknown phrase with a specific context, aiming to help us acquire unknown word senses when reading text. We approached this task by using a variant of encoder-decoder models that capture the given local context with the encoder and global contexts with the decoder initialized by the target phrase's embedding induced from massive text. We performed experiments on three existing datasets and one newly built from Wikipedia and Wikidata. The experimental results confirmed that the local and global contexts complement one another and are both essential; global contexts are crucial when local contexts are short and vague, while the local context is important when the target phrase is polysemous, rare, or unseen.

As future work, we plan to modify our model to use multiple contexts in text to improve the quality of descriptions, considering the "one sense per discourse" hypothesis (Gale et al., 1992). We will release the newly built Wikipedia dataset and the experimental codes for the academic and industrial communities at `https://github.com/shonosuke/ishiwatari-naacl2019` to facilitate the reproducibility of our results and their use in various application contexts.

Abstract

Current state of the art systems in NLP heavily rely on manually annotated datasets, which are expensive to construct. Very little work adequately exploits unannotated data – such as discourse markers between sentences – mainly because of data sparseness and ineffective extraction methods. In the present work, we propose a method to automatically discover sentence pairs with relevant discourse markers, and apply it to massive amounts of data. Our resulting dataset contains 174 discourse markers with at least 10K examples each, even for rare markers such as *coincidentally* or *amazingly*. We use the resulting data as supervision for learning transferable sentence embeddings. In addition, we show that even though sentence representation learning through prediction of discourse markers yields state of the art results across different transfer tasks, it is not clear that our models made use of the semantic relation between sentences, thus leaving room for further improvements. Our datasets are publicly available [1]

1 Introduction

An important challenge within the domain of natural language processing is the construction of adequate semantic representations for textual units – from words over sentences to whole documents. Recently, numerous approaches have been proposed for the construction of vector-based representations for larger textual units, especially sentences. One of the most popular frameworks aims to induce sentence embeddings as an intermediate representation for predicting relations between sentence pairs. For instance, similarity judgements (paraphrases) or inference relations have been used as prediction tasks, and the resulting embeddings perform well in practice, even when the representations are transfered to other semantic tasks (Conneau et al., 2017). However, the kind of annotated data that is needed for such supervised approaches is costly to obtain, prone to bias, and arguably fairly limited with regard to the kind of semantic information captured, as they single out a narrow aspect of the entire semantic content.

Unsupervised approaches have also been proposed, based on sentence distributions in large corpora in relation to their discourse context. For instance, Kiros et al. (2015) construct sentence representations by trying to reconstruct neighbouring sentences, which allows them to take into account different contextual aspects of sentence meaning. In the same vein, Logeswaran et al. (2016) propose to predict if two sentences are consecutive, even though such local coherence can be straightforwardly predicted with relatively shallow features (Barzilay and Lapata, 2008). A more elaborate setting is the prediction of the semantic or rhetorical relation between two sentences, as is the goal of discourse parsing. A number of annotated corpora exist, such as RST-DT (Carlson et al., 2001) and PDTB (Prasad et al., 2008), but in general the available data is fairly limited, and the task of discourse relation prediction is rather difficult. The problem, however, is much easier when there is a marker that makes the semantic link explicit (Pitler et al., 2008), and this observation has often been used in a semi-supervised setting to predict discourse relations in general (Rutherford and Xue, 2015). Building on this observation, one approach to learn sentence representations is to predict such markers or clusters of markers explicitly (Jernite et al., 2017; Malmi et al., 2018; Nie et al., 2017). Consider the following sentence pair:

I live in Paris. But I'm often abroad.

The discourse marker *but* highlights an opposition between the first sentence (the speaker

Table 1: Sample from our *Discovery* dataset

lives in Paris) and the second sentence (the speaker is often abroad). The marker can thus be straightforwardly used as a label between sentence pairs. In this case, the task is to predict c = *but* (among other markers) for the pair (*I live in Paris*, *I'm often abroad*). Note that discourse markers can be considered as noisy labels for various semantic tasks, such as entailment (c = *therefore*), subjectivity analysis (c = *personally*) or sentiment analysis (c = *sadly*). More generally, discourse markers indicate how a sentence contributes to the meaning of a text, and they provide an appealing supervision signal for sentence representation learning based on language use.

A wide variety of discourse usages would be desirable in order to learn general sentence representations. Extensive research in linguistics has resulted in elaborate discourse marker inventories for many languages.[2] These inventories were created by manual corpus exploration or annotation of small-scale corpora: the largest annotated corpus, the English PDTB consists of a few tens of thousand examples, and provides a list of about 100 discourse markers, organized in a number of categories.

Previous work on sentence representation learning with discourse markers makes use of even more restricted sets of discourse markers, as shown in table 2. Jernite et al. (2017) use 9 categories as labels, accounting for 40 discourse markers in total. It should be noted that the aggregate labels do not allow for any fine-grained distinctions; for instance, the TIME label includes both *now* and *next*, which is likely to impair the supervision. Moreover, discourse markers may be ambiguous; for example *now* can be used to express contrast. On the other hand, Nie et al. (2017) make use of 15 discourse markers, 5 of which are accounting for more than 80% of their training data. In order to ensure the quality of their examples, they only select pairs matching a dependency pattern manually specified for each marker. As such, both of these studies use a restricted or impoverished set of discourse markers; they also both use the BookCorpus dataset, whose size ($4.7M$ sentences that contain a discourse marker, according to Nie et al., 2017) is prohibitively small for the prediction of rare discourse markers.

In this work we use web-scale data in order to explore the prediction of a wide range of discourse markers, with more balanced frequency distributions, along with application to sentence representation learning. We use English data for the experiments, but the same method could be applied to any language that bears a typological resemblance with regard to discourse usage, and has sufficient amounts of textual data available (e.g. German or French). Inspired by recent work (Dasgupta et al., 2018; Poliak et al., 2018; Levy et al., 2018; Glockner et al., 2018) on the unexpected properties of recent manually labelled datasets (e.g. SNLI), we will also analyze our dataset to check whether labels are easy to guess, and whether the proposed model architectures make use of high-level reasoning for their predictions. Our contributions are as follows:

- we propose a simple and efficient method to discover new discourse markers, and present a curated list of 174 markers for English;
- we provide evidence that many connectives can be predicted with only simple lexical features;
- we investigate whether relation prediction actually makes use of the relation between sentences;
- we carry out extensive experiments based on the Infersent/SentEval framework.

2 Discovering discourse markers

2.1 Rationale

Our goal is thus to capture semantic aspects of sentences by means of distributional observations. For our training signal, we aim at something more evolved than just plain contextual co-occurrence,

Table 2: Discourse markers or classes used by previous work on unsupervised representation learning

but simpler than a full-fledged encoder-decoder *à la* Skip-Thought. In that respect, discourse relations are an interesting compromise, if we can reliably extract them in large quantities. This objective is shared with semi-supervised approaches to discourse relation prediction, where automatically extracted explicit instances feed a model targetting implicit instances (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2008; Pitler and Nenkova, 2009; Rutherford and Xue, 2015). In this perspective, it is important to collect unambiguous instances of potential discourse markers. To do so, previous work used heuristics based on specific constructs, especially syntactic patterns for intra-sentential relations, based on a fixed list of manually collected discourse markers. Since we focus on sentence representations, we limit ourselves to discourse arguments that are well-formed sentences, thus also avoiding clause segmentation issues.

Following a heuristic from Rutherford and Xue (2015), also considered by Malmi et al. (2018) and Jernite et al. (2017), we collect pairs of sentences (s_1, s_2) where s_2 starts with marker c. We only consider the case where c is a single word, as detecting longer adverbial constructions is more difficult. We remove c from the beginning of s_2 and call the resulting sentence s_2'. Malmi et al. (2018) make use of a list of the 80 most frequent discourse markers in the PDTB in order to extract suitable sentence pairs. We stay faithful to Rutherford and Xue (2015)'s heuristic, as opposed to Malmi et al. (2018); Jernite et al. (2017): if s_2 starts with c followed by a comma, and c is an adverbial or a conjunction, then it is a suitable candidate. By limiting ourselves to sentences that contain a comma, we are likely to ensure that s_2' is meaningful and grammatical. As opposed to all the cited work mentioned above, we do not restrict the pattern to a known list of markers, but try to collect new reliable cues.

This pattern is decisively restrictive, since discourse markers often appear at the clausal level (e.g. *I did it but now I regret it*). But clauses are not meant to be self contained, and it is not obvious that they should be included in a dataset for *sentence* representation learning. At the same time, one could easily think of cases where c is not a discourse marker, e.g. (s_1, s_2)= ("It's cold.", "Very, very cold."). However, these uses might be easily predicted with shallow language models. In the next section, we use the proposed method for the discovery of discourse markers, and we investigate whether the resulting dataset leads to improved model performance.

2.2 Methodology

We use sentences from the Depcc corpus (Panchenko et al., 2017), which consists of English texts harvested from commoncrawl web data. We sample 8.5 billion consecutive sentence pairs from the corpus. We keep 53% of sentence pairs that contain between 3 and 32 words, have a high probability of being English ($> 75\%$) using FastText langid from Grave et al. (2018), have balanced parentheses and quotes, and are mostly lowercase. We use NLTK (Bird et al., 2009) as sentence tokenizer and NLTK PerceptronTagger as part of speech tagger for adverb recognition. In addition to our automatically discovered candidate set, we also include all (not necessarily adverbial) PDTB discourse markers that are not induced by our method. Taking this into account, 3.77% of sentence pairs contained a discourse marker candidate, which is about 170M sentence pairs. An example from the dataset is shown in table 1. We only keep pairs in which the discourse marker occurs at least 10K times. We also subsample pairs so that the maximum occurrence count of a discourse marker is 200K. The resulting dataset con-

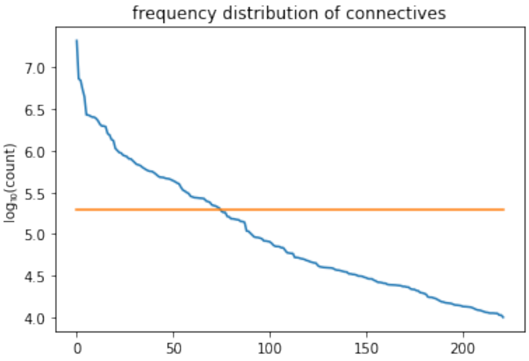

Figure 1: Frequency distribution of candidate discourse markers; the horizontal line indicates the subsampling threshold.

tains 19M pairs.

We discovered 243 discourse marker candidates. Figure 1 shows their frequency distributions. As expected, the most frequent markers dominate the training data, but when a wide range of markers is included, the rare ones still contribute up to millions of training instances. Out of the 42 single word PDTB markers that precede a comma, 31 were found by our rule. Some markers are missing because of NLTK errors, which mainly result from morphological issues.[3]

2.3 Controlling for shallow features

As previously noted, some candidates discovered by our rule may not be actual discourse markers. In order to discard them, we put forward the hypothesis that actual discourse markers cannot be predicted with shallow lexical features. Inspired by Gururangan et al. (2018), we use a Fasttext classifier (Joulin et al., 2016) in order to predict c from s_2'. The Fasttext classifier predicts labels from an average of word embeddings fed to a linear classifier. We split the dataset in 5 folds, and we predict markers for each fold, while training on the remaining folds. We use a single epoch, randomly initialized vectors of size 100 (that can be unigrams, bigrams or trigrams) and a learning rate of 0.5.

In addition, we predict c from the concatenation of s_1 and s_2' (using separate word representations for each case). One might assume that the prediction of c in this case relies on the interaction between s_1 and s_2; however, the features of s_1 and s_2 within Fasttext's setup only interact additively, which means that the classification most likely relies on individual cues in the separate sentences, rather than on their combination. In order to test this hypothesis, we introduce a *random shuffle* operation: for each example (s_1, s_2', c), s_2' is replaced by a random sentence from a pair that is equally linked by c (we perform this operation separately in train and test sets).

Table 3 indicates that shallow lexical features indeed yield relatively high prediction rates. Moreover, the shuffle operation indeed increases accuracy, which corroborates the hypothesis that classification with shallow features relies on individual cues from separate sentences, rather than their combination.

---

[3] For instance, *lovely* is tagged as an adverb because of its suffix, while *besides* was never tagged as an adverb

Interestingly, the two most predictable candidates are not discourse markers. Upon inspection of harvested pairs, we noticed that even legitimate discourse markers can be guessed with relatively simple heuristics in numerous examples. For example, $c =$ *thirdly* is very likely to occur if s_1 contains *secondly*. We use this information to optionally filter out such simple instances, as described in the next section.

2.4 Dataset variations

In the following, we call our method *Discovery*. We create several variations of the sentence pairs dataset. In *DiscoveryHard*, we remove examples where the candidate marker was among the top 5 predictions in our Fasttext shallow model and keep only the 174 candidate markers with a frequency of at least $10k$. Instances are then sampled randomly so that each marker appears exactly $10k$ times in the dataset.

Subsequently, the resulting set of discourse markers is also used in the other variations of our dataset. *DiscoveryBase* designates the dataset for which examples predicted with the Fasttext model were not removed. In order to measure the extent to which the model makes use of the relation between s_1 and s_2', we also create a *DiscoveryShuffled* dataset, which is the *DiscoveryBase* dataset subjected to the *random shuffle* operation described previously. To isolate the contribution of our discovery method, the dataset *DiscoveryAdv* discards all discourse markers from PDTB that were not found by our method. Also, in order to measure the impact of label diversity, *Discovery10* uses $174k$ examples for each of the 10 most frequent markers,[4] thus totalling as many instances as *DiscoveryBase*. Finally, *DiscoveryBig* contains almost twice as many instances as *DiscoveryBase*, i.e. $20k$ instances for each discourse marker (although, for a limited number of markers, the number of instances is slightly lower due to data sparseness).

3 Evaluation of sentence representation learning

3.1 Setup

Our goal is to evaluate the effect of using our various training datasets on sentence encoding, given encoders of equivalent capacity and similar setups. Thus, we follow the exact setup of Infersent (Conneau et al., 2017), also used in the Dissent (Malmi et al., 2018) model: we learn to encode sentences into h with a bi-directional LSTM sentence encoder using element-wise max pooling over time. The dimension size of h is 4096. Word embeddings are fixed GloVe embeddings with 300 dimensions, trained on Common Crawl 840B.[5] A sentence pair (s_1, s_2) is represented with $[h_1, h_2, h_1 \odot h_2, |h_2 - h_1|]$,[6] which is fed to a softmax in order to predict a marker c. Our datasets are split in 90% train, 5% validation, and 5% test. Optimization is done with SGD (learning rate is initialized at 0.1, decayed by 1% at each epoch and by 80% if validation accuracy decreases; learning stops when learning rate is below 10^{-5} and the best model on training task validation loss is used for evaluation; gradient is clipped when its norm exceeds 5). Once the sentence encoder has been trained on a base task, the resulting sentence embeddings are tested with the SentEval library (Conneau et al., 2017).

We evaluate the different variations of our dataset we described above in order to analyze their effect, and compare them to a number of existing models. Table 7 displays the tasks used for evaluation. For further analysis, table 9 displays the result of *Linguistic Probing* using the method by Conneau et al. (2018). Although these tasks are primarily designed for understanding the content of embeddings, they also focus on aspects that are desirable to perform well in general semantic tasks (e.g. prediction of tense, or number of object).

3.2 Results

Table 6 gives an overview of transfer learning evaluation, also comparing to other supervised and unsupervised approaches. Note that we outperform DisSent on all tasks except TREC[7] with less than half the amount of training examples. In addition, our approach is arguably simpler and faster.

MTL (Subramanian et al., 2018) only achieves stronger results than our method on the MRPC and SICK tasks. The MTL model uses $124M$ training examples with an elaborate multi-task setup, training on $45M$ sentences with manual translation, $1M$ pairs from SNLI/MNLI, $4M$ parse trees of sentences, and $74M$ consecutive sentence pairs.

Table 6: SentEval evaluation results with our models trained on various datasets. The first two models are supervised, the other ones unsupervised. All scores are accuracy percentages, except SICK-R, which is Pearson correlation percentage. InferSent is from Conneau et al. (2017), MTL is the multi-task learning based model from Subramanian et al. (2018). Evaluation tasks are described in table 7, and N denotes the number of examples for each dataset (in millions). Dissent is from Nie et al. (2017), QuickThought is from Logeswaran and Lee (2018) with fixed embeddings configuration. The best result per task appears in bold, the best result for unsupervised setups is underlined.

The model also fine-tunes word embeddings in order to achieve a higher capacity. It is therefore remarkable that our model outperforms it on many tasks. Besides, MTL is not a direct competitor to our approach since its main contribution is its multi-task setup, and it could benefit from using our training examples.

Our best model rivals (and indeed often outperforms) QuickThought on all tasks, except relatedness (SICK-R). QuickThought's training task is to predict whether two sentences are contiguous, which might incentivize the model to perform well on a relatedness task. We also outperform InferSent on many tasks except entailment and relatedness. Entailment prediction is the explicit training signal for Infersent.

To help the analysis of our different model variations, table 8 displays the test scores on each dataset for the original training task. It also shows the related PDTB implicit relation prediction scores. The PDTB is annotated with a hierarchy of relations, with 5 classes at level 1 (including the EntRel relation), and 16 at level 2 (with one relation absent from the test). It is interesting to see that this form of simple semi-supervised learning for implicit relation prediction performs quite well, especially for fine-grained relations, as the best model slightly beats the best current dedicated model, listed at 40.9% in Xue et al. (2017).

DiscoveryHard scores lower on its training task than *DiscoveryBase*, and it also performs worse on transfer learning tasks. This makes sense, since lexical features are important to solve the evaluation tasks. Our initial hypothesis was that more difficult instances might force the model to use higher-level reasoning, but this does not seem to be the case. More surprisingly, preventing the encoders to use the relationship between sentences, as in *DiscoveryShuffled*, does not substantially hurt the transfer performance, which remains on average higher than Nie et al. (2017). Additionally, our models score well on linguistic probing tasks. They outperform Infersent on all tasks, which seems to contradict the claim that SNLI data allows for learning of *universal* sentence representations (Conneau et al., 2017). And a final interesting outcome is that the diversity of markers (e.g. using *DiscoveryBase* instead of *Discovery10*) seems to be important for good performance on those tasks, since *Discovery10* has the worst overall performance on average.

name	N	task	C

Table 8: Test results (accuracy) on implicit discursive relation prediction task (PDTB relations level 1 and 2, i.e coarse-grained and fine-grained) and training tasks $\mathcal{T}$. Note that scores for $\mathcal{T}$ are not comparable since the test set changes for each version of the dataset.

3.3 Visualisation

The softmax weights learned during the training phase can be interpreted as embeddings for the markers themselves, and used to visualize their relationships. Figure 2 shows a TSNE (van der Maaten and Hinton, 2008) plot of the markers' representations. Proximity in the feature space seems to reflect semantic similarity (e.g. *usually/normally*). In addition, the markers we discovered, colored in red, blend with the PDTB markers (depicted in black). It would be interesting to cluster markers in order to empirically define discourse relations, but we leave this for future work.

4 Related work

Though discourse marker prediction in itself is an interesting and useful task (Malmi et al., 2017), discourse markers have often been used as a training cue in order to improve implicit relation prediction (Marcu and Echihabi, 2001; Sporleder and Lascarides, 2005; Zhou et al., 2010; Braud and Denis, 2016). This approach has been extended to general representation learning by Jernite et al. (2017)—although with empirically unconvincing results, which might be attributed to an inappropriate training/evaluation set-up, or the use of a limited number of broad categories instead of actual discourse markers. Nie et al. (2017) used the more standard InferSent framework and obtained better results, although they were still outperformed by QuickThought (Logeswaran and Lee, 2018),

	BShift	CoordInv	Depth	ObjNum	SubjNum	OddM	Tense	TC	WC	AVG

Table 9: Accuracy of various models on linguistic probing tasks using logistic regression on SentEval. BShift is detection of token inversion. CoordInv is detection of clause inversion. ObjNum/SubjNum is prediction of the number of object resp. subject. Tense is prediction of the main verb tense. Depth is prediction of parse tree depth. TC is detection of common sequences of constituents. WC is prediction of words contained in the sentence. OddM is detection of random replacement of verbs/nouns by other verbs/nouns. AVG is the average score of those tasks for each model. For more details see Conneau et al. (2018). SkipThought and Infersent results come from Perone et al. (2018), QuickThought results come from Brahma (2018).

which uses a much simpler training task. Both of these rely on pre-established lists of discourse markers provided by the PDTB, and both perform a manual annotation for each marker—Nie et al. (2017) uses dependency patterns, while Jernite et al. (2017) uses broad discourse categories. Our work is the first to automatically discover discourse markers from text.

More generally, various automatically extracted training signals have been used for unsupervised learning tasks. Hashtags (Felbo et al., 2017) have been sucessfully exploited in order to learn sentiment analysis from unlabelled tweets, but their availability is mainly limited to the microblogging domain. Language modeling provides a general training signal for representation learning, even though there is no obvious way to derive sentence representations from language models. BERT (Devlin et al., 2018) currently holds the best results in transfer learning based on language modeling, but it relies on sentence pair classification in order to compute sentence embeddings, and it makes use of a simple sentence contiguity detection task (like QuickThought); this task does not seem challenging enough since BERT reportedly achieves 98% detection accuracy. Phang et al. (2018) showed that the use of SNLI datasets yields significant gains for the sentence embeddings from Radford (2018), which are based on language modeling.

For the analysis of our models, we draw inspiration from critical work on Natural Language Inference datasets (Dasgupta et al., 2018; Levy et al., 2018). Gururangan et al. (2018); Poliak et al. (2018) show that baseline models that disregard the hypothesis yield good results on SNLI, which suggests that the model does not perform the high level reasoning we would expect in order to predict the correct label. They attribute this effect to bias in human annotations. In this work, we show that this issue is not inherent to human labeled data, and propose the *shuffle* perturbation in order to measure to what extent the relationship between sentences is used.

5 Conclusion

In this paper, we introduce a novel and efficient method to automatically discover discourse markers from text, and we use the resulting set of candidate markers for the construction of an extensive dataset for semi-supervised sentence representation learning. A number of dataset variations are evaluated on a wide range of transfer learning tasks (as well as implicit discourse recognition) and a comparison with existing models indicates that our approach yields state of the art results on the bulk of these tasks. Additionally, our analysis shows that removing 'simple' examples is detrimental to transfer results, while preventing the model to exploit the relationship between sentences has a negligible effect. This leads us to believe that, even though our approach reaches state of the art results, there is still room for improvement: models that adequately exploit the relationship between sentences would be better at leveraging the supervision of our dataset, and could yield even better sentence representations. In future work, we also aim to increase the coverage of our method. For instance, we can make use of more lenient patterns that capture an even wider range of discourse markers, such as multi-word markerse.

Abstract

With the rapid development in deep learning, deep neural networks have been widely adopted in many real-life natural language applications. Under deep neural networks, a predefined vocabulary is required to vectorize text inputs. The canonical approach to select predefined vocabulary is based on the word frequency, where a threshold is selected to cut off the long tail distribution. However, we observed that such a simple approach could easily lead to under-sized vocabulary or oversized vocabulary issues. Therefore, we are interested in understanding how the end-task classification accuracy is related to the vocabulary size and what is the minimum required vocabulary size to achieve a specific performance. In this paper, we provide a more sophisticated variational vocabulary dropout (VVD) based on variational dropout to perform vocabulary selection, which can intelligently select the subset of the vocabulary to achieve the required performance. To evaluate different algorithms on the newly proposed vocabulary selection problem, we propose two new metrics: Area Under Accuracy-Vocab Curve and Vocab Size under X% Accuracy Drop. Through extensive experiments on various NLP classification tasks, our variational framework is shown to significantly outperform the frequency-based and other selection baselines on these metrics.

1 Introduction

Over the past decade, deep neural networks have become arguably the most popular model choice for a vast number of natural language processing (NLP) tasks and have constantly been delivering state-of-the-art results. Because neural network models assume continuous data, to apply a neural network on any text data, the first step is to vectorize the discrete text input with a word embedding matrix through look-up operation, which in turn assumes a pre-defined vocabulary set. For many NLP tasks, the vocabulary size can easily go up to the order of tens of thousands, which potentially makes the word embedding the largest portion of the trainable parameters. For example, a document classification task like AG-news (Zhang et al., 2015) can include up to 60K unique words, with the embedding matrix accounting for 97.6% of the trainable parameters (Table 1), which leads to under-representation of the neural networks' own parameters.

Cutoff Freq.	Vocab	Remain Vocab	#Emb	#CNN	#Emb Ratio
1	60K	100%	15M	0.36M	97.6%
5	40K	21.7%	10M	0.36M	95.6%
10	24K	13%	6M	0.36M	94.3%
20	14K	9.4%	3.5M	0.36M	90%
100	4K	2.7%	1M	0.36M	73%

Table 1: Illustration of the frequency-based vocabulary selection heuristic on a typical CNN-based document classification model (Section 4.1). #Emb is the number of parameters in the word embedding matrix (256 dimensions), and #CNN is that in the CNN model.

Intuitively, using the full or very large vocabulary are neither economical, as it limits model applicability on computation- or memory-constrained scenarios (Yogatama et al., 2015; Faruqui et al., 2015), nor necessary, as many words may contribute little to the end task and could have been safely removed from the vocabulary. Therefore, how to select the best vocabulary is a problem of both theoretical and practical interests. Somewhat surprisingly, this *vocabulary selection* problem is largely under-addressed in the literature: The *de facto* standard practice is to do

Proceedings of NAACL-HLT 2019, pages 3487–3497
Minneapolis, Minnesota, June 2 - June 7, 2019.

frequency-based cutoff (Luong et al., 2015; Kim, 2014), and only retain the words more frequent than a certain threshold (Table 1). Although this simple heuristic has demonstrated strong empirical performance, its task-agnostic nature implies that likely it is not the optimal strategy for many tasks (or any task). Task-aware vocabulary selection strategies and a systematic comparison of different strategies are still lacking.

In this work, we present the first systematic study of the vocabulary selection problem. Our study will be based on text classification tasks, a broad family of NLP tasks including document classification (DC), natural language inference (NLI), natural language understanding in dialog systems (NLU), etc. Specifically, we aim to answer the following questions:

1. *How important a role does the vocabulary selection algorithm play in text classification?*
2. *How to dramatically reduce the vocabulary size while retaining the accuracy?*

The rest of the paper is organized as follows: We first formally define the vocabulary selection problem (subsection 2.1) and present a quantitative study on classification accuracy with different vocabulary selections to showcase its importance in the end task (subsection 2.2). We also propose two new metrics for evaluating the performance of vocabulary selection in text classification tasks (subsection 2.3). We then propose a novel, task-aware vocabulary selection algorithm called *Varitional Vocabulary Dropout (VVD)* (section 3) which draws on the idea of variational dropout (Kingma et al., 2015): If we learn a dropout probability p_w for each given word w in the vocabulary $\mathbb{V}$ during the model training on a given task, the learned dropout probabilities p_w will imply the importance of word w to the end task and can, therefore, be leveraged for vocabulary selection. We propose to infer the latent dropout probabilities under a Bayesian inference framework. During test time, we select the sub vocabulary $\hat{\mathbb{V}}$ by only retaining words with dropout probability lower than a certain threshold. For any words deselected using VVD, we will simply regard them as a special token with null vector representation $[0, 0, \cdots, 0]$. Please note that our proposed algorithm needs to re-train a word embedding matrix, thus it is tangential to the research of pre-trained word embedding like Word2Vec (Mikolov et al., 2013) or Glove (Pennington et al., 2014) though we can use them to initialize our embedding.

We conduct comprehensive experiments to evaluate the performance of VVD (section 4) on different end classification tasks. Specifically, we compare against an array of strong baseline selection algorithms, including the frequency-based algorithm (Luong et al., 2015), TF-IDF algorithm (Ramos et al., 2003), and structure lasso algorithm (Friedman et al., 2010), and demonstrate that it can consistently outperform these competing algorithms by a remarkable margin. To show that the conclusions are widely held, our evaluation is based on a wide range of text classification tasks and datasets with different neural networks including Convolutional Neural Network (CNN) (Kim, 2014), Bi-directional Long-Short Term Memory (BiLSTM) (Bahdanau et al., 2014) and Enhanced LSTM (ESIM) (Chen et al., 2017). In summary, our contributions are three-fold:

1. We formally define the vocabulary selection problem, demonstrate its importance, and propose new evaluation metrics for vocabulary selection in text classification tasks.
2. We propose a novel vocabulary selection algorithm based on variational dropout by re-formulating text classification under the Bayesian inference framework. The code will be released in Github[1].
3. We conduct comprehensive experiments to demonstrate the superiority of the proposed vocabulary selection algorithm over a number of strong baselines.

2 Vocabulary Selection

2.1 Problem Definition

We now formally define the problem setting and introduce the notations for our problem. Conventionally, we assume the neural classification model vectorizes the discrete language input into a vector representation via an embedding matrix $W \in \mathbb{R}^{V*D}$, where V denotes the size of the vocabulary, and D denotes the vector dimension. The embedding is associated with a pre-defined word-to-index dictionary $\mathbb{V} = \{w_i : i | 1 \leq i \leq V\}$ where w_i denotes a literal word corresponding to i_{th} row in the embedding matrix. The embedding matrix W covers the subset of a vocabulary of interests for a particular NLP task, note that the value of V

---

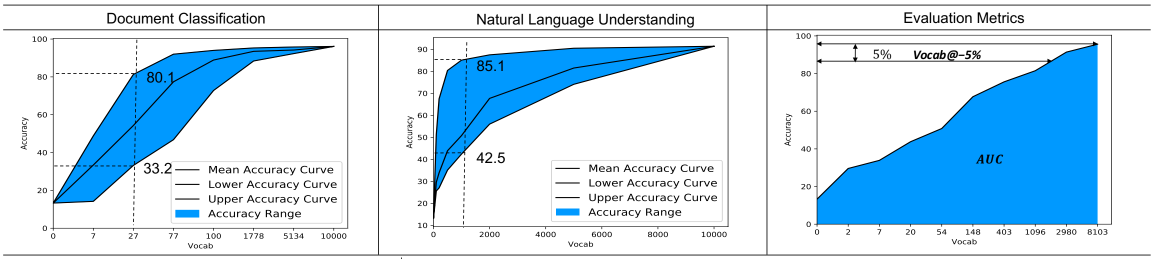

Figure 1: Monte-Carlo simulation on vocabulary selection. Left: CNN-based document classification on AG-news dataset. Middle: Natural language understanding on Snips dataset. Right: Metrics for vocabulary selection.

is known to be very large due to the rich variations in human languages. Here we showcase the embedding matrix size of a popular text classification model[2] on AG-news dataset (Zhang et al., 2015) in Table 1. From which we can easily observe that the embedding matrix is commonly occupying most of the parameter capacity, which could be the bottleneck in many real-world applications with limited computation resources.

In order to alleviate such redundancy problem and make embedding matrix as efficient as possible, we are particularly interested in discovering the minimum row-sized embedding $\hat{W}$ to achieve nearly promising performance as using the full row-sized embedding W. More formally, we define the our problem as follows:

$$\begin{aligned} &\underset{\hat{W},\hat{\theta}}{\operatorname{argmin}} \#Row(\hat{W}) \\ s.t. \quad & Acc(f_{\hat{\theta}}(x;\hat{W}),y) - Acc(f_{\theta}(x;W),y) \leq \epsilon \end{aligned} \tag{1}$$

where #Row is a the number of rows in the matrix $\hat{W}$, f_θ is the learned neural model with parameter θ to predict the class given the inputs x, Acc is the function which measure accuracy between model prediction and y (reference output), and ϵ is the tolerable performance drop after vocabulary selection. It is worth noting that here θ includes all the parameter set of the neural network except embedding matrix W. For each vocabulary selection algorithm $\mathcal{A}$, we propose to draw its characteristic curve $Acc(f_{\hat{\theta}}(x;\hat{W}),y) = g_{\mathcal{A}}(\#Row(\hat{W}))$ to understand the relationship between the vocabulary capacity and classification accuracy, which we call as (characteristic) accuracy-vocab curve throughout our paper.

2.2 Importance of Vocabulary Selection

In order to investigate the importance of the role played by the vocabulary selection algorithm, we design a Monte-Carlo simulation strategy to approximate accuracy's lower bound and upper bound of a given vocabulary size reached by a possible selection algorithm $\mathcal{A}$. More specifically, for a given vocabulary size of $\hat{V}$, there exist $\binom{V}{\hat{V}}$ algorithms which can select distinct vocabulary subset $\hat{\mathbb{V}}$ from the full vocabulary $\mathbb{V}$. Directly enumerating these possibilities are impossible, we instead propose to use a Monte-Carlo vocabulary selection strategy which can randomly pick vocabulary subset $\hat{\mathbb{V}}$ to simulate the possible selection algorithms by running it N times. After simulation, we obtain various point estimations $(Acc_1, \cdots, Acc_N|\hat{V})$ at each given $\hat{V}$ and depict the point estimates in Figure 1 to approximately visualize the upper and lower bound of the accuracy-vocab curve. From Figure 1, we can easily observe that the accuracy range under a limited-vocabulary is extremely large, when the budget $\hat{V}$ increases, the gap gradually shrinks. For example, for document classification with a budget of 1000, a selection algorithm $\mathcal{A}$ can yield a potential accuracy ranging from 42.5 to 85.1, while for natural language understanding task with a budget of 27, a selection algorithm $\mathcal{A}$ can yield a potential accuracy ranging from 33.2 to 80.1. Such a Monte-Carlo simulation study has demonstrated the significance of vocabulary selection strategy in NLP tasks and also implicate the enormous potential of an optimal vocabulary selection algorithm.

2.3 Evaluation Metrics

In order to evaluate how well a given selection algorithm $\mathcal{A}$ performs, we propose evaluation metrics as depicted in Figure 1 by quantitatively studying its characteristic accuracy-vocab curve. These metrics namely Area Under Curve (AUC) and Vocab@-X% separately measure the vocabulary selection performance globally and locally.

---

[2] `https://github.com/dennybritz/cnn-text-classification-tf`

Specifically, AUC computes enclosed area by the curve, which gives an overview of how well the vocabulary selection algorithm performs. In comparison, Vocab@-X% computes the minimum vocabulary size required if X% performance drop is allowed, which straightforwardly represents how large vocabulary is required to achieve a given accuracy. For the local evaluation metric, we mainly consider Vocab@-3% and Vocab@-5%. However, we observe that directly computing AUC lays too much emphasis on the large-vocabulary region, thus unable to represent an algorithm's selection capability under the low-vocabulary conditions. Therefore, we propose to take the logarithm of the vocabulary size and then compute the normalized enclosed area by:

$$AUC = \frac{\int_{\hat{V}} Acc(\log(\hat{V})) d \log(\hat{V})}{\int_{\hat{V}} Acc(V) d \log(\hat{V})} \tag{2}$$

It is worth noting that Vocab@-X% takes value from range $[0, V]$ with smaller values indicate better performance. Since AUC is normalized by Acc(V), it takes value from range $[0, 1]$ regardless of the classification error.

3 Our Method

Inspired by DNN dropout (Srivastava et al., 2014; Wang and Manning, 2013), we propose to tackle the vocabulary selection problem from word-level dropout perspective, where we assume each word w_i (an integer index) is associated with its characteristic dropout rate p_i, which represents the probability of being replaced with an empty placeholder, specifically, higher dropout probability indicates less loss suffered from removing it from the vocabulary. Hence, the original optimization problem in Equation 1 can be thought of as inferring the latent dropout probability vector $\mathbf{p} = [p_1, \cdots, p_V]$. The overview of our philosophy is depicted in Figure 2, where we associate with each row of the embedding matrix a dropout probability and then re-train the complete system, which grasps how much contribution each word from the vocabulary makes to the end NLP task and remove those "less contributory" words from the vocabulary without hurting the performance.

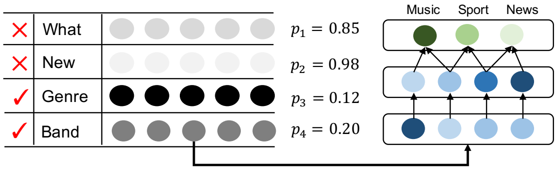

Figure 2: Variational dropout in classification models, "New" and "What" can be safely removed without harming performance due to large dropout probability.

3.1 Bernouli Dropout

Here we first assume that the neural network vectorizes the discrete inputs with an embedding matrix W to project given words x into vector space $\mathbb{R}^D$, and then propose to add random dropout noise into the embedding input to simulate the dropout process as follows:

$$E(x|\mathbf{b}) = (\mathbf{b} \odot OneHot(x)) \cdot W \tag{3}$$

where $OneHot$ is a function to transform a word x into its one-hot form $OneHot(x) \in \mathbb{R}^V$, and $\mathbf{b} \in \mathbb{R}^V$ is the Bernouli dropout noise with $b_i \sim Bern(1 - p_i)$. The embedding output vector $E(x|\mathbf{b})$ is computed with a given embedding matrix W under a sampled Bernouli vector $\mathbf{b}$. In order to infer the latent Bernouli distribution with parameters $\mathbf{p}$ under the Bayesian framework where training pairs $(\mathbf{x} = x_1 \cdots x_n, y)$ are given as the evidence, we first define an objective function as $\mathcal{L}(f_\theta(\mathbf{x}), y)$ and then derive its lower bound as follows (with $\bar{\mathbf{p}} = 1 - \mathbf{p}$):

$$\begin{aligned}
&\log \mathcal{L}(f_\theta(\mathbf{x}), y) = \log \int_{\mathbf{b}} \mathcal{L}(f_\theta(E(\mathbf{x}|\mathbf{b})), y) \mathcal{P}(\mathbf{b}) d\mathbf{b} \\
\geq &\mathop{\mathbb{E}}_{\mathbf{b} \sim Bern(\bar{\mathbf{p}})} [\log \mathcal{L}(f_\theta(E(\mathbf{x}|\mathbf{b})), y)] - KL(Bern(\bar{\mathbf{p}}) || \mathcal{P}(\mathbf{b})) \\
= &\mathcal{L}(W; \theta)
\end{aligned}$$

where $\mathcal{P}(\mathbf{b})$ is the prior distribution, and $Bern(\bar{\mathbf{p}})$ denotes the Bernouli approximate posterior with parameter $\mathbf{p}$. Here we use $E(\mathbf{x})$ as the simplied form of $\{E(x_1), \cdots, E(x_n)\}$, we separate the text classification model's parameters θ with the embedding parameters W and assume the classification model f_θ directly takes embedding E as input.

3.2 Gaussian Relaxation

However, the Bernouli distribution is hard to reparameterize, where we need to enumerate 2^V different values to compute the expectation over the stochastic dropout vector $\mathbf{b}$. Therefore, we follow Wang and Manning (2013) to use a continuous Gaussian approximation, where the Bernouli noise $\mathbf{b}$ is replaced by a Gaussian noise $\mathbf{z}$:

$$E(x|z) = (\mathbf{z} \odot OneHot(x)) \cdot W \tag{4}$$

where $\mathbf{z} \in \mathbb{R}^V$ follows Gaussian distribution $z_i \sim \mathcal{N}(1, \alpha_i = \frac{p_i}{1-p_i})$. It is worth noting that

α and p are one-to-one corresponded, and α is a monotonously increasing function of p. For more details, please refer to Wang and Manning (2013). Based on such approximation, we can use α as dropout criteria, e.g. throw away words with α above a certain given threshold α_T. We further follow Louizos et al. (2017); Kingma et al. (2015); Molchanov et al. (2017) to re-interpret the input noise as the intrinsic stochasticity in the embedding weights B itself as follows:

$$E(x|z) = \mathit{OneHot}(x) \cdot B \tag{5}$$

where $B \in \mathbb{R}^{V*D}$ follows a multi-variate Gaussian distribution $B_{ij} \sim \mathcal{N}(\mu_{ij} = W_{ij}, \sigma_{ij}^2 = \alpha_i W_{ij}^2)$, where the random weights in each row has a tied variance/mean ratio α_i. Thus, we re-write the evidence lower bound as follows:

$$\begin{aligned}&\log \mathcal{L}(f_\theta(\mathbf{x}), y)) = \log \int_B \mathcal{L}(f_\theta(E(\mathbf{x}|z)), y))\mathcal{P}(B)dB \\ \geq &\mathop{\mathbb{E}}_{B\sim\mathcal{N}(\mu,\sigma)}[\log \mathcal{L}(f_\theta(E(\mathbf{x}|z)), y)] - KL(\mathcal{N}(\mu,\sigma)||\mathcal{P}(B)) \\ = &\mathcal{L}(B,\theta)\end{aligned}$$

where $\mathcal{P}(B)$ is the prior distribution and $\mathcal{N}(\mu, \sigma)$ denotes the Gaussian approximate posterior with parameters μ and σ. $\mathcal{L}(B, \theta)$ is used as the relaxed evidence lower bound of marginal log likelihood $\log \mathcal{L}(f_\theta(\mathbf{x}), y))$. Here, we follow Kingma et al. (2015); Louizos et al. (2017) to choose the prior distribution $\mathcal{P}(B)$ as the "improper log-scaled uniform distribution" to guarantee that the regularization term $D_{KL}(\mathcal{N}(\mu, \sigma)||\mathcal{P}(B))$ only depends on dropout ratio α, i.e. irrelevant to μ. Formally, we write the prior distribution as follows:

$$\mathcal{P}(\log |B_{ij}|) = \mathit{const} \rightarrow \mathcal{P}(|B_{ij}|) \propto \frac{1}{|B_{ij}|} \tag{6}$$

Since there exists no closed-form expression for such KL-divergence, we follow Louizos et al. (2017) to approximate it by the following formula with minimum variance:

$$\begin{aligned}D_{KL} = -k_1\sigma(k_2 + k_3 \log \alpha) + \frac{1}{2}\log(1 + \frac{1}{\alpha}) + k_1 \\ k_1 = 0.63576 \quad k_2 = 1.87320 \quad k_3 = 1.48695\end{aligned} \tag{7}$$

By adopting the improper log-uniform prior, more weights are compressed towards zero, and the KL-divergence is negatively correlated with dropout ratio α. Intuitively, the dropout ratio α_i is an redundancy indicator for i_{th} word in the vocabulary, with larger α_i meaning less performance loss caused by dropping i_{th} word. During training, we use re-parameterization trick (Kingma and Welling, 2013) to sample embedding weights from the normal distribution to reduce the Monte-Carlo variance in Bayesian training.

3.3 Vocabulary Selection

After optimization, we can obtain the dropout ratio α_i associated with each word w_i. We propose to select vocabulary subset based on the dropout ratio by using a threshold α_T. Therefore, the remaining vocabulary subset is described as follows:

$$\hat{\mathbb{V}} = \{w_i \in V | \alpha_i < \alpha_T\} \tag{8}$$

where we use $\hat{\mathbb{V}}$ to denote the subset vocabulary of interest, by adjusting α_T we are able to control the selected vocabulary size.

4 Experiments

We compare the proposed vocabulary selection algorithm against several strong baselines on a wide range of text classification tasks and datasets.

4.1 Datasets & Architectures

The main datasets we are using are listed in Table 2, which provides an overview of its description and capacities. Specifically, we follow (Zhang et al., 2015; Goo et al., 2018; Williams et al., 2018) to pre-process the document classification datasets, natural language understanding dataset and natural language inference dataset. We exactly replicate their experiment settings to make our method comparable with theirs. Our models is implemented with TensorFlow (Abadi et al., 2015). In order to evaluate the generalization ability of VVD selection algorithm in deep learning architectures, we study its performance under different established architectures (depicted in Figure 3). In natural language understanding, we use the most recent attention-based model for intention tracking (Goo et al., 2018), this model first uses BiLSTM recurrent network to leverage left-to-right and right-to-left context information to form the hidden representation, then computes self-attention weights to aggregate the hidden representation and predicts user intention. In document classification, we mainly follow the CNN architecture (Kim, 2014) to extract n-gram features and then aggregate these features to predict document category. In natural language inference, we follow the popular ESIM architecture (Williams et al., 2018; Chen et al., 2017) us-

Datasets	Task	Description	#Class	#Train	#Test

ing the Github implementation[3]. In this structure, three main components input encoding, local inference modeling, and inference composition are used to perform sequential inference and composition to simulate the interaction between premises and hypothesis. Note that, we do not apply the syntax-tree based LSTM proposed in (Chen et al., 2017) because we lost the parse tree (Klein and Manning, 2003) after the vocabulary compression, instead, we follow the simpler sequential LSTM framework without any syntax parse as input. Besides, the accuracy curve is obtained using the publicly available test split rather than the official online evaluation because we need to evaluate lots of times at different vocabulary capacity.

4.2 Baselines

Here we mainly consider the following baselines:

Frequency-based (task-agnostic) This approach is already extensively talked about in section 1, its basic idea is to rank the word based on its frequency and then set a threshold to cut off the long tail distribution.

TF-IDF (task-agnostic) This algorithm views the vocabulary selection as a retrieval problem (Ramos et al., 2003), where term frequency is viewed as the word frequency and document frequency is viewed as the number of sentences where such word appears. Here we follow the canonical TF-IDF approach to compute the retrieval score as follows:

$$tfidf(w, D) = tf(w)^{\lambda} * (\log \frac{N}{n_w})^{1-\lambda} \tag{9}$$

where $tf(w)$ denotes the word frequency, λ is the balancing factor, N denotes the number of sentences and n_w denotes the number of sentences in which w appears. We rank the whole vocabulary based on the $tfidf$ and cut off at given threshold.

Group Lasso (task-aware) This baseline aims to find intrinsic sparse structures (Liu et al., 2015; Park et al., 2016; Wen et al., 2016) by grouping each row of word embedding. The regularization objective is described as follows, which aims at finding the row-wise sparse structure:

$$\mathcal{L}_{reg} = \sum_i (\sum_j W_{ij}^2)^{\frac{1}{2}} \tag{10}$$

After optimized with the above regularization, we use a threshold-based selection strategy on the row-norm of embedding matrix, the selected vocabulary is described as $\hat{\mathbb{V}} = \{w_i \in \mathbb{V} | ||W_i||_2 > \beta_T\}$, where β_T is the threshold.

4.3 Experimental Results

Here we demonstrate our results in natural language understanding, document classification, and

Table 3: Experimental Results on various NLP tasks and datasets on the proposed metrics in subsection 2.3. Bold accuracy means the result is statistically significantly better than the competitors.

natural language inference separately in Table 3. From these tables, first of all, we can observe that VVD is able to maintain or even improve the reported accuracy on DC and NLU tasks, the accuracy of VVD is reported under dropping out the words with dropout rate larger than 0.95. The exception is in NLI (Williams et al., 2018), where the common approach uses GloVe (Pennington et al., 2014) for initialization, and we use random initialization, which makes our model fall slightly behind. It is worth noting that Frequency-based/TF-IDF methods are based on the model trained with cross entropy, while both Group-Lasso and VVD modify the objective function by adding additional regularization. It can be seen that VVD is performing very similar to the baseline models on DC and NLU tasks, while consistently outperforming the baseline methods (with random initialized embedding) on more challenging NLI and Yelp-Review tasks, that said, VVD can also be viewed as a generally effective regularization technique to sparsify features and alleviate the over-fitting problem in NLP tasks. In terms of the vocabulary selection capability, our proposed VVD is demonstrated to outperform the competing algorithms in terms of both AUC and Vocab@-X% metrics consistently over different datasets as shown in Table 3. In order to better understand the margin between VVD and frequency-based method, we plot their accuracy-vocab curves in Figure 4, from which we can observe that the accuracy curves start from nearly the same accuracy with the full vocabulary, by gradually decreasing the budget $\hat{V}$, VVD decreases at a much lower rate than the competing algorithms, which clearly reflects its superiority under limited-budget scenario. From the empirical result, we can conclude that: 1) the retrieval-based selection algorithm can yield

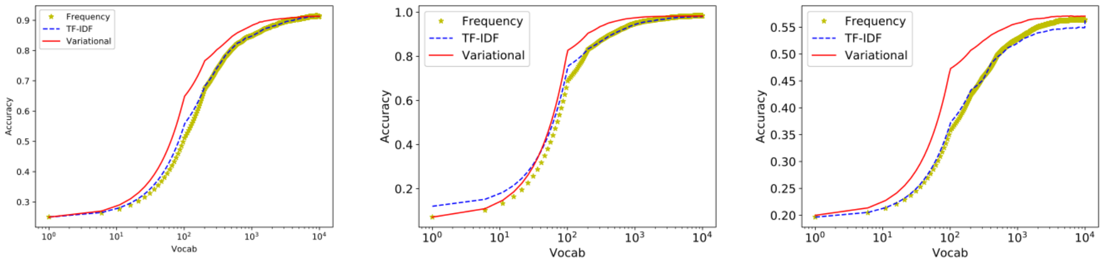

Figure 4: The accuracy-vocab curve of VVD, TF-IDF and frequency-based baseline, the datasets used are AG-news, DBPedia and Yelp-review respectively.

marginal improvement over the AUC metric, but the vocab@-X% metric deteriorates. 2) group-lasso and VVD algorithm directly considers the connection between each word and end classification accuracy; such task-awareness can greatly in improving both evaluation metrics. Here we show that NLU datasets are relatively simpler, which only involves detecting key words from human voice inputs to make decent decisions, a keyword vocabulary within 100 is already enough for promising accuracy. For DC datasets, which involve better inner-sentence and inter-sentence understanding, hundred-level vocabulary is required for most cases. NLI datasets involve more complicated reasoning and interaction, which requires a thousand-level vocabulary.

Figure 7: The vocabulary cloud of Snips NLU dataset.

Case Study To provide an overview of what words are selected, we depict the selection spectrum over different NLP tasks in Figure 5, from which we observe that most of the selected vocabulary are still from the high-frequency area to ensure coverage, which also explains why the frequency-based algorithm is already very strong. Furthermore, we use the Snips dataset (Coucke et al., 2018) to showcase the difference between the vocabularies selected by VVD and by frequency-based baseline. The main goal of this dataset is to understand the speaker's intention such as "BookRestaurant", "PlayMusic", and "SearchLocalEvent". We show the selected/unselected words by our algorithm in Figure 6 under a vocabulary budget of 100, it is observed that many non-informative but frequent functional words like "get", "with", and "five" are unselected while more task-related but less frequent words like "neighborhood", "search", "theatre" are selected. More vividly, we demonstrate the word cloud of the selected vocabulary of Snips (Coucke et al., 2018) in Figure 7.

4.4 Discussion

Here we will talk about some potential issues posed when training and evaluating VVD.

Training Speed Due to the stochasticity of VVD, the training of text classification takes longer than canonical cross entropy objective. More importantly, we observe that with the increase the full vocabulary size, the convergence time of VVD also increases sub-linearly but the convergence time of Cross Entropy remains quite consistent. We conjecture that this is due to the fact that the VVD algorithm has a heavier burden to infer the drop out the probability of the long tail words. Therefore, we propose to use a two-step vocabulary reduction to dramatically decrease VVD's training time, in the first step, we cut off the rare words without having any harm on the final accuracy, then we continue training with VVD on the shrunk vocabulary. By applying such a hybrid methodology, we are able to decrease the training time dramatically.

Evaluation Speed As we know, at each vocabulary point, the network needs to perform once evaluation on the whole test set. Therefore, it is not practical to draw each vocabulary size from 1 to V and perform V times of evaluation. Given the limited computational resources, we need to sample some vocabulary size and estimate the area under curve relying on only these points. Uniformly sampling the data points are proved wasteful, since when the accuracy curve will converge to a point very early, most of the sampled point is actually getting equivalent accuracy. Therefore, we propose to increase the interval exponentially to cover more samples at extremely low vocabulary size. For example, given the total vocabulary of 60000, the interval will be split into 1, 2, 4, 8, 24, 56, ..., 60K. Using such sampling method achieve a reasonably accurate estimation of ROC with only $O(log(|V|))$ sample points, which is affordable under many cases.

5 Related Work

Neural Network Compression In order to better apply the deep neural networks under limited-resource scenarios, much recent research has been performed to compress the model size and decrease the computation resources. In summary, there are mainly three directions, weight matrices approximation (Le et al., 2015; Tjandra et al., 2017), reducing the precision of the weights (Hubara et al., 2017; Han et al., 2015) and sparsification of the weight matrix (Wen et al., 2016). Another group of sparsification relies on the Bayesian inference framework (Molchanov et al., 2017; Neklyudov et al., 2017; Louizos et al., 2017). The main advantage of the Bayesian sparsification techniques is that they have a small number of hyperparameters compared to pruning-based methods. As stated in (Chirkova et al., 2018), Bayesian compression also leads to a higher sparsity level (Molchanov et al., 2017; Neklyudov et al., 2017; Louizos et al., 2017). Our proposed VVD is inspired by these predecessors to specifically tackle the vocabulary redundancy problem in NLP tasks.

Vocabulary Reduction An orthogonal line of research for dealing similar vocabulary redundancy problem is the character-based approaches to reduce vocabulary sise (Kim et al., 2016; Zhang et al., 2015; Costa-Jussà and Fonollosa, 2016; Lee et al., 2017), which decomposes the words into its characters forms for better handling open world inputs. However, these approaches are not applicable to character-free languages like Chinese and Japanese. Moreover, splitting words into characters incurs potential lose of word-level surface form, and thus needs more parameters at the neural network level to recover it to maintain the end task performance (Zhang et al., 2015), which contradicts with our initial motivation of compressing the neural network models for computation- or memory-constrained scenarios.

6 Conclusion

In this paper, we propose a vocabulary selection algorithm which can find sparsity in the vocabulary and dynamically decrease its size to contain only the useful words. Through our experiments, we have empirically demonstrated that the commonly adopted frequency-based vocabulary selection is already a very strong mechanism, further applying our proposed VVD can further improve the compression ratio. However, due to the time and memory complexity issues, our algorithm and evaluation are more suitable for classification-based application. In the future, we plan to investigate broader applications like summarizaion, translation, question answering, etc.

Abstract

The idea of *subword-based* word embeddings has been proposed in the literature, mainly for solving the out-of-vocabulary (OOV) word problem observed in standard *word-based* word embeddings. In this paper, we propose a method of reconstructing pre-trained word embeddings using subword information that can effectively represent a large number of subword embeddings in a considerably small fixed space. The key techniques of our method are twofold: memory-shared embeddings and a variant of the key-value-query self-attention mechanism. Our experiments show that our reconstructed subword-based embeddings can successfully imitate well-trained word embeddings in a small fixed space while preventing quality degradation across several linguistic benchmark datasets, and can simultaneously predict effective embeddings of OOV words. We also demonstrate the effectiveness of our reconstruction method when we apply them to downstream tasks[1].

1 Introduction

Pre-trained word embeddings (or embedding vectors), especially those trained on a vast amount of text data, such as the Common Crawl (CC) corpus[2], are now considered as highly beneficial, fundamental language resources. Typical examples of large, well-trained word embeddings are those trained on the CC corpus with 600 billion tokens by fastText (Bojanowski et al., 2017) and with 840 billion tokens by GloVe (Pennington et al., 2014), which we refer to as `fastText.600B`[3] and `GloVe.840B`[4], respectively. In fact, we often leverage such word embeddings to further improve the task performance of many natural language processing (NLP) tasks, such as constituency parsing (Suzuki et al., 2018; Gómez-Rodríguez and Vilares, 2018), discourse parsing (Yu et al., 2018), semantic parsing (Groschwitz et al., 2018; Dong and Lapata, 2018), and semantic role labeling (Strubell et al., 2018).

Despite their significant impact on the NLP community, well-trained word embeddings still have several disadvantages. In this paper, we focus on two issues surrounding well-trained word embeddings: i) the massive memory requirement and ii) the inapplicability of out-of-vocabulary (OOV) words. It is crucial to address such issues, especially when applying them to real-world open systems. The total number of embeddings (i.e., the total memory requirement of such word embeddings) often becomes unacceptably large, especially in limited-memory environments, including GPUs, since the vocabulary size is more than 2 million words, which require at least 2 gigabytes (GB) of memory for storage.

One possible solution is to merely discard (less important) words from the vocabulary, which can straightforwardly reduce the memory requirement. However, such a naive method can cause another well-known drawback regarding the inapplicability of OOV words. The applicability of OOV words is highly desirable in real systems since input words can be uncontrollably diverse. Therefore, there is a trade-off between the number of embedding vectors and the applicability of OOV words; thus, our goal is to investigate and develop a method that simultaneously has less memory requirement and high applicability of OOV words, which are both desirable properties for word embeddings in real-world open systems.

Recently, methods that leverage subword information have been proposed and have become popular for overcoming the OOV word issue. Con-

---

ceptually, the subword-based approach can cover all the words that can be constructed by a combination of subwords. Thus, the subword-based approach can greatly mitigate (or solve) the OOV word issue. We extend this approach to simultaneously enabling a reduction in the total number of embedding vectors through the reconstruction of word embeddings by subwords. The key techniques of our approach are twofold: memory-shared embeddings and a variant of the key-value-query (KVQ) self-attention mechanism (Vaswani et al., 2017). That is, our approach reconstructs well-trained word embeddings using a limited number of embedding vectors that are shared by all the subwords with an effective weighting calculated by the self-attention mechanism.

In our experiments, we show that our reconstructed subword-based embeddings can successfully imitate well-trained word embeddings, such as `fastText.600B` and `GloVe.840B`, in a small fixed space while preventing quality degradation across several linguistic benchmark datasets from word similarity and analogy tasks. We also demonstrate the effectiveness of our reconstructed embeddings for representing the embeddings of OOV words. Lastly, we confirm the performance of our reconstructed embeddings on several downstream tasks from the named entity recognition task and the textual entailment task.

2 Related Work

The OOV word issue is one of the widely discussed topics in word embedding research, which several researches have recently attempted to solve. For example, methods that leverage subword information, such as character N-grams (including character unigrams) (Bojanowski et al., 2017; Pinter et al., 2017; Zhao et al., 2018) and morphological features (Luong et al., 2013), have recently been discussed as means of constructing word embeddings that consider the applicability of OOV words. Moreover, Pilehvar and Collier (2017) have proposed a method called `SemLand`, which induces OOV word embeddings by leveraging external resources. Bahdanau et al. (2017) and Herbelot and Baroni (2017) have also proposed methods that estimate OOV word embeddings using an additional LSTM and leveraging a small additional dataset, respectively.

Among them, the study most closely related to ours is that of Zhao et al. (2018). Their basic idea is to reconstruct each pre-trained word embedding using a bag-of-character N-grams. We refer to their method as '`BoS`'. The motivation for reconstructing pre-trained word embeddings and utilizing character N-grams in our approach is substantially the same, however, an essential difference from `BoS` is that we additionally consider jointly reducing the total number of embedding vectors.

Another study that shares the same motivation and goal is that of Pinter et al. (2017). Their method, referred to as `MIMICK`, utilizes only character information instead of character N-grams by mixing it with more sophisticated neural networks, i.e., LSTM (Hochreiter and Schmidhuber, 1997). `MIMICK` can produce a more compact model than the original word embeddings. The important difference between their method and ours is that our method only consists of the subword embeddings, whereas their method consists of the character embeddings and several transformation matrices for calculating LSTMs. We compare their method with ours in our experiments and empirically show the effectiveness of our approach.

Moreover, Bojanowski et al. (2017) have proposed a method called `fastText`, which also incorporates character N-gram embeddings in addition to word embeddings. However, they did not explicitly prove the effectiveness of OOV word embeddings. Thus, it is still unclear how well the combination of character N-grams can reconstruct appropriate embeddings for OOV words. In addition, their method trains word embeddings from a corpus, which is not a reconstruction setting we discuss in this paper. Therefore, their method is orthogonal to ours.

We often aim to reduce memory consumption of word embeddings in the real-world since they require relatively large memory. Suzuki and Nagata (2016) proposed a parameter reduction method for word embeddings by using machine learning techniques. Our method can also be interpreted as a kind of parameter reduction method based on the subword features. However, their method only considers the model shrinkage, and does not utilize any subword information nor consider the OOV issue.

To summarize, none of the previous studies have attempted to simultaneously achieve a smaller number of embedding vectors and higher applicability of OOV words. Thus, in this paper, we report the first attempt to investigate how we can simultaneously achieve them.

Additionally, deep contextualized pre-trained language models, such as ELMo (Peters et al., 2018), have recently been proposed as alternatives to the pre-trained word embeddings to further improve task performances. However, ELMo still takes advantage of `Glove.840B` to achieve its state-of-the-art performance. This fact implies that we can still combine the pre-trained word embeddings with strong pre-trained language models; thus, the importance of word embeddings in the literature remains unchanged even though stronger pre-trained models have been established.

3 Reconstruction of Word Embeddings Using Subwords

In this section, we explain a formal task definition that we tackle in this paper.

3.1 Preliminaries

Notation rules: In this paper, we use the following notation rules unless otherwise specified. First, a lower-case bold letter, e.g., $\boldsymbol{v}$ and $\boldsymbol{e}$, represents a column vector, and an upper-case bold letter, e.g., $\boldsymbol{V}$ and $\boldsymbol{E}$, represents a matrix. Then, $\|\boldsymbol{v}\|_p$ represents L_p-norm of the given vector $\boldsymbol{v}$. Next, let a lower-case letter, e.g., z or i, be a scalar variable or index, and an upper-case letter, e.g., C or H, indicate a scalar but hyper-parameter during the training. Here, we introduce the notation $\boldsymbol{V}[i]$ to represent the i-th column vector in the matrix $\boldsymbol{V}$ to simplify the representation. Moreover, an upper-case letter in a calligraphy form, e.g., $\mathcal{W}$ and $\mathcal{S}$, denotes a set, and the absolute value of a set, such as $|\mathcal{W}|$ and $|\mathcal{S}|$, indicates the number of instances in the corresponding set. Finally, the Greek letter, such as Φ and η, indicates a function.

Words and their embedding: Let $\mathcal{W}$ be a vocabulary, i.e., a set of words. Let $\zeta(\cdot)$ represent a mapping function from a word to the corresponding index of the word, namely,

$$\zeta(\cdot) : \mathcal{W} \rightarrow \mathcal{I}_w \text{ where } \mathcal{I}_w = \{1, \dots, |\mathcal{W}|\}. \quad (1)$$

In this paper, we always assume that $\zeta(\cdot)$ is a bijective function; thus, each word has its own unique index between 1 and $|\mathcal{W}|$. This also implies that the relation $|\mathcal{W}| = |\mathcal{I}_w|$ always holds.

Let $\boldsymbol{e}_w$ be a D-dimensional embedding vector for the word $w \in \mathcal{W}$, and let $\boldsymbol{E}$ denote an embedding matrix for all words in $\mathcal{W}$, where $\boldsymbol{E} = \mathbb{R}^{D\times|\mathcal{I}_w|}$. Then, we assume that the following relation always holds between $\boldsymbol{e}_w$ and $\boldsymbol{E}$:

$$\boldsymbol{e}_w = \boldsymbol{E}[z_e] \quad \text{where} \quad z_e = \zeta(w). \quad (2)$$

Therefore, the i-th column vector in the matrix $\boldsymbol{E}$ represents the word embedding of the corresponding word w that satisfies $i = \zeta(w)$.

Subwords and their embedding: Let $\mathcal{S}$ be a vocabulary for all pre-defined subwords obtained from the words in $\mathcal{W}$. Let $\eta_v(\cdot)$ represent a mapping function from a subword to the corresponding index of the subword, that is,

$$\eta_v(\cdot) : \mathcal{S} \rightarrow \mathcal{I}_s \text{ where } \mathcal{I}_s = \{1, \dots, |\mathcal{S}|\}. \quad (3)$$

Similar to ζ in Eq. 1, $\eta_v(\cdot)$ is generally defined as a bijective function[5]. In this case, each subword has its own unique index between 1 and $|\mathcal{S}|$, and the relation $|\mathcal{S}| = |\mathcal{I}_s|$ always holds.

Here, we introduce $\boldsymbol{v}_s$ as a D-dimensional vector for the subword $s \in \mathcal{S}$ and $\boldsymbol{V}$ as an embedding matrix for all subwords in $\mathcal{S}$, where $\boldsymbol{V} = \mathbb{R}^{D\times|\mathcal{I}_s|}$. Then, we also assume the following relation between $\boldsymbol{v}_s$ and $\boldsymbol{V}$:

$$\boldsymbol{v}_s = \boldsymbol{V}[z_v] \quad \text{where} \quad z_v = \eta_v(s). \quad (4)$$

Therefore, the j-th column vector in the matrix $\boldsymbol{V}$ represents the subword embedding of the corresponding subword s that satisfies $j = \eta_v(s)$.

Word to subword mapping: Additionally, we introduce a (abstract) function $\phi(\cdot)$ that maps a word $w \in \mathcal{W}$ to a list of subwords contained in the word w. We can define $\phi(\cdot)$ in detail from several choices. For example, if we define $\phi(\cdot)$ to extract all the character bi-grams appearing in a given word and $w =$ 'higher', then we obtain a list of total seven distinct subword indices of '⟨w⟩h', 'hi', 'ig', 'gh', 'he', 'er', 'r⟨/w⟩' as the return value of $\phi(w)$, where '⟨w⟩' and '⟨/w⟩' are special characters that represent the beginning and end of a word, respectively.

3.2 Task definition

Conceptually, we aim to reconstruct all the embeddings in $\boldsymbol{E}$ using $\boldsymbol{V}$ and a pre-defined subword mixing function $\tau(\cdot)$. Formally, our reconstruction problem is represented as a minimization problem of the following form:

$$\hat{\boldsymbol{V}} = \underset{\boldsymbol{V}}{\arg\min} \big\{\Psi(\boldsymbol{E}, \boldsymbol{V}, \tau)\big\}, \quad (5)$$

---

[5] We redefine η_v as a surjective function in Section 5.2.

where $\Psi(\cdot)$ is a loss function used to calculate the total reconstruction loss between $\boldsymbol{E}$ and $\boldsymbol{V}$.

As a brief summary, our goal is to find $\hat{\boldsymbol{V}}$ at which the loss function $\Psi(\cdot)$ is minimized from the machine learning perspective. Note that the previous study, i.e., `BoS`, also utilized the above formulation for the reconstruction problem. Moreover, `MIMICK` can also be considered to utilize this formulation if $\boldsymbol{V}$ consists of all the single characters.

Subword mixing function $\tau(\cdot)$: The role of the function $\tau(\cdot)$ is to calculate an alternative embedding of the word embedding $\boldsymbol{e}_w$ using a list of subwords contained in the given word w. One of the most popular definitions of $\tau(\cdot)$ is to simply sum-up all the obtained subwords as follows:

$$\tau_{\texttt{sum}}(\boldsymbol{V}, w) = \sum_{s \in \phi(w)} \boldsymbol{v}_s. \tag{6}$$

In fact, a subword mixing function of this form was utilized in the previous studies, such as `fastText` and `BoS`.

Loss function $\Psi(\cdot)$: First, to improve readability, we introduce $\hat{\boldsymbol{v}}_w$ as a short notation of $\tau(\boldsymbol{V}, w)$, namely $\hat{\boldsymbol{v}}_w = \tau(\boldsymbol{V}, w)$. There are also several possible choices for the definition of the loss function $\Psi(\cdot)$. Here, we consider utilizing a squared loss function $\Psi_{\texttt{lsq}}$, which can be written as the summation of the squared losses over an individual embedding vector $\boldsymbol{e}_w$:

$$\Psi(\boldsymbol{E}, \boldsymbol{V}, \tau) = \sum_{w \in \mathcal{W}} C_w \left\| \boldsymbol{e}_w - \hat{\boldsymbol{v}}_w \right\|_2^2, \tag{7}$$

where C_w is a weight factor for each word. Intuitively, $\Psi(\cdot)$ is used to calculate the weighted sum of the L_2-norm distances between the reference vector $\boldsymbol{e}_w$ and a vector calculated by the subword mixing function $\tau(\cdot)$.

4 Reconstruction with Model Shrinkage

In this section, we briefly explains the background that we still need to consider the number of embedding vectors in the subword-based approach. Table 1 shows the statistics of the total number of embedding vectors and the total memory requirement in several different settings. As shown in row `(a)`, the original `fastText.600B` word embeddings consist of 2 million words, which require 2.2 GB to store them since each word has a $D = 300$ dimensional vector. If we consider using all the character N-grams obtained from all the words (row `(e)`), then surprisingly, the memory requirement becomes approximately 25GB, which is too large for practical use. Therefore, it is crucial to technically reduce the memory requirement.

ID	Setting	# of vecs	mem. (GB)
`(a)`	original `fastText.600B`	2.0 M	2.2 GB
`(b)`	char N-gram $N = 1, 2, 3$	0.2 M	0.3 GB
`(c)`	$N = 3, 4, 5, 6$	6.2 M	7.1 GB
`(d)`	$N = 1$ to 6	6.3 M	7.2 GB
`(e)`	$N = 1$ to ∞	21.8 M	24.9 GB

Table 1: Statistics for each setting: The columns '# of vecs' and 'mem.' represent the number of embedding vectors and the memory requirement, respectively. M denotes one million, and we consider that a real value requires 4 bytes of storage in the calculation of the memory requirement.

A practical approach is to partially take advantage of a certain range of smaller N-grams, such as $N = 1$ to 3 (row `(b)`) or $N = 3$ to 6 (row `(c)`). However, smaller subword settings, such as row `(b)`, might markedly degrade the performance from the original word embeddings. Therefore, it is necessary to discover a better balance between the memory requirement (or the total number of embedding vectors) and performance.

5 Modifications to Improve Performance

In this section, we describe several modifications to simultaneously achieve the purpose of smaller number of embedding vectors but higher performance with the applicability of OOV words. To do so, we incorporate several techniques in the baseline word embedding reconstruction approach explained in Section 3. Roughly speaking, we enhance the mapping function $\eta_v(\cdot)$ and the subword mixing function $\tau(\cdot)$.

5.1 Frequent subwords: Modification of $\eta_v(\cdot)$

We take advantage of the top-F frequent subwords that can be counted from the words in vocabulary $\mathcal{W}$ as a subword vocabulary instead of all possible subwords $\mathcal{S}$. Let $\mathcal{S}_F$ represent the set of the top-F frequent subwords, where $\mathcal{S}_F \subseteq \mathcal{S}$. Then, we define a new mapping function $\eta_{v,F}(\cdot)$ as follows:

$$\eta_{v,F}(\cdot) : \mathcal{S}_F \rightarrow \mathcal{I}_{s,F} \text{ where } \mathcal{I}_{s,F} = \{1, \dots, |\mathcal{S}_F|\}. \tag{8}$$

5.2 Memory sharing: Modification of $\eta_v(\cdot)$

In the baseline method, we assumed that the mapping function $\eta_v(\cdot)$ is a bijective function as de-

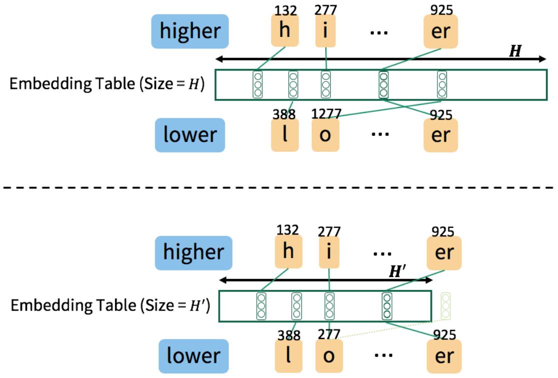

Figure 1: Intuitive idea of our memory-shared embeddings by hashing. Here, we assume $H' < H$.

scribed in Section 3.1. Again, this means that each subword has its own unique subword index. Here, we modify $\eta_v(\cdot)$ as a surjective function by introducing the following new mapping function $\eta_{v,H}(\cdot)$ as a replacement of $\eta_v(\cdot)$ in Eq. 3:

$$\eta_{v,H}(\cdot) : \mathcal{S} \rightarrow \mathcal{I}_{s,H} \;\text{ where }\; \mathcal{I}_{s,H} = \{1, \ldots, H\}. \tag{9}$$

Here, we assume $H < |\mathcal{S}|$. This mapping function $\eta_{v,H}(\cdot)$ implies that each subword is mapped to an index, but the index is not unique and may be shared between other subwords. Therefore, the number of subword embeddings can also be reduced to H by sharing the embeddings; thus, the subword embedding matrix $\boldsymbol{V}$ can also be reduced from $\boldsymbol{V} = \mathbb{R}^{D \times |\mathcal{S}|}$ to $\boldsymbol{V} = \mathbb{R}^{D \times H}$. Here, if we assume the relation $H \ll |\mathcal{S}|$, then we can greatly reduce the total embedding size.

There are several possible choices for the definition of the mapping function $\eta_{v,H}(\cdot)$. We select a simple hash function for $\eta_{v,H}(\cdot)$. This means that subword embeddings are randomly shared over the subwords. One large merit of using simple hash functions is that we require no external mapping structure of every (subword, subword index) pair, which also matches our goal of reducing the memory requirement in actual use cases. Figure 1 illustrates an intuitive idea of memory-shared embeddings by hashing.

5.3 Combination of $\eta_{v,F}(\cdot)$ and $\eta_{v,H}(\cdot)$

Also $\eta_{v,F}(\cdot)$ and $\eta_{v,H}(\cdot)$ can be combined step by step. First, we reduce the subword vocabulary $\mathcal{S}$ to top-F frequent subwords $\mathcal{S}_F$ as described in Section 5.1. Second, we apply our memory sharing method to only $\mathcal{S}_F$ in contrast to applying it to $\mathcal{S}$ in Section 5.2. Here, we define a new mapping function $\eta_{v,FH}(\cdot)$ as follows:

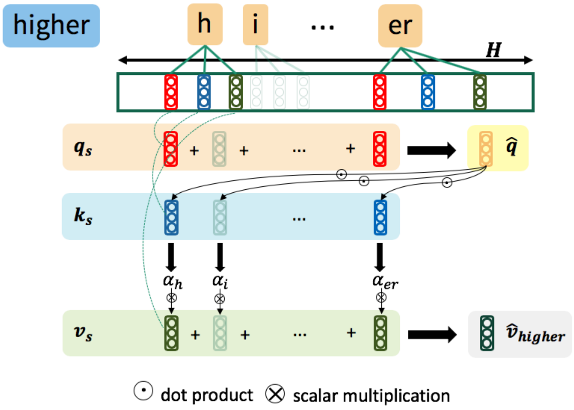

Figure 2: Illustration of how our KVQ self-attention operation calculates each word embedding.

$$\eta_{v,FH}(\cdot) : \mathcal{S}_{\mathcal{F}} \rightarrow \mathcal{I}_{s,H} \;\text{ where }\; \mathcal{I}_{s,H} = \{1, \ldots, H\}. \tag{10}$$

5.4 Attention operation: Modification of $\tau(\cdot)$

Previous researches such as `fastText` and `BoS` treat $\tau(\boldsymbol{V}, w)$ as a summation of all subword embeddings described by Eq. 6. However, the summation is less expressive and it may lack capability in a memory-sharing setting since subwords share their embeddings randomly. One possible improvement is to handle the importance of each subword based on a given word during the calculation of $\Phi(\boldsymbol{V}, w)$.

A simple approach to deal with this phenomenon is to incorporate a “context-dependent” weighting factor for each subword in a given word. Thus, we consider the following subword mixing function $\tau_{\text{kvq}}(\boldsymbol{V}, w)$ as:

$$\tau_{\text{kvq}}(\boldsymbol{V}, w) = \sum_{s \in \phi(w)} a_{s,w} \boldsymbol{v}_s \tag{11}$$

where $a_{s,w}$ represents a context-dependent weighting factor of the subword s, where the “context” here means all the subwords obtained from word w.

To calculate $a_{s,w}$, we first introduce $\boldsymbol{k}_s$ and $\boldsymbol{q}_s$, which are similarly defined to $\boldsymbol{v}_s$ in Eq. 4, namely, $\boldsymbol{k}_s = \boldsymbol{V}[z_k]$, where $z_k = \eta_k(s)$ and $\boldsymbol{q}_s = \boldsymbol{V}[z_q]$, where $z_q = \eta_q(s)$. Similar to $\eta_v(\cdot)$ in Eq. 3, $\eta_k(\cdot)$ and $\eta_q(\cdot)$ are two distinct mapping functions that map a given subword s into a subword index. Then, we introduce a key-value-query (KVQ) self-attention operation inspired by

`Transformer` (Vaswani et al., 2017), that is,

$$a_{s,w} = \frac{\exp(Z\hat{\boldsymbol{q}} \cdot \boldsymbol{k}_s)}{\sum_{s' \in \phi(w)} \exp(Z\hat{\boldsymbol{q}} \cdot \boldsymbol{k}_{s'})}, \tag{12}$$

where Z is a scaling hyper-parameter. and $\hat{\boldsymbol{q}} = \sum_{s \in \phi(w)} \boldsymbol{q}_s$. Figure 2 illustrates how our KVQ self-attention operation calculates each word embedding.

6 Experiments

6.1 Evaluation of model shrinkage

This section describes our experiments for evaluating the performance of the model shrinkage.

6.1.1 Settings

Evaluation data: Table 2 shows a summary of the evaluation datasets used in our experiments. We conducted experiments on well-studied linguistic benchmark datasets, i.e., nine for word similarity (**WordSim**) tasks and two for word analogy (**Analogy**) tasks. In this evaluation, we discarded data in the evaluation datasets if at least one of the words in the data was an OOV word. Note that this is the standard evaluation criterion used in the previous studies. By following this criterion, we investigate the effectiveness in terms of model shrinkage since we can fairly compare the performance with the original (word-based) word embeddings.

Pre-trained word embeddings: For the reconstruction target, we selected `fastText.600B`[6]. Note that it achieved the state-of-the-art performance on the WordSim and Analogy datasets (Bojanowski et al., 2017). The hyper-parameters $D = 300$ and $|\mathcal{W}| = 2$M were automatically obtained from the properties of `fastText.600B`.

Hyper-parameters for training: We took advantage of a N-grams' range of $N = 3$ to 30. We adopted Adam (Kingma and Ba, 2014) as our optimization algorithm to minimize Eq. 5. We set the following hyper-parameters for Adam: $\alpha = 0.0001$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1 \times 10^{-8}$. We leveraged a mini-batch training, whose size was 200, and trained each method for 300 epochs. For C_w in Eq. 7, we utilized the occurrence information calculated from a large external corpus. Then, we set $Z = \sqrt{D}$ for all experiments.

Comparison: We compared the following five distinct settings of subword-based reconstruction of word embeddings.

1. **SUM-F**: Select $\eta_{v,F}(\cdot)$ in Eq. 8 (Section 5.1) for the subword mapping function and $\tau_{\mathtt{sum}}(\cdot)$ in Eq. 6 for the subword mixing function.
2. **SUM-H**: As in the first setting but substitute $\eta_{v,F}(\cdot)$ with $\eta_{v,H}(\cdot)$ in Eq. 9 (Section 5.2).
3. **KVQ-H**: As in the second setting but substitute $\tau_{\mathtt{sum}}(\cdot)$ in Eq. 6 with $\tau_{\mathtt{kvq}}(\boldsymbol{V}, w)$ in Eq. 11 (Section 5.4).
4. **SUM-FH**: As in the second setting but substitute $\eta_{v,H}(\cdot)$ with $\eta_{v,FH}(\cdot)$ in Eq. 10 (Section 5.3).
5. **KVQ-FH**: As in the third setting but substitute $\eta_{v,H}(\cdot)$ with $\eta_{v,FH}(\cdot)$ in Eq. 10 (Section 5.3).

6.1.2 Results

Figures 3 show the performance/model size (or performance/number of embedding vectors)

---

[6] Additionally, we also conducted the same experiments using `GloVe.840B` instead of `fastText.600B`. See Appendix A for the results.

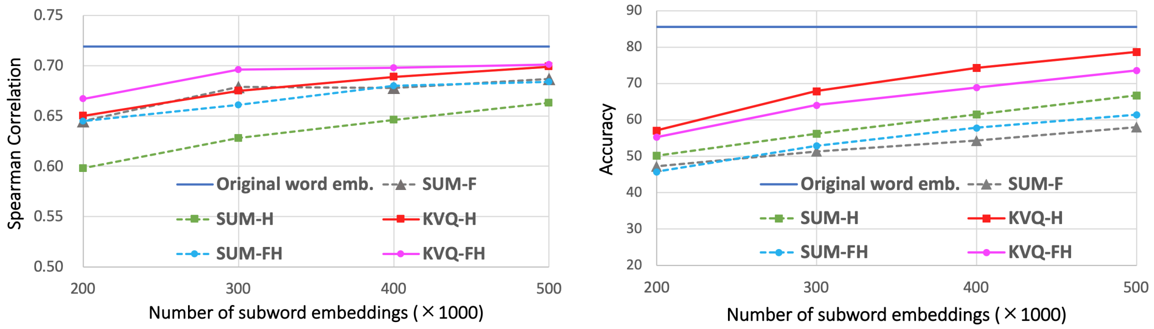

Figure 3: Performance/model size curves for WordSim (left) and Analogy (right). The x-axis represents the number of subword embeddings. The y-axis represents the performance evaluated by macro-average of Spearman's rho (left) and micro-average accuracy (right), respectively.

Table 4: Results of model shrinkage experiments by reconstructing the `fastText.600B` embeddings. Each dataset in WordSim and Analogy was evaluated by Spearman's rho and accuracy, respectively. 'Macro' and 'Micro' represent the macro-average of Spearman's rho over all WordSim datasets and the micro-average of accuracy over all Analogy datasets.

curves for WordSim and Analogy, respectively. Each plot is the macro-average of Spearman's rho (WordSim) or micro-average of accuracy (Analogy) of all evaluation datasets. Moreover, Table 3 shows the statistics of each setting and Table 4 show a summary of the detailed results for all datasets. Overall, we observed a consistent tendency that the methods using KVQ obtained the best performance compared with the methods using SUM. Notably, `KVQ-H` significantly outperformed `SUM-F`, `SUM-H` and `SUM-FH` by more than 10 points in terms of the micro-average accuracy of all Analogy datasets when the model size was 0.5M. The difference between `KVQ-H` and `SUM-H` shows that the approach of memory-shared embeddings is particularly useful when we combined it with the KVQ operation. Moreover, in some cases, we observed that `KVQ-H` achieved the performance of the original word embeddings `fastText.600B` when $H = 0.5$M. This means that `KVQ-H` with $H = 0.5$M with successfully reduced the model size nearly fourfold compared with the original word embeddings while maintaining the original performance.

6.1.3 Analysis

Time efficiency of SUM and KVQ: We investigated the difference in time efficiency between SUM and KVQ. We calculated the time computing word embeddings from subword embeddings using each operation. SUM and KVQ took 5.7×10^{-6} and 1.6×10^{-5} seconds per word, respectively, i.e., KVQ took 2.8 times longer than SUM. However, the calculation speed per word is sufficiently high to be negligible in the real applications since other operations such as calculating deep neural networks may take much longer.

6.2 Experiments of OOV word embeddings

This section describes our experiments for evaluating the performance of OOV word embeddings.

6.2.1 Settings

Evaluation data: We used the identical nine WordSim datasets used in Section 6.1.

method	hyper-parameters		Macro
`Random`	-	-	.110
`SUM-F`	$F = 0.5$M	-	**.640**
`SUM-H`	-	$H = 0.5$M	.609
`KVQ-FH`	-	$H = 0.5$M	.598
`SUM-FH`	$F = 1.0$M	$H = 0.5$M	.626
`KVQ-FH`	$F = 1.0$M	$H = 0.5$M	.636
`SUM-F`	$F = 0.2$M	-	.611
`SUM-H`	-	$H = 0.2$M	.552
`KVQ-H`	-	$H = 0.2$M	.566
`SUM-FH`	$F = 1.0$M	$H = 0.2$M	.609
`KVQ-FH`	$F = 1.0$M	$H = 0.2$M	**.614**

Table 5: Results of (synthetic) OOV word experiments on WordSim by reconstructing the `fastText.600B` embeddings. The performance was evaluated by Spearman's rho.

method	hyper-parameters		$\|\mathcal{W}\|$	$\|\mathcal{S}\|$	RW
`Random`	-	-	0.16M	-	.452
`MIMICK`	-	-	0.16M	<1K	.201
`BoS`	-	-	0.16M	0.53M	.46*
`SUM-F`	$F = 0.04$M	-	0.16M	0.04M	.513
`SUM-H`	-	$H = 0.04$M	0.16M	2.03M	.485
`KVQ-H`	-	$H = 0.04$M	0.16M	2.03M	.509
`SUM-FH`	$F = 0.50$M	$H = 0.04$M	0.16M	0.50M	.488
`KVQ-FH`	$F = 0.50$M	$H = 0.04$M	0.16M	0.50M	**.522**
`fastText`	-	-	0.16M	0.53M	.48*

Table 6: Results of OOV experiments on the Stanford Rare Word dataset. * indicates the values reported by Zhao et al. (2018). Note that `fastText` learned subword embeddings from an English Wikipedia dump since this method is not a reconstruction method.

Preparation of training data: As we showed in Table 2, the numbers of OOV problems for `fastText.600B` and `GloVe.840B` are indeed very small. This is because their vocabulary sizes exceeds 2 million words, and the words contained in the evaluation datasets tend to be 'non-rare words' in general. Therefore, it is difficult to precisely evaluate the effectiveness of the estimation of OOV word embeddings.

To overcome this difficulty, we artificially made our reconstruction problem much more difficult, namely, we discarded the words contained in the evaluation datasets from the vocabulary $\mathcal{W}$ for training. This means that all the problems in the evaluation datasets now became OOV problems. In other words, the number of OOV data in Table 2 in this setting always matches to the evaluation data size, such as 2034 for RW.

Other settings: We used the same experimental settings as used in Section 6.1 unless otherwise specified. For example, we used `fastText.600B` as the reconstruction target and the same training hyper-parameters.

6.2.2 Results

Table 5 shows the results of the (synthetic) OOV word experiments. First, we observed that the performance of the `Random` baseline's was nearly equal to zero across all the datasets. This means that there is no correlation between the `Random` and human-annotated scores. Importantly, the performances of `KVQ-FH`, `SUM-FH` and `SUM-F` were significantly improved by 44-53 points from that of `Random`. This result indicates that `KVQ-FH`, `SUM-FH` and `SUM-F` successfully predicted the OOV word embeddings.

However, we also observed no significant difference between `KVQ-FH`, `SUM-FH` and `SUM-F` for both the $H = 0.5$M and $H = 0.2$M settings.

6.2.3 Comparison with previous studies

As we discussed in Section 2, several closely related methods have also tackled to solve the OOV word issue, such as `MIMICK` and `BoS`. We aim to directly compare our approach with these methods to investigate whether it can outperform them. However, these methods (or available authors' codes) do not work on the large-vocabulary settings employed in Sections 6.1 and 6.2. Thus, as an alternative, we strictly followed the experimental settings described in (Zhao et al., 2018) and compared the performance under fair conditions.

Evaluation data: In their evaluation setting, they evaluated the OOV word performance over RW shown in Table 2. They included all the words appearing in RW as the evaluation data, in contrast to discarding the OOV data as in Section 6.1.

Pre-trained word embeddings: The target word embeddings for the reconstruction were the embeddings trained on Google News with 100 billion tokens[7] that were pre-cleaned by (Zhao et al., 2018). The resultant embeddings consist of 0.16M lower-cased word embeddings.

Comparison: We compared our approach with the following related methods:

1. `Random`: the performance when we used random vectors for OOV words.
2. `MIMICK`[8] (Pinter et al., 2017).
3. `BoS`[9] (Zhao et al., 2018).

Other settings: The shared memory size H was set to 0.04M since the vocabulary of this setting

Table 8: Results of the TE experiments on the SNLI dataset.

was relatively very small compared with that in our experiments, i.e., 2M vs 0.16M.

Results: Table 6 shows a comparison with the related methods. All our reconstruction methods outperformed `BoS`, which was the previous state-of-the-art method, with substantial improvements by 2-6 points. Moreover, `KVQ-FH` achieved the best performance in this comparison.

6.3 Evaluation on downstream tasks

To investigate the effectiveness of our reconstucted embeddings in downstream tasks, we evaluated them in the named entity recognition (NER) and the textual entailment (TE) tasks.

6.3.1 Settings

Evaluation data: We used the CoNLL 2003 dataset (Tjong Kim Sang and De Meulder, 2003) for an NER experiment and the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) for a TE experiment.

Other settings: We used `fastText.600B` and `GloVe.840B` as the target word embeddings for the reconstruction. For our reconstruction embeddings, we calculated the embeddings of all the words in the datasets, thus there exist no OOV words when using our methods.

We used AllenNLP[10] to train base NER and TE models. We basically used the provided hyper-parameter values in their repository for both training and testing. Additionally, we added one hyper-parameter K to re-scale embeddings (i.e., multiply all the elements in the embeddings by K) since we learned that the re-scaling may significantly affect the overall performance of downstream tasks in certain situation. We search K from $[1, 5, 10, 20, 50, 100]$ on the validation set of each dataset.

6.3.2 Results

Tables 7 and 8 show the comparison between the original (large) embeddings and our reconstructed (small) embeddings. When $H = 0.5$M, the performances of our reconstructed embeddings are equivalent to or even better than the ones of the original embeddings. One might be surprised the improved results by `KVQ-FH` since the model sizes of `KVQ-FH` were relatively very small comparing with the original embeddings. However, this may be a reasonable observation since our method additionally offered the embeddings of OOV words that cannot be handled by the original embeddings. Moreover, even when $H = 0.2$M, i.e. the model size was approximately ten times smaller, the degradation was less than 1.0, which is considered to be sufficiently acceptable for real-world systems if we can significantly reduce the model (system) size.

7 Conclusion

We discussed and investigated an approach that reconstructs subword-based word embeddings in a reduced memory space. We demonstrated that memory-shared embeddings with the KVQ self-attention operation significantly outperformed the conventional summation-based approach, such as `BoS`. Moreover, our best setting successfully reduced the number of embedding vectors to approximately ten times smaller than that of the original word embeddings while maintaining an acceptable performance loss on the downstream tasks. We also confirmed the effectiveness of our approach in terms of the applicability of OOV words. We believe that our reconstructed subword-based word embeddings can be better alternatives of `fastText.600B` and `GloVe.840B` because they require less memory requirement and have high applicability of OOV words.

Abstract

While neural dependency parsers provide state-of-the-art accuracy for several languages, they still rely on large amounts of costly labeled training data. We demonstrate that in the small data regime, where uncertainty around parameter estimation and model prediction matters the most, Bayesian neural modeling is very effective. In order to overcome the computational and statistical costs of the approximate inference step in this framework, we utilize an efficient sampling procedure via stochastic gradient Langevin dynamics to generate samples from the approximated posterior. Moreover, we show that our Bayesian neural parser can be further improved when integrated into a multi-task parsing and POS tagging framework, designed to minimize task interference via an adversarial procedure. When trained and tested on 6 languages with less than $5k$ training instances, our parser consistently outperforms the strong BiLSTM baseline (Kiperwasser and Goldberg, 2016). Compared with the BiAFFINE parser (Dozat et al., 2017) our model achieves an improvement of up to 3% for Vietnamese and Irish, while our multi-task model achieves an improvement of up to 9% across five languages: Farsi, Russian, Turkish, Vietnamese, and Irish.

1 Introduction

Dependency parsing is essential for many Natural Language Processing (NLP) tasks (Levy and Goldberg, 2014; Angeli et al., 2015; Toutanova et al., 2016; Hadiwinoto and Ng, 2017; Marcheggiani et al., 2017). While earlier work on dependency parsing required careful feature engineering (McDonald et al., 2005b; Koo et al., 2008), this has become less of a concern in recent years with the emergence of deep neural networks (Kiperwasser and Goldberg, 2016; Dozat et al., 2017). Nonetheless, an accurate parser still requires a large amount of labeled data for training, which is costly to obtain, while the lack of data often causes overfitting and poor generalization.

Several approaches for parsing in the small data regime have been proposed. These include augmenting input data with pretrained embedding (Dozat et al., 2017; Che et al., 2018), leveraging unannotated data via semi-supervised learning (Corro and Titov, 2018), predicting based on a pool of high probability trees (Niculae et al., 2018; Keith et al., 2018), and transferring annotation or model across languages (Agic et al., 2016; Lacroix et al., 2016; Rasooli and Collins, 2017). Despite the empirical success of these approaches, an inherent problem still holds: The maximum likelihood parameter estimation (MLE) in deep neural networks (DNNs) introduces statistical challenges at both estimation (training), due to the risk of overfitting, and at test time as the model ignores the uncertainty around the estimated parameters. When training data is small these challenges are more pronounced.

The Bayesian paradigm provides a statistical framework which addresses both challenges by (i) including prior knowledge to guide the learning in the absence of sufficient data, and (ii) predicting under the full posterior distribution of model parameters which offers the desired degree of uncertainty by exploring the posterior space during inference. However, this solution comes with a high computational cost, specifically in DNNs, and is often replaced by regularization techniques such as dropout (Srivastava et al., 2014) as well as ensemble learning and prediction averaging (Liu et al., 2018; Che et al., 2018).

Bayesian neural networks (BNNs) have attracted some attention (Welling and Teh, 2011; Hernández-Lobato and Adams, 2015; Li et al., 2016; Gong et al., 2018). Yet, its current application to NLP is limited to language modeling (Gan et al., 2017), and BNNs have not been developed for structured

Proceedings of NAACL-HLT 2019, pages 3509–3519
Minneapolis, Minnesota, June 2 - June 7, 2019.

prediction tasks such as dependency parsing.

In this paper we aim to close this gap and propose the first BNN for dependency parsing (BNNP). To address the costs of inference step, we apply an efficient sampling procedure via stochastic gradient Langevin dynamics (SGLD) (Welling and Teh, 2011). At training, samples from the posterior distribution of the parser parameters are generated via controlled noise injection to the maximum a posteriori (MAP) gradient update. The generated samples are then used during the inference step to create multiple viable parses based on which the final dependency parse is generated.

Another means of directing a model towards more accurate predictions in the small data regime is via multi-task learning (Caruana, 1997). Such a framework allows models for multiple tasks to reinforce each other towards more accurate joint solutions, which is particularly useful when training data is scarce. We hence present a multi-task framework where our BNNP is integrated with a POS tagger through an adversarial procedure designed to guide the two models towards improved joint solutions.

Our experiments with monolingual and delexicalized cross-lingual parsing using the Universal Dependency treebank (Zeman et al., 2017) demonstrate the effectiveness of our approach. Particularly, our BNNP consistently outperforms the single task BiLSTM baseline (Kiperwasser and Goldberg, 2016), while outperforming the BiAFFINE parser (Dozat et al., 2017) by up to 3% on Vietnamese and Irish. Additionally, our multi-task model achieves an improvement of up to 9% over the BiAFFINE parser for five low-resource languages: Farsi, Russian, Turkish, Vietnamese, and Irish.

2 BiLSTM Dependency Parsing

Our parser extends the graph-based BiLSTM parser of Kiperwasser and Goldberg (2016). We briefly review their work and its notable extensions, and then discuss our extension of their architecture and the limitations of MLE training.

Model Given an input word sequence $w_{1:n}$,[1] and its corresponding POS tag sequence $p_{1:n}$, each input word is encoded as a d-dimensional representation,

$$w_i = e(w_i) \circ e(p_i) \circ \hat{e}(w_i),$$

where $e(.)$ denotes trainable embedding, $\hat{e}$ denotes pretrained external embedding, and $\circ$ denotes concatenation. The context dependent representation of each word is generated through a BiLSTM,

$$v_i = \overrightarrow{\text{LSTM}}_{\zeta}(w_{1:i}) \circ \overleftarrow{\text{LSTM}}_{\phi}(w_{n:i}).$$

Here, ζ and ϕ denote the LSTMs' parameters. The resulting sequence of l-dimensional vectors, $v_{1:n}$, is then used for computing the ARC-SCORE matrix $(n \times n)$ where cell ARC-SCORE(i, j) is computed as,

$$V \times \tanh\Bigg(\underbrace{W^{(arc-head)} v_i}_{\text{head specialized } w_i} + \underbrace{W^{(arc-mod)} v_j}_{\text{modifier specialized } w_j} + b \Bigg),$$

indicating the likelihood of having the arc from w_i to w_j. Here, V is $(1 \times h)$, b is $(h \times 1)$, and $W^{(.)}$ is a $(h \times l)$ matrix used for creating specialized versions of words in $w_{1:n}$. The h-dimensional specialized representation of w_i as a head or a modifier is generated via multiplication with $W^{(arc-head)}$ and $W^{(arc-mod)}$, respectively. Following a first-order dependence assumption between the arcs, the parsing is done via a dynamic programming solution that finds the dependency parse T^* such that,

$$T^* = \underset{T}{\text{argmax}} \Bigg(\text{SCORE}(T) = \sum_{(i,j) \in T} \text{ARC-SCORE}(i, j) \Bigg).$$

Next, given T^*, for each arc $(i, j) \in T^*$ the LABEL-SCORE(i, j, r) is computed as:

$$\Bigg(V' \times \tanh(\underbrace{W'^{(arc-head)} v_i}_{\text{head specialized } w_i} + \underbrace{W'^{(arc-mod)} v_j}_{\text{modifier specialized } w_j} + b') \Bigg)[r],$$

where r is a dependency relation type, $r \in \{r_z\}_{z=1}^{\mathbf{r}}$, V' is $(\mathbf{r} \times h)$, b' is $(\mathbf{r} \times 1)$, and $W'^{(.)}$ is $(h \times l)$. The label for each dependency arc (i, j) is then chosen by a max operation.

Dozat et al. (2017) proposed an extension of the BiLSTM parser by replacing the non-linear transformation of ARC-SCORE and LABEL-SCORE with a linear transformation (BiAFFINE). This was further extended by Che et al. (2018) who utilized contextualized word embeddings (Peters et al., 2018). Both extensions showed success in dependency parsing shared tasks (Zeman et al., 2017, 2018).

Our Neural Parser Architecture Our network architecture extends the BiLSTM model with an additional BiLSTM layer and input signals. While our

---

[1] We overload the notation w_i, and it refers to both a word and its d-dimensional representation.

architecture is not the core contribution of this paper, we aim to implement our BNNP on a strong architecture. In §5.3 we demonstrate the contribution of these additions to our final results.

In our BNNP, each word is represented as,

$$w_i = e(w_i) \circ e(p_i) \circ \hat{e}(w_i) \circ e(c_i),$$

where, similar to the BiAFFINE parser, $e(c_i)$ is a character-level representation of the word w_i, generated by a BiLSTM:

$$e(c_i) = \overrightarrow{\text{LSTM}}_\alpha(c_{1:|w_i|}) \circ \overleftarrow{\text{LSTM}}_\beta(c_{|w_i|:1}).$$

We consider a maximum of two layers of BiLSTMs, denoted as *1st* and *2nd*.[2] The output of the *2nd* BiLSTM is denoted as,

$$u_i = \overrightarrow{\text{LSTM}}_\kappa(v_{1:i}) \circ \overleftarrow{\text{LSTM}}_\delta(v_{n:i}),$$

where v_i is the encoding generated by the *1st* layer of the BiLSTMs.

Learning For structured prediction, the objective function is to maximize the margin between the gold structure $\mathbb{T}$ and the other structures. To achieve this, the cost augmented hinge loss is used, where the fixed margin m is replaced by a cost function, $\text{COST}(\mathbb{T}, T)$, sensitive to the local mistakes (here, each local mistake has a constant cost of 1), and computed as:

$$\mathcal{L}_{arc} = \max\Big(0, \text{COST}(\mathbb{T}, T) + \text{SCORE}(T) - \text{SCORE}(\mathbb{T})\Big)$$

For label prediction, hinge loss with $m = 1$ is used (denoted by $\mathcal{L}_{rel}$). We refer to the parser loss as:

$$\mathcal{L}_{parse} = \mathcal{L}_{arc} + \mathcal{L}_{rel}.$$

Beyond MLE Training The point-estimate of DNN parameters is computationally efficient, but ignores the uncertainty around model parameters during learning. This results in an overconfidence over model predictions during the inference phase. A common generic practice to incorporate a degree of uncertainty is to consider an ensemble of models. Indeed, for dependency parsing ensemble learning has shown to improve accuracy (Surdeanu and Manning, 2010; Kuncoro et al., 2016; Che et al., 2018). However, ensembles are computationally demanding due to the large number of participating models. The de-facto approach to overcome this has been to randomly perturb the structure of the network for each training instance by switching off connections between the nodes, a practice known as dropConnect (Wan et al., 2013), or eliminating the nodes entirely, which is known as dropout (Srivastava et al., 2014).

Hinton et al. (2012) demonstrated that dropping out a node with probability ρ from a neural model $\mathcal{M}$ at training, and scaling the same node's output at test time (in the fully connected $\mathcal{M}$), performs very well in practice. While this scaling trick avoids the need for running multiple models at test time, it lacks theoretical guarantees when applied to DNNs. Gal and Ghahramani (2016) showed that dropout can be casted as integrating out the posterior of model parameters, and in this regard is a form of Bayesian approximation. Still, dropout is not as effective when applied to the small data regime (Goodfellow et al., 2016). We hence propose a fully Bayesian approach.

3 Bayesian Neural Parsing

The Bayesian paradigm is appealing in its ability to capture uncertainty around parameters, avoid overfitting, and incorporate prior knowledge to compensate for the lack of sufficient training data in resource lean settings. Dependency parsing may be a natural candidate for Bayesian modeling since a typical sentence can have multiple viable parses corresponding to different grammatical ambiguities, and considering these possibilities have shown to improve predictive accuracy (Niculae et al., 2018; Keith et al., 2018). In the same spirit, Bayesian inference can be interpreted as a statistically grounded means to generate this pool of high quality trees.

In detail, Bayesian inference for parsing computes the *predictive distribution* $P(T|s, \mathcal{D})$[3] of the dependency parse tree T for an input sentence s given the training data $\mathcal{D}$ by *posterior averaging*:

$$P(T|s, \mathcal{D}) = \int P(T|s, \theta) P(\theta|\mathcal{D}) d\theta,$$

where $P(\theta|\mathcal{D}) \propto p(\mathcal{D}|\theta)p(\theta)$ denotes the posterior distribution of the BNNP parameters θ given observations $\mathcal{D}$. Here the prior distribution $p(\theta)$ is a standard Gaussian $\mathcal{N}(0, I)$, and, by assuming i.i.d training datapoints, the likelihood term

---

[2] Stacking BiLSTMs is believed to be helpful. In our case, the addition of a third layer led to overfitting.

[3] When $P(T|s, \theta)$ is replaced by the unnormalized score from the first-order arc-factored model, $P(T|s, \mathcal{D})$ can be interpreted as the expected score assigned to a dependency tree under the full posterior distribution of model parameters.

is $P(\mathcal{D}|\theta) = \prod_{x_i \in D} P(x_i|\theta)$ where $x_i = (s_i, T_i)$ is a training instance.

The above integral is intractable, however an empirical estimate can be computed using $\mathcal{K}$ samples from the posterior,

$$P(T|s,\mathcal{D}) \approx \frac{1}{\mathcal{K}} \sum_{\{\theta_k \sim P(\theta|D)\}_{k=1}^{\mathcal{K}}} P(T|s,\theta_k). \tag{1}$$

Therefore, efficient generation of posterior samples is the key for applying the Bayesian treatment. Since the posterior is intractable in DNNs, additional machineries such as Markov Chain Monte Carlo (MCMC) (Robert and Casella, 2010) are required for sampling. In this paper we explore an efficient class of Stochastic Gradient Markov Chain Monte Carlo (SG-MCMC) methods, designed for NNs by adjusting stochastic gradient descent with properly scaled Gaussian noise to generate posterior samples.

3.1 Stochastic Gradient Langevin Dynamics

We first consider the Stochastic Gradient Langevin Dynamics (SGLD) (Welling and Teh, 2011) sampler to generate posterior samples. Intuitively, this mechanism guides SGD to explore the posterior distribution rather than finding the maximum a posteriori (MAP) solution. More concretely, at each time step t we first compute a stochastic estimate of the gradient for the negative log-posterior distribution on a mini-batch b_t:

$$\nabla_{\theta_t}\mathcal{L} \approx -\left(\nabla_{\theta_t}\log P(\theta_t) + \frac{|\mathcal{D}|}{|b_t|}\sum_{x_i \in b_t}\nabla_{\theta_t}\log P(x_i|\theta_t)\right),$$

and then update the BNNP parameters by SGD with noise injection,

$$\theta_{t+1} \leftarrow \theta_t - \frac{\eta_t}{2}\nabla_{\theta_t}\mathcal{L} + \xi_t, \quad \xi_t \sim \mathcal{N}(0, \eta_t \mathbf{I}) \tag{2}$$

Theoretically, the distribution of θ_t converges to the true posterior $p(\theta|\mathcal{D})$ when $b_t = \mathcal{D}$, $t \to \infty$ and $\eta_t \to 0$ (see Teh et al. (2016) for SGLD convergence rate proofs and analysis).

In practice, the learning rate $\eta_t = a(b+t)^{-\gamma}$, starting high and decaying, plays a crucial role in eqn. 2 dynamics. Intuitively, while the variance of the injected noise is η_t, the variance of the gradient is of $\mathcal{O}(\eta_t^2)$. In the earlier stages of the optimization, the $\frac{\eta_t}{2}\nabla_\theta \mathcal{L}$ term is dominant as gradients are of greater impact and the learning rate is high, simulating stochastic gradient descent. As the optimization proceeds, the impact of the gradient shrinks and the injected Gaussian noise becomes the dominant term, transitioning from SGD to Langevin Monte Carlo (Neal, 2011).

Since $\eta_t \to 0$ might cause slow mixing in practice, we also set a minimum threshold for the learning rate to allow mixing at later stages. SGLD and SGD have the same time complexity as sampling occurs along with parameter updates with a negligible overhead of drawing ξ_ts.

3.2 Preconditioned SGLD

As SGLD relies on a single learning rate along all dimensions of θ, it has the same potential inefficiencies of SGD for optimizing functions with different curvatures along each dimension. Inspired by more advanced optimization techniques that adjust to the geometry of parameter space, Li et al. (2016) proposed preconditioning of SGLD (similar to RMSprop (Tieleman and Hinton, 2012)) which scales the gradients with respect to the weighted average of the gradients along each dimension, such that a unified learning rate is sufficient. The proposed preconditioner diagonal matrix is computed as follows,

$$G(\theta_t) = \mathrm{diag}(1 \oslash (\lambda 1 + \sqrt{V(\theta_t)})),$$
$$V(\theta_t) = \alpha V(\theta_{t-1}) + (1-\alpha)\nabla_{\theta_t}\mathcal{L} \odot \nabla_{\theta_t}\mathcal{L},$$

where $\odot, \oslash$ are element-wise matrix product and division, and λ, α are hyperparameters controlling the extremes of the curvature, and weighting average of previous and current gradients, respectively. The updated preconditioned eqn. 2 is,

$$\theta_{t+1} \leftarrow \theta_t - \frac{\eta_t}{2}G(\theta_t)\nabla_{\theta_t}\mathcal{L} + \xi_t, \quad \xi_t \sim \mathcal{N}(0, \eta_t G(\theta_t)).$$

Here, replacing the preconditioner matrix $G(\theta_t)$ with an identity matrix will recover the SGLD update formulation. In case of a diagonal preconditioner, it has the same time complexity of SGLD, although the constant factors in the complexity figure can be slightly higher due to additional computations involved in $G(\theta_t)$ and $V(\theta_t)$.

While SGLD is designed to explore different modes of the posterior distribution, we found (§5.4) that in practice we still require dropout to facilitate modes exploration via random perturbation of the model structure.

3.3 Prediction

The generated posterior samples can be used to compute the approximate expectation of eqn. 1 by scoring all plausible parses via explicit model averaging.

As this solution is not computationally feasible, we use the sampled parameters and follow a procedure that minimizes the Bayes risk (MBR) (Goodman, 1996). Given each sampled parameter, first we generate the maximum scoring parse using the arc-factored decomposition (McDonald et al., 2005a) and dynamic programming (Eisner, 1996). This can be done concurrently for all samples, resulting in a running time identical to the non-Bayesian approach. For each labelled edge, we replace its score in the ARC-SCORE matrix with its occurrence count in the collection of sampled trees and infer the final tree using counts as scores. The predicted structure is then passed to the label predictor, which assigns labels to the edges (§2). This decoding approach, while selecting the global structure with the highest probability under the approximate posterior, could potentially allow for additional corrections of the highest scoring tree in the pool of samples (Shareghi et al., 2015; Kuncoro et al., 2016).

4 Multi-Task Learning

Multi-task learning (Caruana, 1997) lends itself as a natural choice for low-resource settings as it aims at leveraging the commonality between tasks to improve their performance in the absence of sufficient amount of training data. This framework hence naturally complements Bayesian modeling in dealing with the challenges of the small data regime.

We couple our BNNP with POS tagging due to the strong connection between the two tasks (Rush et al., 2010) and the availability of joint training data in several languages (Zeman et al., 2017). While multi-task frameworks have shown success in some areas (Reichart et al., 2008; Finkel and Manning, 2009; Liu et al., 2016; Malca and Reichart, 2018), in our case we found that our two tasks interfered with each other and degraded the parser performance (see similar findings for other tasks at Søgaard and Goldberg (2016); Plank and Alonso (2017)).

To minimize task interference, an approach shown effective (Ganin and Lempitsky, 2015; Kim et al., 2017; Chen et al., 2017; ZareMoodi and Haffari, 2018) is to implicitly guide the update signals during training via an adversarial procedure that avoids shared parameters contamination. We adapt this idea to our multi-task learning.

Architecture Given an input word, w_i, the score for a POS tag p is computed as $\tanh(W''v_i + b'')[p]$, where $p \in \{p_z\}_{z=1}^{\mathbf{p}}$, W'' is $(\mathbf{p} \times l)$, and b'' is $(\mathbf{p} \times 1)$. To train the POS tagger, the cross-entropy loss is used (denoted by $\mathcal{L}_{pos}$). Taking w_is as input, the *shared* BiLSTM strictly encodes a task-agnostic l-dimensional representation of the input (explained in the next subsection),

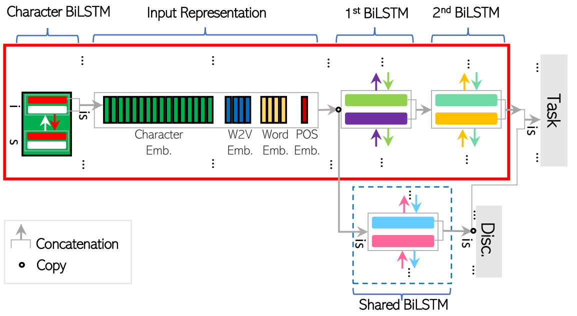

Figure 1: The **MULTI TASK** architecture flow for a single word in a sequence.

$$s_i = \overrightarrow{\text{LSTM}}_\rho(w_{1:i}) \circ \overleftarrow{\text{LSTM}}_\chi(w_{n:i}).$$

The input to each task is then defined as the concatenation of task-agnostic and task-specific representations. We considered a basic architecture where both tasks have their separate parameters (identical number of layers, dimensions, etc.) and they only share the *shared* BiLSTM (denoted as **MULTI TASK** in Table 1). [4]

Adversarial Training The *shared* BiLSTM output, s_i, is meant to encode a task-agnostic representation of the input word w_i. In order to enforce this criterion, we apply an adversarial training procedure. The shared representation, s_i, is forwarded to a task discriminator (denoted as *Disc.* in Figure 1) through a gradient reversal layer. The task discriminator predicts the task identity for each word in the input via a linear transformation $(W'''s_i + b''')[\tau]$ followed by a softmax, where $\tau \in \{\texttt{parser}, \texttt{tagger}\}$ and W''' and b''' are $(2 \times l)$ and (2×1), respectively. To train the discriminator, a sum of the cross-entropy losses for $w_{1:n}$ is used (denoted by $\mathcal{L}_{disc}$). As the parameters of the discriminators are being updated, the gradient signals to minimize the discriminator's error are backpropagated with an opposite sign to the *shared* BiLSTM layer, which adversarially encourages the *shared* BiLSTM to fool the discriminator.

Our training schedule alternates between the two modes, in one mode optimizing the shared and task-specific parameters based on $\mathcal{L}_{parse}$ and $\mathcal{L}_{pos}$ (in

---

[4] We also tried layer-wise placements of tasks (Søgaard and Goldberg, 2016; Hashimoto et al., 2017) and the results were slightly worse. Details are omitted for space reason.

random order), while in the other mode optimizing $\mathcal{L}_{disc}$ which includes the shared and discriminator-specific parameters.

5 Experiments and Results

We experiment with mono-lingual and cross-lingual dependency parsing using the treebanks of the CoNLL 2017 shared task on parsing to Universal Dependencies (UD) (Zeman et al., 2017).[5]

5.1 Experimental Setup

We use the UDPipe baseline outputs for segmentation and POS tagging of the raw test data (released along with the raw test data). While segmentation and POS errors substantially impact the quality of the final predicted parse, their exploration is beyond our scope. Our evaluation metric is Labeled Attachment Score (LAS), computed by the shared task evaluation script. Statistical significance, when mentioned, is computed over 20 runs, via the Kolmogorov-Smirnov test (Reimers and Gurevych, 2017; Dror et al., 2018) with $p = 0.01$.

Mono-Lingual Experiments We experiment with Persian (fa), Korean (ko), Russian (ru), Turkish (tr), Vietnamese (vi) and Irish (ga), all with less than $5k$ training sentences (Table 1). For comparison we report the scores published by the top system of the CoNLL 2017 shared task, BiAFFINE (Dozat et al., 2017), noting the following differences between their input and output and ours. The BiAFFINE parser: (i) uses the UDPipe outputs for segmentation but corrects POS errors before parsing, (ii) includes both language specific and universal POS tags in the input layer while we only include the universal POS tags, and (iii) applies post-process correction for non-projective languages.

Cross-Lingual Experiments We use the English (en), French (fr), Russian (ru), and Persian (fa) datasets of the UD treebanks as our training and test data, with the addition of 3 languages for which we did not have any training data: Kurmanji (kmr), Buriat (bxr), and Northern Sami (sme). We also report the results for each language, where the combination of training datasets for the rest of the languages (marked as +) was used for training. The cross-lingual experiments are done on delexicalized parses after replacing the words with their Universal POS tags.

Models and Baselines - Single-Task We consider the following models: **BASE** is the BiLSTM model of Kiperwasser and Goldberg (2016); **BASE++** extends BASE by having 2 layers of BiLSTMs and using 1 layer of character level BiLSTM (§2); **+SHARED** includes an additional BiLSTM (dashed box in Figure 1). We included this to provide a fair comparison (in terms of the number of parameters) with the multi-task experiments but we apply a higher dropout rate to resolve overfitting; **ENSEMBLE** denotes a collection of 9 +SHARED models each randomly initialized (Reimers and Gurevych, 2017) and trained for MLE with MBR (§3.3) applied for prediction; **MAP** denotes the +SHARED model optimized for MAP instead of MLE; **+SGLD** denotes Bayesian learning and prediction (§3.1), and **+PRECOND** denotes preconditioned SGLD (§3.2). **+SGLD** and **+PRECOND** are applied to the +SHARED model.

Models and Baselines - Multi-Task We consider the same models as in the single-task setup, with the following changes. **BASEMT** is the variant of **MULTI TASK** architecture where the *shared* BiLSTM is removed and all components except for decoders are shared between the two tasks. **+SHARED** and **+ADV** denote the results without and with the adversarial training (§4), respectively.

5.2 Hyperparameters

Training is done for 330 epochs with early stopping, using successive[6] mini-batches of 5000 words,[7] with drop-out rate 0.33 unless stated otherwise. SGLD is only applied for learning the parameters of the parser, with learning rate decaying from 0.01 to 0.0001 ($\gamma = 0.5$), and the preconditioned matrix hyperparameters are $\lambda = 10^{-5}, \alpha = 0.99$. The rest of the parameters are updated using Adam (Kingma and Ba, 2014) with default DyNet parameters (Neubig et al., 2017). The size and selection of the samples used in Bayesian inference are tuned on Irish (see §6.1 of the main paper). In all experiments, training stops based on loss convergence of a single model on the dev set. We also tried GRUs and our results were substantially worse than LSTMs.

We consider the following sizes within the models: **BASE** is 1 layer of BiLSTM with 125 hidden

---

[5] For train and dev sets (1-1983), test set (1-2184), and pretrained embeddings (1-1989) see: `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/{1-1983,1-2184,1-1989}`

[6] We found that random batches perform slightly worse.

[7] When the 5000 words limit lands in the middle of a sentence, the entire sentence is included.

units, 100-D word embeddings, 25-D POS embeddings, and dropout rate of 0.33; **BASE++** extends BASE by having 2 layers of BiLSTMs with 200-D hidden units, 100-D external word embeddings, and using 1 layer of character level BiLSTM with 200-D hidden units to generate 100-D character embeddings (§2); **+SHARED** includes an additional BiLSTM with 200-D hidden units in BASE++ to provide a fair comparison (in terms of the number of parameters) with the multi-task experiments but we apply a higher dropout rate of 0.66 to resolve overfitting.

5.3 Results

Mono-Lingual Parsing Table 1 summarizes the training data statistics and the LAS results of the various models, with bold-font marking cases where a model outperforms the BiAFFINE parser.

+SGLD	85.89	79.50	83.06	62.13	**44.57**	**72.52**
+PRECOND	**86.75**	80.97	**84.51**	**63.24**	**45.96**	**74.12**

Table 1: Mono-Lingual results. Models that outperform the BiAFFINE parser are highlighted in bold.

1. SINGLE TASK Comparison between BASE++ and +SHARED reveals that the additional BiLSTM in the +SHARED does not improve the results. As expected, model averaging in ENSEMBLE improved the results over the +SHARED model. Additionally, the MAP results show slight improvements compared with +SHARED. Both of these findings suggest that the quality of predictions is likely to improve if some notion of uncertainty (via averaging, or prior insertion) is included.

For Bayesian solutions, both +SGLD and +PRECOND consistently (and in a statistically significant manner) outperform the ENSEMBLE models and the strong BiLSTM baselines on all languages, while PRECOND outperforms BiAFFINE by up to 3% on two languages (vi, and ga). The consistency of improvements as we incorporate richer means of capturing the uncertainty suggests that these gains are independent of our specific choice of neural architecture and that they might also hold for future parsing architectures.

2. MULTI TASK As explained earlier (§4), comparing the parser performances under +SHARED models in single and multi task settings indicates that parser quality was degraded with the inclusion of a POS tagging task, possibly due to interference between the tasks. This issue was alleviated with the inclusion of task discriminator and the adversarial training. The +ADV model consistently improves the results (in a statistically significant manner), while outperforming the **SINGLE TASK (+SHARED)** by 2.2% for Persian (fa), and 5.2% for Irish (ga). This is an indicator that low-resource languages could potentially benefit more from multi-task learning. Other variants of +ADV are also reported in Table 1 and similar patterns to the single task setting are observed.

Next, we test the effectiveness of Bayesian learning and inference using $\mathcal{K} = 9$ thinned samples (§5.4). For all languages in the multi-task setting the gain from including +SGLD in +ADV is statistically significant. However, the gain decays as the amount of training data increases: from 3.8% on Irish (ga) to 1.1% on Persian (fa). This verifies our expectation that Bayesian learning helps parameter estimation and prediction in the small data regime. Compared to +SGLD, +PRECOND provides further improvements (all are statistically significant) of 2.2% on Irish and 1% on Persian, showing a similar generic negative correlation with data size.

To summarize our mono-lingual results, the Bayesian framework shows its merit in improving predictive quality, and multi-task learning introduces new and informative signal via a related task which allows for better parameter estimation. The integration of a Bayesian parser into a multi-task learning framework outperforms the BiAFFINE parser on up to 5 languages, while we observe decreasing improvements as the data size grows. Also, since our Bayesian approach builds on the BASE model, it is subject to the shortcomings of this model: For instance, on Korean (ko) the difference between BASE and BiAFFINE is too large to be closed without further adjustment of model design,

(a) Performance of different sampling strategies.

(b) Dropout, SGLD, and mini-batch size interdependence.

Figure 2: Ablation analysis for Irish. Similar patterns are observed for the other languages.

or its inputs and outputs.

Cross-Lingual Delexicalized Parsing We tested our most successful mono-lingual model, **MULTI TASK**(+PRECOND), in the cross-lingual setup against an ensemble of $\mathcal{K} = 9$ randomly initialized **SINGLE TASK** (BASE++) models. Table 2 summarizes the training data size (rounded up) and the LAS results of both models.

As expected, the ensemble models perform best when the training and test data come from the same language or language family (as in Buryat to Russian and Kurmanji to Persian). Showing a similar pattern to mono-lingual parsing, in all cases the performance gain of the Bayesian **MULTI TASK** (+PRECOND) setting, reported as under-text in the table, consistently outperforming the ENSEMBLE (in a statistically significant manner) and the impact decays with the training set size.

5.4 Ablation Analysis

We aim to answer two questions: (i) how many of the generated samples are used during inference? and (ii) how much the success of SGLD depends on other sources of noise during training?

1. UTILIZING SAMPLES Once the training stops, different strategies could be applied to utilize the collection of $\mathcal{M}$ posterior samples to recompute ARC-SCORE matrix (see §3.3). An extreme option is including all samples (denoted by *All*), another option is to only use the last sample (denoted by *Last*). An intermediate alternative is to choose $\mathcal{K}$ samples with interval $\lfloor \frac{\mathcal{M}}{\mathcal{K}} \rfloor$, an approach known as *Thinning* (Gan et al., 2017).

Comparing the results in Figure 2a, *Thinning* consistently outperforms the other strategies. Interestingly, when we compared *Thinning* with a variant (denoted by Δ in Figure 2a) that just uses the last 5 samples , it appears that *Thinning* which includes earlier samples is still superior. This is likely to be an indicator that a larger (and more diverse) set of trees can potentially improve MBR decoding. In practice, we use *Thinned* samples.

2. DROPOUT, SGLD, AND MINI-BATCH We would next like to better understand the interdependence between SGLD and two existing sources of noise: dropout and mini-batch size. Results are reported in Figure 2b. In all four stacked bars, the top segment demonstrates the gain when including +SGLD. The right-most stacked bar illustrates the performance of **MULTI TASK (+ADV)** without (bottom part of the bar) and with +SGLD. This is our reference and in the following three experiments, we make a single change to this model while keeping everything else fixed.

In the left-most stacked bar, we exclude dropout. This significantly hurts the performance, an indication that the random perturbation of model by dropout can provide a positive complimentary effect for better exploration of the posterior modes via SGLD. Comparing the top parts of all stacked bars (representing the gain with +SGLD) reveals that this gain is at its maximum when dropout is switched off. An interpretation can be that in the absence of dropout, SGLD becomes the main component for countering overfitting.

In the second stacked bar from the right, we remove the noise caused by mini-batching and use the entire dataset as one batch. This slightly improves the results, although this improvement is not statistically significant. Based on eqn. 2, full training data gradient updates cause $\nabla_\theta \mathcal{L} \to 0$ in fewer steps. Consequently, the learning rate (which controls the variance of the noise) is at a higher value when the gradient is close to zero, giving a better chance for the sampler to mix via ξ_t.

In the second stacked bar from left, parameters are updated for each training sentence. In this setting the learning rate, η_t, is consumed much faster and can potentially reach zero on the MAP solution, discarding the effect of the injected noise and +SGLD. Hence, the gain for including SGLD is at its minimum. We speculate that adjusting the decaying speed of the learning rate (which we left untouched) could allow for this extreme case to perform better.

6 Conclusion

We proposed a Bayesian framework for neural dependency parsing (BNNP). We employ efficient SG-MCMC approximate inference mechanisms through stochastic gradient Langevin dynamics to generate posterior samples during optimization. The collected samples are then used via a minimum Bayes risk parsing algorithm to generate the final parse tree. In mono-lingual and cross-lingual experiments in the small data regime, where Bayesian learning in expected to be most effective, our BNNP consistently outperformed the strong BiLSTM baselines. Moreover, when integrating the BNNP into a multi-task learning framework, utilized to prevent task interference, we outperformed the BiAFFINE parser (best system of the CoNLL17 shared task) on 5 low-resource languages by up to 9% LAS.

In future work, we intend to investigate other types of priors over the network parameters (e.g., sparse priors (Lobacheva et al., 2017)). We would also like to explicitly quantify the uncertainty captured in our framework under different sampling strategies or MCMC-SG methods (e.g., similar to McClure and Kriegeskorte (2016); Teye et al. (2018)).

AutoSeM: Automatic Task Selection and Mixing in Multi-Task Learning

Han Guo **Ramakanth Pasunuru** **Mohit Bansal**
UNC Chapel Hill
`{hanguo, ram, mbansal}@cs.unc.edu`

Abstract

Multi-task learning (MTL) has achieved success over a wide range of problems, where the goal is to improve the performance of a primary task using a set of relevant auxiliary tasks. However, when the usefulness of the auxiliary tasks w.r.t. the primary task is not known a priori, the success of MTL models depends on the correct choice of these auxiliary tasks and also a balanced mixing ratio of these tasks during alternate training. These two problems could be resolved via manual intuition or hyper-parameter tuning over all combinatorial task choices, but this introduces inductive bias or is not scalable when the number of candidate auxiliary tasks is very large. To address these issues, we present AutoSeM, a two-stage MTL pipeline, where the first stage automatically selects the most useful auxiliary tasks via a Beta-Bernoulli multi-armed bandit with Thompson Sampling, and the second stage learns the training mixing ratio of these selected auxiliary tasks via a Gaussian Process based Bayesian optimization framework. We conduct several MTL experiments on the GLUE language understanding tasks, and show that our AutoSeM framework can successfully find relevant auxiliary tasks and automatically learn their mixing ratio, achieving significant performance boosts on several primary tasks. Finally, we present ablations for each stage of AutoSeM and analyze the learned auxiliary task choices.

1 Introduction

Multi-task Learning (MTL) (Caruana, 1997) is an inductive transfer mechanism which leverages information from related tasks to improve the primary model's generalization performance. It achieves this goal by training multiple tasks in parallel while sharing representations, where the training signals from the auxiliary tasks can help improve the performance of the primary task. Multi-task learning has been applied to a wide range of natural language processing problems (Luong et al., 2015; Pasunuru and Bansal, 2017; Hashimoto et al., 2017; Ruder et al., 2017b; Kaiser et al., 2017; McCann et al., 2018). Despite its impressive performance, the design of a multi-task learning system is non-trivial. In the context of improving the primary task's performance using knowledge from other auxiliary tasks (Luong et al., 2015; Pasunuru and Bansal, 2017), two major challenges include selecting the most relevant auxiliary tasks and also learning the balanced mixing ratio for synergized training of these tasks. One can achieve this via manual intuition or hyper-parameter tuning over all combinatorial task choices, but this introduces human inductive bias or is not scalable when the number of candidate auxiliary tasks is considerable. To this end, we present AutoSeM, a two-stage Bayesian optimization pipeline to this problem.

In our AutoSeM framework[1], the first stage addresses automatic task selection from a pool of auxiliary tasks. For this, we use a non-stationary multi-armed bandit controller (MAB) (Bubeck et al., 2012; Raj and Kalyani, 2017) that dynamically alternates among task choices within the training loop, and eventually returns estimates of the utility of each task w.r.t. the primary task. We model the utility of each task as a Beta distribution, whose expected value can be interpreted as the probability of each task making a non-negative contribution to the training performance of the primary task. Further, we model the observations as Bernoulli variables so that the posterior distribution is also Beta-distributed. We use Thompson sampling (Chapelle and Li, 2011; Russo et al., 2018) to trade off exploitation and exploration.

The second stage then takes the auxiliary tasks

---

[1] We make all our code and models publicly available at: `https://github.com/HanGuo97/AutoSeM`

Proceedings of NAACL-HLT 2019, pages 3520–3531
Minneapolis, Minnesota, June 2 - June 7, 2019.

selected in the first stage and automatically learns the training mixing ratio of these tasks, through the framework of Bayesian optimization, by modeling the performance of each mixing ratio as a sample from a Gaussian Process (GP) to sequentially search for the optimal values (Rasmussen, 2004; Snoek et al., 2012). For the covariance function in the GP, we use the Matern kernel which is parameterized by a smoothness hyperparameter so as to control the level of differentiability of the samples from GP. Further, following Hoffman et al. (2011), we use a portfolio of optimistic and improvement-based policies as acquisition functions (Shahriari et al., 2016) for selecting the next sample point from the GP search space.

We conduct several experiments on the GLUE natural language understanding benchmark (Wang et al., 2018), where we choose each of RTE, MRPC, QNLI, CoLA, and SST-2 as the primary task, and treat the rest of the classification tasks from the GLUE benchmark as candidate auxiliary tasks. Results show that our AUTOSEM framework can successfully find useful auxiliary tasks and automatically learn their mixing ratio, achieving significant performance boosts on top of strong baselines for several primary tasks, e.g., 5.2% improvement on QNLI, 4.7% improvement on RTE, and 2.8%/0.8% improvement on MRPC.

We also ablate the usefulness of our two stages of auxiliary task selection and automatic mixing ratio learning. The first ablation removes the task selection stage and instead directly performs the second GP mixing ratio learning stage on all auxiliary tasks. The second ablation performs the task selection stage (with multi-armed bandit) but replaces the second stage Gaussian Process with manual tuning on the selected tasks. Our 2-stage model performs better than both these ablations, showing that both of our stages are crucial. Further, we also discuss the learned auxiliary task choices in terms of their intuitive relevance w.r.t. the corresponding primary task.

2 Related Work

Multi-task learning (Caruana, 1998), known for improving the generalization performance of a task with auxiliary tasks, has successfully been applied to many domains of machine learning, including natural language processing (Collobert and Weston, 2008; Girshick, 2015; Luong et al., 2015; Pasunuru and Bansal, 2017; Pasunuru et al., 2017), computer vision (Misra et al., 2016; Kendall et al., 2017; Dai et al., 2016), and reinforcement learning (Teh et al., 2017; Parisotto et al., 2015; Jaderberg et al., 2016). Although there are many variants of multi-task learning (Ruder et al., 2017b; Hashimoto et al., 2017; Luong et al., 2015; McCann et al., 2018), our goal is to improve the performance of a primary task using a set of relevant auxiliary tasks, where different tasks share some common model parameters with alternating mini-batches optimization, similar to Luong et al. (2015).

To address the problem of automatic shared parameter selection, Ruder et al. (2017a) automatically learned the latent multi-task sharing architecture, and Xiao et al. (2018) used a gate mechanism that filters the feature flows between tasks. On the problem of identifying task relatedness, Ben-David and Schuller (2003) provided a formal framework for task relatedness and derived generalization error bounds for learning of multiple tasks. Bingel and Søgaard (2017) explored task relatedness via exhaustively experimenting with all possible two task tuples in a non-automated multi-task setup. Other related works explored data selection, where the goal is to select or reorder the examples from one or more domains (usually in a single task) to either improve the training efficiency or enable better transfer learning. These approaches have been applied in machine translation (van der Wees et al., 2017), language models (Moore and Lewis, 2010; Duh et al., 2013), dependency parsing (Søgaard, 2011), etc. In particular, Ruder and Plank (2017) used Bayesian optimization to select relevant training instances for transfer learning, and Tsvetkov et al. (2016) applied it to learn a curriculum for training word embeddings via reordering data. Graves et al. (2017) used the bandit approach (Exp3.S algorithm) in the context of automated curriculum learning, but in our work, we have two stages with each stage addressing a different problem (automatic task selection and learning of the training mixing ratio). Recently, Sharma and Ravindran (2017) used multi-armed bandits (MAB) to learn the choice of hard vs. easy domain data selection as input feed for the model. Guo et al. (2018) used MAB to effectively switch across tasks in a dynamic multi-task learning setup. In our work, we use MAB with Thompson Sampling for the novel paradigm of automatic auxiliary task selection;

and next, we use a Matern-kernel Gaussian Process to automatically learn an exact (static) mixing ratio (i.e., relatedness ratio) for the small number of selected tasks.

Many control problems can be cast as a multi-armed bandits problem, where the goal of the agent is to select the arm/action from one of the N choices that minimizes the regrets (Bubeck et al., 2012). One problem in bandits learning is the trade-off between exploration and exploitation, where the agent needs to make a decision between taking the action that yields the best payoff on current estimates or exploring new actions whose payoffs are not yet certain. Many previous works have explored various exploration and exploitation strategies to minimize regret, including Boltzmann exploration (Kaelbling et al., 1996), adversarial bandits (Auer et al., 2002b), UCB (Auer et al., 2002a), and information gain using variational approaches (Houthooft et al., 2016). In this work, for task selection, we use Thompson Sampling (Russo et al., 2018; Chapelle and Li, 2011), an algorithm for sequential decision making problems, which addresses a broad range of problems in a computationally efficient manner and is therefore enjoying wide use.

Gaussian Process (GP) is a non-parametric Bayesian approach, and it can capture a wide variety of underlying functions or relations between inputs and outputs by taking advantage of the full information provided by the history of observations and is thus very data-efficient (Rasmussen, 2004; Shahriari et al., 2016; Schulz et al., 2018). Gaussian Processes have been widely used as a black-box optimizer and hyper-parameter optimization (Snoek et al., 2012; Brochu et al., 2010; Knudde et al., 2017; Cully et al., 2018; Swersky et al., 2013; Golovin et al., 2017). In our work, we use Gaussian Process for automatic learning of the multi-task mixing ratio in our stage-2 among the selected tasks from stage-1.

3 Models

We will first introduce our baseline model and its integration for multiple classification tasks in a multi-task learning (MTL) setup. Next, we will introduce our AutoSem framework, an automatic way of selecting auxiliary tasks and learning their optimal training mixing ratio w.r.t. the primary task, via a Beta-Bernoulli bandit with Thompson Sampling and a Gaussian Process framework.

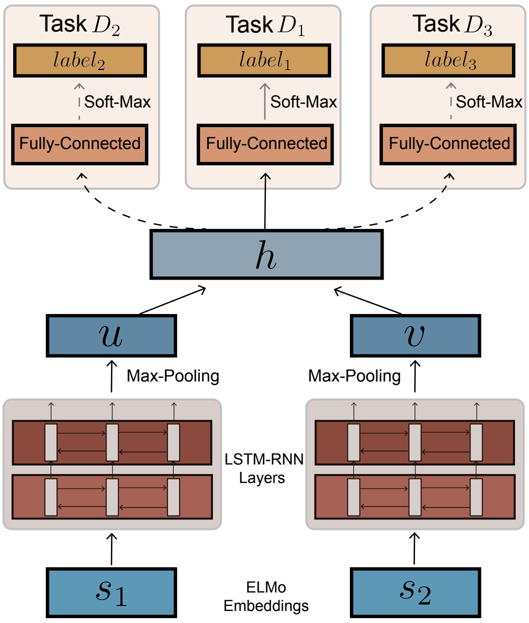

Figure 1: Overview of our baseline model where we use different projection layers for each task during MTL, while sharing rest of the model parameters.

3.1 Bi-Text Classification Model

Let s_1 and s_2 be the input sentence pair in our classification task, where we encode these sentences via bidirectional LSTM-RNN, similar to that of Conneau et al. (2017). Next, we do max-pooling on the output hidden states of both encoders where $\boldsymbol{u}$ and $\boldsymbol{v}$ are the outputs from the max-pooing layer for s_1 and s_2 respectively. Later, we map these two representations ($\boldsymbol{u}$ and $\boldsymbol{v}$) into a single rich dense representation vector $\boldsymbol{h}$:

$$\boldsymbol{h} = [\boldsymbol{u}; \boldsymbol{v}; \boldsymbol{u} \star \boldsymbol{v}; |\boldsymbol{u} - \boldsymbol{v}|] \qquad (1)$$

where $[;]$ represents the concatenation and $\boldsymbol{u} \star \boldsymbol{v}$ represents the element-wise multiplication of $\boldsymbol{u}$ and $\boldsymbol{v}$. We project this final representation $\boldsymbol{h}$ to label space to classify the given sentence pair (see Fig. 1). We also use ELMo (Peters et al., 2018) representations for word embeddings in our model. For this, we extract the three ELMo layer representations for each of the sentence pair and use their weighted sum as the ELMo output representation, where the weights are trainable.

3.2 Multi-Task Learning

In this work, we focus on improving a task (primary task) by allowing it to share parameters with related auxiliary tasks via multi-task learning (MTL). Let $\{D_1, ..., D_N\}$ be a set of N tasks, where we set D_1 to be the primary task and the rest of them as auxiliary tasks. We can extend

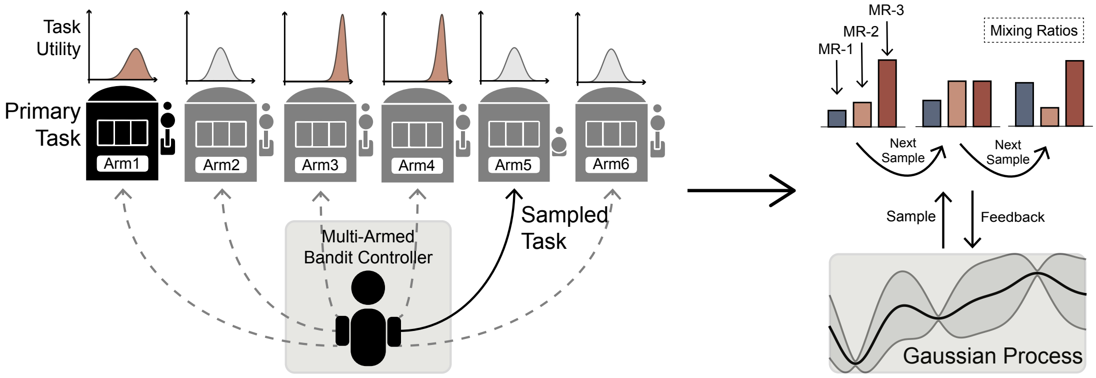

Figure 2: Overview of our AUTOSEM framework. **Left**: the multi-armed bandit controller used for task selection, where each arm represents a candidate auxiliary task. The agent iteratively pulls an arm, observes a reward, updates its estimates of the arm parameters, and samples the next arm. **Right**: the Gaussian Process controller used for automatic mixing ratio (MR) learning. The GP controller sequentially makes a choice of mixing ratio, observes a reward, updates its estimates, and selects the next mixing ratio to try, based on the full history of past observations.

our single-task learning baseline (see Sec. 3.1) into multi-task learning model by augmenting the model with N projection layers while sharing the rest of the model parameters across these N tasks (see Fig. 1). We employ MTL training of these tasks in alternate mini-batches based on a mixing ratio η_1:η_2:..η_N, similar to previous work (Luong et al., 2015), where we optimize η_i mini-batches of task i and go to the next task.

In MTL, choosing the appropriate auxiliary tasks and properly tuning the mixing ratio can be important for the performance of multi-task models. The naive way of trying all combinations of task selections is hardly tractable. To solve this issue, we propose AUTOSEM, a two-stage pipeline in the next section. In the first stage, we automatically find the relevant auxiliary tasks (out of the given $N-1$ options) which improve the performance of the primary task. After finding the relevant auxiliary tasks, in the second stage, we take these selected tasks along with the primary task and automatically learn their training mixing ratio.

3.3 Automatic Task Selection: Multi-Armed Bandit with Thompson Sampling

Tuning the mixing ratio for N tasks in MTL becomes exponentially harder as the number of auxiliary tasks grows very large. However, in most circumstances, only a small number of these auxiliary tasks are useful for improving the primary task at hand. Manually searching for this optimal choice of relevant tasks is intractable. Hence, in this work, we present a method for automatic task selection via multi-armed bandits with Thompson Sampling (see the left side of Fig. 2).

Let $\{a_1, ..., a_N\}$ represent the set of N arms (corresponding to the set of tasks $\{D_1, ..., D_N\}$) of the bandit controller in our multi-task setting, where the controller selects a sequence of actions/arms over the current training trajectory to maximize the expected future payoff. At each round t_b, the controller selects an arm based on the noisy value estimates and observes rewards r_{t_b} for the selected arm. Let $\theta_k \in [0, 1]$ be the utility (usefulness) of task k. Initially, the agent begins with an independent prior belief over θ_k. We take these priors to be Beta-distributed with parameters α_k and β_k, and the prior probability density function of θ_k is:

$$p(\theta_k) = \frac{\Gamma(\alpha_k + \beta_k)}{\Gamma(\alpha_k)\Gamma(\beta_k)} \theta_k^{\alpha_k - 1}(1 - \theta_k)^{\beta_k - 1} \quad (2)$$

where Γ denotes the gamma function. We formulate the reward $r_{t_b} \in \{0, 1\}$ at round t_b as a Bernoulli variable, where an action k produces a reward of 1 with a chance of θ_k and a reward of 0 with a chance of $1 - \theta_k$. The true utility of task k, i.e., θ_k, is unknown, and may or may not change over time (based on stationary vs. non-stationary of task utility). We define the reward as whether sampling the task k improves (or maintains) the validation metric of the primary task,

$$r_{t_b} = \begin{cases} 1, & \text{if } R_{t_b} \geq R_{t_b - 1} \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

where R_{t_b} represents the validation performance of the primary task at time t_b. With our reward setup above, the utility of each task (θ_k) can be intuitively interpreted as the probability that multi-task learning with task k can improve (or maintain) the performance of the primary task. The conjugacy properties of the Beta distribution assert that the posterior distribution is also Beta with parameters that can be updated using a simple Bayes rule, which is defined as follows (Russo et al., 2018),

$$\begin{aligned} p(\theta_k|r) &\propto \text{Bern}_\theta(r)\text{Beta}_{\alpha,\beta}(\theta_k) \\ &\propto \text{Beta}_{\alpha+r,\beta+1-r}(\theta_k) \end{aligned} \tag{4}$$

$$(\alpha_k, \beta_k) = \begin{cases} (\alpha_k, \beta_k), & \text{if } x^s_{t_b} \neq k \\ (\alpha_k, \beta_k)+(r_{t_b}, 1 - r_{t_b}), & \text{if } x^s_{t_b} = k \end{cases} \tag{5}$$

where $x^s_{t_b}$ is the sampled task at round t_b. Finally, at the end of the training, we calculate the expected value of each arm as follows:

$$\mathbb{E}_p[\theta_k] = \frac{\alpha_k}{\alpha_k + \beta_k} \tag{6}$$

Here, the expectation measures the probability of improving (or maintaining) the primary task by sampling this task. To decide the next action to take, we apply Thompson Sampling (Russo et al., 2018; Chapelle and Li, 2011) to trade off exploitation (maximizing immediate performance) and exploration (investing to accumulate new information that might improve performance in the future). In Thompson Sampling (Russo et al., 2018), instead of taking action k that maximizes the expectation (i.e., $\arg\max_k \mathbb{E}_p[\theta_k]$), we randomly sample the primary task improvement probability $\hat{\theta}_k$ from the posterior distribution $\hat{\theta}_k \sim p(\theta_k)$, and take the action k that maximizes the sampled primary task improvement probability, i.e., $\arg\max_k \hat{\theta}_k$. At the end of the training, the task selection can proceed either via a threshold on the expectation, or take the top-K tasks, and run stage-2 using the selected task subset as auxiliary tasks (details in Sec. 3.4).

Stronger Prior for Primary Task Note that at the beginning of training, model performance is usually guaranteed to improve from the initial random choices. This causes issues in updating arm values because less useful tasks will be given high arm values when they happen to be sampled at the beginning. To resolve this issue, we initially set a slightly stronger prior/arm-value in favor of the arm corresponding to the primary task. Intuitively, the bandit will then sample the primary model more often at the beginning, and then start exploring auxiliary tasks when the primary model's performance stabilizes (as the arm value of the primary model will start decreasing because sampling it in later rounds produces smaller additional improvements).

Algorithm 1 BernThompson$(N, \alpha, \beta, \gamma, \alpha_0, \beta_0)$

```
for $t_b = 1, 2, \ldots$ do
    # sample model:
    for $k = 1, \ldots, N$ do
        Sample $\hat{\theta}_k \sim \text{Beta}(\alpha_k, \beta_k)$
    end for
    # select and apply action:
    $x^s_{t_b} \leftarrow \arg\max_k \hat{\theta}_k$
    Apply $x^s_{t_b}$ and observe $r_{t_b}$
    # non-stationarity
    for $k = 1, \ldots, N$ do
        $\hat{\alpha}_k = (1 - \gamma)\alpha_k + \gamma\alpha_0$
        $\hat{\beta}_k = (1 - \gamma)\beta_k + \gamma\beta_0$
        if $k \neq x^s_{t_b}$ then
            $(\alpha_k, \beta_k) \leftarrow (\hat{\alpha}_k, \hat{\beta}_k)$
        else
            $(\alpha_k, \beta_k) \leftarrow (\hat{\alpha}_k, \hat{\beta}_k)+(r_{t_b}, 1 - r_{t_b})$
        end if
    end for
end for
```

Non-Stationary Multi-Armed Bandit Also note that the intrinsic usefulness of each task varies throughout the training (e.g., the primary task might be more important at the beginning, but not necessarily at the end), and thus the agent faces a non-stationary system. In such cases, the agent should always be encouraged to explore in order to track changes as the system drifts. One simple approach to inject non-stationarity is to discount the relevance of previous observations. Thus we introduce a tunable decay ratio γ, and modify Eq. 3.3 as follows:

$$(\alpha_k, \beta_k) = \begin{cases} (\hat{\alpha}_k, \hat{\beta}_k), & \text{if } k \neq x^s_{t_b} \\ (\hat{\alpha}_k, \hat{\beta}_k)+(r_{t_b}, 1 - r_{t_b}), & \text{if } k = x^s_{t_b} \end{cases} \tag{7}$$

where $\hat{\alpha}_k = (1-\gamma)\alpha_k+\gamma\alpha_0$ and $\hat{\beta}_k = (1-\gamma)\beta_k+\gamma\beta_0$, and γ controls how quickly uncertainty is injected into the system (α_0, β_0 are parameters of the prior). Algorithm 1 presents the Thompson Sampling algorithm with a Beta-Bernoulli MAB.

3.4 Automatic Mixing Ratio Learning via Gaussian Process

The right side of Fig. 2 illustrates our Gaussian Process controller for automatic learning of the MTL training mixing ratio (see definition in Sec. 3.2). Given the selected auxiliary tasks from the previous section, the next step is to find a proper mixing ratio of training these selected tasks along with the primary task.[2] Manual tuning of this mixing ratio via a large grid search over the hyperparameter values is very time and compute expensive (even when the number of selected auxiliary tasks is small, e.g., 2 or 3). Thus, in our second stage, we instead apply a non-parametric Bayesian approach to search for the approximately-optimal mixing ratio. In particular, we use a 'Gaussian Process' to sequentially search for the mixing ratio by trading off exploitation and exploration automatically. Next, we describe our Gaussian Process approach in detail.

A Gaussian Process (Rasmussen, 2004; Snoek et al., 2012; Shahriari et al., 2016), GP(μ_0, k), is a non-parametric model that is fully characterized by a mean function $\mu_0 : \mathcal{X} \mapsto \mathbb{R}$ and a positive-definite kernel or covariance function $k : \mathcal{X} \times \mathcal{X} \mapsto \mathbb{R}$. Let $\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n$ denote any finite collections of n points, where each $\boldsymbol{x}_i$ represents a choice of the mixing ratio (i.e., the ratio η_1:η_2:..η_N described in Sec. 3.2), and $f_i = f(\boldsymbol{x}_i)$ is the (unknown) function values evaluated at $\boldsymbol{x}_i$ (true performance of the model given the selected mixing ratio). Let $y_1, y_2, ..., y_n$ be the corresponding noisy observations (the validation performance at the end of training). In the context of GP Regression (GPR), $\boldsymbol{f} = \{f_1, ..., f_n\}$ are assumed to be jointly Gaussian (Rasmussen, 2004), i.e., $\boldsymbol{f}|\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{m}, \boldsymbol{K})$, where, $\boldsymbol{m}_i = \mu_0(\boldsymbol{x}_i)$ is the mean vector, and $\boldsymbol{K}_{i,j} = k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is the covariance matrix. Then the noisy observations $\boldsymbol{y} = y_1, ..., y_n$ are normally distributed around $\boldsymbol{f}$ as follows: $\boldsymbol{y}|\boldsymbol{f} \sim \mathcal{N}(\boldsymbol{f}, \sigma^2 \boldsymbol{I})$.

Given $\mathcal{D} = (\boldsymbol{x}_1, y_1), ..., (\boldsymbol{x}_{n_0}, y_{n_0})$, the set of random initial observations, where $\boldsymbol{x}_i$ represents a mixing ratio and y_i represents the corresponding model's validation performance. Next, we model the GP based on these initial observations as described above. We sample a next point $\boldsymbol{x}_{n_0+1}$ (a mixing ratio in our case) from this GP and get its corresponding model performance y_{n_0+1}, and update the GP again by now considering the $n_0 + 1$ points (Rasmussen, 2004). We continue this process for a fixed number of steps. Next, we will discuss how we perform the sampling (based on acquisition functions) and the kernels used for calculating the covariance.

Acquisition Functions Here, we describe the acquisition functions for deciding where to sample next. While one could select the points that maximize the mean function, this does not always lead to the best outcome (Hoffman et al., 2011). Since we also have the variance of the estimates along with the mean value of each point $\boldsymbol{x}_i$, we can incorporate this information into the optimization. In this work, we use the GP-Hedge approach (Hoffman et al., 2011; Auer et al., 1995), which probabilistically chooses one of three acquisition functions: probability of improvement, expected improvement, and upper confidence bound. Probability of improvement acquisition functions measure the probability that the sampled mixing ratio $\boldsymbol{x}_i$ leads to an improvement upon the best observed value so far (τ), $\mathbb{P}(f(\boldsymbol{x}_i) > \tau)$. Expected improvement additionally incorporates the amount of improvement, $\mathbb{E}[(f(\boldsymbol{x}_i) - \tau)\mathbb{I}(f(\boldsymbol{x}_i) > \tau)]$. The Gaussian Process upper confidence bound (GP-UCB) algorithm measures the optimistic performance upper bound of the sampled mixing ratio (Srinivas et al., 2009), $\mu_i(\boldsymbol{x}_i) + \lambda\sigma_i(\boldsymbol{x}_i)$, for some hyper-parameter λ.

Matern Kernel The covariance function (or kernel) defines the nearness or similarity of two points in the Gaussian Process. Here, we use the automatic relevance determination (ARD) Matern kernel (Rasmussen, 2004), which is parameterized by $\nu > 0$ that controls the level of smoothness. In particular, samples from a GP with such a kernel are differentiable $\lfloor \nu - 1 \rfloor$ times. When ν is half-integer (i.e. $\nu = p + 1/2$ for non-negative integer p), the covariance function is a product of an exponential and a polynomial of order p. In the context of machine learning, usual choices of ν include $3/2$ and $5/2$ (Shahriari et al., 2016).

4 Experiment Setup

Datasets: We evaluate our models on several datasets from the GLUE benchmark (Wang et al., 2018): RTE, QNLI, MRPC, SST-2, and CoLA. For all these datasets, we use the standard splits provided by Wang et al. (2018). For dataset details, we refer the reader to the GLUE paper.[3]

---

[2] Note that ideally Gaussian Process can also learn to set the mixing ratio of less important tasks to zero, hence allowing it to essentially also perform the task selection step. However, in practice, first applying our task selection Thompson-Sampling model (Sec. 3.3) allows GP to more efficiently search the mixing ratio space for the small number of filtered auxiliary tasks, as shown in results of Sec. 6.1.

[3] We did not include the remaining tasks as primary tasks, because STS-B is a regression task; MNLI is a very large dataset and does not benefit much from MTL with other tasks in the GLUE benchmark; and QQP and WNLI have dev/test discrepancies and adversarial label issues as per the GLUE

Models	RTE	MRPC	QNLI	CoLA	SST-2
BiLSTM+ELMo (Single-Task) (Wang et al., 2018)	50.1	69.0/80.8	69.4	**35.0**	90.2
BiLSTM+ELMo (Multi-Task) (Wang et al., 2018)	55.7	76.2/83.5	66.7	27.5	89.6
Our Baseline	54.0	75.7/83.7	74.0	30.8	91.3
Our AutoSeM	**58.7**	**78.5/84.5**	**79.2**	32.9	**91.8**

Table 1: Test GLUE results of previous work, our baseline, and our AutoSeM MTL framework. We report accuracy and F1 for MRPC, Matthews correlation for CoLA, and accuracy for all others.

Training Details: We use pre-trained ELMo[4] to obtain sentence representations as inputs to our model (Peters et al., 2018), and the Gaussian Process implementation is based on Scikit-Optimize[5], and we adopt most of the default configurations. We use accuracy as the validation criterion for all tasks. For all of our experiments except QNLI and SST-2, we apply early stopping on the validation performance plateau.[6] The set of candidate auxiliary tasks consists of all 2-sentence classification tasks when the primary task is a classification of two sentences, whereas it consists of all two-sentence and single-sentence classification tasks when the primary task is a classification of a single sentence.[7] Since the utility estimates from the multi-armed bandit controller are noisy, we choose the top two tasks based on expected task utility estimates, and include additional tasks if their utility estimate is above 0.5. All the results reported are the aggregate of the same experiment with two runs (with different random seeds) unless explicitly mentioned.[8] We use a two-layer LSTM-RNN with hidden size of 1024 for RTE and 512 for the rest of the models, and use Adam Optimizer (Kingma and Ba, 2014). The prior parameters of each task in stage-1 are set to be $\alpha_0 = 1$, $\beta_0 = 1$, which are commonly used in other literature. For stage-1, the bandit controller iteratively selects batches of data from different tasks during training to learn the approximate importance of each auxiliary task (Graves et al., 2017). In stage-2 (Gaussian Process), we sequentially draw samples of mixing ratios and evaluate each sample after full training (Snoek et al., 2012). Without much tuning, we used approximately 200 rounds for the stage-1 bandit-based approach, where each round consist of approximately 10 mini-batches of optimization. For stage-2, we experimented with 15 and 20 as the number of samples to draw and found that 15 samples for MRPC and 20 samples for the rest of the tasks work well. This brings the total computational cost for our two-stage pipeline to be approximately (15+1)x and (20+1)x, where x represents the time taken to run the baseline model for the given task. This is significantly more efficient than a grid-search based manually-tuned mixing ratio setup (which would scale exponentially with the number of tasks).

5 Results

5.1 Baseline Models

Table 1 shows the results of our baseline and previous works (Wang et al., 2018). We can see that our single-task baseline models achieve stronger performance on almost all tasks in comparison to previous work's single-task models.[9] Next, we present the performance of our AutoSeM framework on top of these strong baselines.

5.2 Multi-Task Models

Table 1 also presents the performance of our AutoSeM framework-based MTL models. As can be seen, our MTL models improve significantly (see Table 3 for standard deviations) upon their corresponding single-task baselines for all tasks, and achieve strong improvements as compared to the fairly-comparable[9] multi-task results of previous work (Wang et al., 2018).[10] During the task

website's FAQ: `https://gluebenchmark.com/faq`

[4] `https://allennlp.org/elmo`

[5] `https://scikit-optimize.github.io`

[6] In our initial experiments, we found early stopping on larger datasets led to sub-optimal performance, and hence we used a pre-specified maximum number of steps instead.

[7] We made this design decision because there are only two single-sentence tasks in GLUE, so we mix them with 2-sentence tasks to allow more auxiliary choices.

[8] We use the average of validation results across runs as the tuning criterion, and use the ensemble of models across runs for reporting the test results.

[9] Note that we do not report previous works which *fine-tune* large external language models for the task (e.g., OpenAI-GPT and BERT), because they are not fairly comparable w.r.t. our models. Similarly, we report the non-attention based best GLUE models (i.e., BiLSTM+ELMo) for a fair comparison to our non-attention baseline. Our approach should ideally scale to large pre-training/fine-tuning models like BERT, given appropriate compute resources.

[10] Note that even though the performance improvement gaps of Wang et al. (2018) (MTL vs. baseline) and our improvements (AutoSeM vs. our improved baseline) are similar, these are inherently two different setups. Wang et al. (2018) MTL is based on a 'one model for all' setup (Kaiser et al., 2017; McCann et al., 2018), whereas our approach in-

selection stage of our AUTOSEM framework, we observe that MultiNLI is chosen as one of the auxiliary tasks in all of our MTL models. This is intuitive given that MultiNLI contains multiple genres covering diverse aspects of the complexity of language (Conneau et al., 2017). Also, we observe that WNLI is sometimes chosen in the task selection stage; however, it is always dropped (mixing ratio of zero) by the Gaussian Process controller, showing that it is not beneficial to use WNLI as an auxiliary task (intuitive, given its small size). Next, we discuss the improvements on each of the primary tasks and the corresponding auxiliary tasks selected by AUTOSEM framework.

RTE: Our AUTOSEM approach achieves stronger results w.r.t. the baseline on RTE (58.7 vs. 54.0). During our task selection stage, we found out that QQP and MultiNLI tasks are important for RTE as auxiliary tasks. For the second stage of automatic mixing ratio learning via Gaussian Process, the model learns that a mixing ratio of 1:5:5 works best to improve the primary task (RTE) using related auxiliary tasks of QQP and MultiNLI.

MRPC: AUTOSEM here performs much better than the baseline on MRPC (78.5/84.5 vs. 75.7/83.7). During our task selection stage, we found out that RTE and MultiNLI tasks are important for MRPC as auxiliary tasks. In the second stage, AUTOSEM learned a mixing ratio of 9:1:4 for these three tasks (MRPC:RTE:MultiNLI).

QNLI: Again, we achieve substantial improvements with AUTOSEM w.r.t. baseline on QNLI (79.2 vs. 74.0). Our task selection stage learned that WNLI and MultiNLI tasks are best as auxiliary tasks for QNLI. We found that the Gaussian Process further drops WNLI by setting its mixing ratio to zero, and returns 20:0:5 as the best mixing ratio for QNLI:WNLI:MultiNLI.

CoLA: We also observe a strong performance improvement on CoLA with our AUTOSEM model w.r.t. our baseline (32.9 vs. 30.8). During our task selection stage, we found out that MultiNLI and WNLI tasks are important for CoLA as auxiliary tasks. In the second stage, GP learns to drop WNLI, and found the mixing ratio of 20:5:0 for CoLA:MultiNLI:WNLI.

SST-2: Here also our AUTOSEM approach performs better than the baseline (91.8 vs. 91.3). The task selection stage chooses MultiNLI, MRPC, and WNLI as auxiliary tasks and the stage-2 Gaussian Process model drops MRPC and WNLI by setting their mixing ratio to zero (learns ratio of 13:5:0:0 for SST-2:MultiNLI:MRPC:WNLI).

Name	Validation	Test
Baseline	78.3	75.7/83.7
w/o Stage-1	80.3	76.3/83.8
w/o Stage-2	80.3	76.7/83.8
Final MTL	81.2	78.5/84.5

Table 2: Ablation results on the two stages of our AUTOSEM framework on MRPC.

6 Analysis

6.1 Ablation on MTL stages

In this section, we examine the usefulness of each stage of our two-stage MTL pipeline.[11]

Removing Stage-1: The purpose of the Beta-Bernoulli MAB in stage-1 is to find useful auxiliary tasks for the given primary task. Here, to understand its importance, we remove the task selection part, and instead directly run the Gaussian Process (GP) model on all tasks (see 'w/o Stage-1' row in Table 2). We can see that by removing the task selection stage, the Gaussian Process model can still outperform the baseline, indicating the usefulness of the GP, but the large mixing ratio search space causes the GP to be unable to efficiently find the best mixing ratio setting.

Removing Stage-2: Given the selected tasks from stage-1, the goal of the Gaussian Process in stage-2 is to efficiently find the approximately-optimal mixing ratio. To examine its usefulness, we replace the Gaussian Process controller by manually tuning a grid of mixing ratios, where the number of tuning experiments equals to the number of steps used in the Gaussian Process model (for a fair comparison). Table 2 shows the results by removing stage-2. We can see that a grid search over hyper-parameters can improve upon the baseline, indicating the usefulness of stage-1 task selection, but a reasonable-sized fair-comparison grid search (i.e., not exhaustive over all ratio values) is not able to match our stage-2 GP process that leverages prior experimental results to more efficiently find the best setting.

---

terpretably chooses the 2-3 tasks that are most beneficial for the given primary task. Also see Sec. 4 for comparison of training speeds for these two setups.

[11] We present this ablation only on MRPC for now, because GP stage-2 takes a lot of time without the task selection stage.

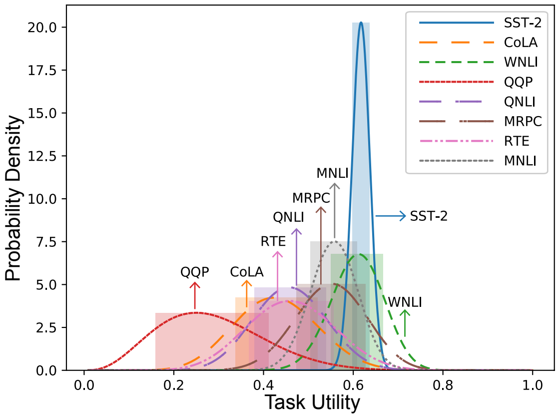

Figure 3: Visualization of task utility estimates from the multi-armed bandit controller on SST-2 (primary task). The x-axis represents the task utility, and the y-axis represents the corresponding probability density. Each curve corresponds to a task and the bar corresponds to their confidence interval.

6.2 Stability of MTL Models

In this section, we provide the mean and standard deviation of our baseline and multi-task models (over three runs) on the validation set. Note that the test set is hidden, so we cannot do these studies on it. As seen in Table 3, our multi-task models clearly surpass the performance of baseline models w.r.t. standard deviation gaps, in all tasks.

6.3 Visualization of Task Selection

In Fig. 3, we show an example of the task utility estimates from the stage-1 multi-armed bandit controller (Eq. 3.3) on SST-2. The x-axis represents the task utility, and the y-axis represents the probability density over task utility. Each curve represents a task (the blue curve corresponds to the primary task, SST-2, and the rest of the curves correspond to auxiliary tasks), and the width of the bars represents the confidence interval of their estimates. We can see that the bandit controller gives the highest (and most confident) utility estimate for the primary task, which is intuitive given that the primary task should be the most useful task for learning itself. Further, it gives 2-3 tasks moderate utility estimates (the corresponding expected values are around 0.5), and relatively lower utility estimates for the remaining tasks (the corresponding expected values are lower than 0.5).

6.4 Educated-Guess Baselines

Name	RTE	MRPC	QNLI	CoLA	SST-2
BASELINES					
Mean Std	58.6 0.94	78.3 0.31	74.9 0.30	74.6 0.44	91.4 0.36
MULTI-TASK MODELS					
Mean Std	62.0 0.62	81.1 0.20	76.0 0.18	75.7 0.18	91.8 0.29

Table 3: Validation-set performance mean and standard deviation (based on three runs) of our baselines and Multi-task models in accuracy.

We additionally experimented with 'educated-guess' baseline models, where MTL is performed using manual intuition mixtures that seem a priori sensible.[12] For example, with MRPC as the primary task, our first educated-guess baseline is to choose other similar paraphrasing-based auxiliary tasks, i.e., QQP in case of GLUE. This MRPC+QQP model achieves 80.8, whereas our AUTOSEM framework chose MRPC+RTE+MultiNLI and achieved 81.2. Furthermore, as our second educated-guess baseline, we added MultiNLI as an auxiliary task (in addition to QQP), since MultiNLI was helpful for all tasks in our MTL experiments. This educated-guess MRPC+QQP+MultiNLI model achieves 80.9 (vs. 81.2 for our AUTOSEM model). This suggests that our AUTOSEM framework (that automatically chose the seemingly less-related RTE task for MRPC) is equal or better than manual intuition based educated-guess models.

7 Conclusion

We presented the AUTOSEM framework, a two-stage multi-task learning pipeline, where the first stage automatically selects the relevant auxiliary tasks for the given primary task and the second stage automatically learns their optimal mixing ratio. We showed that AUTOSEM performs better than strong baselines on several GLUE tasks. Further, we ablated the importance of each stage of our AUTOSEM framework and also discussed the intuition of selected auxiliary tasks.

---

[12] These educated-guess models replace our stage-1 automatic auxiliary task section with manual intuition task-mixtures; but we still use our stage-2 Gaussian Process for mixing ratio learning, for fair comparison.

Abstract

How do typological properties such as word order and morphological case marking affect the ability of neural sequence models to acquire the syntax of a language? Cross-linguistic comparisons of RNNs' syntactic performance (e.g., on subject-verb agreement prediction) are complicated by the fact that any two languages differ in multiple typological properties, as well as by differences in training corpus. We propose a paradigm that addresses these issues: we create synthetic versions of English, which differ from English in one or more typological parameters, and generate corpora for those languages based on a parsed English corpus. We report a series of experiments in which RNNs were trained to predict agreement features for verbs in each of those synthetic languages. Among other findings, (1) performance was higher in subject-verb-object order (as in English) than in subject-object-verb order (as in Japanese), suggesting that RNNs have a recency bias; (2) predicting agreement with both subject and object (polypersonal agreement) improves over predicting each separately, suggesting that underlying syntactic knowledge transfers across the two tasks; and (3) overt morphological case makes agreement prediction significantly easier, regardless of word order.

1 Introduction

The strong performance of recurrent neural networks (RNNs) in applied natural language processing tasks has motivated an array of studies that have investigated their ability to acquire natural language syntax without syntactic annotations; these studies have identified both strengths (Linzen et al., 2016; Giulianelli et al., 2018; Gulordava et al., 2018; Kuncoro et al., 2018; van Schijndel and Linzen, 2018; Wilcox et al., 2018) and limitations (Chowdhury and Zamparelli, 2018; Marvin and Linzen, 2018; Wilcox et al., 2018).

Most of the work so far has focused on English, a language with a specific word order and relatively poor morphology. Do the typological properties of a language affect the ability of RNNs to learn its syntactic regularities? Recent studies suggest that they might. Gulordava et al. (2018) evaluated language models on agreement prediction in English, Russian, Italian and Hebrew, and found worse performance on English than the other languages. In the other direction, a study on agreement prediction in Basque showed substantially *worse* average-case performance than reported for English (Ravfogel et al., 2018).

Existing cross-linguistic comparisons are difficult to interpret, however. Models were inevitably trained on a different corpus for each language. The constructions tested can differ across languages (Gulordava et al., 2018). Perhaps most importantly, any two natural languages differ in a number of typological dimensions, such as morphological richness, word order, or explicit case marking. This paper proposes a controlled experimental paradigm for studying the interaction of the inductive bias of a neural architecture with particular typological properties. Given a parsed corpus for a particular natural language (English, in our experiments), we generate corpora for synthetic languages that differ from the original language in one of more typological parameters (Chomsky, 1981), following Wang and Eisner (2016). In a synthetic version of English with a subject-object-verb order, for example, sentence (1-a) would be transformed into (1-b):

(1) a. The man eats the apples.
b. The man the apples eats.

Figure 1: The sentences generated in our synthetic languages based on an original English sentence. All verbs in the experiments reported in the paper carried subject and object agreement suffixes as in the polypersonal agreement experiment; we omitted these suffixes from the word order variation examples in the table for ease of reading.

We then train a model to predict the agreement features of the verb; in the present paper, we focus on predicting the plurality of the subject and the object (that is, whether they are singular or plural). The subject plurality prediction problem for (1-b), for example, can be formulated as follows:

(2) The man the apples ⟨singular/plural subject?⟩.

We illustrate the potential of this approach in a series of case studies. We first experiment with polypersonal agreement, in which the verb agrees with both the subject and the object (§3). We then manipulate the order of the subject, the object and the verb (§4), and experiment with overt morphological case (§5). For a preview of our synthetic languages, see Figure 1.

2 Setup

Synthetic Language Generation We used an expert-annotated corpus, to avoid potential confounds between the typological parameters we manipulated and possible parse errors in an automatically parsed corpus. As our starting point, we took the English Penn Treebank (Marcus et al., 1993), converted to the Universal Dependencies scheme (Nivre et al. 2016) using the Stanford converter (Schuster and Manning, 2016). We then manipulated the tree representations of the sentences in the corpus to generate parametrically modified English corpora, varying in case systems, agreement patterns, and order of core elements. For each parametric version of English, we recorded the verb-argument relations within each sentence, and created a labeled dataset. We exposed our models to sentences from which one of the verbs was omitted, and trained them to predict the plurality of the arguments of the unseen verb. The following paragraph describes the process of collecting verb-argument relations; a detailed discussion of the parametric generation process for agreement marking, word order and case marking is given in the corresponding sections. We have made our synthetic language generation code publicly available.[1]

Argument Collection We created a labeled agreement prediction dataset by first collecting verb-arguments relations from the parsed corpus. We collected nouns, proper nouns, pronouns, adjectives, cardinal numbers and relative pronouns connected to a verb (identified by its part-of-speech tag) with an *nsubj*, *nsubjpass* or *dobj* dependency edge, and record the plurality of those arguments. Verbs that were the head of a clausal complement without a subject (*xcomp* dependencies) were excluded. We recorded the plurality of the dependents of the verb regardless of whether the tense and person of the verb condition agreement in English (that is, not only in third-person

Prediction task	Subject accuracy	Object accuracy	Object recall
Subject	94.7 ± 0.3	-	-
Object	-	88.9 ± 0.26	81.8 ± 1.4
Joint	95.7 ± 0.23	90.0 ± 0.1	85.4 ± 2.3

Table 1: Results of the polypersonal agreement experiments. "Joint" refers to multitask prediction of subject and object plurality.

	Singular	Plural
Subject	-kar	-kon
Object	-kin	-ker
Indirect Object	-ken	-kre

Table 2: Case suffixes used in the experiments. Verbs are marked by a concatenation of the suffixes of their corresponding arguments.

present-tense verbs). For relative pronouns that function as subjects or objects, we recorded the plurality of their referent; for instance, in the phrase *Treasury bonds, which pay lower interest rates*, we considered the verb *pay* to have a plural subject.

Prediction Task We experimented both with prediction of one of the arguments of the verb (subject or object), and with a joint setting in which the model predicted both arguments of each verb. Consider, for example, the prediction problem (3) (the verb in the original sentence was *gave*):

(3) The state ⟨verb⟩ CenTrust 30 days to sell the Rubens .

In the joint prediction setting the system is expected to make the prediction ⟨subject: singular, object: plural⟩. For each argument, the model predicts one of three categories: SINGULAR, PLURAL or NONE. The NONE label was used in the object prediction task for intransitive verbs, which do not have an object; it was never used in the subject prediction task.

Model We used bidirectional LSTMs with 150 hidden units. The bidirectional LSTM's representation of the left and right contexts of the verb was fed into a multilayer perceptron (MLP) with two hidden layers of sizes 100 and 50. We used independent MLPs to predict subject and object plurality. To capture morphological information, words were represented as the sum of the word embedding and embeddings of the character n-grams that made up the word.[2]

The model (including the embedding layer) was trained end-to-end using the Adam optimizer (Kingma and Ba, 2014). For each of the experiments described in the paper, we trained four models with different random initializations; we report averaged results alongside standard deviations.

3 Polypersonal Agreement

In languages with polypersonal agreement, verbs agree not only with their subject (as in English), but also with their direct object. Consider the following Basque example:[3]

(4) *Kutxazain-ek bezeroa-ri liburu-ak*
cashier-PL.ERG customer-SG.DAT book-PL.ABS
eman dizkiote
gave they-them-to-her/him
The cashiers gave the books to the customer.

Information about the grammatical role of certain constituents in the sentence may disambiguate the function of others; most trivially, if a word is the subject of a given verb, it cannot simultaneously be its object. The goal of the present experiment is to determine whether jointly predicting both object and subject plurality improves the overall performance of the model.

Corpus Creation In sentences with multiple verbs, agreement markers on verbs other than the prediction target could plausibly help predict the features on the target verb. In a preliminary experiment, we did not observe clear differences between different verb marking schemes (e.g., avoiding marking agreement on verbs other than the prediction target). We thus opted for full marking in all experiments: verbs are modified with suffixes that encode the number of all their arguments (see Figure 1). The suffixes we used for verbs are a concatenation of the respective case suffixes of their arguments (Table 2). For consistency, we remove plurality markers from English

---

[2] Specifically, let E_t and E_{ng} be word and n-gram embedding matrices, and let t_w and NG_w be the word and the set of all n-grams of lengths 1 to 5, for a given word w. The final vector representation of w, e_w, is given by $e_w = E_t[t] + \sum_{ng \in NG_w} E_{ng}[ng]$.

[3] The verb in Basque agrees with the indirect object as well. In preliminary experiments, the recall of models trained on indirect object prediction was very low, due to the small number of indirect objects in the training corpus; we therefore do not include this task.

verbs before adding our suffixes (for example, by replacing *has* with *have*).

Single Task Results The basic results are summarized in Table 1. Recall is calculated as the proportion of the sentences with a direct object for which the model predicted either SINGULAR or PLURAL, but not NONE. Since all verbs included in the experiment had a subject, subject recall was 100% and is therefore not reported.

Plurality prediction accuracy was higher for subjects than objects. Recall for object prediction was 81.8%, indicating that in many sentences the model was unable to identify the direct object. The lower performance on object plurality prediction is likely to be due to the fact that only about third of the sentences contain a direct object. This hypothesis is supported by the results of a preliminary experiment, in which the model was trained only on transitive sentences (with a direct object). Transitive-only training led to a reversal of the pattern: object plurality was predicted with higher accuracy than subject plurality. We conjecture that this is due to the fact that most noun modifiers in English follow the head, making the head of the object, which in general determines the plurality of the phrase, closer on average to the verb than the head of the subject (see Table 3 below).

The accuracy we report for subject prediction, 94.7%, is lower than the accuracy of over 99% reported by Linzen et al. (2016). This may be due to one of several reasons. First, our training set was smaller: ∼35,000 sentences in our treebank corpus compared to ∼121,000 in their automatically parsed corpus. Second, sentences in the Wall Street Journal corpus may be more syntactically complex on average than sentences in Wikipedia, making it more challenging to identify the verb's arguments. Finally, we predicted agreement in all tenses, whereas Linzen et al. (2016) limited their study to the present tense (where English does in fact show agreement); it may be the case that sentences with past tense verbs are on average more complex than those with present tense verbs, regardless of the corpus.

Multitask Training Accuracy was higher in the joint setting: polypersonal agreement prediction is easier for the model. Subject prediction accuracy rose from 94.7% to 95.7%, object precision was slightly higher (90.0% compared to 88.9%), and object recall was significantly higher, increasing from 81.8% to 85.4%. We hypothesize that supervision signals from the prediction of both arguments lead to more robust abstract syntactic representations that transfer across the two tasks (Enguehard et al., 2017); for example, the model may be better able to identify the head of a noun phrase, regardless of whether it is the subject or the object. These findings suggest that when training on an auxiliary agreement prediction task in order to improve a language model's syntactic performance, additional supervision—in the form of predicting both subject and object—may be beneficial.

4 Order of Core Elements

Languages vary in the typical order of the core elements of a clause: the subject, the object and the verb (Dryer, 2013). For example, whereas in English the canonical order is Subject-Verb-Object (SVO, *The priests are reading the book*), in Irish it is Verb-Subject-Object (VSO, Dillon and Ó Cróinin 1961):

(5)	Léann	[na	sagairt]	[na	leabhair].
	read.PRES	the.PL	priest.PL	the.PL	book.PL

'The priests are reading the books.'

While there are six possible orderings of these three elements, in most human languages the subject precedes both the object and the verb: about 86.5% of the languages use either SOV or SVO orders, 9% of the languages use VOS order, and OVS and OSV languages are extremely rare (Tomlin, 1986).

To test whether RNNs have inductive biases favoring certain word orders over others, we created synthetic versions of English with all six possible orders of core elements. While natural languages often allow at least a limited degree of word order flexibility, our experiments used a simplified setting in which word order was either completely fixed (e.g., always SVO) or fully flexible, where one of the six orders was selected uniformly at random for each sentence in the corpus (the same order is used for all of the clauses of the sentence).

4.1 Corpus Creation

Given a dependency parse for a sentence, we modulated the order of the subject and object nodes with respect to their verb. When changing the position of an argument node, we moved the entire subtree rooted in that node, including verbs and other arguments in this subtree. In the permutation process, we moved to the subject position not only nominal subjects (*nsubj* and *nsubjpass* edges in UD), but also clausal subjects (*csubj* edges). Similarly, we moved to the object position not only nominal objects (*dobj* edge), but also clausal complements (*ccomp* and *xcomp*).

We kept negations, adverbial modifiers, particles and auxiliaries in their original position with respect to the verb. Other non-core dependents of the verb (i.e. not the subject or the object), such as prepositional phrases, were placed according to their original position relative to the verb. For instance, in the clause *the broker took them out for lunch*, the phrase *for lunch* appeared directly following the verb and the arguments of the subtree in which it resides (*took*, *them*, *the broker*) in all word orders, reflecting its original position relative to the verb *took* (see Figure 1). Relative pronouns and complementizers remained in their original position.[4]

In all experiments in this section, we trained the model to jointly predict the plurality of the subject and the object. For consistency across the object and subject plurality prediction tasks, we used the polypersonal agreement markers on all verbs in the sentence (except, of course, for the prediction target, which was withheld completely). For example, in the OVS version of the sentence presented in Figure 1, the input was (6), where *kon* marks the fact that *say* has a plural subject:

(6) them ⟨verb⟩ out frequently the broker for lunch say*kon* they .

4.2 Results

Performance varied significantly across word orders (Table 3). Subject plurality prediction accuracy was inversely correlated with the frequency of attractors (intervening nouns of the opposite plurality) in the language: accuracy was lowest for subject prediction in the VOS and SOV languages, in which objects intervene between the subject and the verb (Figure 2). The degraded performance in these languages is consistent with the attraction effects found in previous studies of agreement in natural languages (Linzen et al., 2016; Gulordava et al., 2018), and support the hypothesis that RNNs have an inductive bias favoring dependencies with recent elements; we test this hypothesis in a more controlled way in §4.3.

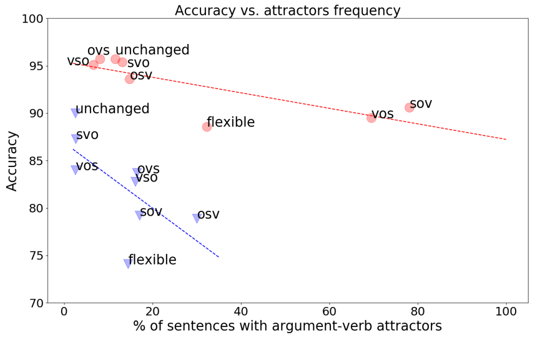

Figure 2: Subject and object plurality prediction accuracy as a function of the percentage of sentences with attractors that are arguments of the verb. Red circles represent subject prediction and blue triangles represent object prediction. R^2: 0.61 for subject, 0.43 for object.

Attractors affected object prediction accuracy as well. The highest accuracy among the synthetic languages was in the SVO language and the worst performance observed in the OSV language. As in §3, subjects were easier to predict than objects, likely because all verbs in the training set had a subject, but only 35% had an object.

Flexible word order was especially challenging for the model, with a subject plurality prediction accuracy of 88.6%, object plurality prediction accuracy of 74.1%, and object recall of 60.2%. This does not necessarily bear on the RNNs' inductive biases: flexible word order without case marking would make it difficult for any learner to infer syntactic relations. Without overt cues, the model must resort to selectional restrictions (e.g., in *the apples ate the man*, the only plausible subject is *the man*), but those are difficult to learn from a small corpus. What's more, some sentences are truly ambiguous when there are no case markers or word order cues; this happens for example when both arguments are animate, as in *the lawyer saw the doctor* (Gibson et al., 2013; Ettinger et al., 2018).

4.3 Withholding Direct Objects in Training

The previous experiments suggested that the RNN has a tendency to identify the more recent argument as the subject, leading to attraction effects

---

[4] For example, the result of transforming (i) to VSO word order was (ii) rather than (iii):

(i) But these are not the differences that make headlines.

(ii) But are these not the differences that make headlines.

(iii) But are these not the differences make headlines that.

	Subject		Object		
Order	% Attractors	Accuracy	% Attractors	Accuracy	Recall
Unchanged	11.56	95.7 ± 0.23	2.55	90.0 ± 0.1	85.4 ± 2.37

VSO	6.65	95.1 ± 0.12	16.09	82.8 ± 0.7	70.0 ± 1.91
OSV	14.81	93.6 ± 0.23	30.00	78.9 ± 0.17	63.5 ± 4.59
OVS	8.13	95.7 ± 0.37	16.42	83.7 ± 0.32	72.8 ± 1.58
Flexible	32.24	88.6 ± 0.43	14.44	74.1 ± 0.70	60.2 ± 3.24

Table 3: Subject and object plurality prediction for different word orders (recall for the subject is 100% and is not indicated). The % attractors columns indicate the percentage of sentences containing verb-argument attractors. The number are averaged over four runs and the error interval represents the standard deviation.

caused by the object. We conjectured that this is due to the fact that many verbs are intransitive, that is, have a subject but not an object. The clauses in which those verbs appear provide ambiguous evidence: they are equally compatible with a generalization in which the subject is the *most recent* core element before the verb, and with a generalization in which the subject is the *first* core constituent of the clause. Attraction effects suggest that the inductive bias of the RNN leads it to adopt the incorrect recency-based generalization. To test this hypothesis in a controlled way, we adopt the "poverty of the stimulus" paradigm (Wilson, 2006; Culbertson and Adger, 2014; McCoy et al., 2018): we withhold all evidence that disambiguates these two hypotheses (namely, all transitive sentences), and test how the RNN generalizes to the withheld sentence type.

We used the SOV and VOS corpora described before; in both of these languages, the object intervened between the subject and the verb, potentially causing agreement attraction. Crucially, we train only on sentences *without* a direct object, and test on the following three types of sentences:

1. Sentences with an object of the opposite plurality from the subject (object attractor).

2. Sentences with an object of the same plurality as the subject (non-attractor object).[5]

3. Sentences without an object, but with one or more nouns of the opposite plurality intervening between the subject and the verb (non-object attractor); e.g., *The gap between winners and losers will grow* is intransitive, but the plural words *winners* and *losers*, which are a part of a modifier of the subject, may serve as attractors for the singular subject *gap*.

The results are shown in Table 4. Withholding direct objects during training dramatically degraded the performance of the model on sentences with an object attractor: the accuracy decreased from 90.6% for the model trained on the full SOV corpus (Table 3) to 60.0% for the model trained only on intransitive sentences from the same corpus. There was an analogous drop in performance in the case of VOS (89.5% compared to 48.3%). By contrast, attractors that were not core arguments, or objects that were not attractors, did not hurt performance in a comparable way. This suggests that in our poverty of the stimulus experiments RNNs were able to distinguish between core and non-core elements, but struggled on instances in which where the object directly preceded the verb (the instances that were withheld in training). This constitutes strong evidence for the RNN's recency bias: our models extracted the generalization that subjects directly precede the verb, even though the data were equally compatible with the generalization that the subject is the first core argument in the clause.

These findings align with the results of Khandelwal et al. (2018), who demonstrated that RNN language models are more sensitive to perturbations in recent input words compared with perturbations to more distant parts of the input. While in their case the model's recency preference can

---

[5] When the object is a noun-noun compound, it is considered a non-attractor if its head is not of the opposite plurality of the subject, regardless of the plurality of other elements. This can only make the task harder compared with the alternative of considering compound objects such as "screen displays" as attractors for plural subjects.

	Object (attractor)	Object (non attractor)	Non-object attractor
SOV	60.3 ± 3.7	92.8 ± 0.3	79.2 ± 3
VOS	48.3 ± 2.3	94.0 ± 2.3	83.1 ± 1.1

Table 4: Subject prediction accuracy in the "poverty of the stimulus" paradigm of Section 4.3, where transitive sentences were withheld during training. Numbers are averaged over four runs and the error interval represents the standard deviation.

be a learned property (since recent information is more relevant for the task of next-word prediction), our experiment focuses on the inherent inductive biases of the model, as the cues that are necessary for differentiating between the two generalizations were absent in training.

4.4 Discussion

Our reordering manipulation was limited to core element (subjects, objects and verbs). Languages also differ in word order inside other types of phrases, including noun phrases (e.g., does an adjective precede or follow the noun?), adpositional phrases (does the language use prepositions or postpositions?), and so on. Greenberg (1963) pointed out correlations between head-modifier orders across phrase categories; while a significant number of exceptions exist, these correlations have motivated proposals for a language-wide setting of a Head Directionality Parameter (Stowell, 1981; Baker, 2001). In future work, we would like to explore whether consistent reordering across categories improves the model's performance.

In practice, even languages with a relatively rigid word order almost never enforce this order in every clause. The order of elements in English, for example, is predominately SVO, but constructions in which the verb precedes the subject do exist, e.g., *Outside were three police officers*. Other languages are considerably more flexible than English (Dryer, 2013). Given that word order flexibility makes the task more difficult, our setting is arguably simpler than the task the model would face when learning a natural language.

The fact that the agreement dependency between the subject and the verb was more challenging to establish in the SOV order compared to the SVO order is consistent with the hypothesis that SVO languages make it easier to distinguish the subject from the object (Gibson et al., 2013); indeed, to compensate for this issue, SOV languages more frequently employ case marking (Matthew Dryer, quoted in Gibson et al. 2013).

There was not a clear relationship between the prevalence of a particular word order in the languages of the world and the difficulty that our models experienced with that order. The model performed best on the OVS word order, which is present in a very small number of languages ($\sim$1%). SOV languages were more difficult for our RNNs to learn than SVO languages, even though SOV languages are somewhat *more* common (Dryer, 2013). These results weakly support functional explanations of these typological tendencies; such explanations appeal to communicative efficiency considerations rather than learning biases (Maurits et al., 2010). Of course, since the inductive biases of humans and RNNs are likely to be different in many respects, our results do not rule out the possibility that the distribution of word orders is driven by a human learning bias after all.

5 Overt Morphological Case Systems

The vast majority of noun phrases in English are not overtly marked for grammatical function (case), with the exception of pronouns; e.g., the first-person singular pronoun is *I* when it is a subject and *me* when it is an object. Other languages mark case on most nouns. Consider, for example, the following example from Russian:[6]

(7) a. ya kupil knig-u.
I bought book-OBJECT
'I bought the book.'
b. knig-a ischezla.
book-SUBJECT disappeared
'The book disappeared.'

Overt case marking reduces ambiguity and facilitates parsing languages with flexible word order. To investigate the influence of case on agreement prediction—and on the ability to infer sentence structure—we experimented with different case systems. In all settings, we used "fused" suffixes, which encode both plurality and grammatical function. We considered three case systems (see Figure 1):

1. An unambiguous case system, with a unique

---

[6] The standard grammatical term for these cases are nominative (for subject) and accusative (for object); we use SUBJECT and OBJECT for clarity.

Case system	Flexible word order		VOS		OVS	
	Subject A	Object A/R	Subject A	Object A/R	Subject A	Object A/R
Unambiguous	99.2 ± 0.5	98.7 ± 0.2 $/98.0 \pm 0.5$	98.9 ± 0.2	99.5 ± 0.1 $/99.1 \pm 0.1$	99.5 ± 0.2	98.6 ± 0.3 $/98.4 \pm 0.6$
Syncretic	99.3 ± 0.2	93.6 ± 0.4 $/88.9 \pm 1.7$	99.1 ± 0.2	97.1 ± 0.2 $/95.0 \pm 1.1$	99.4 ± 0.1	97.8 ± 0.2 $/97.4 \pm 1.2$
Argument marking	96.0 ± 0.3	86.1 ± 0.9 $/79.7 \pm 4.9$	96.9 ± 0.1	93.6 ± 0.1 $/89.8 \pm 2.4$	99.6 ± 0.1	96.8 ± 0.1 $/95.5 \pm 0.5$

Table 5: Accuracy (A) and recall (R) in predicting subject and object agreement with different case systems.

suffix for each combination of number and grammatical function.

2. A partially syncretic (ambiguous) case system, in which the same suffix was attached to both singular subjects and plural objects (modeled after Basque).

3. A fully syncretic case system (argument marking only): the suffix indicated only the plurality of the argument, regardless of its grammatical function (cf. subject/object syncretism in Russian neuter nouns).

In the typological survey reported in Baerman and Brown (2013), 62% of the languages had no or minimal case marking, 20% had syncretic case systems, and 18% had case systems with no syncretism.

Corpus Creation The suffixes we used are listed in Table 2. We only attached the suffix to the head of the relevant argument; adjectives and other modifiers did not carry case suffixes. The same suffix was used to mark plurality/case on noun and the agreement features on the verb; e.g., if the verb *eat* had a singular subject and plural object, it appeared as eat*karker* (the singular subject suffix was *kar* and the plural object suffix was *ker*). We stripped off plurality and case markers from the original English noun phrases before adding these suffixes.

Setup We evaluated the interaction between different case marking schemes and three word orders: flexible word order and the two orders on which the model achieved the best (OVS) and worst (VOS) subject prediction accuracy. We train one model for each combination of case system and word order. We jointly predicted the plurality of subject and the object.

Results and Analysis The results are summarized in Table 5. Unambiguous case marking dramatically improved subject and object plurality prediction compared with the previous experiments; accuracy was above 98% for all three word orders. Partial syncretism hurt performance somewhat relative to the unambiguous setting (except with flexible word order), especially for object prediction. The fully syncretic case system, which marked only the plurality of the head of each argument, further decreased performance. At the same time, even this limited marking scheme was helpful: accuracy in the most challenging setting, flexible word order (subject: 96.0%; object: 86.1%), was not very different from the results on unmodified English (95.7% and 90.0%). This contrasts with the poor results on the flexible setting without cases (subject: 88.6%; object: 60.2%). On the rigid orders, a fully syncretic system still significantly improved agreement prediction. The moderate effect of case syncretism on performance suggests that most of the benefits of case marking stems from the overt marking of the heads of all arguments.

Overall, these results are consistent with the observation that languages with explicit case marking tend to allow a more flexible word orders compared with languages such as English that make use of word order to express grammatical function of words.

6 Related Work

Our approach of constructing synthetic languages by parametrically modifying parsed corpora for natural languages is closely inspired by Wang and Eisner (2016) (see also Wang and Eisner 2017). While they trained a model to mimic the POS tags order-statistics of the target language, we manually modified the parsed corpora; this allows us to control for selected parameters, at the expense of reducing generality.

Simpler synthetic languages (not based on natural corpora) have been used in a number of recent studies to examine the inductive biases of different neural architectures (Bowman et al., 2015; Lake and Baroni, 2018; McCoy et al., 2018). In another recent study, Cotterell et al. (2018) measured the ability of RNN and n-gram models to perform character-level language modeling in a sample of languages, using a parallel corpus; the main typological property of interest in that study was morphological complexity. Finally, a large number of studies, some mentioned in the introduction, have used syntactic prediction tasks to examine the generalizations acquired by neural models (see also Bernardy and Lappin 2017; Futrell et al. 2018; Lau et al. 2017; Conneau et al. 2018; Ettinger et al. 2018; Jumelet and Hupkes 2018).

7 Conclusions

We have proposed a methodology for generating parametric variations of existing languages and evaluating the performance of RNNs in syntactic feature prediction in the resulting languages. We used this methodology to study the grammatical inductive biases of RNNs, assessed whether certain grammatical phenomena are more challenging for RNNs to learn than others, and began to compare these patterns with the linguistic typology literature.

In our experiments, multitask training on polypersonal agreement prediction improved performance, suggesting that the models acquired syntactic representations that generalize across argument types (subjects and objects). Performance varied significantly across word orders. This variation was not correlated with the frequency of the word orders in the languages of the world. Instead, it was inversely correlated with the frequency of attractors, demonstrating a recency bias. Further supporting this bias, in a poverty-of -the-stimulus paradigm, where the data were equally consistent with two generalizations—first, the generalization that the subject is the first argument in the clause, and second, the generalization that the subject is the most recent argument preceding the verb—RNNs adopted the recency-based generalization. Finally, we found that overt case marking on the heads of arguments dramatically improved plurality prediction performance, even when the case system was highly syncretic.

Agreement feature prediction in some of our synthetic languages is likely to be difficult not only for RNNs but for many other classes of learners, including humans. For example, agreement in a language with very flexible word order and without case marking is impossible to predict in many cases (see §4.2), and indeed such languages are very rare. In future work, a human experiment based on the agreement prediction task can help determine whether the difficulty of our languages is consistent across humans and RNNs.

Attention is not Explanation

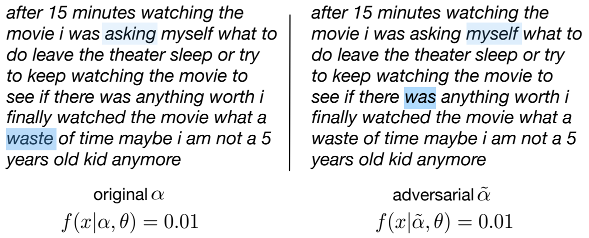
Abstract

Attention mechanisms have seen wide adoption in neural NLP models. In addition to improving predictive performance, these are often touted as affording transparency: models equipped with attention provide a distribution over attended-to input units, and this is often presented (at least implicitly) as communicating the relative importance of inputs. However, it is unclear what relationship exists between attention weights and model outputs. In this work we perform extensive experiments across a variety of NLP tasks that aim to assess the degree to which attention weights provide meaningful "explanations" for predictions. We find that they largely do not. For example, learned attention weights are frequently uncorrelated with gradient-based measures of feature importance, and one can identify very different attention distributions that nonetheless yield equivalent predictions. Our findings show that standard attention modules do not provide meaningful explanations and should not be treated as though they do. Code to reproduce all experiments is available at `https://github.com/successar/AttentionExplanation`.

1 Introduction and Motivation

Attention mechanisms (Bahdanau et al., 2014) induce conditional distributions over input units to compose a weighted context vector for downstream modules. These are now a near-ubiquitous component of neural NLP architectures. Attention weights are often claimed (implicitly or explicitly) to afford insights into the "inner-workings" of models: for a given output one can inspect the inputs to which the model assigned large attention weights. Li *et al.* (2016) summarized this commonly held view in NLP: "Attention provides an important way to explain the workings of neural models". Indeed, claims that attention provides interpretability are common in the literature, e.g., (Xu et al., 2015; Choi et al., 2016; Lei et al., 2017; Martins and Astudillo, 2016; Xie et al., 2017).[1]



after 15 minutes watching the movie i was asking myself what to do leave the theater sleep or try to keep watching the movie to see if there was anything worth i finally watched the movie what a waste of time maybe i am not a 5 years old kid anymore

after 15 minutes watching the movie i was asking myself what to do leave the theater sleep or try to keep watching the movie to see if there was anything worth i finally watched the movie what a waste of time maybe i am not a 5 years old kid anymore

Figure 1: Heatmap of attention weights induced over a negative movie review. We show observed model attention (left) and an adversarially constructed set of attention weights (right). Despite being quite dissimilar, these both yield effectively the same prediction (0.01).

Implicit in this is the assumption that the input units (e.g., words) accorded high attention weights are responsible for model outputs. But as far as we are aware, this assumption has not been formally evaluated, and our findings here suggest that it is problematic. More specifically, we empirically investigate the relationship between attention weights, inputs, and outputs. Assuming attention provides an explanation for model predictions, we might expect the following properties to hold. (i) Attention weights should correlate with feature importance measures (e.g., gradient-based measures); (ii) Alternative (or *counterfactual*) attention weight configurations ought to yield corresponding changes in prediction (and if they do not then are equally plausible as explanations). We report that neither property is consistently observed by standard attention mechanisms in the context of text classification, question answering (QA), and Natural Language Inference (NLI) tasks when RNN encoders are used.

---

[1] We do not intend to single out any particular work; indeed one of the authors has himself presented (supervised) attention as providing interpretability (Zhang et al., 2016).

Proceedings of NAACL-HLT 2019, pages 3543–3556
Minneapolis, Minnesota, June 2 - June 7, 2019.

Consider Figure 1. The left panel shows the original attention distribution α over the words of a particular movie review using a standard attentive BiLSTM architecture for sentiment analysis. It is tempting to conclude from this that the token *waste* is largely responsible for the model coming to its disposition of 'negative' ($\hat{y} = 0.01$). But one can construct an alternative attention distribution $\tilde{\alpha}$ (right panel) that attends to entirely different tokens yet yields an essentially identical prediction (holding all other parameters of f, θ, constant).

Such counterfactual distributions imply that explaining the original prediction by highlighting attended-to tokens is misleading insofar as alternative attention distributions would have yielded an equivalent prediction (e.g., one might conclude from the right panel that model output was due primarily to *was* rather than *waste*). Further, the attention weights in this case correlate only weakly with gradient-based measures of feature importance ($\tau_g = 0.29$). And arbitrarily permuting the entries in α yields a median output difference of 0.006 with the original prediction.

These and similar findings call into question the view that attention provides meaningful insight into model predictions. We thus caution against using attention weights to highlight input tokens "responsible for" model outputs and constructing just-so stories on this basis, particularly with complex encoders.

Research questions and contributions. We examine the extent to which the (often implicit) narrative that attention provides model *transparency*[2] holds across tasks by exploring the following empirical questions.

1. To what extent do induced attention weights correlate with measures of feature importance – specifically, those resulting from gradients and *leave-one-out* methods?

2. Would alternative attention weights (and hence distinct heatmaps/"explanations") necessarily yield different predictions?

Our findings with respect to these questions (assuming a BiRNN encoder) are summarized as follows: (1) Only weakly and inconsistently, and, (2) No; it is very often possible to construct *adversarial* attention distributions that yield effectively equivalent predictions as when using the originally induced attention weights, despite attending to entirely different input features. Further, randomly permuting attention weights often induces only minimal changes in output.

2 Preliminaries and Assumptions

We consider exemplar NLP tasks for which attention mechanisms are commonly used: classification, natural language inference (NLI), and question answering.[3] We adopt the following general modeling assumptions and notation.

We assume model inputs $\mathbf{x} \in \mathbb{R}^{T \times |V|}$, composed of one-hot encoded words at each position. These are passed through an embedding matrix $\mathbf{E}$ which provides dense (d dimensional) token representations $\mathbf{x}_e \in \mathbb{R}^{T \times d}$. Next, an encoder **Enc** consumes the embedded tokens in order, producing T m-dimensional hidden states: $\mathbf{h} = \textbf{Enc}(\mathbf{x}_e) \in \mathbb{R}^{T \times m}$. We predominantly consider a Bi-RNN as the encoder module, but for completeness we also analyze convolutional and (unordered) 'average embedding' variants.[4]

A similarity function ϕ maps $\mathbf{h}$ and a query $\mathbf{Q} \in \mathbb{R}^m$ (e.g., hidden representation of a question in QA, or the hypothesis in NLI) to scalar scores, and attention is then induced over these: $\hat{\boldsymbol{\alpha}} = \text{softmax}(\phi(\mathbf{h}, \mathbf{Q})) \in \mathbb{R}^T$. In this work we consider two common similarity functions: *Additive* $\phi(\mathbf{h}, \mathbf{Q}) = \mathbf{v}^T \tanh(\mathbf{W_1 h} + \mathbf{W_2 Q})$ (Bahdanau et al., 2014) and *Scaled Dot-Product* $\phi(\mathbf{h}, \mathbf{Q}) = \frac{\mathbf{hQ}}{\sqrt{m}}$ (Vaswani et al., 2017), where $\mathbf{v}, \mathbf{W_1}, \mathbf{W_2}$ are model parameters.

Finally, a dense layer **Dec** with parameters $\boldsymbol{\theta}$ consumes a weighted instance representation and yields a prediction $\hat{y} = \sigma(\boldsymbol{\theta} \cdot h_\alpha) \in \mathbb{R}^{|\mathcal{Y}|}$, where $h_\alpha = \sum_{t=1}^{T} \hat{\alpha}_t \cdot h_t$; σ is an output activation function; and $|\mathcal{Y}|$ denotes the label set size.

3 Datasets and Tasks

For **binary text classification**, we use:

Stanford Sentiment Treebank (SST) (Socher et al., 2013). 10,662 sentences tagged with sentiment on a scale from 1 (most negative) to 5 (most positive). We filter out neutral instances and dichotomize the remaining sentences into positive (4, 5) and negative (1, 2).

---

[2] Defined as per (Lipton, 2016); we are interested in whether attended-to features are responsible for outputs.

[3] While attention is perhaps *most* common in seq2seq tasks like translation, our impression is that interpretability is not typically emphasized for such tasks, in general.

[4] In the latter case, h_t is the embedding of token t after being passed through a linear layer and ReLU activation.

Dataset	$\|V\|$	*Avg. length*	*Train size*	*Test size*	*Test performance*
SST	16175	19	3034 / 3321	863 / 862	0.81
IMDB	13916	179	12500 / 12500	2184 / 2172	0.88
ADR Tweets	8686	20	14446 / 1939	3636 / 487	0.61
20 Newsgroups	8853	115	716 / 710	151 / 183	0.94
AG News	14752	36	30000 / 30000	1900 / 1900	0.96
Diabetes (MIMIC)	22316	1858	6381 / 1353	1295 / 319	0.79
Anemia (MIMIC)	19743	2188	1847 / 3251	460 / 802	0.92
CNN	74790	761	380298	3198	0.64

SNLI	20982	14	182764 / 183187 / 183416	3219 / 3237 / 3368	0.78

Table 1: Dataset characteristics. For train and test size, we list the cardinality for each class, where applicable: 0/1 for binary classification (top), and 0 / 1 / 2 for NLI (bottom). Average length is in tokens. Test metrics are F1 score, accuracy, and micro-F1 for classification, QA, and NLI, respectively; all correspond to performance using a BiLSTM encoder. We note that results using convolutional and average (i.e., non-recurrent) encoders are comparable for classification though markedly worse for QA tasks.

IMDB Large Movie Reviews Corpus (Maas et al., 2011). Binary sentiment classification dataset containing 50,000 polarized (positive or negative) movie reviews, split into half for training and testing.

Twitter Adverse Drug Reaction dataset (Nikfarjam et al., 2015). A corpus of ∼8000 tweets retrieved from Twitter, annotated by domain experts as mentioning adverse drug reactions.

20 Newsgroups (Hockey vs Baseball). Collection of ∼20,000 newsgroup correspondences, partitioned (nearly) evenly across 20 categories. We extract instances belonging to *baseball* and *hockey*, which we designate as 0 and 1, respectively, to derive a binary classification task.

AG News Corpus (Business vs World).[5] 496,835 news articles from 2000+ sources. We follow (Zhang et al., 2015) in filtering out all but the top 4 categories. We consider the binary classification task of discriminating between *world* (0) and *business* (1) articles.

MIMIC ICD9 (Diabetes) (Johnson et al., 2016). A subset of discharge summaries from the MIMIC III dataset of electronic health records. The task is to recognize if a given summary has been labeled with the ICD9 code for diabetes (or not).

MIMIC ICD9 (Chronic vs Acute Anemia) (Johnson et al., 2016). A subset of discharge summaries from MIMIC III dataset (Johnson et al., 2016) known to correspond to patients with anemia. Here the task to distinguish the type of anemia for each report – *acute* (0) or *chronic* (1).

For **Question Answering (QA)**:

CNN News Articles (Hermann et al., 2015). A corpus of cloze-style questions created via automatic parsing of news articles from CNN. Each instance comprises a paragraph-question-answer triplet, where the answer is one of the anonymized entities in the paragraph.

bAbI (Weston et al., 2015). We consider the three tasks presented in the original bAbI dataset paper, training separate models for each. These entail finding (i) a single supporting fact for a question and (ii) two or (iii) three supporting statements, chained together to compose a coherent line of reasoning.

Finally, for **Natural Language Inference** (NLI):

The *SNLI dataset* (Bowman et al., 2015). 570k human-written English sentence pairs manually labeled for balanced classification with the labels *neutral*, *contradiction*, and *entailment*, supporting the task of natural language inference (NLI). In this work, we generate an attention distribution over premise words conditioned on the hidden representation induced for the hypothesis.

We restrict ourselves to comparatively simple instantiations of attention mechanisms, as described in the preceding section. This means we do not consider recently proposed 'BiAttentive' architectures that attend to tokens in the respective inputs, conditioned on the other inputs (Parikh et al., 2016; Seo et al., 2016; Xiong et al., 2016).

Table 1 provides summary statistics for all datasets, as well as the observed test performances for additional context.

4 Experiments

We run a battery of experiments that aim to examine empirical properties of learned attention weights and to interrogate their interpretability and transparency. The key questions are: *Do*

Table 2: Mean and std. dev. of correlations between gradient/leave-one-out importance measures and attention weights. *Sig. Frac.* columns report the fraction of instances for which this correlation is statistically significant; note that this largely depends on input length, as correlation does tend to exist, just weakly. Encoders are denoted parenthetically. These are representative results; exhaustive results for all encoders are available to browse online.

learned attention weights agree with alternative, natural measures of feature importance? And, *Had we attended to different features, would the prediction have been different*?

More specifically, in Section 4.1, we empirically analyze the correlation between gradient-based feature importance and learned attention weights, and between 'leave-one-out' (LOO) measures and the same. In Section 4.2 we then consider counterfactual (to those observed) attention distributions. Under the assumption that attention weights are explanatory, such counterfactual distributions may be viewed as alternative potential explanations; if these do not correspondingly change model output, then the original attention weights do not provide unique explanation for predictions, i.e., attending to other features could have resulted in the same output.

To generate counterfactual attention distributions, we first consider randomly permuting observed attention weights and recording associated changes in model outputs (4.2.1). We then propose explicitly searching for "adversarial" attention weights that maximally differ from the observed attention weights (which one might show in a heatmap and use to explain a model prediction), and yet yield an effectively equivalent prediction (4.2.2). The latter strategy also provides a useful potential metric for the reliability of attention weights as explanations: we can report a measure quantifying how different attention weights can be for a given instance without changing the model output by more than some threshold ϵ.

All results presented below are generated on test sets. We present results for *Additive* attention below. The results for *Scaled Dot Product* in its place are comparable. We provide a web interface to interactively browse the (very large set of) plots for all datasets, model variants, and experiment types: `https://successar.github.io/AttentionExplanation/docs/`.

In the following sections, we use Total Variation Distance (TVD) as the measure of change between output distributions, defined as follows. $\text{TVD}(\hat{y}_1, \hat{y}_2) = \frac{1}{2}\sum_{i=1}^{|\mathcal{Y}|} |\hat{y}_{1i} - \hat{y}_{2i}|$. We use the Jensen-Shannon Divergence (JSD) to quantify the difference between two attention distributions: $\text{JSD}(\alpha_1, \alpha_2) = \frac{1}{2}\text{KL}[\alpha_1 || \frac{\alpha_1+\alpha_2}{2}] + \frac{1}{2}\text{KL}[\alpha_2 || \frac{\alpha_1+\alpha_2}{2}]$.

4.1 Correlation Between Attention and Feature Importance Measures

We empirically characterize the relationship between attention weights and corresponding feature importance scores. Specifically we measure correlations between attention and: (1) gradient based measures of feature importance (τ_g), and, (2) differences in model output induced by leaving features out (τ_{loo}). While these measures are themselves insufficient for interpretation of neu-

ral model behavior (Feng et al., 2018), they do provide measures of individual feature importance with known semantics (Ross et al., 2017). It is thus instructive to ask whether these measures correlate with attention weights.

The process we follow to quantify this is described in Algorithm 1. We denote the input resulting from removing the word at position t in $\mathbf{x}$ by $\mathbf{x}_{-t}$. Note that we disconnect the computation graph at the attention module so that the gradient does not flow through this layer.

Algorithm 1 Feature Importance Computations

```
$\mathbf{h} \leftarrow \text{Enc}(\mathbf{x}),\ \hat{\alpha} \leftarrow \text{softmax}(\phi(\mathbf{h}, \mathbf{Q}))$
$\hat{y} \leftarrow \text{Dec}(\mathbf{h}, \alpha)$
$g_t \leftarrow |\sum_{w=1}^{|V|} \mathbb{1}[\mathbf{x}_{tw} = 1] \frac{\partial y}{\partial \mathbf{x}_{tw}}|\ , \forall t \in [1, T]$
$\tau_g \leftarrow \text{Kendall-}\tau(\alpha, g)$
$\Delta\hat{y}_t \leftarrow \text{TVD}(\hat{y}(\mathbf{x}_{-t}), \hat{y}(\mathbf{x}))\ , \forall t \in [1, T]$
$\tau_{loo} \leftarrow \text{Kendall-}\tau(\alpha, \Delta\hat{y})$
```

Table 2 reports summary statistics of Kendall τ correlations for each dataset. Full distributions are shown in Figure 2, which plots histograms of τ_g for every data point in the respective corpora. (Corresponding plots for τ_{loo} are similar and the full set can be browsed via the online supplement.) We plot these separately for each class: orange (🟧) represents instances predicted as positive, and purple (🟪) those predicted to be negative. For SNLI, colors 🟪, 🟧 and 🟩 code for contradiction, entailment, and neutral respectively.

In general, observed correlations are modest (recall: 0 indicates no correspondence, 1 implies perfect concordance) for the BiRNN encoder. The centrality of observed densities hovers around or below 0.5 in most of the corpora considered. Moreover, as per Table 2, correlation is sufficiently weak that a statistically significant correlation between attention weights and feature importance scores (both gradient and feature erasure based) cannot consistently be established across corpora.

In contrast, gradients in "average" embedding based models show very high degree of correspondence with attention weights – on average across corpora, correlation between LOO scores and attention weights is ∼0.375 points higher for this encoder, compared to the BiLSTM. These results suggest that, in general, attention weights do not strongly or consistently agree with such feature importance scores in models with contextualized embeddings. This is problematic for the view of attention weights as explanatory, given the face validity of input gradient/erasure based explanations (Ross et al., 2017; Li et al., 2016). On some datasets — notably the MIMIC tasks, and to a lesser extent the QA corpora — this correlation is consistently significant but remains relatively weak. This could be attributed to increased length of documents for these datasets providing stronger signal to standard hypothesis testing methods.

For reference we report correlations between gradients and LOO scores in the Appendix and online materials; these are consistently stronger than the correlation between attention weights and either feature importance score for the recurrent (BiLSTM) encoder. These exhibit, on average, a (i) 0.2 and (ii) ~ 0.25 greater correlation with each other than BiLSTM attention and (i) LOO and (ii) gradient scores.

4.2 Counterfactual Attention Weights

We next consider *what-if* scenarios corresponding to alternative (counterfactual) attention weights. The idea is to investigate whether the prediction would have been different, had the model emphasized (attended to) different input features. More precisely, suppose $\hat{\alpha} = \{\hat{\alpha}_t\}_{t=1}^{T}$ are the attention weights induced for an instance, giving rise to model output $\hat{y}$. We then consider counterfactual distributions over y, under alternative α.

We experiment with two means of constructing such distributions. First, we simply scramble the original attention weights $\hat{\alpha}$, re-assigning each value to an arbitrary, randomly sampled index (input feature). Second, we generate an *adversarial attention distribution*: this is a set of attention weights that is maximally distinct from $\hat{\alpha}$ but that nonetheless yields an equivalent prediction (i.e., prediction within some ϵ of $\hat{y}$).

4.2.1 Attention Permutation

To characterize model behavior when attention weights are shuffled, we follow Algorithm 2.

Algorithm 2 Permuting attention weights

```
$\mathbf{h} \leftarrow \text{Enc}(\mathbf{x}),\ \hat{\alpha} \leftarrow \text{softmax}(\phi(\mathbf{h}, \mathbf{Q}))$
$\hat{y} \leftarrow \text{Dec}(\mathbf{h}, \hat{\alpha})$
for $p \leftarrow 1$ to 100 do
    $\alpha^p \leftarrow \text{Permute}(\hat{\alpha})$
    $\hat{y}^p \leftarrow \text{Dec}(\mathbf{h}, \alpha^p)$        ▷ Note : $\mathbf{h}$ is not changed
    $\Delta\hat{y}^p \leftarrow \text{TVD}[\hat{y}^p, \hat{y}]$
end for
$\Delta\hat{y}^{med} \leftarrow \text{Median}_p(\Delta\hat{y}^p)$
```

Figure 3 depicts the relationship between the maximum attention value in the original $\hat{\alpha}$ and the median induced change in model output ($\Delta\hat{y}^{med}$) across instances in the respective datasets. Colors again indicate class predictions, as above.

We observe that there exist many points with small $\Delta\hat{y}^{med}$ despite large magnitude attention weights. These are cases in which the attention weights might suggest explaining an output by a small set of features (this is how one might reasonably read a heatmap depicting the attention weights), but where scrambling the attention makes little difference to the prediction.

In some cases, such as predicting ICD codes from notes using the MIMIC dataset, one can see different behavior for the respective classes. For the *Diabetes* task, e.g., attention behaves intuitively for at least the positive class; perturbing attention in this case causes large changes to the prediction. We again conjecture that this is due to a few tokens serving as high precision indicators for the positive class; in their absence (or when they are not attended to sufficiently), the prediction drops considerably. However, this is the exception rather than the rule.

4.2.2 Adversarial Attention

We next propose a more focused approach to counterfactual attention weights, which we will refer to as *adversarial attention*. The intuition is to explicitly seek out attention weights that differ as much as possible from the observed attention distribution and yet leave the prediction effectively unchanged. Such adversarial weights violate an intuitive property of explanations: shifting model attention to very different input features should yield corresponding changes in the output. Alternative attention distributions identified adversarially may then be viewed as equally plausible explanations for the same output.

Operationally, realizing this objective requires specifying a value ϵ that defines what qualifies as a "small" difference in model output. Once this is specified, we aim to find k adversarial distributions $\{\alpha^{(1)}, ..., \alpha^{(k)}\}$, such that each $\alpha^{(i)}$ maximizes the distance from original $\hat{\alpha}$ but does not change the output by more than ϵ. In practice we simply set this to 0.01 for text classification and 0.05 for QA datasets.[6]

We propose the following optimization problem to identify adversarial attention weights.

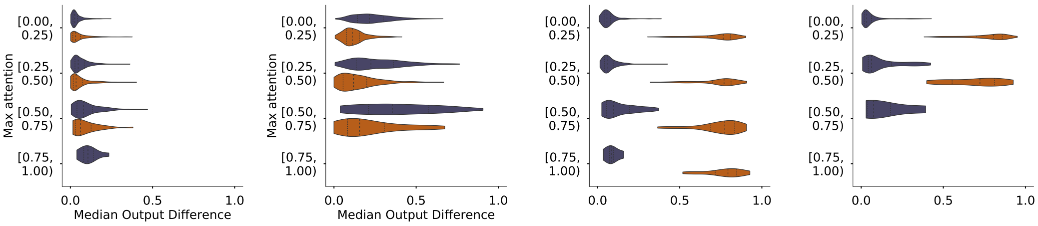
$$\begin{aligned} &\underset{\alpha^{(1)},...,\alpha^{(k)}}{\text{maximize}} && f(\{\alpha^{(i)}\}_{i=1}^{k}) \\ &\text{subject to} && \forall i\ \text{TVD}[\hat{y}(\mathbf{x}, \alpha^{(i)}), \hat{y}(\mathbf{x}, \hat{\alpha})] \leq \epsilon \end{aligned} \tag{1}$$

Where $f(\{\alpha^{(i)}\}_{i=1}^{k})$ is:

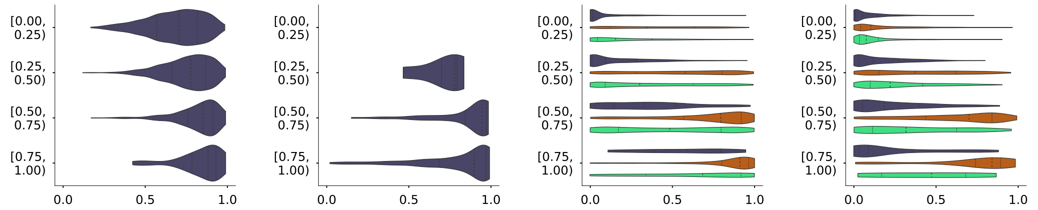
$$\sum_{i=1}^{k} \text{JSD}[\alpha^{(i)}, \hat{\alpha}] + \frac{1}{k(k-1)} \sum_{i<j} \text{JSD}[\alpha^{(i)}, \alpha^{(j)}] \tag{2}$$

---

[6] We make the threshold slightly higher for QA because the output space is larger and thus small dimension-wise perturbations can produce comparatively large TVD.



(a) SST (BiLSTM) (b) SST (CNN) (c) Diabetes (BiLSTM) (d) Diabetes (CNN)



(e) CNN-QA (BiLSTM) (f) bAbI 1 (BiLSTM) (g) SNLI (BiLSTM) (h) SNLI (CNN)

Figure 3: Median change in output ($\Delta\hat{y}^{med}$) (x-axis) densities in relation to the max attention ($\max\hat{\alpha}$) (y-axis) obtained by randomly permuting instance attention weights. Encoders denoted parenthetically. Plots for all corpora and using all encoders are available online.

Algorithm 3 Finding adversarial attention weights

```
$\mathbf{h} \leftarrow \text{Enc}(\mathbf{x})$, $\hat{\alpha} \leftarrow \text{softmax}(\phi(\mathbf{h}, \mathbf{Q}))$
$\hat{y} \leftarrow \text{Dec}(\mathbf{h}, \hat{\alpha})$
$\alpha^{(1)}, ..., \alpha^{(k)} \leftarrow$ Optimize Eq 1
for $i \leftarrow 1$ to $k$ do
    $\hat{y}^{(i)} \leftarrow \text{Dec}(\mathbf{h}, \alpha^{(i)})$        ▷ $\mathbf{h}$ is not changed
    $\Delta\hat{y}^{(i)} \leftarrow \text{TVD}[\hat{y}, \hat{y}^{(i)}]$
    $\Delta\alpha^{(i)} \leftarrow \text{JSD}[\hat{\alpha}, \alpha^{(i)}]$
end for
$\epsilon$-max JSD $\leftarrow \max_i \mathbb{1}[\Delta\hat{y}^{(i)} \leq \epsilon]\Delta\alpha^{(i)}$
```

In practice we maximize a relaxed version of this objective via the Adam SGD optimizer (Kingma and Ba, 2014): $f(\{\alpha^{(i)}\}_{i=1}^{k}) + \frac{\lambda}{k}\sum_{i=1}^{k}\max(0, \text{TVD}[\hat{y}(\mathbf{x}, \alpha^{(i)}), \hat{y}(\mathbf{x}, \hat{\alpha})] - \epsilon)$.[7]

Equation 1 attempts to identify a set of new attention distributions over the input that is as far as possible from the observed α (as measured by JSD) and from each other (and thus diverse), while keeping the output of the model within ϵ of the original prediction. We denote the output obtained under the i^{th} adversarial attention by $\hat{y}^{(i)}$. Note that the JS Divergence between any two categorical distributions (irrespective of length) is bounded from above by 0.69.

One can view an attentive decoder as a function that maps from the space of latent input representations and attention weights over input words Δ^{T-1} to a distribution over the output space $\mathcal{Y}$. Thus, for any output $\hat{y}$, we can define how likely each attention distribution α will generate the output as inversely proportional to $\text{TVD}(y(\alpha), \hat{y})$.

Figure 4 depicts the distributions of max JSDs realized over instances with adversarial attention weights for a subset of the datasets considered. Colors again indicate predicted class. Mass toward the upper-bound of 0.69 indicates that we are frequently able to identify maximally different attention weights that hardly budge model output. We observe that one can identify adversarial attention weights associated with high JSD for a significant number of examples. This means that is often the case that quite different attention distributions over inputs would yield essentially the same (within ϵ) output.

In the case of the *diabetes* task, we again observe a pattern of low JSD for positive examples (where evidence is present) and high JSD for negative examples. In other words, for this task, if one perturbs the attention weights when it is inferred that the patient is diabetic, this does change the output, which is intuitively agreeable. However, this behavior again is an exception to the rule.

We also consider the relationship between max attention weights (indicating strong emphasis on a particular feature) and the dissimilarity of identified adversarial attention weights, as measured via JSD, for adversaries that yield a prediction within ϵ of the original model output. Intuitively, one might hope that if attention weights are peaky, then counterfactual attention weights that are very different but which yield equivalent predictions

---

[7] We set $\lambda = 500$.

would be more difficult to identify.

Figure 5 illustrates that while there is a negative trend to this effect, it is realized only weakly. Put another way: there exist many cases (in all datasets) in which despite a high attention weight, an alternative and quite different attention configuration over inputs yields effectively the same output. In light of this, presenting a heatmap implying that a particular set of features is primarily responsible for an output would seem to be misleading.

5 Related Work

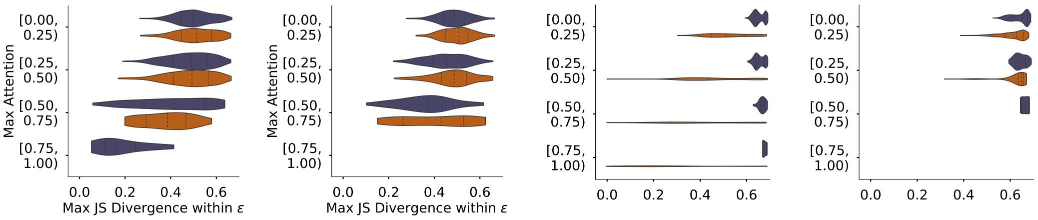
We have focused on attention mechanisms and the question of whether they afford transparency, but a number of interesting strategies unrelated to attention mechanisms have been recently proposed to provide insights into neural NLP models. These include approaches that measure feature importance based on gradient information (Ross et al., 2017; Sundararajan et al., 2017) (aligned with the gradient-based measures that we have used here), and methods based on *representation erasure* (Li et al., 2016), in which dimensions are removed and then the resultant change in output is recorded (similar to our experiments with removing tokens from inputs, albeit we do this at the input layer).

Comparing such importance measures to attention scores may provide additional insights into the working of attention based models (Ghaeini et al., 2018). Another novel line of work in this direction involves explicitly identifying explanations of black-box predictions via a causal framework (Alvarez-Melis and Jaakkola, 2017). We also note that there has been complementary work demonstrating correlation between human attention and induced attention weights, which was relatively strong when humans agreed on an explanation (Pappas and Popescu-Belis, 2016). It would be interesting to explore if such cases present explicit 'high precision' signals in the text (for example, the positive label in diabetes dataset).

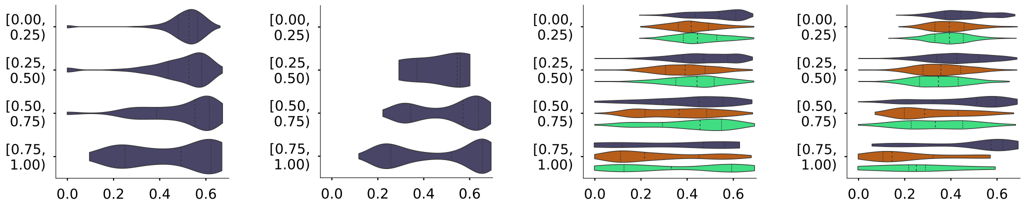
More specific to attention mechanisms, recent promising work has proposed more principled attention variants designed explicitly for interpretability; these may provide greater transparency by imposing *hard*, *sparse* attention. Such instantiations explicitly select (modest) subsets of inputs to be considered when making a prediction, which are then by construction responsible for model output (Lei et al., 2016; Peters et al., 2018). *Structured attention* models (Kim et al., 2017) provide a generalized framework for describing and fitting attention variants with explicit probabilistic semantics. Tying attention weights to human-provided rationales is another potentially promising avenue (Bao et al., 2018). We hope our work motivates further development of these methods, resulting in attention variants that both improve predictive performance and provide insights into model predictions.

6 Discussion and Conclusions

We have provided evidence that correlation between intuitive feature importance measures (in-



(a) SST (BiLSTM) (b) SST (CNN) (c) Diabetes (BiLSTM) (d) Diabetes (CNN)



(e) CNN-QA (BiLSTM) (f) bAbI 1 (BiLSTM) (g) SNLI (BiLSTM) (h) SNLI (CNN)

Figure 5: Densities of maximum JS divergences (ϵ-max JSD) (x-axis) as a function of the max attention (y-axis) in each instance for obtained between original and adversarial attention weights.

cluding gradient and feature erasure approaches) and learned attention weights is weak when using a BiRNN encoder (Section 4.1). We also established that counterfactual attention distributions — which would tell a different story about why a model made the prediction that it did — often have no effect on model output (Section 4.2).

These results suggest that while attention modules consistently yield improved performance on NLP tasks, their ability to provide transparency for model predictions is (in the sense of pointing to inputs responsible for outputs) questionable. More generally, how one is meant to interpret the 'heatmaps' of attention weights placed over inputs that are commonly presented is unclear. These seem to suggest a story about how a model arrived at a particular disposition, but the results here indicate that the relationship between this and attention is not obvious, at least for RNN encoders.

There are important **limitations** to this work and the conclusions we can draw from it. We have reported the (generally weak) correlation between learned attention weights and various alternative measures of feature importance, e.g., gradients. We do not imply that such alternative measures are necessarily ideal or should be considered 'ground truth'. While such measures do enjoy a clear intrinsic (to the model) semantics, their interpretation for non-linear neural networks can nonetheless be difficult for humans (Feng et al., 2018). Still, that attention consistently correlates poorly with *multiple* such measures ought to give pause to practitioners. That said, exactly how strong such correlations 'should' be to establish reliability as explanation is an admittedly subjective question.

We note that the counterfactual attention experiments demonstrate the existence of alternative heatmaps that yield equivalent predictions; thus one cannot conclude that the model made a particular prediction *because* it attended over inputs in a specific way. But these adversarial weights may themselves be unlikely under the attention module parameters. Further, it may be that multiple plausible explanations exist, complicating interpretation. We would maintain that in such cases the model should highlight all plausible explanations, but one may instead view a model that provides 'sufficient' explanation as reasonable.

An additional limitation is that we have only considered a handful of attention variants, selected to reflect common module architectures for the respective tasks included in our analysis. Alternative attention specifications may yield different conclusions; and indeed we hope this work motivates further development of principled attention mechanisms (or encoders). Finally, we have limited our evaluation to tasks with unstructured output spaces, i.e., we have not considered seq2seq tasks, which we leave for future work. However we believe interpretability is more often a consideration in, e.g., classification than in translation.

Appendices

A Model details

For all datasets, we use spaCy for tokenization. We map out of vocabulary words to a special `<unk>` token and map all words with numeric characters to 'qqq'. Each word in the vocabulary was initialized to pretrained embeddings. For general domain corpora we used either (i) FastText Embeddings (SST, IMDB, 20News, and CNN) trained on Simple English Wikipedia, or, (ii) GloVe 840B embeddings (AGNews and SNLI). For the MIMIC dataset, we learned word embeddings using Gensim over all discharge summaries in the corpus. We initialize words not present in the vocabulary using samples from a standard Gaussian $\mathcal{N}(\mu = 0, \sigma^2 = 1)$.

A.1 BiLSTM

We use an embedding size of 300 and hidden size of 128 for all datasets except bAbI (for which we use 50 and 30, respectively). All models were regularized using ℓ_2 regularization ($\lambda = 10^{-5}$) applied to all parameters. We use a sigmoid activation functions for binary classification tasks, and a softmax for all other outputs. We trained the model using maximum likelihood loss using the Adam Optimizer with default parameters in PyTorch.

A.2 CNN

We use an embedding size of 300 and 4 kernels of sizes [1, 3, 5, 7], each with 64 filters, giving a final hidden size of 256 (for bAbI we use 50 and 8 respectively with same kernel sizes). We use ReLU activation function on the output of the filters. All other configurations remain same as BiLSTM.

A.3 Average

We use the embedding size of 300 and a projection size of 256 with ReLU activation on the output of the projection matrix. All other configurations remain same as BiLSTM.

B Further details regarding attentional module of gradient

In the gradient experiments, we made the decision to cut-off the computation graph at the attention module so that gradient does not flow through this layer and contribute to the gradient feature importance score. For the sake of gradient calculation this effectively treats the attention as a separate input to the network, independent of the input. We argue that this is a natural choice to make for our analysis because it calculates: *how much does the output change as we perturb particular inputs (words) by a small amount, while paying the same amount of attention to said word as originally estimated and shown in the heatmap*?

C Correlations between Feature Importance measures

A question one might have here is how well correlated LOO and gradients are with *one another*. We report such results in their entirety on the paper website, and we summarize their correlations relative to those realized by attention in a BiLSTM model with LOO measures in Figure 6. This reports the mean differences between (i) gradient

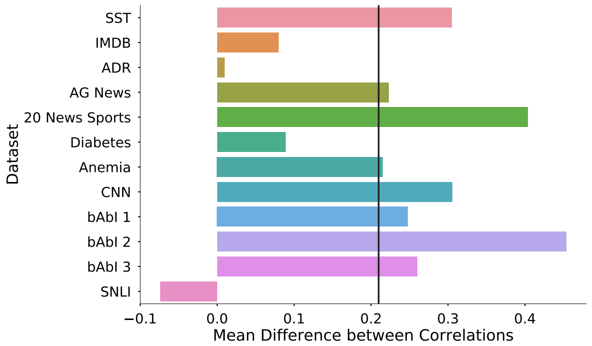

Figure 6: Mean difference in correlation of (i) LOO vs. Gradients and (ii) Attention vs. LOO scores using BiLSTM Encoder + Tanh Attention. On average the former is more correlated than the latter by >0.2 τ_{loo}.

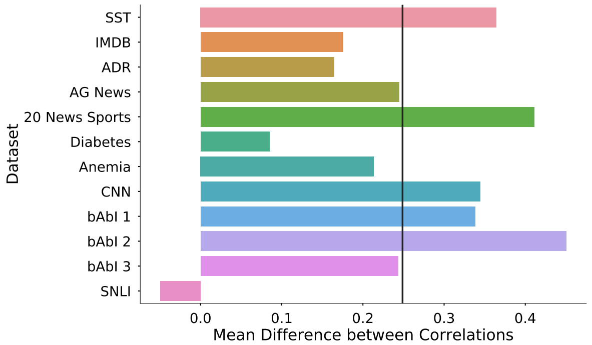

Figure 7: Mean difference in correlation of (i) LOO vs. Gradients and (ii) Attention vs. Gradients using BiLSTM Encoder + Tanh Attention. On average the former is more correlated than the latter by ~0.25 τ_g.

and LOO correlations, and (ii) attention and LOO correlations. As expected, we find that these exhibit, in general, considerably higher correlation with one another (on average) than LOO does with attention scores. (The lone exception is on SNLI.) Figure 7 shows the same for gradients and attention scores; the differences are comparable. In the *ADR* and *Diabetes* corpora, a few high precision tokens indicate (the positive) class, and in these cases we see better agreement between LOO/gradient measures with attention; this is consistent with Figure 4 which shows that it is difficult for the BiLSTM variant to find adversarial attention distributions for *Diabetes*.

A potential issues with using Kendall τ as our metric here is that (potentially many) irrelevant features may add noise to the correlation measures. We acknowledge that this as a shortcoming of the metric. One observation that may mitigate this concern is that we might expect such noise to depress the LOO and gradient correlations to the same extent as they do the correlation between attention and feature importance scores; but as per Figure 7, they do not. We also note that the correlations between the attention weights on top of feedforward (projection) encoder and LOO scores are much stronger, on average, than those between BiLSTM attention weights and LOO. This is shown in Figure 8. Were low correlations due simply to noise, we would not expect this.[8]

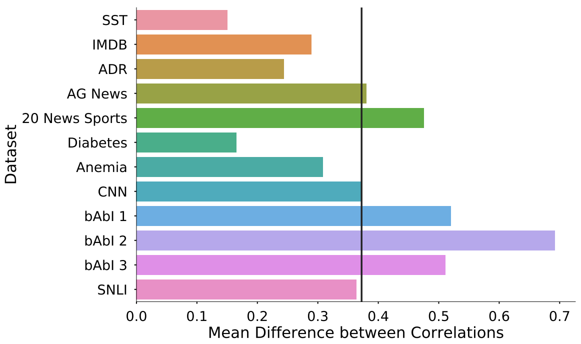

Figure 8: Difference in mean correlation of attention weights vs. LOO importance measures for (i) Average (feed-forward projection) and (ii) BiLSTM Encoders with Tanh attention. Average correlation (vertical bar) is on average ~0.375 points higher for the simple feedforward encoder, indicating greater correspondence with the LOO measure.

D Graphs

To provide easy navigation of our (large set of) graphs depicting attention weights on various datasets/tasks under various model configuration we have created an interactive interface to browse these results, accessible at: `https://successar.github.io/AttentionExplanation/docs/`.

Abstract

Text-based adventure games provide a platform on which to explore reinforcement learning in the context of a combinatorial action space, such as natural language. We present a deep reinforcement learning architecture that represents the game state as a knowledge graph which is learned during exploration. This graph is used to prune the action space, enabling more efficient exploration. The question of which action to take can be reduced to a question-answering task, a form of transfer learning that pre-trains certain parts of our architecture. In experiments using the TextWorld framework, we show that our proposed technique can learn a control policy faster than baseline alternatives. We have also open-sourced our code at https://github.com/rajammanabrolu/KG-DQN.

1 Introduction

Natural language communication can be used to affect change in the real world. Text adventure games, in which players must make sense of the world through text descriptions and declare actions through natural language, can provide a stepping stone toward more real-world environments where agents must communicate to understand the state of the world and indirectly affect change in the world. Text adventure games are also useful for developing and testing reinforcement learning algorithms that must deal with the partial observability of the world (Narasimhan et al., 2015; He et al., 2016).

In text adventure games, the agent receives an incomplete textual description of the current state of the world. From this information, and previous interactions with the world, a player must determine the next best action to take to achieve some quest or goal. The player must then compose a textual description of the action they intend to make and receive textual feedback of the effects of the action. Formally, a text-based game is a partially observable Markov decision process (POMDP), represented as a 7-tuple of $\langle S, T, A, \Omega, O, R, \gamma \rangle$ representing the set of environment states, conditional transition probabilities between states, words used to compose text commands, observations, observation conditional probabilities, reward function, and the discount factor respectively (Côté et al., 2018).

In text-based games, the agent never has access to the true underlying world state and has to reason about how to act in the world based only on the textual observations. Additionally, the agent's actions must be expressed through natural language commands, ensuring that the action space is combinatorially large. Thus, text-based games pose a different set of challenges than traditional video games. Text-based games require a greater understanding of previous context to be able to explore the state-action space more effectively. Such games have historically proven to be difficult to play for AI agents, and the more complex variants such as *Zork* still remain firmly out of the reach of existing approaches.

We introduce three contributions to text-based game playing to deal with the combinatorially large state and action spaces. First, we show that a state representation in the form of a *knowledge graph* gives us the ability to effectively prune an action space. A knowledge graph captures the relationships between entities as a directed graph. The knowledge graph provides a persistent memory of the world over time and enables the agent to have a prior notion of what actions it should not take at a particular stage of the game.

Our second contribution is a deep reinforcement learning architecture, *Knowledge Graph DQN* (KG-DQN), that effectively uses this state rep-

Proceedings of NAACL-HLT 2019, pages 3557–3565
Minneapolis, Minnesota, June 2 - June 7, 2019.

resentation to estimate the Q-value for a state-action pair. This architecture leverages recent advances in graph embedding and attention techniques (Guan et al., 2018; Veličković et al., 2018) to learn which portions of the graph to pay attention to given an input state description in addition to having a mechanism that allows for natural language action inputs. Finally, we take initial steps toward framing the POMDP as a question-answering (QA) problem wherein a knowledge-graph can be used to not only prune actions but to answer the question of what action is most appropriate. Previous work has shown that many NLP tasks can be framed as instances of question-answering and that we can transfer knowledge between these tasks (McCann et al., 2017). We show how pre-training certain parts of our KG-DQN network using existing QA methods improves performance and allows knowledge to be transferred from different games.

We provide results on ablative experiments comparing our knowledge-graph based approach approaches to strong baselines. Results show that incorporating a knowledge-graph into a reinforcement learning agent results in converges to the highest reward more than 40% faster than the best baseline. With pre-training using a question-answering paradigm, we achieve this fast convergence rate while also achieving high quality quest solutions as measured by the number of steps required to complete the quests.

2 Related Work

A growing body of research has explored the challenges associated with text-based games (Bordes et al., 2010; Narasimhan et al., 2015; He et al., 2016; Fulda et al., 2017; Haroush et al., 2018; Côté et al., 2018; Tao et al., 2018). Narasimhan et al. (2015) attempts to solve parser-based text games by encoding the observations using an LSTM. This encoding vector is then used by an action scoring network that determines the scores for the action verb and each of the corresponding argument objects. The two scores are then averaged to determine Q-value for the state-action pair. He et al. (2016) present the Deep Reinforcement Relevance Network (DRRN) which uses two separate deep neural networks to encode the state and actions. The Q-value for a state-action pair is then computed by a pairwise interaction function between the two encoded representations. Both of these methods are not conditioned on previous observations and so are at a disadvantage when dealing with complex partially observable games. Additionally, neither of these approaches prune the action space and so end up wasting trials exploring state-action pairs that are likely to have low Q-values, likely leading to slower convergence times for combinatorially large action spaces.

Haroush et al. (2018) introduce the Action Eliminating Network (AEN) that attempts to restrict the actions in each state to the top-k most likely ones, using the emulator's feedback. The network learns which actions should not be taken given a particular state. Their work shows that reducing the size of the action space allows for more effective exploration, leading to better performance. Their network is also not conditioned on previous observations.

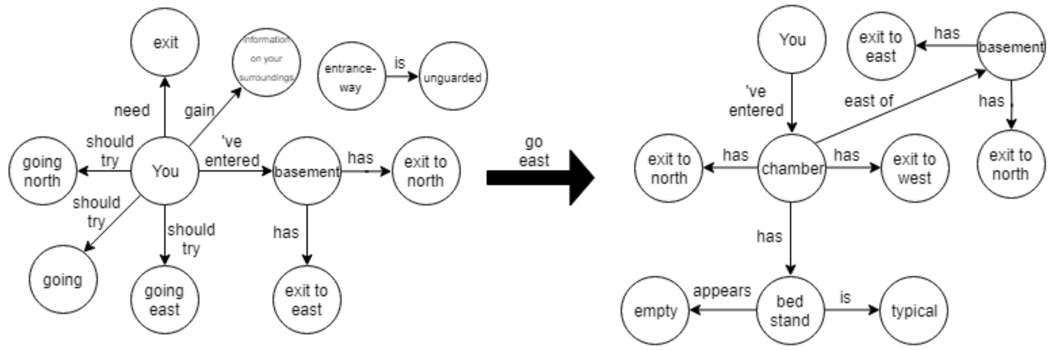
Knowledge graphs have been demonstrated to improve natural language understanding in other domains outside of text adventure games. For example, Guan et al. (2018) use commonsense knowledge graphs such as *ConceptNet* (Speer and Havasi, 2012) to significantly improve the ability of neural networks to predict the end of a story. They represent the graph in terms of a knowledge context vector using features from *ConceptNet* and graph attention (Veličković et al., 2018). The state representation that we have chosen as well as our method of action pruning builds on the strengths of existing approaches while simultaneously avoiding the shortcomings of ineffective exploration and lack of long-term context.

3 Knowledge Graph DQN

In this section we introduce our knowledge graph representation, action pruning and deep Q-network architecture.

3.1 Knowledge Graph Representation

In our approach, our agent learns a knowledge graph, stored as a set of RDF triples, i.e. 3-tuples of $\langle subject, relation, object\rangle$. These triples are extracted from the observations using Stanford's Open Information Extraction (OpenIE) (Angeli et al., 2015). OpenIE is not optimized to the regularities of text adventure games and there are a lot of relations that can be inferred from the typical structure of descriptive texts. For example, from a phrase such as "There is an exit to the north" one can infer a *has* relation between the current



You've entered a basement. You try to gain information on your surroundings by using a technique you call "looking." You need an unguarded exit? You should try going east. You don't like doors? Why not try going north, that entranceway is unguarded.

You've entered a chamber. You can see a bed stand. The bed stand is typical. The bed stand appears to be empty. There is an exit to the north. Don't worry, it is unblocked. There is an unblocked exit to the west.

Figure 1: Graph state update example given two observations

location and the direction of the exit. These additional rules fill in the information not provided by OpenIE. The resultant knowledge graph gives the agent what essentially amounts to a mental map of the game world.

The knowledge graph is updated after every agent action (see Figure 1). The update rules are defined such that there are portions of the graph offering short and long-term context. A special node—designated "you"—represents the agent and relations out of this node are updated after every action with the exception of relations denoting the agent's inventory. Other relations persist after each action. We intend for the update rules to be applied to text-based games in different domains and so only hand-craft a minimal set of rules that we believe apply generally. They are:

- Linking the current room type (e.g. "basement", "chamber') to the items found in the room with the relation "has", e.g. $\langle chamber, has, bed\ stand\rangle$
- Extracting information regarding entrances and exits and linking them to the current room, e.g. $\langle basement, has, exit\ to\ north\rangle$
- Removing all relations relating to the "you" node with the exception of inventory every action, e.g. $\langle you, have, cubical\ key\rangle$
- Linking rooms with directions based on the action taken to move between the rooms, e.g. $\langle chamber, east\ of, basement\rangle$ after the action "go east" is taken to go from the basement to the chamber

All other RDF triples generated are taken from OpenIE.

3.2 Action Pruning

The number of actions available to an agent in a text adventure game can be quite large: $A = \mathcal{O}(|V| \times |O|^2)$ where V is the number of action verbs, and O is the number of distinct objects in the world that the agent can interact with, assuming that verbs can take two arguments. Some actions, such as movement, inspecting inventory, or observing the room, do not have arguments.

The knowledge graph is used to prune the combinatorially large space of possible actions available to the agent as follows. Given the current state graph representation G_t, the action space is pruned by ranking the full set of actions and selecting the top-k. Our action scoring function is:

- +1 for each object in the action that is present in the graph; and
- +1 if there exists a valid directed path between the two objects in the graph.

We assume that each action has at most two objects (for example inserting a key in a lock).

3.3 Model Architecture and Training

Following Narasimhan et al. (2015), all actions A that will be accepted by the game's parser are available to the agent at all times. When playing the game, the agent chooses an action and receives an observation o_t from the simulator, which is a textual description of current game state. The state graph G_t is updated according to the given observation, as described in Section 3.1.

We use the Q-Learning technique (Watkins and Dayan, 1992) to learn a control policy $\pi(a_t|s_t)$, $a_t \in A$, which gives us the probability of taking action a_t given the current state s_t. The policy is determined by the Q-value of a particular state-action pair, which is updated using the Bellman equation (Sutton and Barto, 2018):

$$Q_{t+1}(s_{t+1},a_{t+1}) = E[r_{t+1} + \gamma \max_{a \in A_t} Q_t(s,a) | s_t, a_t] \quad (1)$$

where γ refers to the discount factor and r_{t+1} is the observed reward. The policy is thus to take the action that maximizes the Q-value in a particular state, which will correspond to the action that maximizes the reward expectation given that the agent has taken action a_t at the current state s_t and followed the policy $\pi(a|s)$ after.

The architecture in Figure 2 is responsible for computing the representations for both the state s_t and the actions $a^{(i)} \in A$ and coming to an estimation of the Q-value for a particular state and action. During the forward activation, the agent uses the observation to update the graph G_t using the rules outlined in Section 3.2.

The graph is then embedded into a single vector $\mathbf{g_t}$. We use Graph Attention (Veličković et al., 2018) with an attention mechanism similar to that described in Bahdanau et al. (2014). Formally, the Multi-headed Graph Attention component receives a set of node features $H = \{\mathbf{h_1}, \mathbf{h_2}, \dots, \mathbf{h_N}\}$, $\mathbf{h_i} \in \mathrm{I\!R}^{\mathrm{F}}$, where N is the number of nodes and F the number of features in each node, and the adjacency matrix of G_t. Each of the node features consist of the averaged word embeddings for the tokens in that node, as determined by the preceding graph embedding layer. The attention mechanism is set up using self-attention on the nodes after a learnable linear transformation $W \in \mathrm{I\!R}^{2\mathrm{F}\times\mathrm{F}}$ applied to all the node features:

$$e_{ij} = LeakyReLU(\mathbf{p} \cdot W(\mathbf{h_i} \oplus \mathbf{h_j})) \quad (2)$$

where $\mathbf{p} \in \mathrm{I\!R}^{2\mathrm{F}}$ is a learnable parameter. The attention coefficients α_{ij} are then computed by normalizing over the choices of $k \in \mathcal{N}$ using the softmax function. Here $\mathcal{N}$ refers to the neighborhood in which we compute the attention coefficients. This is determined by the adjacency matrix for G_t and consists of all third-order neighbors of a particular node.

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k \in \mathcal{N}} exp(e_{ik})} \quad (3)$$

Multi-head attention is then used, calculating multiple independent attention coefficients. The resulting features are then concatenated and passed into a linear layer to determine $\mathbf{g_t}$:

$$\mathbf{g_t} = f(W_g(\|_{k=1}^{K} \sigma(\sum_{j \in \mathcal{N}} \alpha_{ij}^{(k)} \mathbf{W}^{(k)} \mathbf{h}_j)) + b_g) \quad (4)$$

where k refers to the parameters of the k^{th} independent attention mechanism, W_g and b_g the weights and biases of this component's output linear layer, and $\|$ represents concatenation.

Simultaneously, an encoded representation of the observation $\mathbf{o_t}$ is computed using a Sliding Bidirectional LSTM (SB-LSTM). The final state representation $\mathbf{s_t}$ is computed as:

$$\mathbf{s_t} = f(W_l(\mathbf{g_t} \oplus \mathbf{o_t}) + b_l) \quad (5)$$

where W_l, b_l represent the final linear layer's weights and biases and $\mathbf{o_t}$ is the result of encoding the observation with the SB-LSTM.

The entire set of possible actions A is pruned by scoring each $a \in A$ according to the mechanism previously described using the newly updated G_{t+1}. We then embed and encode all of these action strings using an LSTM encoder (Sutskever et al., 2014). The dashed lines in Figure 2 denotes non-differentiable processes.

The final Q-value for a state-action pair is:

$$Q(\mathbf{s_t}, \mathbf{a_t}) = \mathbf{s_t} \cdot \mathbf{a_t} \quad (6)$$

This method of separately computing the representations for the state and action is similar to the approach taken in the DRRN (He et al., 2016).

We train the network using experience replay (Lin, 1993) with prioritized sampling (cf., (Moore and Atkeson, 1993)) and a modified version of the ϵ-greedy algorithm (Sutton and Barto, 2018) that we call the ϵ_1, ϵ_2-greedy learning algorithm. The experience replay strategy finds paths in the game, which are then stored as transition tuples in a experience replay buffer D. The ϵ_1, ϵ_2-greedy algorithm explores by choosing actions randomly from A with probability ϵ_1 and from A_t with a probability ϵ_2. The second threshold is needed to account for situations where an action must be chosen to advance the quest for which the agent has no prior in G_t. That is, action pruning may remove actions essential to quest completion because those actions involve combinations of entities that have not been encountered before.

We then sample a mini-batch of transition tuples consisting of $\langle \mathbf{s_k}, \mathbf{a_k}, r_{k+1}, \mathbf{s_{k+1}}, \mathbf{A_{k+1}}, p_k \rangle$ from

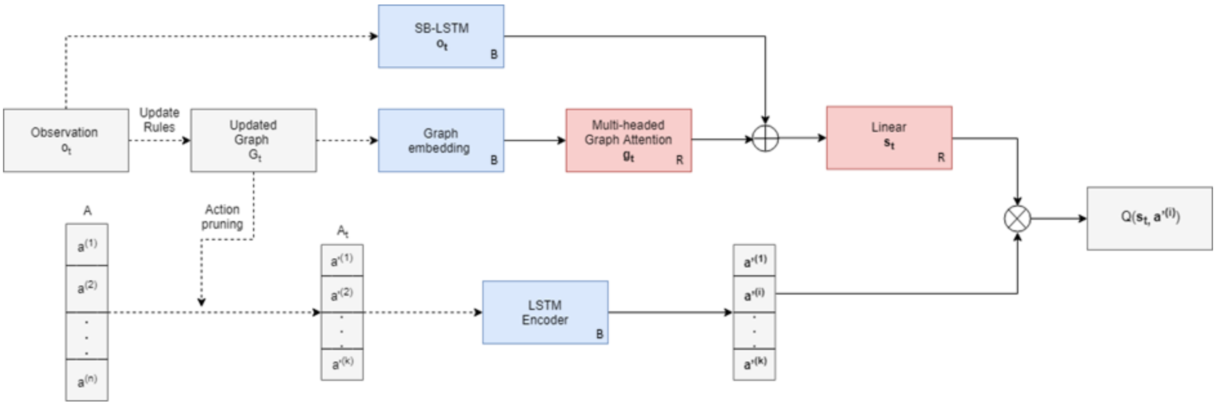


Figure 2: KG-DQN architecture, blue shading (or the symbol 'B') indicates components that can be pre-trained and red (or the symbol 'R') indicates no pre-training. The solid lines indicate gradient flow for learnable components.

D and compute the temporal difference loss as:

$$\begin{aligned} L(\theta) =& r_{k+1} + \\ & \gamma \max_{\mathbf{a} \in \mathbf{A_{k+1}}} Q(\mathbf{s_t}, \mathbf{a}; \theta) - Q(\mathbf{s_t}, \mathbf{a_t}; \theta) \end{aligned} \quad (7)$$

Replay sampling from D is done by sampling a fraction ρ from transition tuples with a positive reward and $1 - \rho$ from the rest. As shown in (Narasimhan et al., 2015), prioritized sampling from experiences with a positive reward helps the deep Q-network more easily find the sparse set of transitions that advance the game. The exact training mechanism is described in Algorithm 1.

4 Game Play as Question Answering

Previous work has shown that many NLP tasks can be framed as instances of question-answering and that in doing so, one can transfer knowledge between these tasks (McCann et al., 2017). In the abstract, an agent playing a text adventure game can be thought of as continuously asking the question "What is the right action to perform in this situation?" When appropriately trained, the agent may be able to answer the question for itself and select a good next move to execute. Treating the problem as question-answering will not replace the need for exploration in text-adventure games. However, we hypothesize that it will cut down on the amount of exploration needed during testing time, theoretically allowing it to complete quests faster; one of the challenges of text adventure games is that the quests are puzzles and even after training, execution of the policy requires a significant amount of exploration.

To teach the agent to answer the question of what action is best to take given an observation, we use an offline, pre-training approach. The data for the pre-training approach is generated using an oracle, an agent capable of finishing a game perfectly in the least number of steps possible. Specifically, the agent knows exactly what action to take given the state observation in order to advance the game in the most optimal manner possible. Through this process, we generate a set of traces consisting of state observations and actions such that the state observation provides the context for the implicit question of "What action should be taken?" and the oracle's correct action is the answer. We then use the DrQA (Chen et al., 2017) question-answering technique to train a paired question encoder and an answer encoder that together predict the answer (action) from the question (text observation). The weights from the SB-LSTM in the document encoder in the DrQA system are then used to initialize the weights of the SB-LSTM. Similarly, embedding layers of both the graph and the LSTM action encoder are initialized with the weights from the embedding layer of same document encoder. Since the DrQA embedding layers are initialized with GloVe, we are transferring word embeddings that are tuned during the training of the QA architecture.

The game traces used to train the question-answering come from a set of games of the same domain but have different specific configurations of the environment and different quests. We use the TextWorld framework (Côté et al., 2018), which uses a grammar to generate random worlds and quests. The types of rooms are the same, but their relative spatial configuration, the types of objects, and the specific sequence of actions needed to complete the quest are different each time. This

	Small	Large
Rooms	10	20
Total objects	20	40
Quest length	5	10
Branching factor	143	562
Vocab size	746	819
Average words per obs.	67.5	94.0
Average new RDF triples per obs.	7.2	10.5

Table 1: Generated game details.

means that the agent cannot simply memorize quests. For pre-training to work, the agent must develop a general question-answering competence that can transfer to new quests. Our approach to question-answering in the context of text adventure game playing thus represents a form of transfer learning.

5 Experiments

We conducted experiments in the TextWorld framework (Côté et al., 2018) using their "home" theme. TextWorld uses a grammar to randomly generate game worlds and quests with given parameters. Games generated with TextWorld start with a zero-th observation that gives instructions for the quest; we do not allow our agent to access this information. The TextWorld API also provides a list of *admissible* actions at each state—the actions that can be performed based on the objects that are present. We do not allow our agent to access the admissible actions.

We generated two sets of games with different random seeds, representing different game difficulties, which we denote as *small* and *large*. Small games have ten rooms and quests of length five and large games have twenty rooms and quests of length ten. Statistics on the games are given in Table 1. Quest length refers to the number of actions that the agent is required to perform in order to finish the quest; more actions are typically necessary to move around the environment and find the objects that need to be interacted with. The branching factor is the size of the action set A for that particular game.

The reward function provided by TextWorld is as follows: +1 for each action taken that moves the agent closer to finishing the quest; -1 for each action taken that extends the minimum number of steps needed to finish the quest from the current stage; 0 for all other situations. The maximum achievable reward for the small and large sets of games are 5 and 10 respectively. This allows for a large amount of variance in quest quality—as measured by steps to complete the quest—that receives maximum reward.

	EM	Precision	Recall	F1
Small	46.20	56.57	63.38	57.94
Large	34.13	52.53	64.72	55.06

Table 2: Pre-training accuracy.

The following procedure for pre-training was done separately for each set of games. Pre-training of the SB-LSTM within the question-answering architecture is conducted by generating 200 games from the same TextWorld theme. The QA system was then trained on data from walkthroughs of a randomly-chosen subset of 160 of these generated games, tuned on a dev set of 20 games, and evaluated on the held-out set of 20 games. Table 2 provides details on the Exact Match (EM), precision, recall, and F1 scores of the QA system after training for the small and large sets of games. Precision, recall, and F1 scores are calculated by counting the number of tokens between the predicted answer and ground truth. An Exact Match is when the entire predicted answer matches with the ground truth. This score is used to tune the model based on the dev set of games.

A random game was chosen from the test-set of games and used as the environment for the agent to train its deep Q-network on. Thus, at no time did the QA system see the final testing game prior to the training of the KG-DQN network.

We compare our technique to three baselines:

- Random command, which samples from the list of admissible actions returned by the TextWorld simulator at each step.
- LSTM-DQN, developed by Narasimhan et al. (2015).
- Bag-of-Words DQN, which uses a bag-of-words encoding with a multi-layer feed forward network instead of an LSTM.

To achieve the most competitive baselines, we used a randomized grid search to choose the best hyperparameters (e.g., hidden state size, γ, ρ, final ϵ, update frequency, learning rate, replay buffer size) for the BOW-DQN and LSTM-DQN baselines.

We tested three versions of our KG-DQN:

1. Un-pruned actions with pre-training

Algorithm 1 ϵ_1, ϵ_2-greedy learning algorithm for KG-DQN

```
for episode=1 to $M$ do
    Initialize action dictionary $A$ and graph $G_0$
    Reset the game simulator
    Read initial observation $o_1$
    $G_1 \leftarrow updateGraph(G_0, o_1); A_1 \leftarrow pruneActions(A, G_0)$        ▷ Section 3.2
    for step $t$=1 to $T$ do
        if $random() < \epsilon_1$ then
            if $random() < \epsilon_2$ then
                Select random action $a_t \in A$
            else
                Select random action $a_t \in A_t$
        else
            Compute $Q(\mathbf{s_t}, \mathbf{a^{(i)}}; \theta)$ for $a^{(i)} \in A$ for network parameters $\theta$        ▷ Section 3.3, Eq. 6
            Select $a_t$ based on $\pi(a|s_t)$
        Execute action $a_t$ in the simulator and observe reward $r_t$
        Receive next observation $ot + 1$
        $G_{t+1} \leftarrow updateGraph(G_t, o_{t+1}); A_{t+1} \leftarrow pruneActions(A, G_{t+1})$        ▷ Section 3.1
        Compute $\mathbf{s_{t+1}}$ and $\mathbf{A_{t+1}} = \{\mathbf{a'^{(i)}}$ for all $a'^{(i)} \in A\}$        ▷ Section 3.3
        Set priority $p_t = 1$ if $r_t > 0$, else $p_t = 0$
        Store transition $(\mathbf{s_t}, \mathbf{a_t}, r_t, \mathbf{s_{t+1}}, \mathbf{A_{t+1}}, p_t)$ in replay buffer $D$
        Sample mini-batch of transitions $(\mathbf{s_k}, \mathbf{a_k}, r_k, \mathbf{s_{k+1}}, \mathbf{A_{k+1}}, p_k)$ from $D$, with fraction $\rho$ having $p_k = 1$
        Set $y_k = r_k + \gamma \max_{\mathbf{a} \in \mathbf{A_{k+1}}} Q(\mathbf{s_t}, \mathbf{a}; \theta)$, or $y_k = r_k$ if $s_{k+1}$ is terminal
        Perform gradient descent step on loss function $L(\theta) = (y_k - Q(\mathbf{s_t}, \mathbf{a_t}; \theta))^2$
```

2. Pruned actions without pre-training
3. Pruned actions with pre-training (full)

Our models use 50-dimensional word embeddings, 2 heads on the graph attention layers, mini-batch size of 16, and perform a gradient descent update every 5 steps taken by the agent.

All models are evaluated by observing the (a) time to reward convergence, and (b) the average number of steps required for the agent to finish the game with $\epsilon = 0.1$ over 5 episodes after training has completed. Following Narasimhan et al. (2015) we set ϵ to a non-zero value because text adventure games, by nature, require exploration to complete the quests. All results are reported based on multiple independent trials. For the large set of games, we only perform experiments on the best performing models found in the small set of games. Also note that for experiments on large games, we do not display the entire learning curve for the LSTM-DQN baseline, as it converges significantly more slowly than KG-DQN. We run each experiment 5 times and average the results.

Additionally, human performance on the both the games was measured by counting the number of steps taken to finish the game, with and without instructions on the exact quest. We modified Textworld to give the human players reward feedback in the form of a score, the reward function itself is identical to that received by the deep reinforcement learning agents. In one variation of this experiment, the human was given instructions on the potential sequence of steps that are required to finish the game in addition to the reward in the form of a score and in the other variation, the human received no instructions.

6 Results and Discussion

Recall that the number of steps required to finish the game for the oracle agent is 5 and 10 for the small and large maps respectively. It is impossible to achieve this ideal performance due to the structure of the quest. The player needs to interact with objects and explore the environment in order to figure out the exact sequence of actions required to finish the quest. To help benchmark our agent's performance, we observed people unaffiliated with the research playing through the same TextWorld "home" quests as the other models. Those who did not receive instructions on how to finish the quest never finished a single quest and gave up after an average of 184 steps on the small map and an average of 190 steps on the large map. When given instructions, human players completed the quest on the large map in an average of 23 steps, finishing the game with the maximum reward possible. Also note that none of the deep reinforcement learning agents received instructions.

On both small and large maps, all versions of KG-DQN tested converge faster than baselines (see Figure 3 for the small game and Figure 4 for the large game). We don't show BOW-DQN because it is strictly inferior to LSTM-DQN in all situations). KG-DQN converges 40% faster than baseline on the small game; both KG-DQN and the LSTM-DQN baseline reaches the maximum reward of five. On the large game, no

Model	Steps
Random Command	319.8
BOW-DQN	83.1 ± 8.0
LSTM-DQN	72.4 ± 4.6
Unpruned, pre-trained KG-DQN	131.7 ± 7.7
Pruned, non-pre-trained KG-DQN	97.3 ± 9.0
Full KG-DQN	73.7 ± 8.5

Table 3: Average number of steps (and standard deviation) taken to complete the small game.

agents achieve the maximum reward of 10, and the LSTM-DQN requires more than 300 episodes to converge at the same level as KG-DQN. Since all versions of KG-DQN converge at approximately the same rate, we conclude that the knowledge graph—i.e., persistent memory—is the main factor helping convergence time since it is the common element across all experiments.

After training is complete, we measure the number of steps each agent needs to complete each quest. Full KG-DQN requires an equivalent number of steps in the small game (Table 3) and in the large game (Table 4). Differences between LSTM-DQN and full KG-DQN are not statistically significant, $p = 0.199$ on an independent T-test. The ablated versions of KG-DQN—unpruned KG-DQN and non-pre-trained KG-DQN—require many more steps to complete quests. TextWorld's reward function allows for a lot of exploration of the environment without penalty so it is possible for a model that has converged on reward to complete quests in as few as five steps or in many hundreds of steps. From these results, we conclude that the pre-training using our question-answering paradigm is allowing the agent to find a general understanding of how to pick good actions even when the agent has never seen the final

Model	Steps
Random Command	2054.8
LSTM-DQN	260.3 ± 4.5
Pruned, non-pre-trained KG-DQN	340 ± 6.4
Full KG-DQN	265.9 ± 9.4

Table 4: Average number of steps (and standard deviation) taken to complete the large game.

test game. LSTM-DQN also learns how to choose actions efficiently, but this knowledge is captured in the LSTM's cell state, whereas in KG-DQN this knowledge is made explicit in the knowledge graph and retrieved effectively by graph attention. Taken together, KG-DQN converges faster without loss of quest solution quality.

7 Conclusions

We have shown that incorporating knowledge graphs into an deep Q-network can reduce training time for agents playing text-adventure games of various lengths. We speculate that this is because the knowledge graph provides a persistent memory of the world as it is being explored. While the knowledge graph allows the agent to reach optimal reward more quickly, it doesn't ensure a high quality solution to quests. Action pruning using the knowledge graph and pre-training of the embeddings used in the deep Q-network result in shorter action sequences needed to complete quests.

The insight into pre-training portions of the agent's architecture is based on converting text-adventure game playing into a question-answering activity. That is, at every step, the agent is asking—and trying to answer—what is the most important thing to try. The pre-training acts as a form of transfer learning from different, but related games. However, question-answering alone cannot solve the text-adventure playing problem because there will always be some trial and error required.

By addressing the challenges of partial observability and combinatorially large action, spaces through persistent memory, our work on playing text-adventure games addresses a critical need for reinforcement learning for language. Text-adventure games can be seen as a stepping stone toward more complex, real-world tasks; the human world is one of partial understanding through communication and acting on the world using language.

Abstract

Multi-head attention is appealing for its ability to jointly extract different types of information from multiple representation subspaces. Concerning the information aggregation, a common practice is to use a concatenation followed by a linear transformation, which may not fully exploit the expressiveness of multi-head attention. In this work, we propose to improve the information aggregation for multi-head attention with a more powerful *routing-by-agreement* algorithm. Specifically, the routing algorithm iteratively updates the proportion of how much a part (i.e. the distinct information learned from a specific subspace) should be assigned to a whole (i.e. the final output representation), based on the agreement between parts and wholes. Experimental results on linguistic probing tasks and machine translation tasks prove the superiority of the advanced information aggregation over the standard linear transformation.

1 Introduction

Attention model becomes a standard component of the deep learning networks, contributing to impressive results in machine translation (Bahdanau et al., 2015; Luong et al., 2015), image captioning (Xu et al., 2015), speech recognition (Chorowski et al., 2015), among many other applications. Its superiority lies in the ability of modeling the dependencies between representations without regard to their distance. Recently, the performance of attention is further improved by multi-head mechanism (Vaswani et al., 2017), which parallelly performs attention functions on different representation subspaces of the input sequence. Consequently, different attention heads are able to capture distinct linguistic properties of the input, which are embedded in different subspaces (Raganato and Tiedemann, 2018). Subsequently, a linear transformation is generally employed to aggregate the partial representations extracted by different attention heads (Vaswani et al., 2017; Ahmed et al., 2018).

Most existing work focus on extracting informative or distinct partial-representations from different subspaces (e.g. Lin et al., 2017; Li et al., 2018), while few studies have paid attention to the aggregation of the extracted partial-representations. Arguably, information extraction and aggregation are both crucial for multi-head attention to generate an informative representation. Recent studies in multimodal learning show that a straightforward linear transformation for fusing features in different sets of representations usually limits the extent of abstraction (Fukui et al., 2016; Ben-Younes et al., 2017). A natural question arises: *whether the straightforward linear transformation is expressive enough to fully capture the rich information distributed in the extracted partial-representations?*

In this work, we provide the first answer to this question. We propose to empirically validate the importance of information aggregation in multi-head attention, by comparing the performance of the standard linear function and advanced aggregation functions on various tasks. Specifically, we cast information aggregation as the *assigning-parts-to-wholes* problem (Hinton et al., 2011), and investigate the effectiveness of the routing-by-agreement algorithm – an appealing alternative to solving this problem (Sabour et al., 2017; Hinton et al., 2018). The routing algorithm iteratively updates the proportion of how much a part should be assigned to a whole, based on the agreement between parts and wholes. We leverage the routing algorithm to aggregate the information distributed in the extracted partial-representations.

Proceedings of NAACL-HLT 2019, pages 3566–3575
Minneapolis, Minnesota, June 2 - June 7, 2019.

We evaluate the performance of the aggregated representations on both linguistic probing tasks as well as machine translation tasks. The probing tasks (Conneau et al., 2018) consists of 10 classification problems to study what linguistic properties are captured by input representations. Probing analysis show that our approach indeed produces more informative representation, which embeds more syntactic and semantic information. For translation tasks, we validate our approach on top of the advanced TRANSFORMER model (Vaswani et al., 2017) on both WMT14 English⇒German and WMT17 Chinese⇒English data. Experimental results show that our approach consistently improves translation performance across languages while keeps the computational efficiency.

The main contributions of this paper can be summarized as follows:

- To our best knowledge, this is the first work to demonstrate the necessity and effectiveness of advanced information aggregation for multi-head attention.
- Our work is among the few studies (*cf.* (Gong et al., 2018; Zhao et al., 2018; Dou et al., 2019)) which prove that the idea of capsule networks can have promising applications on natural language processing tasks.

2 Background

Attention mechanism aims at modeling the relevance between representation pairs, thus a representation is allowed to build a direct relation with another representation. Instead of performing a single attention function, Vaswani et al. (2017) found it is beneficial to capture different context features with multiple individual attention functions, namely multi-head attention. Formally, attention function maps a sequence of query $\mathbf{Q} = \{\mathbf{q}_1, \dots, \mathbf{q}_J\}$ and a set of key-value pairs $\{\mathbf{K}, \mathbf{V}\} = \{(\mathbf{k}_1, \mathbf{v}_1), \dots, (\mathbf{k}_M, \mathbf{v}_M)\}$ to outputs, where $\mathbf{Q} \in \mathbb{R}^{J \times d}$, $\{\mathbf{K}, \mathbf{V}\} \in \mathbb{R}^{M \times d}$. More specifically, multi-head attention model first transforms $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ into H subspaces with different, learnable linear projections:

$$\mathbf{Q}_h, \mathbf{K}_h, \mathbf{V}_h = \mathbf{Q}\mathbf{W}_h^Q, \mathbf{K}\mathbf{W}_h^K, \mathbf{V}\mathbf{W}_h^V, \quad (1)$$

where $\{\mathbf{Q}_h, \mathbf{K}_h, \mathbf{V}_h\}$ are respectively the query, key, and value representations of the h-th head. $\{\mathbf{W}_h^Q, \mathbf{W}_h^K, \mathbf{W}_h^V\} \in \mathbb{R}^{d \times \frac{d}{H}}$ denote parameter matrices associated with the h-th head, where d represents the dimensionality of the model hidden states. Furthermore, H attention functions are applied in parallel to produce the output states $\{\mathbf{O}_1, \dots, \mathbf{O}_H\}$, among them:

$$\mathbf{O}_h = \textsc{Att}(\mathbf{Q}_h, \mathbf{K}_h)\mathbf{V}_h, \quad (2)$$

where $\mathbf{O}_h \in \mathbb{R}^{J \times \frac{d}{H}}$, $\textsc{Att}(\cdot)$ is an attention model. In this work, we use scaled dot-product attention (Luong et al., 2015), which achieves similar performance with its additive counterpart (Bahdanau et al., 2015) while is much faster and more space-efficient in practice (Vaswani et al., 2017).

Finally, the H output states are concatenated and linearly transformed to produce the final state:

$$\begin{aligned} \text{Concat:} \quad \widehat{\mathbf{O}} &= [\mathbf{O}_1, \dots, \mathbf{O}_H], && (3) \\ \text{Linear:} \quad \mathbf{O} &= \widehat{\mathbf{O}}\mathbf{W}^O, && (4) \end{aligned}$$

where $\mathbf{O} \in \mathbb{R}^{J \times d}$ denotes the final output states, $\mathbf{W}^O \in \mathbb{R}^{d \times d}$ is a trainable matrix.

As shown in Equations 3 and 4, the conventional multi-head attention uses a straightforward concatenation and linear mapping to aggregate the output representations of multiple attention heads. We argue that this straightforward strategy may not fully exploit the expressiveness of multi-head attention, which can benefit from advanced information aggregation by exploiting the intrinsic relationship among the learned representations.

3 Related Work

Our work synthesizes two strands of research work, namely *multi-head attention* and *information aggregation*.

3.1 Multi-Head Attention

Multi-head attention has shown promising empirical results in many NLP tasks, such as machine translation (Vaswani et al., 2017; Domhan, 2018), semantic role labeling (Strubell et al., 2018), and subject-verb agreement task (Tang et al., 2018). The strength of multi-head attention lies in the rich expressiveness by using multiple attention functions in different representation subspaces.

Previous work show that multi-head attention can be further enhanced by encouraging individual attention heads to extract distinct information. For example, Lin et al. (2017) introduce a penalization term to reduce the redundancy of attention weights among different attention heads. Li et al. (2018) propose disagreement regularizations to encourage different attention heads to capture distinct features, and Yang et al. (2019) model the interactions among attention heads. Shen et al. (2018) explicitly use multiple attention heads to model different dependencies of the same word pair, and Strubell et al. (2018) employ different attention heads to capture different linguistic features. Our approach is complementary to theirs, since they focus on extracting distinct information while ours aims at effectively aggregating the extracted information. Our study shows that information aggregation is as important as information extraction for multi-head attention.

3.2 Information Aggregation

Information aggregation in multi-head attention (e.g. Equations 3 and 4) aims at composing the partial representations of the input captured by different attention heads to a final representation. Recent work shows that representation composition benefits greatly from advanced functions beyond simple concatenation or mean/max pooling. For example, Fukui et al. (2016) and Ben-Younes et al. (2017) succeed on fusing multi-modal features (e.g., visual features and textual features) more effectively via employing the higher-order bilinear pooling instead of vector concatenation or element-wise operations. In NLP tasks, Peters et al. (2018) aggregate layer representations with linear combination, and Dou et al. (2018) compose deep representations with layer aggregation and multi-layer attention mechanisms.

Recently, the routing-by-agreement algorithm, which origins from the capsule networks (Hinton et al., 2011), becomes an appealing alternative to representation composition. The majority of existing work on capsule networks has focused on computer vision tasks, such as MNIST tasks (Sabour et al., 2017; Hinton et al., 2018), CIFAR tasks (Xi et al., 2017), and object segmentation task (LaLonde and Bagci, 2018). The applications of capsule networks in NLP tasks, however, have not been widely investigated to date. Zhao et al. (2018) testify capsule networks on text classification tasks and Gong et al. (2018) propose to aggregate a sequence of vectors via dynamic routing for sequence encoding. Dou et al. (2019) use routing-by-agreement strategies to aggregate layer representations dynamically. Inspired by these successes, we apply the routing algorithms to multi-head attention on both linguistic probing and machine translation tasks, which demonstrates the necessity and effectiveness of advanced information aggregation for multi-head attention.

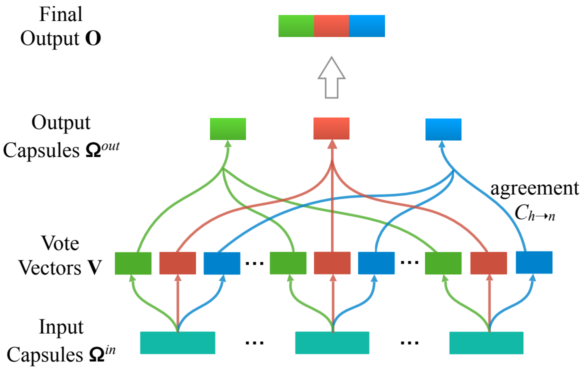

Figure 1: Illustration of routing-by-agreement.

4 Approach

In this work, we cast information aggregation in multi-head attention as the problem of *assigning-parts-to-wholes*. Specifically, each attention head extracts different linguistic properties of the same input (Raganato and Tiedemann, 2018), and the goal of information aggregation is to compose the partial representations extracted by different heads to a whole representation. An appealing solution to this problem is the *routing-by-agreement* algorithm, as shown in Figure 1.

The routing algorithm consists of two layers: *input capsules* and *output capsules*. The input capsules are constructed from the transformation of the partial representations extracted by different attention heads. For each output capsule, each input capsule proposes a distinct "voting vector", which represents the proportion of how much the information is transformed from this input capsule (i.e parts) to the corresponding output capsule (i.e. wholes). The proportion is iteratively updated based on the agreement between the voting vectors and the output capsule. Finally, all output capsules are concatenated to form the final representation.

4.1 Routing-by-Agreement

Mathematically, the input capsules $\mathbf{\Omega}^{in} = \{\mathbf{\Omega}^{in}_1, \ldots, \mathbf{\Omega}^{in}_H\}$ with $\mathbf{\Omega}^{in} \in \mathbb{R}^{n\times d}$ are constructed from the outputs of multi-head attention:

$$\mathbf{\Omega}^{in}_h = f_h(\widehat{\mathbf{O}}), \tag{5}$$

where $f_h(\cdot)$ is a distinct non-linear transformation function associated with the input capsule

Algorithm 1 Iterative Simple Routing.

```
1: procedure ROUTING($\mathbf{V}$, $T$):
2:     $\forall \mathbf{V}_{h\to *}$: $B_{h\to n} = 0$
3:     for $T$ iterations do
4:         $\forall \mathbf{V}_{h\to *}$: $C_{h\to n} = \frac{\exp(B_{h\to n})}{\sum_{n'=1}^{N} \exp(B_{h\to n'})}$
5:         $\forall \mathbf{\Omega}_n^{out}$: compute $\mathbf{\Omega}_n^{out}$ by Eq. 7
6:         $\forall \mathbf{V}_{h\to *}$: $B_{h\to n}$ += $\mathbf{\Omega}_n^{out} \cdot \mathbf{V}_{h\to n}$
    return $\mathbf{\Omega}$
```

Algorithm 2 Iterative EM Routing.

```
1: procedure EM ROUTING($\mathbf{V}$, $T$):
2:     $\forall \mathbf{V}_{h\to *}$: $C_{l\to n} = 1/N$
3:     for $T$ iterations do
4:         $\forall \mathbf{\Omega}_n^{out}$: M-STEP($\mathbf{V}$, $C$)        ▷ hold $C$ constant, adjust $(\boldsymbol{\mu}_n, \boldsymbol{\sigma}_n, A_n)$
5:         $\forall \mathbf{V}_{h\to *}$: E-STEP($\mathbf{V}$, $\boldsymbol{\mu}$, $\boldsymbol{\sigma}$, $A$)    ▷ hold $(\boldsymbol{\mu}, \boldsymbol{\sigma}, A)$ constant, adjust $C_{h\to *}$
6:     $\forall \mathbf{\Omega}_n^{out}$: $\mathbf{\Omega}_n^{out} = A_n * \boldsymbol{\mu}_n$
    return $\mathbf{\Omega}$
```

$\mathbf{\Omega}_h^{in}$. Given N output capsules, each input capsule $\mathbf{\Omega}_h^{in}$ propose N "vote vectors" $\mathbf{V}_{h\to *} = \{\mathbf{V}_{h\to 1}, \dots, \mathbf{V}_{h\to N}\}$, which is calculated by

$$\mathbf{V}_{h\to n} = \mathbf{\Omega}_h^{in} \mathbf{W}_{h\to n}, \tag{6}$$

Each output capsule $\mathbf{\Omega}_n^{out}$ is calculated as the normalization of its total input, which is a weighted sum over all "vote vectors" $\mathbf{V}_{*\to n}$:

$$\mathbf{\Omega}_n^{out} = \frac{\sum_{h=1}^{H} C_{h\to n} \mathbf{V}_{h\to n}}{\sum_{h=1}^{H} C_{h\to n}}, \tag{7}$$

The weight $C_{h\to n}$ with $\sum_n C_{h\to n} = 1$ measures the agreement between vote vector $\mathbf{V}_{h\to n}$ and output capsule $\mathbf{\Omega}_n^{out}$, which is determined by the iterative routing as described in the next section. Note that $\sum_{h=1}^{H} C_{h\to n}$ is not necessarily equal to 1. After the routing process, following Gong et al. (2018), we concatenate the N output capsules to form the final representation: $\mathbf{O} = [\mathbf{\Omega}_1^{out}, \dots, \mathbf{\Omega}_N^{out}]$. To make the dimensionality of the final output be consistent with that of hidden layer (i.e. d), we set the dimensionality of each output capsule be $\frac{d}{N}$.

4.2 Routing Mechanisms

In this work, we explore two representative routing mechanisms, namely *simple routing* (Sabour et al., 2017) and *EM routing* (Hinton et al., 2018), which differ at how the agreement weights $C_{h\to n}$ are calculated.

4.2.1 Simple Routing

Algorithm 1 lists a straightforward implementation of routing mechanism. $B_{h\to n}$ measures the degree that the input capsule $\mathbf{\Omega}_h^{in}$ should be coupled to the output capsule $\mathbf{\Omega}_n^{out}$, which is initialized as all 0 (Line 2). The agreement weights $C_{h\to n}$ are then iteratively refined by measuring the agreement between vote vector $\mathbf{V}_{h\to n}$ and output capsule $\mathbf{\Omega}_n^{out}$ (Lines 4-6), which is implemented as a simple scalar product $\mathbf{\Omega}_n^{out} \cdot \mathbf{V}_{h\to n}$ (Line 6).

To represent the probability that the output capsule $\mathbf{\Omega}_n^{out}$ is activated, Sabour et al. (2017) use a non-linear "squashing" function:

$$\mathbf{\Omega}_n^{out} = \frac{||\mathbf{\Omega}_n^{out}||^2}{1 + ||\mathbf{\Omega}_n^{out}||^2} \frac{\mathbf{\Omega}_n^{out}}{||\mathbf{\Omega}_n^{out}||}, \tag{8}$$

The scalar product $\mathbf{\Omega}_n^{out} \cdot \mathbf{V}_{h\to n}$ saturates at 1, which makes it insensitive to the difference between a quite good agreement and a very good agreement. In response to this problem, Hinton et al. (2018) propose a novel Expectation-Maximization (EM) routing algorithm.

4.2.2 EM Routing

Comparing with simple routing, EM routing has two modifications. First, it explicitly assigns an activation probability A to represent the probability of whether each output capsule is activated, rather than the length of vector calculated by a squashing function (Equation 8). Second, it casts the routing process as fitting a mixture of Gaussians using EM algorithm, where the output capsules play the role of Gaussians and the means of the input capsules play the role of the datapoints. Accordingly, EM routing can better estimate the agreement by allowing activated output capsules to receive a cluster of similar votes.

Algorithm 2 lists the EM routing, which iteratively adjusts the means, variances, and activation probabilities $(\boldsymbol{\mu}, \boldsymbol{\sigma}, A)$ of the output capsules, as well as the agreement weights C of the input capsules (Lines 4-5). The representation of output capsule $\mathbf{\Omega}_n^{out}$ is calculated as

$$\mathbf{\Omega}_n^{out} = A_n * \boldsymbol{\mu}_n = A_n * \frac{\sum_{h=1}^{H} C_{h\to n} \mathbf{V}_{h\to n}}{\sum_{h=1}^{H} C_{h\to n}}, \tag{9}$$

The EM algorithm alternates between an E-step and an M-step. The E-step determines, for each datapoint (i.e. input capsule), the probability of agreement (i.e. C) between it and each of the Gaussians (i.e. output capsules). The M-step holds the agreement weights constant, and for each Gaussian (i.e. output capsule) consists of finding the mean of these weighted datapoints (i.e. input capsules) and the variance about that mean.

M-Step for each Gaussian (i.e. $\mathbf{\Omega}_n^{out}$) consists of finding the mean $\boldsymbol{\mu}_n$ of the votes from input capsules and the variance $\boldsymbol{\sigma}_n$ about that mean:

$$\boldsymbol{\mu}_n = \frac{\sum_{h=1}^{H} C_{h\to n}\mathbf{V}_{h\to n}}{\sum_{h=1}^{H} C_{h\to n}}, \quad (10)$$

$$(\boldsymbol{\sigma}_n)^2 = \frac{\sum_{h=1}^{H} C_{h\to n}(\mathbf{V}_{h\to n}-\boldsymbol{\mu}_n)^2}{\sum_{h=1}^{H} C_{h\to n}}. \quad (11)$$

The incremental cost of using an active capsule $\mathbf{\Omega}_n^{out}$ is

$$\chi_n = \sum_i \big(\log(\boldsymbol{\sigma}_n^i) + \frac{1+\log(2\pi)}{2}\big)\sum_{h=1}^{H} C_{h\to n},$$

where $\boldsymbol{\sigma}_n^i$ denotes the i-th dimension of the variance vector $\boldsymbol{\sigma}_n$. The activation probability of capsule $\mathbf{\Omega}_n^{out}$ is calculated by

$$A_n = logistic\big(\lambda(\beta_A - \beta_\mu \sum_{h=1}^{H} C_{h\to n} - \chi_n)\big),$$

where β_A is a fixed cost for coding the mean and variance of $\mathbf{\Omega}_n^{out}$ when activating it, β_μ is another fixed cost per input capsule when not activating it, and λ is an inverse temperature parameter set with a fixed schedule. We refer the readers to (Hinton et al., 2018) for more details.

E-Step adjusts the assignment probabilities $C_{h\to *}$ for each input $\mathbf{\Omega}_h^{in}$. First, we compute the negative log probability density of the vote $\mathbf{V}_{h\to n}$ from $\mathbf{\Omega}_h^{in}$ under the Gaussian distribution fitted by the output capsule $\mathbf{\Omega}_n^{out}$ it gets assigned to:

$$P_{h\to n} = \sum_i \frac{1}{\sqrt{2\pi(\boldsymbol{\sigma}_n^i)^2}} \exp(-\frac{(\mathbf{V}_{h\to n}^i - \boldsymbol{\mu}_n^i)^2}{2(\boldsymbol{\sigma}_n^i)^2}).$$

Again, i denotes the i-th dimension of the vectors $\{\mathbf{V}_{h\to n}, \boldsymbol{\mu}_n, \boldsymbol{\sigma}_n\}$. Accordingly, the agreement weight is re-normalized by

$$C_{h\to n} = \frac{A_n P_{h\to n}}{\sum_{n'=1}^{N} A_{n'} P_{h\to n'}}. \quad (12)$$

5 Experiments

In this section, we evaluate the performance of our proposed models on both linguistic probing tasks and machine translation tasks.

5.1 Linguistic Probing Tasks

5.1.1 Setup

Tasks Recently, Conneau et al. (2018) designed 10 probing tasks to study what linguistic properties are captured by input representations. A probing task is a classification problem that focuses on simple linguistic properties of sentences. 'SeLen' is to predict the length of sentences in terms of number of words. 'WC' tests whether it is possible to recover information about the original words given its sentence embedding. 'TrDep' checks whether an encoder infers the hierarchical structure of sentences. In 'ToCo' task, sentences should be classified in terms of the sequence of top constituents immediately below the sentence node. 'Bshif' tests whether two consecutive tokens within the sentence have been inverted. 'Tense' asks for the tense of the main-clause verb. 'SubNm' focuses on the number of the subject of the main clause. 'ObjNm' tests for the number of the direct object of the main clause. In 'SOMO', some sentences are modified by replacing a random noun or verb with another noun or verb and the classifier should tell whether a sentence has been modified. 'CoIn' benchmark contains sentences made of two coordinate clauses. Half of the sentences are inverted the order of the clauses and the task is to tell whether a sentence is intact or modified. We conduct probing tasks to study whether the routing-based aggregation benefits multi-head attention to produce more informative representation.

Data and Models The models on each classification task are trained and examined using the open-source dataset provided by Conneau et al. (2018), where each task is assigned 100k sentences for training and 10k sentences for validating and testing. Each of our probing model consists of 3 encoding layers followed by a MLP classifier. For each encoding layer, we employ a multi-head self-attention block and a feed-forward block as in TRANSFORMER-BASE, which have achieved promising results on several NLP tasks (Dehghani et al., 2018; Devlin et al., 2018). The mean of the top encoding layer is served as the sentence

Model	Surface		Syntactic			Semantic				
	SeLen	WC	TrDep	ToCo	BShif	Tense	SubNm	ObjNm	SOMO	CoIn
BASE	**97.22**	97.92	44.48	84.44	49.30	84.20	87.66	82.94	50.24	68.77
SIMPLE	97.10	**98.85**	43.37	86.15	49.87	**88.22**	87.25	85.07	48.77	69.12
EM	96.26	98.75	**47.72**	**87.00**	**51.82**	88.17	**89.97**	**86.40**	**51.55**	**69.86**

Table 1: Classification accuracies on 10 probing tasks of evaluating the linguistic properties ("Surface", "Syntectic", and "Semantic") learned by sentence encoder. "BASE" denotes the standard linear transformation, "SIMPLE" is the simple routing algorithm, and "EM" is the EM routing algorithm.

representation passed to the classifier. The difference between the compared models merely lies in the aggregation mechanism of multiple attention heads: "BASE" uses a standard concatenation and linear transformation, "SIMPLE" and "EM" are assigned simple routing and EM routing algorithms, respectively. For routing algorithms, the number of output capsules and routing iterations are empirically set to 512 and 3.

5.1.2 Results

Table 1 lists the classification accuracies of the three models on the 10 probing tasks. We highlight the best accuracies in bold. Several observations can be made here.

First, *routing-based models produce more informative representation.* The representation produced by encoders with routing-based aggregation outperforms that by the baseline in most tasks, proving that routing mechanisms indeed aggregate attention heads more effectively. The only exception is the sentence length classification task ('SeLen'), which is consistent with the conclusion in (Conneau et al., 2018): as a model captures deeper linguistic properties, it will tend to forget about this superficial feature.

Second, *EM routing outperforms simple routing by embedding more syntactic and semantic information.* As shown in the last row, EM routing for multi-head aggregation consistently achieves best performances on most syntactic and semantic tasks. Especially on task 'TrDep', 'Tense' and 'ObjNm', EM routing-based model surpasses the baseline more than 3 points, demonstrating that EM routing benefits multi-head attention to capture more syntax structure and sentence meaning. Simple routing, however, underperforms the baseline model in some cases such as 'TrDep' and 'SubNm'. We attribute the superiority of EM routing to generating more accurate agreement weights with the Gaussian estimation.

5.2 Machine Translation Tasks

5.2.1 Setup

Data We conduct experiments on the widely-used WMT2014 English⇒German (En⇒De) and WMT2017 Chinese⇒English (Zh⇒En) machine translation tasks. For the En⇒De task, the dataset consists of 4.6M sentence pairs. We use newstest2013 as the development set and newstest2014 as the test set. For the Zh⇒En task, we use all of the available parallel data, consisting of about 20.6M sentence pairs. We use newsdev2017 as the development set and newstest2017 as the test set. We employ byte-pair encoding (BPE) (Sennrich et al., 2016) with 32K merge operations for both language pairs. We use the case-sensitive 4-gram NIST BLEU score (Papineni et al., 2002) as evaluation metric, and bootstrap resampling (Koehn, 2004) for statistical significance test.

Models We implement the proposed approaches on top of the advanced TRANSFORMER model (Vaswani et al., 2017). We follow Vaswani et al. (2017) to set the configurations and have reproduced their reported results on the En⇒De task. The *Base* and *Big* models differ at hidden size (512 vs. 1024) and number of attention heads (8 vs. 16). All the models are trained on eight NVIDIA P40 GPUs where each is allocated with a batch size of 4096 tokens.

TRANSFORMER consists of three attention components: encoder-side self-attention, decoder-side self-attention and encoder-decoder attention, all of which are implemented as multi-head attention. For the information aggregation in multi-head attention, we replace the standard linear transformation with the proposed routing mechanisms. We experimentally set the number of iterations to 3 and the number of output capsules as model hidden size, which outperform other configurations during our investigation.

5.2.2 Component Analysis

Table 2 lists the results on the En⇒De translation task with TRANSFORMER-BASE. As seen, the proposed routing mechanism outperforms the standard aggregation in all cases, demonstrating the necessity of advanced aggregation functions for multi-head attention.

Routing Mechanisms (Rows 3-4) We first apply simple routing and EM routing to encoder self-attention. Both strategies perform better than the standard multi-head aggregation (Row 1), verifying the effectiveness of the non-linear aggregation mechanisms. Specifically, the two strategies require comparable parameters and computational speed, but EM routing achieves better performance on translation qualities. Considering the training speed and performance, *EM routing* is used as the default multi-head aggregation method in subsequent experiments.

Effect on Attention Components (Rows 4-8) Concerning the individual attention components (Rows 4-6), we found that the encoder and decoder self-attention benefit more from the routing-based information aggregation than the encoder-decoder attention. This is consistent with the finding in (Tang et al., 2018), which shows that self-attention is a strong semantic feature extractor. Encouragingly, applying EM routing in the encoder (Row 4) significantly improve the translation quality with almost no decrease in decoding speed, which matches the requirement of online MT systems. We find that this is due to the auto-regressive generation schema, modifications on the decoder influence the decoding speed more than the encoder.

Compared with individual attention components, applying routing to multiple components (Rows 7-8) marginally improves translation performance, at the cost of a significant decrease of the training and decoding speeds. Possible reasons include that the added complexity makes the model harder to train, and the benefits enjoyed by different attention components are overlapping to some extent. To balance translation performance and efficiency, we only apply EM routing to aggregate multi-head self-attention at the *encoder* in subsequent experiments.

Encoder Layers As shown in Row 4 of Table 2, applying EM routing to all encoder layers significantly decreases the training speed by 37.5%, which is not acceptable since TRANSFORMER is best known for both good performance and quick training. We expect applying to fewer layers can alleviate the training burden. Recent studies show that different layers of NMT encoder can capture different levels of syntax and semantic features (Shi et al., 2016; Peters et al., 2018). There-

Table 4: Comparing with existing NMT systems on WMT14 English⇒German ("En⇒De") and WMT17 Chinese⇒English ("Zh⇒En") tasks. "$\uparrow$ / $\Uparrow$": significantly better than the baseline counterpart ($p < 0.05/0.01$).

fore, an investigation to study whether EM routing works for multi-head attention at different layers is highly desirable.

As shown in Table 3, we respectively employ EM routing for multi-head attention at the high-level three layers (Row 3) and low-level three layers (Row 4). The translation quality marginally drop while parameters are fewer and training speeds are quicker. This phenomena verifies that it is unnecessary to apply the proposed model to all layers. We further reduce the applied layers to low-level two (Row 5), the above phenomena still holds. However, a big drop on translation quality occurs when the number of layer is reduced to 1 (Rows 6-7).

Accordingly, to balance translation performance and efficiency, we only apply EM routing for multi-head aggregation at the *low-level two layers of the encoder*, which we term "Effective Aggregation" in the following sections.

5.2.3 Main Results

In this section, we validate the proposed "Effective Aggregation" for multi-head attenion on both WMT17 Zh⇒En and WMT14 En⇒De translation tasks. The results are listed in Table 4. Our implementations of both Transformer-Base and Transformer-Big outperform the reported NMT systems on the same data and match the strong results of Transformer reported in previous works, which we believe make the evaluation convincing. Incorporating the effective aggregation consistently and significantly improves translation performance for both base and big Transformer models across language pairs, demonstrating the efficiency and universality of our proposed multi-head aggregation mechanism.

Moreover, it is encouraging to see that Transformer-Base with effective aggregation strategy even achieves comparable performances to that of Transformer-Big, with about two thirds fewer parameters, which further demonstrates that our performance gains are not simply brought by additional parameters.

6 Conclusion

In this work, we provide first empirical validation on the importance of information aggregation for multi-head attention. Instead of the conventional linear transformation, we propose to aggregate the partial representations learned by multiple attention heads via *routing-by-agreement*. The routing algorithm iteratively updates the proportion of how much a partial representation should be assigned to the final output representation, based on the agreement between parts and wholes.

Experimental results across 10 linguistic probing tasks reveal that our EM routing-based model indeed produces more informative representation, which benefits multi-head attention to capture more syntactic and semantic information. In addition, our approach on various machine translation tasks consistently and significantly outperforms the strong Transformer baseline. Extensive analysis further suggests that only applying EM routing to low-level two layers of the encoder can best balance the translation performance and computational efficiency.

Future work includes combining our information aggregation techniques together with other advanced information extraction models for multi-head attention (Li et al., 2018). We expect that the two kinds of approaches can complement each other to further improve the expressiveness of multi-head attention.

Context-Dependent Semantic Parsing over Temporally Structured Data

Charles Chen and Razvan Bunescu
School of Electrical Engineering and Computer Science, Ohio University

Abstract

We describe a new semantic parsing setting that allows users to query the system using both natural language questions and actions within a graphical user interface. Multiple time series belonging to an entity of interest are stored in a database and the user interacts with the system to obtain a better understanding of the entity's state and behavior, entailing sequences of actions and questions whose answers may depend on previous factual or navigational interactions. We design an LSTM-based encoder-decoder architecture that models context dependency through copying mechanisms and multiple levels of attention over inputs and previous outputs. When trained to predict tokens using supervised learning, the proposed architecture substantially outperforms standard sequence generation baselines. Training the architecture using policy gradient leads to further improvements in performance, reaching a sequence-level accuracy of 88.7% on artificial data and 74.8% on real data.

1 Introduction and Motivation

Wearable sensors are being increasingly used in medicine to monitor important physiological parameters. Patients with type I diabetes, for example, wear a sensor inserted under the skin which provides measurements of the interstitial blood glucose level (BGL) every 5 minutes. Sensor bands provide a non-invasive solution to measuring additional physiological parameters, such as temperature, skin conductivity, heart rate, and acceleration of body movements. Patients may also self-report information about discrete life events such as meals, sleep, or stressful events, while an insulin pump automatically records two types of insulin interventions: a continuous stream of insulin called the basal rate, and discrete self-administered insulin dosages called boluses. The data acquired from sensors and patients accumulates rapidly and leads to a substantial data overload for the health provider.

To help doctors more easily browse the wealth of generated patient data, we built a graphical user interface (GUI) that displays the various time series of measurements corresponding to a patient. As shown in Figure 1, the GUI displays the data corresponding to one day, whereas buttons allow the user to move to the next or previous day. While the graphical interface was enthusiastically received by doctors, it soon became apparent that the doctor-GUI interaction could be improved substantially if the tool also allowed for natural language (NL) interactions. Most information needs are highly contextual and local. For example, if the blood glucose spiked after a meal, the doctor would often want to know more details about the meal or about the bolus that preceded the meal. The doctor often found it easier to express their queries in natural language (e.g. "show me how much he ate", "did he bolus before that"), resulting in a sub-optimal situation where the doctor would ask this type of *local questions* in English while a member of our team would perform the clicks required to answer the question, e.g. click on the meal event, to show details such as amount of carbohydrates. Furthermore, there were also *global questions*, such as "How often does the patient go low in the morning and the evening", whose answers would require browsing the entire patient history in the worst case, which would be very inefficient. This motivated us to start work on a new system component that would allow the doctor to interact using both natural language queries and direct actions within the GUI. A successful solution to the task described in this paper has the potential for applications in many areas of medicine where sensor data and life events are pervasive. Intelligent user interfaces for the proposed task will also benefit the exploration and interpretation of data in other domains such as experimental

physics, where large amounts of time series data are generated from high-throughput experiments.

2 Task Definition

Given an input from the user (a NL query or a direct GUI interaction), the aim is to parse it into a logical form representation that can be run by an inference engine in order to automatically extract the answer from the database. Table 1 shows sample inputs paired with their logical forms. For each input, the examples also show relevant previous inputs from the interaction sequence. In the following sections we describe a number of major features that, on their own or through their combination, distinguish this task from other semantic parsing tasks.

2.1 Time is essential

All events and measurements in the knowledge base are organized in time series. Consequently, many queries contain time expressions, such as the relative “midnight" or the coreferential “then", and temporal relations between relevant entities, expressed through words such as “after" or “when". This makes processing of temporal relations essential for a good performance. Furthermore, the GUI serves to anchor the system in time, as most of the information needs expressed in local questions are relative to the day shown in the GUI, or the last event that was clicked.

2.2 GUI interactions vs. NL questions

The user can interact with the system 1) directly within the GUI (e.g. mouse clicks); 2) through natural language questions; or 3) through a combination of both, as shown in Examples 1 and 2 in Table 1. Although the result of every direct interaction with the GUI can also be obtained using natural language questions, sometimes it can be more convenient to use the GUI directly, especially when all events of interest are in the same area of the screen and thus easy to move the mouse or hand from one to the other. For example, a doctor interested in what the patient ate that day can simply click on the blue squares at the top of the bottom pane in Figure 1, one after another. Sometimes a click can be used to anchor the system at a particular time during the day, after which the doctor can ask short questions implicitly focused on that region in time. An example of such hybrid behavior is shown in Example 2, where a click on a Bolus event is followed by a question about a snack, which implicitly should be the meal right after the bolus.

Example 1

Click on Exercise event at 9:29am.
$Click(e) \wedge e.type = \text{Exercise} \wedge e.time = \text{9:29am}$

Click on Miscellaneous event at 9:50am
$Click(e) \wedge e.type = \text{Misc} \wedge e.time = \text{9:50am}$

Q_1: What was she doing mid afternoon
when her heart rate went up?
$Answer(e) \wedge Behavior(e_1.value, \text{Up})$
$\wedge Around(e.time, e_1.time)$
$\wedge e.type == DiscreteType$
$\wedge e1.type == HeartRate$
$\wedge e1.time == MidAfternoon()$

Q_2: What time did that start?
$Answer(e(-1).time)$

Example 2

Click on Bolus at 8:03pm.
$Click(e) \wedge e.type = \text{Bolus} \wedge e.time = \text{8:03pm}$

Q_3: What did she eat for her snack?
$Answer(e.food) \wedge e.kind == Snack$

Example 3

Click on Exercise at 7:52pm.
$Click(e) \wedge e.type = \text{Exercise} \wedge e.time = \text{7:52pm}$

Q_4: What did she do then?
$Answer(e(-1).kind)$

Q_5: Did she take a bolus before then?
$Answer(Any(d.type == Bolus$
$\wedge Before(d.time, e(-1).time)))$

Example 4

Q_6: What is the first day they have heart rate reported?
$Answer(e.date)$
$\wedge Order(e, 1, Sequence(d, d.type == HeartRate))$

Example 5

Q_7: Is there another day he goes low in the morning?
$Answer(Any(Hypo(d1) \wedge x! = CurrentDate$
$\wedge x.type == Date \wedge d1.time == Morning(x))$

Table 1: Examples of interactions and logical forms.

2.3 Factual queries vs. GUI commands

Most of the time, doctors have information needs that can be satisfied by clicking on an event shown in the GUI or by asking factual questions about a particular event of interest from that day. In contrast, a different kind of interaction happens when the doctor wants to change what is shown in the tool, such as toggling on/off particular time series (e.g. “toggle on heart rate"), or navigating to a different day (e.g. “go to next day", “look at the previous day"). Sometimes, a question may be a combination of both, as in “What is the first day they have a meal without a bolus?", for which the expectation is that the system navigates to that day and also clicks on the meal event to show additional information and anchor the system at the time of that meal.

2.4 Sequential dependencies

The user interacts with the system through a sequence of questions or clicks. The logical form of a question, and implicitly its answer, may depend on the previous interaction with the system. Examples 1 to 3 in Table 1 are all of this kind. In example 1, the pronoun “that" in question 2 refers to the answer to question 1. In example 2, the snack refers to the meal around the time of the bolus event that was clicked previously – this is important, as there may be multiple snacks that day. In example 3, the adverb “then" in question 5 refers to the time of the event that is the answer of the previous question. As can be seen from these examples, sequential dependencies can be expressed as coreference between events from different questions. Coreference may also happen within questions, as in question 4 for example. Overall, solving coreferential relations will be essential for good performance.

3 Semantic Parsing Datasets

To train and evaluate semantic parsing approaches, we created two datasets of sequential interactions: a dataset of real interactions (Section 3.1) and a much larger dataset of artificial interactions (Section 3.2).

3.1 Real Interactions

We recorded interactions with the GUI in real time, using data from 9 patients, each with around 8 weeks worth of time series data. In each recording session, the tool was loaded with data from one patient and the physician was instructed to explore the data in order to understand the patient behavior as usual, by asking NL questions or interacting directly with the GUI. Whenever a question was asked, a member of our study team found the answer by navigating in and clicking on the corresponding event. After each session, the question segments were extracted manually from the speech recordings, transcribed, and timestamped. All direct interactions (e.g. mouse clicks) were recorded automatically by the tool, timestamped, and exported into an XML file. The sorted list of questions and the sorted list of mouse clicks were then merged using the timestamps as key, resulting in a chronologically sorted list of questions and GUI interactions. Mouse clicks were automatically translated into logical forms, whereas questions were parsed into logical forms manually.

Event Types
Physiological Parameters:
BGL, BasalRate, TemporaryBasal, Carbs, GSR, InfusionSet, AirTemperature, SkinTemperature, HeartRate, StepCount.
Life Events:
FingerSticks, Bolus, Hypo, HypoAction, Misc, Illness, Meal, Exercise, ReportedSleep, Wakeup, Work, Stressors.
Constants
Up, Down, On, Off, Monday, Tuesday, ..., Sunday.
Functions
$Interval(t_1, t_2)$, $Before(t)$, $After(t)$, ...
return corresponding intervals (default lengths).
$Morning([d])$, $Afternoon([d])$, $Evening([d])$, ...
return corresponding intervals for day d.
$WeekDay(d)$:
return the day of the week of date d.
$Sequence(var, statements)$:
return a chronologically ordered sequence of possible values for var that satisfy $statements$.
$Count(var[, statements])$:
returns the number of possible values for var that satisfy $statements$.
Predicates
$Answer(e)$, $Click(e)$
$Morning(t)$, $Afternoon(t)$, $Evening(t)$, ...
$Overlap(t_1, t_2)$, $Before(t_1, t_2)$, $Around(t_1, t_2)$, ...
$Behavior(variable, direction)$:
whether $variable$ increases, if $direction$ is Up, (or decrease if $direction$ is $Down$).
$High(variable)$, $Low(variable)$:
whether $variable$ has some low value.
$Order(event, ordinal, sequence[, attribute])$:
whether the $event$ is at place $ordinal$ in $sequence$
Commands
DoClick, DoToggle, DoSetDate, DoSetTime, ...

Table 2: Vocabulary for logical forms.

A snapshot of the vocabulary for logical forms is shown in Table 2, showing the Event Types, Constants, Functions, Predicates, and Commands. Every life event or physiological measurement stored in the database is represented in the logical forms as an event object e with 3 major attributes: $e.type$, $e.date$, and $e.time$. Depending on its type, an event object may contain additional fields. For example, if $e.type = BGL$, then it has an attribute $e.value$. If $e.type = Meal$, then it has attributes $e.food$ and $e.carbs$. We use $e(-i)$ to represent the event appearing in the i^{th} previous logical form (LF). Thus, to reference the event mentioned in the previous LF, we use $e(-1)$, as shown for question Q_5. If more than one event appears in the previous LF, we use an additional index j to match the event index in the previous LF. Coreference between events is represented simply using the equality operator, e.g. $e = e(-1)$.The dataset contains logical forms for 237 interactions: 74 mouse clicks and 163 NL queries.

3.2 Artificial Interactions

The number of annotated real interactions is too small for training an effective semantic parsing model. To increase the number of training examples, we designed and implemented an artificial data generator that simulates user-GUI interactions, with sentence *templates* defining the skeleton of each entry in order to maintain high-quality sentence structure and grammar. This approach is similar to (Weston et al., 2015), with the difference that we need a much higher degree of variation such that the machine learning model does not memorize all possible sentences, and consequently a much richer template database. We therefore implemented a *template language* with recursive grammar, that can be used to define as many templates and generate as many data examples as desired. We used the same vocabulary as for the real interactions dataset. To generate contextual dependencies (e.g. event coreference), the implementation allows for more complex *combo templates* where a sequence of templates are instantiated together. A more detailed description of the template language and the simulator implementation is given in (Chen et al., 2019) and Appendix A, together with illustrative examples. The simulator was used to generate 1,000 interactions and their logical forms: 312 mouse clicks and 688 NL queries.

4 Baseline Models for Semantic Parsing

This section describes two baseline models: a standard LSTM encoder-decoder for sequence generation *SeqGen* (Section 4.1) and its attention-augmented version *SeqGen+Att2In* (Section 4.2). This last model will be used later in Section 5 as a component in the context-dependent semantic parsing architecture.

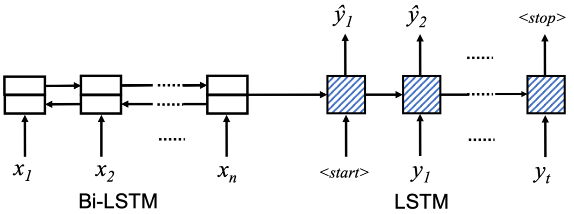

Figure 2: The *SeqGen* model takes a sequence of interactions as input $X = x_1, \ldots, x_n$ and encodes it with a Bi-LSTM (left). The decoder LSTM (right) generates a logical form $\hat{Y} = \hat{y}_1, \ldots, \hat{y}_T$.

4.1 *SeqGen*

As shown in Figure 2, the sequence-generation model *SeqGen* uses Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) units in an encoder-decoder architecture (Bahdanau et al., 2017; Cho et al., 2014), composed of a bi-directional LSTM for the encoder over the input sequence X and an LSTM for the decoder of the output LF sequence Y. We use $Y_t = y_1, \ldots, y_t$ to denote the sequence of output tokens up to position t. We use $\hat{Y}$ to denote the generated logical form.

The initial state $\boldsymbol{s}_0$ is created by running the bi-LSTM encoder over the input sequence X and concatenating the last hidden states. Starting from the initial hidden state $\boldsymbol{s}_0$, the decoder produces a sequence of states $\boldsymbol{s}_1, \ldots, \boldsymbol{s}_T$, using embeddings $e(y_t)$ to represent the previous tokens in the sequence. A softmax is used to compute token probabilities at each position as follows:

$$\begin{aligned} p(y_t|Y_{t-1}, X) &= softmax(\boldsymbol{W}_h \boldsymbol{s}_t) \qquad (1) \\ \boldsymbol{s}_t &= h(\boldsymbol{s}_{t-1}, e(y_{t-1})) \end{aligned}$$

The transition function h is implemented by the LSTM unit.

4.2 *SeqGen+Att2In*

This model (Figure 3) is similar to *SeqGen*, except that it attends to the current input (NL query or mouse click) during decoding. Equation 2 defines the corresponding attention mechanism *Att2In* used to create the context vector $\boldsymbol{d}_t$:

$$e_{tj} = \boldsymbol{v}_a^T \tanh(\boldsymbol{W}_a \boldsymbol{f}_j + \boldsymbol{U}_a \boldsymbol{s}_{t-1}) \qquad (2)$$

$$\alpha_{tj} = \frac{\exp(e_{tj})}{\sum_{k=1}^{m} \exp(e_{tk})}, \quad \boldsymbol{d}_t = \boldsymbol{c}_t = \sum_{j=1}^{n} \alpha_{tj} \boldsymbol{f}_j$$

Here $\boldsymbol{f}_j$ is the j-th hidden states for Bi-LSTM corresponding to $\boldsymbol{x}_j$ and α_{tj} is an attention weight.

Both the context vector $\boldsymbol{d}_t$ and $\boldsymbol{s}_t$ are used to predict the next token $\hat{y}_t$ in the logical form:

$$\hat{y}_t \sim \text{softmax}(\boldsymbol{W}_h \boldsymbol{s}_t + \boldsymbol{W}_d \boldsymbol{d}_t)$$

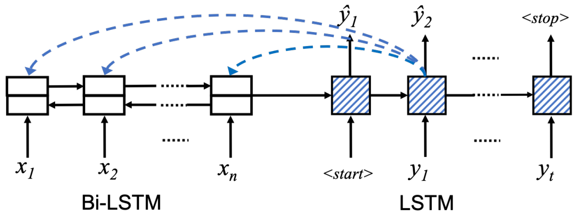

Figure 3: The *SeqGen+Att2In* model augments the *SeqGen* model with an attention mechanism. At each decoding step t, it attends to all input tokens in order to compute a context vector $\boldsymbol{d}_t$.

5 Context-Dependent Semantic Parsing

In Figure 4 we show our proposed semantic parsing model, *SP+Att2All+Copy* (*SPAAC*). Similar to the baseline models, we use a bi-directional LSTM to encode the input and another LSTM as the decoder. Context-dependency is modeled using two types of mechanisms: *attention* and *copying*. The attention mechanism (Section 5.1) is comprised of 3 models: *Att2HisIn* attending to the previous input, *Att2HisLF* attending to the previous logical form, and the *Att2In* introduced in Section 4.2 that attends to the current input. The copying mechanism (Section 5.2) is comprised of two models: one for handling unseen tokens, and one for handling coreference to events in the current and previous logical forms.

5.1 Attention Mechanisms

At decoding step t, the *Att2HisIn* attention model computes the context vector $\hat{\boldsymbol{c}}_t$ as follows:

$$\hat{e}_{tk} = \boldsymbol{v}_b^T \tanh(\boldsymbol{W}_b \boldsymbol{r}_k + \boldsymbol{U}_b \boldsymbol{s}_{t-1}) \qquad (3)$$

$$\beta_{tk} = \frac{\exp(\hat{e}_{tk})}{\sum_{l=1}^{m^2} \exp(\hat{e}_{tl})}, \quad \hat{\boldsymbol{c}}_t = \sum_{k=1}^{n} \beta_{tk} \cdot \boldsymbol{r}_k$$

where $\boldsymbol{r}_k$ is the encoder hidden state corresponding to $\boldsymbol{x}_k$ in the previous input X^{-1}, $\hat{\boldsymbol{c}}_t$ is the context vector, and β_{tk} is an attention weight.

Similarly, the *Att2HisLF* model computes the context vector $\tilde{\boldsymbol{c}}_t$ as follows:

$$\tilde{e}_{tj} = \boldsymbol{v}_c{}^T \tanh(\boldsymbol{W}_c \boldsymbol{l}_j + \boldsymbol{U}_c \boldsymbol{s}_{t-1}) \qquad (4)$$

$$\gamma_{tj} = \frac{\exp(\tilde{e}_{tj})}{\sum_{j=1}^{n} \exp(\tilde{e}_{tj})}, \quad \tilde{\boldsymbol{c}}_t = \sum_{j=1}^{n} \gamma_{tj} \cdot \boldsymbol{l}_j$$

where $\boldsymbol{l}_j$ is the j-th hidden state of the decoder for the previous logical form Y^{-1}.

The context vector used in the decoder is comprised of the context vectors from the three attention models *Att2In*, *Att2HisIn* and *Att2HisLF*:

$$\boldsymbol{d}_t = concat(\boldsymbol{c}_t, \hat{\boldsymbol{c}}_t, \tilde{\boldsymbol{c}}_t) \qquad (5)$$

5.2 Copying Mechanisms

In order to handle out-of-vocabulary (OOV) tokens and coreference (REF) between entities in the current and the previous logical forms, we add two special tokens *OOV* and *REF* to the vocabulary. Inspired by the copying mechanism in (Gu et al., 2016), we train the model to learn which token in the current input $X = \{x_j\}$ is an OOV by minimizing the following loss:

$$L_{oov}(Y) = -\sum_{t=1}^{Y.l} \sum_{j=1}^{X.l} \log p_o(O_j | \boldsymbol{s}_j^X, \boldsymbol{s}_t^Y) \qquad (6)$$

where $X.l$ is the length of current input, $Y.l$ is the length of the current logical form, $\boldsymbol{s}_j^X$ is the LSTM state for x_j and $\boldsymbol{s}_t^Y$ is the LSTM state for y_t, $O_j \in \{0, 1\}$ is a label indicating whether x_j is an OOV. We use logistic regression to compute the OOV probability, i.e. $p_o(O_j = 1 | \boldsymbol{s}_j^X, \boldsymbol{s}_t^Y) = \sigma(\boldsymbol{w}_o^T [\boldsymbol{s}_j^X, \boldsymbol{s}_t^Y])$.

Similarly, to solve coreference, the model is trained to learn which entity in the previously generated logical form $\hat{Y}^{-1} = \{\hat{y}_j\}$ is coreferent with the entity in the current logical form by minimizing the following loss:

$$L_{ref}(Y) = -\sum_{t=1}^{Y.l} \sum_{j=1}^{\hat{Y}^{-1}.l} \log p_r(R_j | \boldsymbol{s}_j^{\hat{Y}^{-1}}, \boldsymbol{s}_t^Y) \qquad (7)$$

where $\hat{Y}^{-1}.l$ is the length of the previous generated logical form, $Y.l$ is the length of the current logical form, $\boldsymbol{s}_j^{\hat{Y}^{-1}}$ is the LSTM state at position j in $\hat{Y}^{-1}$ and $\boldsymbol{s}_t^Y$ is the LSTM state for position t in Y, and $R_j \in \{0, 1\}$ is a label indicating whether $\hat{y}_j$ is an entity referred by y_t in the next logical form Y. We use logistic regression to compute the coreference probability, i.e. $p_r(R_j = 1 | \boldsymbol{s}_j^{\hat{Y}^{-1}}, \boldsymbol{s}_t^Y) = \sigma(\boldsymbol{w}_r^T [\boldsymbol{s}_j^{\hat{Y}^{-1}}, \boldsymbol{s}_t^Y])$.

Finally, we use "Teacher forcing" (Williams and Zipser, 1989) to train the model to learn which token in the vocabulary (including special tokens *OOV* and *REF*) should be generated, by minimizing

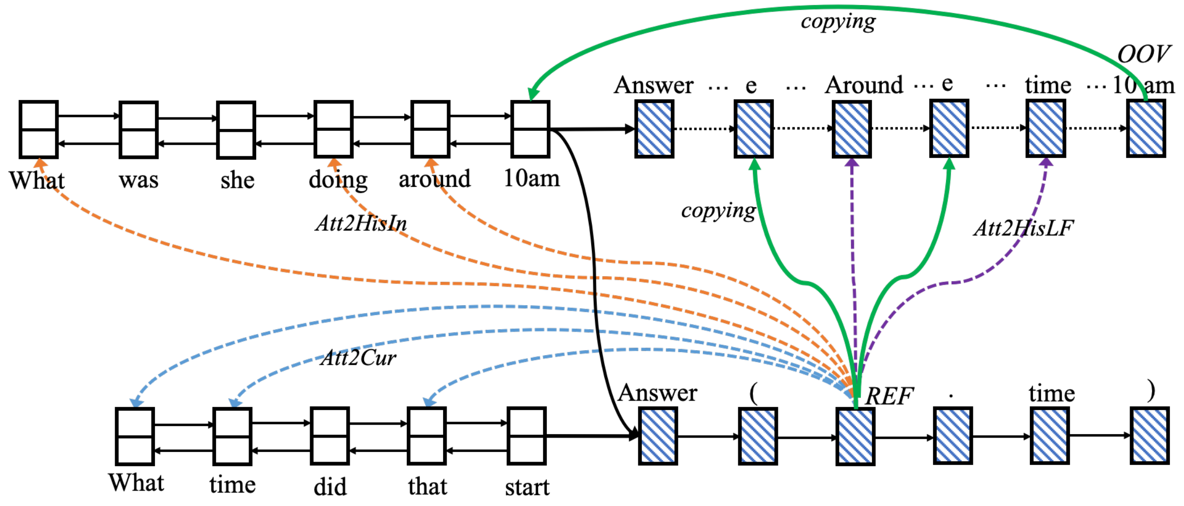

Figure 4: Context-dependent semantic parsing architecture. We use a Bi-LSTM (left) to encode the input and a LSTM (right) as the decoder. We show only parts of the LF to save space. The complete generated LF at time T-1 is Y^{-1} = [*Answer, (, e,),* $\wedge$, *Around, (, e, ., time, OOV,),* $\wedge$, *e, ., type,* ==, *DiscreteType*]. The token *10am* is copied from the input to replace the generated *OOV* token (solid green arrow). The complete generated LF at time T is Y = [*Answer, (, REF, ., time,)*]. The entity token *e* is copied from the previous LF to replace the generated *REF* token (solid green arrow). Orange dash arrows attend to historical input. Blue dash arrows attend to current input. Purple dash arrows attend to previous logical form.

the following token generation loss:

$$L_{gen}(Y) = -\sum_{t=1}^{Y.l} \log p(y_t|Y_{t-1}, X) \qquad (8)$$

where $Y.l$ is the length of the current logical form.

5.3 Supervised Learning: *SPAAC-MLE*

The supervised learning model *SPAAC-MLE* is obtained by training the semantic parsing architecture from Figure 4 to minimize the sum of the 3 negative log-likelihood losses:

$$L_{MLE}(Y) = L_{gen}(Y) + L_{oov}(Y) + L_{ref}(Y) \quad (9)$$

At inference time, beam search is used to generate the LF sequence (Ranzato et al., 2015; Wiseman and Rush, 2016). During inference, if the generated token at position t is *OOV*, we copy the token from the current input X that has the maximum OOV probability, i.e. $\arg\max_j p_o(O_j = 1|\boldsymbol{s}_j^X, \boldsymbol{s}_t^Y)$. Similarly, if the generated entity token at position t is *REF*, we copy the entity token from the previous LF Y^{-1} that has the maximum coreference probability, i.e. $\arg\max_j p_r(R_j = 1|\boldsymbol{s}_j^{Y^{-1}}, \boldsymbol{s}_t^Y)$.

5.4 Reinforcement Learning: *SPAAC-RL*

All models described in this paper are evaluated using sequence-level accuracy, a discrete metric where a generated logical form is considered to be correct if it is equivalent with the ground truth logical form. This is a strict evaluation measure in the sense that it is sufficient for a token to be wrong to invalidate the entire sequence. At the same time, there can be many generated sequences that are correct, e.g. any reordering of the clauses from the ground truth sequence is correct. The large number of potentially correct generations can lead MLE-trained models to have sub-optimal performance (Paulus et al., 2017; Rennie et al., 2017; Zeng et al., 2016; Norouzi et al., 2016). Furthermore, although "teacher forcing" (Williams and Zipser, 1989) is widely used for training sequence generation models, it leads to *exposure bias* (Ranzato et al., 2015): the network has knowledge of the ground truth LF tokens up to the current token during training, but not during testing, which can lead to propagation of errors at generation time.

Like Paulus et al. (2017), we address these problems by using policy gradient to train a token generation policy that aims to directly maximize sequence-level accuracy. We use the self-critical policy gradient training algorithm proposed by Rennie et al. (2017). We model the sequence generation process as a sequence of actions taken according to a policy, which takes an action (token $\hat{y}_t$) at each step t as a function of the current state (history $\hat{Y}_{t-1}$), according to the probability $p(\hat{y}_t|\hat{Y}_{t-1})$. The algorithm uses this probability to define two policies: a greedy, baseline policy π^b

that takes the action with the largest probability, i.e. $\pi^b(\hat{Y}_{t-1}) = \arg\max_{\hat{y}_t} p(\hat{y}_t|\hat{Y}_{t-1})$; and a sampling policy π^s that samples the action according to the same distribution, i.e. $\pi^s(\hat{Y}_{t-1}) \propto p(\hat{y}_t|\hat{Y}_{t-1})$.

The baseline policy is used to generate a sequence $\hat{Y}^b$, whereas the sampling policy is used to generate another sequence $\hat{Y}^s$. The reward $R(\hat{Y}^s)$ is then defined as the difference between the sequence-level accuracy (A) of the sampled sequence $\hat{Y}^s$ and the baseline sequence $\hat{Y}^b$. The corresponding self-critical policy gradient loss is:

$$\begin{aligned} L_{RL} &= -R(\hat{Y}^s) \times L_{MLE}(\hat{Y}^s) \\ &= -\Big(A(\hat{Y}^s) - A(\hat{Y}^b)\Big) \times L_{MLE}(\hat{Y}^s) \end{aligned} \quad (10)$$

Thus, minimizing the RL loss is equivalent to maximizing the likelihood of the sampled $\hat{Y}^s$ if it obtains a higher sequence-level accuracy than the baseline $\hat{Y}^b$.

6 Experimental Evaluation

All models are implemented in Tensorflow using dropout to deal with overfitting. For both datasets, 10% of the data is put aside for validation. After tuning on the artificial validation data, the feed-forward neural networks dropout rate was set to 0.5 and the LSTM units dropout rate was set to 0.3. The word embeddings had dimensionality of 64 and were initialized at random. Optimization is performed with the Adam algorithm. For each dataset, we use five-fold cross evaluation, where the data is partitioned into five folds, one fold is used for testing and the other folds for training. The process is repeated five times to obtain test results on all folds. We use an early-stop strategy on the validation set. The number of gradient updates is typically more than 20,000. All the experiments are performed on a single NVIDIA GTX1080 GPU.

The models are trained and evaluated on the artificial interactions first. To evaluate on real interactions, the models are pre-trained on the entire artificial dataset and then fine-tuned using real interactions. *SPAAC-RL* is pre-trained with MLE loss to provide more efficient policy exploration. We use sequence level accuracy as evaluation metric for all models: a generated sequence is considered correct if and only if all the generated tokens match the ground truth tokens.

We report experimental evaluations of the proposed models *SPAAC-MLE* and *SPAAC-RL* and baseline models *SeqGen*, *SeqGen+Att2In* on the Real and Artificial Interactions Datasets in Table 3. We also report examples generated by the SPAAC models in Tables 4 and 5.

Models	Artificial	Real
SeqGen	51.8	22.2
SeqGen+Att2In	72.7	35.4
SPAAC-MLE	**84.3**	**66.9**
SPAAC-RL	**88.7**	**74.8**

Table 3: Sequence-level accuracy on the 2 datasets.

Well the Finger Stick is 56. T&MLE&RL: $e.type == Fingerstick \wedge e.value == 56$ It looks like she suspended her pump. T&MLE&RL: $Suspended(e) \wedge around(e.time, e(-1).time)$

6.1 Discussion

The results in Table 3 demonstrate the importance of modeling context-dependency, as the two *SPAAC* models outperform the baselines on both datasets. The RL model also obtains substantially better accuracy than the MLE model. The improvement in performance over the MLE model for the real data is statistically significant at $p = 0.05$ in a one-tailed paired t-test.

Analysis of the generated logical forms revealed that one common error made by *SPAAC-MLE* is the generation of incorrect event types. Some of these errors are fixed by the current RL model. However, there are instances where even the RL-trained model outputs the wrong event type. By comparing

Does he always get some sleep around 4:30pm? T&MLE&RL: $Answer(cond(around(x, 4:30pm) => any(e.type == reportedsleep \wedge e.time == x)))$
Is it the first week of the patient? T&MLE&RL: $Answer(week(currentdate) == x) \wedge order(x, 1, sequence(e, e.type == week))$
Does she ever get some rest around 5:37pm? T&MLE&RL: $Answer(any(e.type == reportedsleep \wedge around(e.time, 5:37pm)))$
When is the first time he changes his infusion set? T&MLE&RL: $Answer(e.date) \wedge order(e, 1, sequence(e, e.type == infusionset))$
How many months she has multiple exercises? T&RL: $Answer(count(x, count(e, e.type == exercise \wedge e.date == x) > 1 \wedge x.type == \boldsymbol{month}))$ MLE: $Answer(count(x, count(e, e.type == exercise \wedge e.date == x) > 1 \wedge x.type == \boldsymbol{week}))$
Toggle so we can see fingersticks. T&RL: $DoToggle(on, \boldsymbol{fingersticks})$ MLE: $DoToggle(on, \boldsymbol{bgl})$

the sampled logical forms $\hat{Y}^s$ and the generated baseline logical forms $\hat{Y}^b$, we found that sometimes the sampled tokens for event types are the same as those in the baseline. An approach that we plan to investigate in future work is to utilize more advanced sampling methods to generate $\hat{Y}^s$, in order to achieve a better balance between exploration and exploitation.

7 Related Work

Question Answering has been the topic of recent research (Yih et al., 2014; Dong et al., 2015; Andreas et al., 2016; Hao et al., 2017; Abujabal et al., 2017; Chen and Bunescu, 2017). Semantic parsing, which maps text in natural language to meaning representations in formal logic, has emerged as an important component for building QA systems, as in (Liang, 2016; Jia and Liang, 2016a; Zhong et al., 2017). Context-dependent processing has been explored in complex, interactive QA (Harabagiu et al., 2005; Kelly and Lin, 2007) and semantic parsing (Zettlemoyer and Collins, 2009; Artzi and Zettlemoyer, 2011; Iyyer et al., 2017; Suhr et al., 2018; Long et al., 2016). Although these approaches take into account sequential dependencies between questions or sentences, the setting in our work has a number of significant distinguishing features, such as the importance of time – data is represented naturally as multiple time series of events – and the anchoring on a graphical user interface that also enables direct interactions through mouse clicks and a combination of factual queries and interface commands.

Dong and Lapata (2016) use an attention-enhanced encoder-decoder architecture to learn the logical forms from natural language without using hand-engineered features. Their proposed Seq2Tree architecture can capture the hierarchical structure of logical forms. Jia and Liang (2016b) train a sequence-to-sequence RNN model with a novel attention-based copying mechanism to learn the logical forms from questions. The copying mechanism has been investigated by Gu et al. (2016) and Gulcehre et al. (2016) in the context of a wide range of NLP applications. These semantic parsing models considered sentences in isolation. In contrast, generating correct logical forms in our task required modeling sequential dependencies between logical forms. In particular, coreference is modeled between events mentioned in different logical forms by repurposing the copying mechanism originally used for modeling out-of-vocabulary tokens.

8 Conclusion

We introduced a new semantic parsing setting in which users can query a system using both natural language and direct interactions (mouse clicks) within a graphical user interface. Correspondingly, we created a dataset of real interactions and a much larger dataset of artificial interactions. The correct interpretation of a natural language query often requires knowledge of previous interactions with the system. We proposed a new sequence generation architecture that modeled this context dependency through multiple attention models and a copying mechanism for solving coreference. The proposed architecture is shown to outperform standard LSTM encoder-decoder architectures that are context agnostic. Furthermore, casting the sequence generation process in the framework of reinforcement learning alleviates the exposure bias and leads to substantial improvements in sequence-level accuracy.

The two datasets and the implementation of the systems presented in this paper are made publicly available at `https://github.com/charleschen1015/SemanticParsing`. The data visualization GUI is available under the name OHIOT1DMVIEWER at `http://smarthealth.cs.ohio.edu/nih.html`.

Acknowledgments

This work was partly supported by grant 1R21EB022356 from the National Institutes of Health. We would like to thank Frank Schwartz and Cindy Marling for contributing real interactions, Quintin Fettes and Yi Yu for their help with recording and pre-processing the interactions, and Sadegh Mirshekarian for the design of the artificial data generation. We would also like to thank the anonymous reviewers for their useful comments.

Structural Scaffolds for Citation Intent Classification in Scientific Publications

Arman Cohan, Waleed Ammar, Madeleine van Zuylen, Field Cady
Allen Institute for Artificial Intelligence
`{armanc,waleeda,madeleinev,fieldc}@allenai.org`

Abstract

Identifying the intent of a citation in scientific papers (e.g., *background information, use of methods, comparing results*) is critical for machine reading of individual publications and automated analysis of the scientific literature. We propose structural scaffolds, a multitask model to incorporate structural information of scientific papers into citations for effective classification of citation intents. Our model achieves a new state-of-the-art on an existing ACL anthology dataset (ACL-ARC) with a 13.3% absolute increase in F1 score, without relying on external linguistic resources or hand-engineered features as done in existing methods. In addition, we introduce a new dataset of citation intents (SciCite) which is more than five times larger and covers multiple scientific domains compared with existing datasets. Our code and data are available at: `https://github.com/allenai/scicite`.

1 Introduction

Citations play a unique role in scientific discourse and are crucial for understanding and analyzing scientific work (Luukkonen, 1992; Leydesdorff, 1998). They are also typically used as the main measure for assessing impact of scientific publications, venues, and researchers (Li and Ho, 2008). The nature of citations can be different. Some citations indicate direct use of a method while some others merely serve as acknowledging a prior work. Therefore, identifying the intent of citations (Figure 1) is critical in improving automated analysis of academic literature and scientific impact measurement (Leydesdorff, 1998; Small, 2018). Other applications of citation intent classification are enhanced research experience (Moravcsik and Murugesan, 1975), information retrieval (Ritchie, 2009), summarization (Cohan and Goharian, 2015), and studying evolution of scientific fields (Jurgens et al., 2018).

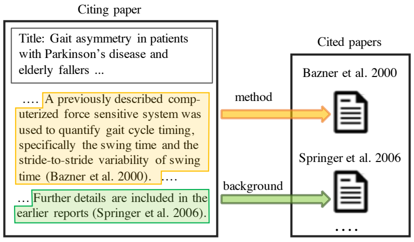

Figure 1: Example of citations with different intents (BACKGROUND and METHOD).

In this work, we approach the problem of citation intent classification by modeling the language expressed in the citation context. A citation context includes text spans in a citing paper describing a referenced work and has been shown to be the primary signal in intent classification (Teufel et al., 2006; Abu-Jbara et al., 2013; Jurgens et al., 2018). Existing models for this problem are feature-based, modeling the citation context with respect to a set of predefined hand-engineered features (such as linguistic patterns or cue phrases) and ignoring other signals that could improve prediction.

In this paper we argue that better representations can be obtained directly from data, sidestepping problems associated with external features. To this end, we propose a neural multitask learning framework to incorporate knowledge into citations from the structure of scientific papers. In particular, we propose two auxiliary tasks as *structural scaffolds* to improve citation intent prediction:[1] (1) predicting the section title in which the citation occurs and (2) predicting whether a sentence needs a citation. Unlike the primary task of citation intent prediction, it is easy to collect large

---

[1] We borrow the scaffold terminology from Swayamdipta et al. (2018) in the context of multitask learning.

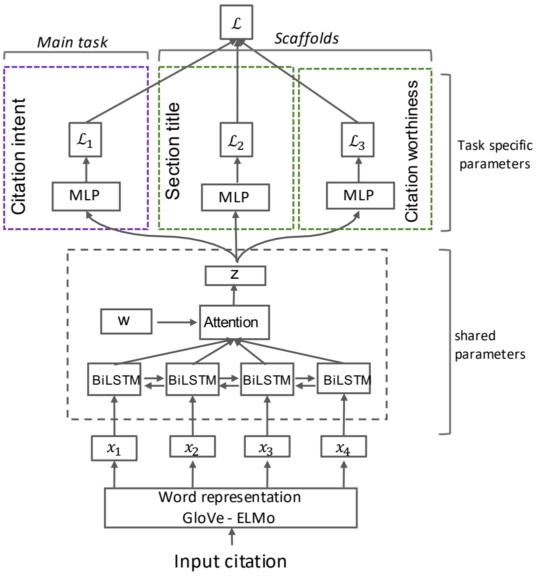

Figure 2: Our proposed scaffold model for identifying citation intents. The main task is predicting the citation intent (top left) and two scaffolds are predicting the section title and predicting if a sentence needs a citation (citation worthiness).

amounts of training data for scaffold tasks since the labels naturally occur in the process of writing a paper and thus, there is no need for manual annotation. On two datasets, we show that the proposed neural scaffold model outperforms existing methods by large margins.

Our contributions are: *(i)* we propose a neural scaffold framework for citation intent classification to incorporate into citations knowledge from structure of scientific papers; *(ii)* we achieve a new state-of-the-art of 67.9% F1 on the ACL-ARC citations benchmark, an absolute 13.3% increase over the previous state-of-the-art (Jurgens et al., 2018); and *(iii)* we introduce SciCite, a new dataset of citation intents which is at least five times as large as existing datasets and covers a variety of scientific domains.

2 Model

We propose a neural multitask learning framework for classification of citation intents. In particular, we introduce and use two structural scaffolds, auxiliary tasks related to the structure of scientific papers. The auxiliary tasks may not be of interest by themselves but are used to inform the main task. Our model uses a large auxiliary dataset to incorporate this structural information available in scientific documents into the citation intents. The overview of our model is illustrated in Figure 2.

Let C denote the citation and $\mathbf{x}$ denote the citation context relevant to C. We encode the tokens in the citation context of size n as $\mathbf{x} = \{\mathbf{x}_1, ..., \mathbf{x}_n\}$, where $\mathbf{x}_i \in \mathcal{R}^{d_1}$ is a word vector of size d_1 which concatenates non-contextualized word representations (GloVe, Pennington et al., 2014) and contextualized embeddings (ELMo, Peters et al., 2018), i.e.:

$$\mathbf{x}_i = \left[\mathbf{x}_i^{\text{GloVe}}; \mathbf{x}_i^{\text{ELMo}}\right]$$

We then use a bidirectional long short-term memory (Hochreiter and Schmidhuber, 1997) (BiLSTM) network with hidden size of d_2 to obtain a contextual representation of each token vector with respect to the entire sequence:[2]

$$\mathbf{h}_i = \left[\overrightarrow{\text{LSTM}}(\mathbf{x}, i); \overleftarrow{\text{LSTM}}(\mathbf{x}, i)\right],$$

where $\mathbf{h} \in \mathcal{R}^{(n, 2d_2)}$ and $\overrightarrow{\text{LSTM}}(\mathbf{x}, i)$ processes $\mathbf{x}$ from left to write and returns the LSTM hidden state at position i (and vice versa for the backward direction $\overleftarrow{\text{LSTM}}$). We then use an attention mechanism to get a single vector representing the whole input sequence:

$$\mathbf{z} = \sum_{i=1}^{n} \alpha_i \mathbf{h}_i, \quad \alpha_i = \text{softmax}(\mathbf{w}^\top \mathbf{h}_i),$$

where $\mathbf{w}$ is a parameter served as the query vector for dot-product attention.[3] So far we have obtained the citation representation as a vector $\mathbf{z}$. Next, we describe our two proposed structural scaffolds for citation intent prediction.

2.1 Structural scaffolds

In scientific writing there is a connection between the structure of scientific papers and the intent of citations. To leverage this connection for more effective classification of citation intents, we propose a multitask framework with two structural scaffolds (auxiliary tasks) related to the structure of scientific documents. A key point for our proposed scaffolds is that they do not need any additional manual annotation as labels for these tasks occur naturally in scientific writing. The structural scaffolds in our model are the following:

---

[2] In our experiments BiGRUs resulted in similar performance.

[3] We also experimented BiLSTMs without attention; we found that BiLSTMs/BiGRUs along with attention provided best results. Other types of attention such as additive attention result in similar performance.

Citation worthiness. The first scaffold task that we consider is "citation worthiness" of a sentence, indicating whether a sentence needs a citation. The language expressed in citation sentences is likely distinctive from regular sentences in scientific writing, and such information could also be useful for better language modeling of the citation contexts. To this end, using citation markers such as "[12]" or "Lee et al (2010)", we identify sentences in a paper that include citations and the negative samples are sentences without citation markers. The goal of the model for this task is to predict whether a particular sentence needs a citation.[4]

Section title. The second scaffold task relates to predicting the section title in which a citation appears. Scientific documents follow a standard structure where the authors typically first introduce the problem, describe methodology, share results, discuss findings and conclude the paper. The intent of a citation could be relevant to the section of the paper in which the citation appears. For example, method-related citations are more likely to appear in the methods section. Therefore, we use the section title prediction as a scaffold for predicting citation intents. Note that this scaffold task is different than simply adding section title as an additional feature in the input. We are using the section titles from a larger set of data than training data for the main task as a proxy to learn linguistic patterns that are helpful for citation intents. In particular, we leverage a large number of scientific papers for which the section information is known for each citation to automatically generate large amounts of training data for this scaffold task.[5]

Multitask formulation. Multitask learning as defined by Caruana (1997) is an approach to inductive transfer learning that improves generalization by using the domain information contained in the training signals of related tasks as an inductive bias. It requires the model to have at least some sharable parameters between the tasks. In a general setting in our model, we have a main task $Task^{(1)}$ and $n-1$ auxiliary tasks $Task^{(i)}$. As shown in Figure 2, each scaffold task will have its task-specific parameters for effective classification and the parameters for the lower layers of the network are shared across tasks. We use a Multi Layer Perceptron (MLP) for each task and then a softmax layer to obtain prediction probabilites. In particular, given the vector $\mathbf{z}$ we pass it to n MLPs and obtain n output vectors $\mathbf{y}^{(i)}$:

$$\mathbf{y}^{(i)} = \mathrm{softmax}(\mathrm{MLP}^{(i)}(\mathbf{z}))$$

We are only interested in the output $\mathbf{y}^{(1)}$ and the rest of outputs $(\mathbf{y}^{(2)}, ..., \mathbf{y}^{(n)})$ are regarding the scaffold tasks and only used in training to inform the model of knowledge in the structure of the scientific documents. For each task, we output the class with the highest probability in $\mathbf{y}$. An alternative inference method is to sample from the output distribution.

2.2 Training

Let $\mathcal{D}_1$ be the labeled dataset for the main task $Task^{(1)}$, and $\mathcal{D}_i$ denote the labeled datasets corresponding to the scaffold task $Task^{(i)}$ where $i \in \{2, ..., n\}$. Similarly, let $\mathcal{L}_1$ and $\mathcal{L}_i$ be the main loss and the loss of the auxiliary task i, respectively. The final loss of the model is:

$$\mathcal{L} = \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}_1} \mathcal{L}_1(\mathbf{x},\mathbf{y}) + \sum_{i=2}^{n} \lambda_i \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}_i} \mathcal{L}_i(\mathbf{x},\mathbf{y}), \quad (1)$$

where λ_i is a hyper-parameter specifying the sensitivity of the parameters of the model to each specific task. Here we have two scaffold tasks and hence n=3. λ_i could be tuned based on performance on validation set (see §4 for details).

We train this model jointly across tasks and in an end-to-end fashion. In each training epoch, we construct mini-batches with the same number of instances from each of the n tasks. We compute the total loss for each mini-batch as described in Equation 1, where $\mathcal{L}_i$=0 for all instances of other tasks $j{\neq}i$. We compute the gradient of the loss for each mini-batch and tune model parameters using the AdaDelta optimizer (Zeiler, 2012) with gradient clipping threshold of 5.0. We stop training the model when the development macro F1 score does not improve for five consecutive epochs.

3 Data

We compare our results on two datasets from different scientific domains. While there has been a long history of studying citation intents, there are only a few existing publicly available datasets on

---

[4] We note that this task may also be useful for helping authors improve their paper drafts. However, this is not the focus of this work.

[5] We also experimented with adding section titles as additional feature to the input, however, it did not result in any improvements.

Intent cateogry	Definition	Example
Background information	The citation states, mentions, or points to the background information giving more context about a problem, concept, approach, topic, or importance of the problem in the field.	Recent evidence suggests that co-occurring alexithymia may explain deficits [12]. Locally high-temperature melting regions can act as permanent termination sites [6-9]. One line of work is focused on changing the objective function (Mao et al., 2016).
Method	Making use of a method, tool, approach or dataset	Fold differences were calculated by a mathematical model described in [4]. We use Orthogonal Initialization (Saxe et al., 2014)
Result comparison	Comparison of the paper's results/findings with the results/findings of other work	Weighted measurements were superior to T2-weighted contrast imaging which was in accordance with former studies [25-27] Similar results to our study were reported in the study of Lee et al (2010).

Table 1: The definition and examples of citation intent categories in our SciCite.

Dataset	Categories (distribution)	Source	#papers	#instances
ACL-ARC	Background (0.51) Extends (0.04) Uses (0.19) Motivation (0.05) Compare/Contrast (0.18) Future work (0.04)	Computational Linguistics	186	1,941
SciCite	Background (0.58) Method (0.29) Result comparison (0.13)	Computer Science & Medicine	6,627	11,020

Table 2: Characteristics of SciCite compared with ACL-ARC dataset by Jurgens et al. (2018)

the task of citation intent classification. We use the most recent and comprehensive (ACL-ARC citations dataset) by Jurgens et al. (2018) as a benchmark dataset to compare the performance of our model to previous work. In addition, to address the limited scope and size of this dataset, we introduce SciCite, a new dataset of citation intents that addresses multiple scientific domains and is more than five times larger than ACL-ARC. Below is a description of both datasets.

3.1 ACL-ARC citations dataset

ACL-ARC is a dataset of citation intents released by Jurgens et al. (2018). The dataset is based on a sample of papers from the ACL Anthology Reference Corpus (Bird et al., 2008) and includes 1,941 citation instances from 186 papers and is annotated by domain experts in the NLP field. The data was split into three standard stratified sets of train, validation, and test with 85% of data used for training and remaining 15% divided equally for validation and test. Each citation unit includes information about the immediate citation context, surrounding context, as well as information about the citing and cited paper. The data includes six intent categories outlined in Table 2.

3.2 SciCite dataset

Most existing datasets contain citation categories that are too fine-grained. Some of these intent categories are very rare or not useful in meta analysis of scientific publications. Since some of these fine-grained categories only cover a minimal percentage of all citations, it is difficult to use them to gain insights or draw conclusions on impacts of papers. Furthermore, these datasets are usually domain-specific and are relatively small (less than 2,000 annotated citations).

To address these limitations, we introduce SciCite, a new dataset of citation intents that is significantly larger, more coarse-grained and general-domain compared with existing datasets. Through examination of citation intents, we found out many of the categories defined in previous work such as motivation, extension or future work, can be considered as background information providing more context for the current research topic. More interesting intent categories are a direct use of a method or comparison of results. Therefore, our dataset provides a concise annotation scheme that is useful for navigating research topics and machine reading of scientific papers. We consider three intent categories outlined in Table 1: BACKGROUND, METHOD and RESULTCOMPARISON. Below we describe data collection and annotation details.

3.2.1 Data collection and annotation

Citation intent of sentence extractions was labeled through the crowdsourcing platform Figure Eight.[6] We selected a sample of papers from the Semantic Scholar corpus,[7] consisting of papers in general computer science and medicine domains. Citation contexts were extracted using science-

---

[6] `https://www.figure-eight.com/platform/`

[7] `https://semanticscholar.org/`

parse.[8] The annotators were asked to identify the intent of a citation, and were directed to select among three citation intent options: METHOD, RESULTCOMPARISON and BACKGROUND. The annotation interface also included a dummy option OTHER which helps improve the quality of annotations of other categories. We later removed instances annotated with the OTHER option from our dataset (less than 1% of the annotated data), many of which were due to citation contexts which are incomplete or too short for the annotator to infer the citation intent.

We used 50 test questions annotated by a domain expert to ensure crowdsource workers were following directions and disqualify annotators with accuracy less than 75%. Furthermore, crowdsource workers were required to remain on the annotation page (five annotations) for at least ten seconds before proceeding to the next page. Annotations were dynamically collected. The annotations were aggregated along with a confidence score describing the level of agreement between multiple crowdsource workers. The confidence score is the agreement on a single instance weighted by a trust score (accuracy of the annotator on the initial 50 test questions).

To only collect high quality annotations, instances with confidence score of $\leq$0.7 were discarded. In addition, a subset of the dataset with 100 samples was re-annotated by a trained, expert annotator to check for quality, and the agreement rate with crowdsource workers was **86%**. Citation contexts were annotated by 850 crowdsource workers who made a total of 29,926 annotations and individually made between 4 and 240 annotations. Each sentence was annotated, on average, 3.74 times. This resulted in a total 9,159 crowdsourced instances which were divided to training and validation sets with 90% of the data used for the training set. In addition to the crowdsourced data, a separate test set of size 1,861 was annotated by a trained, expert annotator to ensure high quality of the dataset.

3.3 Data for scaffold tasks

For the first scaffold (citation worthiness), we sample sentences from papers and consider the sentences with citations as positive labels. We also remove the citation markers from those sentences such as numbered citations (e.g., [1]) or name-year combinations (e.g, Lee et al (2012)) to not make the second task artificially easy by only detecting citation markers. For the second scaffold (citation section title), respective to each test dataset, we sample citations from the ACL-ARC corpus and Semantic Scholar corpus[9] and extract the citation context as well as their corresponding sections. We manually define regular expression patterns mappings to normalized section titles: "introduction", "related work", "method", "experiments", "conclusion". Section titles which did not map to any of the aforementioned titles were excluded from the dataset. Overall, the size of the data for scaffold tasks on the ACL-ARC dataset is about 47K (section title scaffold) and 50K (citation worthiness) while on SciCite is about 91K and 73K for section title and citation worthiness scaffolds, respectively.

4 Experiments

4.1 Implementation

We implement our proposed scaffold framework using the AllenNLP library (Gardner et al., 2018). For word representations, we use 100-dimensional GloVe vectors (Pennington et al., 2014) trained on a corpus of 6B tokens from Wikipedia and Gigaword. For contextual representations, we use ELMo vectors released by Peters et al. (2018)[10] with output dimension size of 1,024 which have been trained on a dataset of 5.5B tokens. We use a single-layer BiLSTM with a hidden dimension size of 50 for each direction[11]. For each of scaffold tasks, we use a single-layer MLP with 20 hidden nodes , ReLU (Nair and Hinton, 2010) activation and a Dropout rate (Srivastava et al., 2014) of 0.2 between the hidden and input layers. The hyperparameters λ_i are tuned for best performance on the validation set of the respective datasets using a 0.0 to 0.3 grid search. For example, the following hyperparameters are used for the ACL-ARC. Citation worthiness saffold: λ_2=0.08, λ_3=0, section title scaffold: λ_3=0.09, λ_2=0; both scaffolds: λ_2=0.1, λ_3=0.05. Batch size is 8 for ACL-ARC dataset and 32 for SciCite dataset (recall that SciCite is larger than ACL-ARC). We

[10] `https://allennlp.org/elmo`

[11] Experiments with other types of RNNs such as BiGRUs and more layers showed similar or slightly worst performance

use Beaker[12] for running the experiments. On the smaller dataset, our best model takes approximately 30 minutes per epoch to train (training time without ELMo is significantly faster). It is known that multiple runs of probabilistic deep learning models can have variance in overall scores (Reimers and Gurevych, 2017)[13]. We control this by setting random-number generator seeds; the reported overall results are average of multiple runs with different random seeds. To facilitate reproducibility, we release our code, data, and trained models.[14]

4.2 Baselines

We compare our results to several baselines including the model with state-of-the-art performance on the ACL-ARC dataset.

- *BiLSTM Attention (with and without ELMo).* This baseline uses a similar architecture to our proposed neural multitask learning framework, except that it only optimizes the network for the main loss regarding the citation intent classification ($\mathcal{L}_1$) and does not include the structural scaffolds. We experiment with two variants of this model: with and without using the contextualized word vector representations (ELMo) of Peters et al. (2018). This baseline is useful for evaluating the effect of adding scaffolds in controlled experiments.

- *Jurgens et al. (2018).* To make sure our results are competitive with state-of-the-art results on this task, we also compare our model to Jurgens et al. (2018) which has the best reported results on the ACL-ARC dataset. Jurgens et al. (2018) incorporate a variety of features, ranging from pattern-based features to topic-modeling features, to citation graph features. They also incorporate section titles and relative section position in the paper as features. Our implementation of this model achieves a macro-averaged F1 score of 0.526 using 10-fold cross-validation, which is in line with the highest reported results in Jurgens et al. (2018): 0.53 using leave-one-out cross validation. We were not able to use leave-one-out cross validation in our experiments since it is impractical to re-train each variant of our deep learning models thousands of times. Therefore, we opted for a standard setup of stratified train/validation/test data splits with 85% data used for training and the rest equally split between validation and test.

	Model	macro F1
Baselines	BiLSTM-Attn	51.8
	BiLSTM-Attn w/ ELMo	54.3
	Previous SOTA (Jurgens et al., 2018)	54.6
This work	BiLSTM-Attn + section title scaffold	56.9
	BiLSTM-Attn + citation worthiness scaffold	56.3
	BiLSTM-Attn + both scaffolds	63.1
	BiLSTM-Attn w/ ELMo + both scaffolds	**67.9**

Table 3: Results on the ACL-ARC citations dataset.

4.3 Results

Our main results for the ACL-ARC dataset (Jurgens et al., 2018) is shown in Table 3. We observe that our scaffold-enhanced models achieve clear improvements over the state-of-the-art approach on this task. Starting with the 'BiLSTM-Attn' baseline with a macro F1 score of 51.8, adding the first scaffold task in 'BiLSTM-Attn + section title scaffold' improves the F1 score to 56.9 (Δ=5.1). Adding the second scaffold in 'BiLSTM-Attn + citation worthiness scaffold' also results in similar improvements: 56.3 (Δ=4.5). When both scaffolds are used simultaneously in 'BiLSTM-Attn + both scaffolds', the F1 score further improves to 63.1 (Δ=11.3), suggesting that the two tasks provide complementary signal that is useful for citation intent prediction.

The best result is achieved when we also add ELMo vectors (Peters et al., 2018) to the input representations in 'BiLSTM-Attn w/ ELMo + both scaffolds', achieving an F1 of 67.9, a major improvement from the previous state-of-the-art results of Jurgens et al. (2018) 54.6 (Δ=13.3). We note that the scaffold tasks provide major contributions on top of the ELMo-enabled baseline (Δ=13.6), demonstrating the efficacy of using structural scaffolds for citation intent prediction. We note that these results were obtained without using hand-curated features or additional linguistic resources as used in Jurgens et al. (2018). We also experimented with adding features used in Jurgens et al. (2018) to our best model and not only we did not see any improvements, but we observed

	BiLSTM-Attn w/ ELMo + both scaffolds	**84.0**

Table 4: Results on the SciCite dataset.

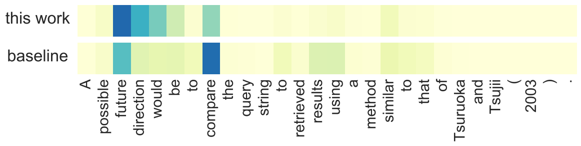
at least 1.7% decline in performance. This suggests that these additional manual features do not provide the model with any additional useful signals beyond what the model already learns from the data.

Table 4 shows the main results on SciCite dataset, where we see similar patterns. Each scaffold task improves model performance. Adding both scaffolds results in further improvements. And the best results are obtained by using ELMo representation in addition to both scaffolds. Note that this dataset is more than five times larger in size than the ACL-ARC, therefore the performance numbers are generally higher and the F1 gains are generally smaller since it is easier for the models to learn optimal parameters utilizing the larger annotated data. On this dataset, the best baseline is the neural baseline with addition of ELMo contextual vectors achieving an F1 score of 82.6 followed by Jurgens et al. (2018), which is expected because neural models generally achieve higher gains when more training data is available and because Jurgens et al. (2018) was not designed with the SciCite dataset in mind.

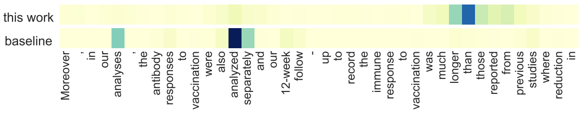
The breakdown of results by intent on ACL-ARC and SciCite datasets is respectively shown in Tables 5 and 6. Generally we observe that results on categories with more number of instances are higher. For example on ACL-ARC, the results on the Background category are the highest as this category is the most common. Conversely, the results on the FutureWork category are the lowest. This category has the fewest data points (see distribution of the categories in Table 2) and thus it is harder for the model to learn the optimal parameters for correct classification in this category.

4.4 Analysis

To gain more insight into why the scaffolds are helping the model in improved citation intent classification, we examine the attention weights assigned to inputs for our best proposed model



(a) Example from ACL-ARC: Correct label is FutureWork. Our model correctly predicts it while baseline predicts Compare.



(b) Example from SciCite: Correct label is ResultComparison; our model correctly predicts it, while baseline considers it as Background.

Figure 3: Visualization of attention weights corresponding to our best scaffold model compared with the best baseline neural baseline model without scaffolds.

('BiLSTM-Attn w/ ELMo + both scaffolds') compared with the best neural baseline ('BiLSTM-Attn w/ ELMO'). We conduct this analysis for examples from both datasets. Figure 3 shows an example input citation along with the horizontal line and the heatmap of attention weights for this input resulting from our model versus the baseline. For first example (3a) the true label is FutureWork. We observe that our model puts more weight on words surrounding the word "future" which is plausible given the true label. On the other hand, the baseline model attends most to the words "compare" and consequently incorrectly predicts a Compare label. In second example (3b) the true label is ResultComparison. The baseline incorrectly classifies it as a Background, likely due to attending to another part of the sentence ("analyzed seprately"). Our model correctly classifies this instance by putting more attention weights on words that relate to comparison of the results. This suggests that the our model is more successful in learning optimal parameters for representing the citation text and classifying its respective intent compared with the baseline. Note that the only difference between our model and the neural baseline is inclusion of the structural scaffolds. Therefore, suggesting the effectiveness the scaffolds in informing the main task of relevant signals for citation intent classification.

Error analysis. We next investigate errors made by our best model (Figure 4 plots classification errors). One general error pattern is that the model has more tendency to make false positive errors in the Background category likely due to this category dominating both datasets. It's interesting that for the ACL-ARC dataset some prediction

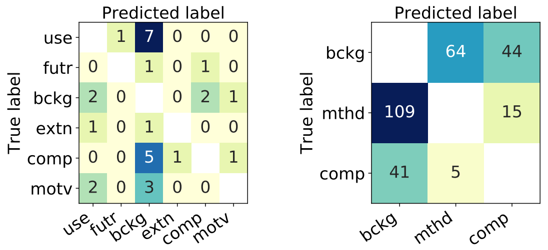
Table 7: A sample of model's classification errors on ACL-ARC dataset

errors are due to the model failing to properly differentiate the Use category with Background. We found out that some of these errors would have been possibly prevented by using additional context. Table 7 shows a sample of such classification errors. For the citation in the first row of the table, the model is likely distracted by "model in (citation)" and "ILP formulation from (citation)" deeming the sentence is referring to the use of another method from a cited paper and it misses the first part of the sentence describing the motivation. This is likely due to the small number of training instances in the Motivation category, preventing the model to learn such nuances. For the examples in the second and third row, it is not clear if it is possible to make the correct prediction without additional context. And similarly in the last row the instance seems ambiguous without accessing to additional context. Similarly as shown in Figure 4a two of FutureWork labels are wrongly classified. One of them is illustrated in the forth row of Table 7 where perhaps additional context could have helped the model in identifying the correct label. One possible way to prevent this type of errors, is to provide the model with an additional input, modeling the extended surrounding context. We experimented with encoding the extended surrounding context using a BiLSTM and concatenating it with the main citation context vector (z), but it resulted in a large decline in overall performance likely due to the overall noise introduced by the additional context. A possible future work is to investigate alternative effective approaches for incorporating the surrounding extended context.

5 Related Work

There is a large body of work studying the intent of citations and devising categorization systems (Stevens and Giuliano, 1965; Moravcsik and Murugesan, 1975; Garzone and Mercer, 2000; White, 2004; Ahmed et al., 2004; Teufel et al., 2006; Agarwal et al., 2010; Dong and Schäfer, 2011). Most of these efforts provide citation categories that are too fine-grained, some of which rarely occur in papers. Therefore, they are hardly useful for automated analysis of scientific publications. To address these problems and to unify previous



(a) ACL-ARC (test size: 139) (b) SciCite (test size: 1,861)

Figure 4: Confusion matrix showing classification errors of our best model on two datasets. The diagonal is masked to bring focus only on errors.

efforts, in a recent work, Jurgens et al. (2018) proposed a six category system for citation intents. In this work, we focus on two schemes: (1) the scheme proposed by Jurgens et al. (2018) and (2) an additional, more coarse-grained general-purpose category system that we propose (details in §3). Unlike other schemes that are domain-specific, our scheme is general and naturally fits in scientific discourse in multiple domains.

Early works in automated citation intent classification were based on rule-based systems (e.g., (Garzone and Mercer, 2000; Pham and Hoffmann, 2003)). Later, machine learning methods based on linguistic patterns and other hand-engineered features from citation context were found to be effective. For example, Teufel et al. (2006) proposed use of “cue phrases”, a set of expressions that talk about the act of presenting research in a paper. Abu-Jbara et al. (2013) relied on lexical, structural, and syntactic features and a linear SVM for classification. Researchers have also investigated methods of finding cited spans in the cited papers. Examples include feature-based methods (Cohan et al., 2015), domain-specific knowledge (Cohan and Goharian, 2017), and a recent CNN-based model for joint prediction of cited spans and citation function (Su et al., 2018). We also experimented with CNNs but found the attention BiLSTM model to work significantly better. Jurgens et al. (2018) expanded all pre-existing feature-based efforts on citation intent classification by proposing a comprehensive set of engineered features, including boostrapped patterns, topic modeling, dependency-based, and metadata features for the task. We argue that we can capture necessary information from the citation context using a data driven method, without the need for hand-engineered domain-dependent features or external resources. We propose a novel scaffold neural model for citation intent classification to incorporate structural information of scientific discourse into citations, borrowing the “scaffold” terminology from Swayamdipta et al. (2018) who use auxiliary syntactic tasks for semantic problems.

6 Conclusions and future work

In this work, we show that structural properties related to scientific discourse can be effectively used to inform citation intent classification. We propose a multitask learning framework with two auxiliary tasks (predicting section titles and citation worthiness) as two scaffolds related to the main task of citation intent prediction. Our model achieves state-of-the-art result (F1 score of 67.9%) on the ACL-ARC dataset with 13.3 absolute increase over the best previous results. We additionally introduce SciCite, a new large dataset of citation intents and also show the effectiveness of our model on this dataset. Our dataset, unlike existing datasets that are designed based on a specific domain, is more general and fits in scientific discourse from multiple scientific domains.

We demonstrate that carefully chosen auxiliary tasks that are inherently relevant to a main task can be leveraged to improve the performance on the main task. An interesting line of future work is to explore the design of such tasks or explore the properties or similarities between the auxiliary and the main tasks. Another relevant line of work is adapting our model to other domains containing documents with similar linked structured such as Wikipedia articles. Future work may benefit from replacing ELMo with other types of contextualized representations such as BERT in our scaffold model. For example, at the time of finalizing the camera ready version of this paper, Beltagy et al. (2019) showed that a BERT contextualized representation model (Devlin et al., 2018) trained on scientific text can achieve promising results on the SciCite dataset.

Acknowledgments

We thank Kyle Lo, Dan Weld, and Iz Beltagy for helpful discussions, Oren Etzioni for feedback on the paper, David Jurgens for helping us with their ACL-ARC dataset and reproducing their results, and the three anonymous reviewers for their comments and suggestions. Computations on `beaker.org` were supported in part by credits from Google Cloud.

Abstract

Reasoning about implied relationships (e.g. paraphrastic, common sense, encyclopedic) between pairs of words is crucial for many cross-sentence inference problems. This paper proposes new methods for learning and using embeddings of word *pairs* that implicitly represent background knowledge about such relationships. Our pairwise embeddings are computed as a compositional function on word representations, which is learned by maximizing the pointwise mutual information (PMI) with the contexts in which the two words co-occur. We add these representations to the cross-sentence attention layer of existing inference models (e.g. BiDAF for QA, ESIM for NLI), instead of extending or replacing existing word embeddings. Experiments show a gain of 2.7% on the recently released SQuAD 2.0 and 1.3% on MultiNLI. Our representations also aid in better generalization with gains of around 6-7% on adversarial SQuAD datasets, and 8.8% on the adversarial entailment test set by Glockner et al. (2018).

1 Introduction

Reasoning about relationships between pairs of words is crucial for cross sentence inference problems such as question answering (QA) and natural language inference (NLI). In NLI, for example, given the premise "*golf is prohibitively expensive*", inferring that the hypothesis "*golf is a cheap pastime*" is a contradiction requires one to know that *expensive* and *cheap* are antonyms. Recent work (Glockner et al., 2018) has shown that current models, which rely heavily on unsupervised single-word embeddings, struggle to learn such relationships. In this paper, we show that they can be learned with word *pair* vectors (`pair2vec`[1]), which are trained unsupervised, and which significantly improve performance when added to existing cross-sentence attention mechanisms.

Table 1: Example word pairs and their contexts.

Unlike single-word representations, which typically model the co-occurrence of a target word x with its context c, our word-pair representations are learned by modeling the three-way co-occurrence between words (x, y) and the context c that ties them together, as seen in Table 1. While similar training signals have been used to learn models for ontology construction (Hearst, 1992; Snow et al., 2005; Turney, 2005; Shwartz et al., 2016) and knowledge base completion (Riedel et al., 2013), this paper shows, for the first time, that large scale learning of pairwise embeddings can be used to directly improve the performance of neural cross-sentence inference models.

More specifically, we train a feedforward network $R(x, y)$ that learns representations for the individual words x and y, as well as how to compose them into a single vector. Training is done by maximizing a generalized notion of the pointwise mutual information (PMI) among x, y, and their context c using a variant of negative sampling (Mikolov et al., 2013a). Making $R(x, y)$ a

Minneapolis, Minnesota, June 2 - June 7, 2019.

compositional function on individual words alleviates the sparsity that necessarily comes with embedding pairs of words, even at a very large scale.

We show that our embeddings can be added to existing cross-sentence inference models, such as BiDAF++ (Seo et al., 2017; Clark and Gardner, 2018) for QA and ESIM (Chen et al., 2017) for NLI. Instead of changing the word embeddings that are fed into the encoder, we add the pretrained *pair* representations to *higher layers* in the network where cross sentence attention mechanisms are used. This allows the model to use the background knowledge that the pair embeddings implicitly encode to reason about the likely relationships between the pairs of words it aligns.

Experiments show that simply adding our word-pair embeddings to existing high-performing models, which already use ELMo (Peters et al., 2018), results in sizable gains. We show 2.72 F1 points over the BiDAF++ model (Clark and Gardner, 2018) on SQuAD 2.0 (Rajpurkar et al., 2018), as well as a 1.3 point gain over ESIM (Chen et al., 2017) on MultiNLI (Williams et al., 2018). Additionally, our approach generalizes well to adversarial examples, with a 6-7% F1 increase on adversarial SQuAD (Jia and Liang, 2017) and a 8.8% gain on the Glockner et al. (2018) NLI benchmark. An analysis of `pair2vec` on word analogies suggests that it complements the information in single-word representations, especially for encyclopedic and lexicographic relations.

2 Unsupervised Pretraining

Extending the distributional hypothesis to word pairs, we posit that similar word *pairs* tend to occur in similar contexts, and that the contexts provide strong clues about the likely relationships that hold between the words (see Table 1). We assume a dataset of (x, y, c) triplets, where each instance depicts a word pair (x, y) and the context c in which they appeared. We learn two compositional representation functions, $R(x, y)$ and $C(c)$, to encode the pair and the context, respectively, as d-dimensional vectors (Section 2.1). The functions are trained using a variant of negative sampling, which tries to embed word pairs (x, y) close to the contexts c with which they appeared (Section 2.2).

2.1 Representation

Our word-pair and context representations are both fixed-length vectors, composed from individual words. The word-pair representation function $R(x, y)$ first embeds and normalizes the individual words with a shared lookup matrix E_a:

$$\mathbf{x} = \frac{E_a(x)}{\|E_a(x)\|} \qquad \mathbf{y} = \frac{E_a(y)}{\|E_a(y)\|}$$

These vectors, along with their element-wise product, are fed into a four-layer perceptron:

$$R(x, y) = MLP^4(\mathbf{x}, \mathbf{y}, \mathbf{x} \circ \mathbf{y})$$

The context $c = c_1 ... c_n$ is encoded as a d-dimensional vector using the function $C(c)$. $C(c)$ embeds each token c_i with a lookup matrix E_c, contextualizes it with a single-layer Bi-LSTM, and then aggregates the entire context with attentive pooling:

$$\begin{aligned}
\mathbf{c}_i &= E_c(c_i) \\
\mathbf{h_1} ... \mathbf{h_n} &= \text{BiLSTM}(\mathbf{c}_1 ... \mathbf{c}_n) \\
w &= \text{softmax}_i(\mathbf{k}\mathbf{h_i}) \\
C(c) &= \sum_i w_i \mathbf{W}\mathbf{h}_i
\end{aligned}$$

where $\mathbf{W} \in \mathbb{R}^{d \times d}$ and $\mathbf{k} \in \mathbb{R}^d$. All parameters, including the lookup tables E_a and E_c, are trained.

Our representation is similar to two recently-proposed frameworks by Washio and Kato (2018a,b), but differs in that: (1) they use dependency paths as context, while we use surface form; (2) they encode the context as either a lookup table or the last state of a unidirectional LSTM. We also use a different objective, which we discuss next.

2.2 Objective

To optimize our representation functions, we consider two variants of negative sampling (Mikolov et al., 2013a): bivariate and multivariate. The original bivariate objective models the two-way distribution of context and (monolithic) word pair co-occurrences, while our multivariate extension models the three-way distribution of word-word-context co-occurrences. We further augment the multivariate objective with typed sampling to upsample harder negative examples. We discuss the impact of the bivariate and multivariate objectives (and other components) in Section 4.3.

Bivariate Negative Sampling Our objective aspires to make $R(x, y)$ and $C(c)$ similar (have high inner products) for (x, y, c) that were observed together in the data. At the same time, we wish

Bivariate	$J_{2NS}(x,y,c) = \log\sigma\left(R(x,y)\cdot C(c)\right) + \sum_{i=1}^{k_c}\log\sigma\left(-R(x,y)\cdot C(c_i^N)\right)$
Multivariate	$J_{3NS}(x,y,c) = J_{2NS}(x,y,c) + \sum_{i=1}^{k_x}\log\sigma\left(-R(x_i^N,y)\cdot C(c)\right) + \sum_{i=1}^{k_y}\log\sigma\left(-R(x,y_i^N)\cdot C(c)\right)$

Table 2: The bivariate and multivariate negative sampling objectives. The superscript ^{N} marks randomly sampled components, with k_* being the negative sample size per instance. The equations present per-instance objectives.

to keep our pair vectors *dis*-similar from random context vectors. In a straightforward application of the original (bivariate) negative sampling objective, we could generate a negative example from each observed (x, y, c) instance by replacing the original context c with a randomly-sampled context c^N (Table 2, J_{2NS}).

Assuming that the negative contexts are sampled from the empirical distribution $P(\cdot,\cdot,c)$ (with $P(x,y,c)$ being the portion of (x,y,c) instances in the dataset), we can follow Levy and Goldberg (2014) to show that this objective converges into the pointwise mutual information (PMI) between the word pair and the context.

$$R(x,y)\cdot C(c) = \log\frac{P(x,y,c)}{k_c P(x,y,\cdot)P(\cdot,\cdot,c)}$$

This objective mainly captures co-occurrences of monolithic pairs and contexts, and is limited by the fact that the training data, by construction, only contains pairs occurring within a sentence. For better generalization to cross-sentence tasks, where the pair distribution differs from that of the training data, we need a multivariate objective that captures the full three-way (x,y,c) interaction.

Multivariate Negative Sampling We introduce negative sampling of target words, x and y, in addition to negative sampling of contexts c (Table 2, J_{3NS}). Our new objective also converges to a novel multivariate generalization of PMI, different from previous PMI extensions that were inspired by information theory (Van de Cruys, 2011) and heuristics (Jameel et al., 2018).[2] Following Levy and Goldberg (2014), we can show that when replacing target words in addition to contexts, our objective will converge[3] to the optimal value in Equation 1:

$$R(x,y)\cdot C(c) = \log\frac{P(x,y,c)}{Z_{x,y,c}} \quad (1)$$

where $Z_{x,y,c}$, the denominator, is:

$$\begin{aligned} Z_{x,y,c} = {} & k_c P(\cdot,\cdot,c)P(x,y,\cdot) \\ & + k_x P(x,\cdot,\cdot)P(\cdot,y,c) \\ & + k_y P(\cdot,y,\cdot)P(x,\cdot,c) \end{aligned} \quad (2)$$

This optimal value deviates from previous generalizations of PMI by having a linear mixture of marginal probability products in its denominator. By introducing terms such as $P(x,\cdot,c)$ and $P(\cdot,y,c)$, the objective penalizes spurious correlations between words and contexts that disregard the other target word. For example, it would assign the pattern "*X is a Y*" a high score with (*banana*, *fruit*), but a lower score with (*cat*, *fruit*).

Typed Sampling In multivariate negative sampling, we typically replace x and y by sampling from their unigram distributions. In addition to this, we also sample uniformly from the top 100 words according to cosine similarity using distributional word vectors. This is done to encourage the model to learn relations between specific instances as opposed to more general types. For example, using *California* as a negative sample for *Oregon* helps the model to learn that the pattern "*X is located in Y*" fits the pair (*Portland*, *Oregon*), but not the pair (*Portland*, *California*). Similar adversarial constraints were used in knowledge base completion (Toutanova et al., 2015) and word embeddings (Li et al., 2017).[4]

3 Integrating `pair2vec` into Models

We first present a general outline for incorporating `pair2vec` into attention-based architectures, and then discuss changes made to BiDAF++ and ESIM. The key idea is to inject our pairwise representations into the attention layer by reusing the cross-sentence attention weights. In addition to attentive pooling over single word representations, we also pool over cross-sentence word pair embeddings (Figure 1).

---

[2] See supplementary material for their exact formulations.

[3] A full proof is provided in the supplementary material.

[4] Applying typed sampling also changes the value to which our objective will converge, and will replace the unigram probabilities in Equation (2) to reflect the type-based distribution.

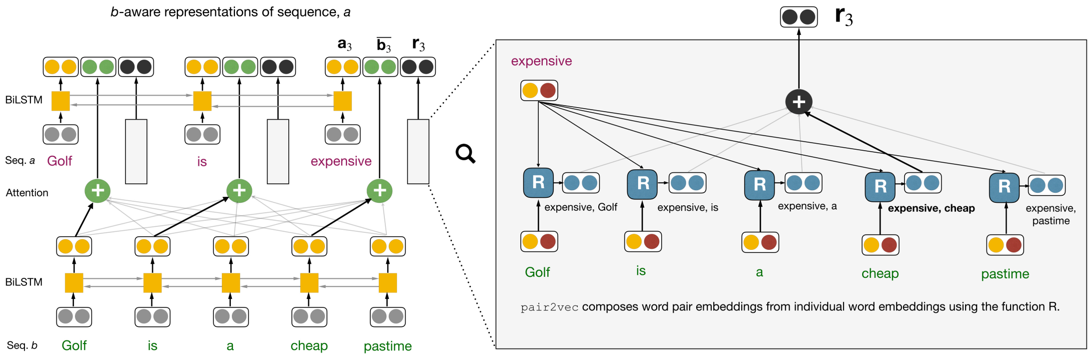

Figure 1: A typical architecture of a cross-sentence inference model (left), and how `pair2vec` is added to it (right). Given two sequences, a and b, existing models create b-aware representations of words in a. For any word a_i, this typically involves the BiLSTM representation of word a_i ($\mathbf{a}_i$), and an attention-weighted sum over b's BiLSTM states with a_i as the query ($\overline{\mathbf{b}}_i$). To these, we add the word-pair representation of a_i and each word in b, weighted by attention ($\mathbf{r}_i$). Thicker attention arrows indicate stronger word pair alignments (e.g. *cheap*, *expensive*).

3.1 General Approach

Pair Representation We assume that we are given two sequences $a = a_1 ... a_n$ and $b = b_1 ... b_m$. We represent the word-pair embeddings between a and b using the pretrained `pair2vec` model as:

$$\mathbf{r}_{i,j} = \left[\frac{R(a_i, b_j)}{\|R(a_i, b_j)\|}; \frac{R(b_j, a_i)}{\|R(b_j, a_i)\|} \right] \tag{3}$$

We include embeddings in both directions, $R(a_i, b_j)$ and $R(b_j, a_i)$, because the many relations can be expressed in both directions; e.g., hypernymy can be expressed via "*X is a type of Y*" as well as "*Y such as X*". We take the L_2 normalization of each direction's pair embedding because the heavy-tailed distribution of word pairs results in significant variance of their norms.

Base Model Let $\mathbf{a}_1 ... \mathbf{a}_n$ and $\mathbf{b}_1 ... \mathbf{b}_m$ be the vector representations of sequences a and b, as produced by the input encoder (e.g. ELMo embeddings contextualized with model-specific BiLSTMs). Furthermore, we assume that the base model computes soft word alignments between a and b via co-attention (4, 5), which are then used to compute b-aware representations of a:

$$s_{i,j} = f_{att}(\mathbf{a}_i, \mathbf{b}_j) \tag{4}$$

$$\alpha = \text{softmax}_j(s_{i,j}) \tag{5}$$

$$\overline{\mathbf{b}}_i = \sum_{j=0}^{m} \alpha_{i,j} \mathbf{b}_j \tag{6}$$

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i\right] \tag{7}$$

The symmetric term $\mathbf{b}_j^{inf}$ is defined analogously. We refer to $\mathbf{a}^{inf}$ and $\mathbf{b}^{inf}$ as the inputs to the *inference* layer, since this layer computes some function over aligned word pairs, typically via a feed-forward network and LSTMs. The inference layer is followed by aggregation and output layers.

Injecting `pair2vec` We conjecture that the inference layer effectively learns word-pair relationships from training data, and it should, therefore, help to augment its input with `pair2vec`. We augment $\mathbf{a}_i^{inf}$ (7) with the pair vectors $\mathbf{r}_{i,j}$ (3) by concatenating a weighted average of the pair vectors $r_{i,j}$ involving a_i, where the weights are the same $\alpha_{i,j}$ computed via attention in (5):

$$\mathbf{r}_i = \sum_j \alpha_{i,j} \mathbf{r}_{i,j} \tag{8}$$

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i; \mathbf{r}_i\right] \tag{9}$$

The symmetric term $\mathbf{b}_j^{inf}$ is defined analogously.

3.2 Question Answering

We augment the inference layer in the BiDAF++ model with `pair2vec`. BiDAF++ is an improved version of the BiDAFNoAnswer (Seo et al., 2017; Levy et al., 2017) which includes self-attention and ELMo embeddings from Peters et al. (2018). We found this variant to be stronger than the baselines presented in Rajpurkar et al. (2018) by over 2.5 F1. We use BiDAF++ as a baseline since its architecture is typical for QA systems, and, until recently, was state-of-the-art on SQuAD 2.0 and other benchmarks.

BiDAF++ Let $\mathbf{a}$ and $\mathbf{b}$ be the outputs of the passage and question encoders respectively (in place of the standard $\mathbf{p}$ and $\mathbf{q}$ notations). The inference layer's inputs $\mathbf{a}_i^{inf}$ are defined similarly to the generic model's in (7), but also contain an aggregation of the elements in $\mathbf{a}$, with better-aligned elements receiving larger weights:

$$\mu = \text{softmax}_i(\max_j s_{i,j}) \tag{10}$$

$$\hat{\mathbf{a}}_i = \sum_i \mu_i \mathbf{a}_i \tag{11}$$

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i; \mathbf{a}_i \circ \overline{\mathbf{b}}_i; \hat{\mathbf{a}}\right] \tag{12}$$

In the later layers, $\mathbf{a}^{inf}$ is recontextualized using a BiGRU and self attention. Finally a prediction layer predicts the start and end tokens.

BiDAF++ with `pair2vec` To add our pair vectors, we simply concatenate $\mathbf{r}_i$ (3) to $\mathbf{a}_i^{inf}$ (12):

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i; \mathbf{a}_i \circ \overline{\mathbf{b}}_i; \hat{\mathbf{a}}; \mathbf{r}_i\right] \tag{13}$$

3.3 Natural Language Inference

For NLI, we augment the ESIM model (Chen et al., 2017), which was previously state-of-the-art on both SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) benchmarks.

ESIM Let $\mathbf{a}$ and $\mathbf{b}$ be the outputs of the premise and hypothesis encoders respectively (in place of the standard $\mathbf{p}$ and $\mathbf{h}$ notations). The inference layer's inputs $\mathbf{a}_i^{inf}$ (and $\mathbf{b}_j^{inf}$) are defined similarly to the generic model's in (7):

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i; \mathbf{a}_i \circ \overline{\mathbf{b}}_i; \mathbf{a}_i - \overline{\mathbf{b}}_i\right] \tag{14}$$

In the later layers, $\mathbf{a}^{inf}$ and $\mathbf{b}^{inf}$ are projected, recontextualized, and converted to a fixed-length vector for each sentence using multiple pooling schemes. These vectors are then passed on to an output layer, which predicts the class.

ESIM with `pair2vec` To add our pair vectors, we simply concatenate $\mathbf{r}_i$ (3) to $\mathbf{a}_i^{inf}$ (14):

$$\mathbf{a}_i^{inf} = \left[\mathbf{a}_i; \overline{\mathbf{b}}_i; \mathbf{a}_i \circ \overline{\mathbf{b}}_i; \mathbf{a}_i - \overline{\mathbf{b}}_i; \mathbf{r}_i\right] \tag{15}$$

A similar augmentation of ESIM was recently proposed in KIM (Chen et al., 2018). However, their pair vectors are composed of WordNet features, while our pair embeddings are learned directly from text (see further discussion in Section 6).

4 Experiments

For experiments on QA (Section 4.1) and NLI (Section 4.2), we use our full model which includes multivariate and typed negative sampling. We discuss ablations in Section 4.3

Benchmark		BiDAF	+ `pair2vec`	Δ
SQuAD 2.0	EM	65.66	68.02	+2.36
	F1	68.86	71.58	+2.72
AddSent	EM	37.50	44.20	+6.70
	F1	42.55	49.69	+7.14
AddOneSent	EM	48.20	53.30	+5.10
	F1	54.02	60.13	+6.11

Table 3: Performance on SQuAD 2.0 and adversarial SQuAD (AddSent and AddOneSent) benchmarks, with and without `pair2vec`. All models have ELMo.

Benchmark	ESIM	+ `pair2vec`	Δ
Matched	79.68	81.03	+1.35
Mismatched	78.80	80.12	+1.32

Table 4: Performance on MultiNLI, with and without `pair2vec`. All models have ELMo.

Data We use the January 2018 dump of English Wikipedia, containing 96M sentences to train `pair2vec`. We restrict the vocabulary to the 100K most frequent words. Preprocessing removes all out-of-vocabulary words in the corpus. We consider each word pair within a window of 5 in the preprocessed corpus, and subsample[5] instances based on pair probability with a threshold of $5 \cdot 10^{-7}$. We define the context as one word each to the left and right, and all the words in between each pair, replacing both target words with placeholders X and Y (see Table 1). More details can be found in the supplementary material.

4.1 Question Answering

We experiment on the SQuAD 2.0 QA benchmark (Rajpurkar et al., 2018), as well as the adversarial datasets of SQuAD 1.1 (Rajpurkar et al., 2016; Jia and Liang, 2017). Table 3 shows the performance of BiDAF++, with ELMo , before and after adding `pair2vec`. Experiments on SQuAD 2.0 show that our pair representations improve performance by 2.72 F1. Moreover, adding `pair2vec` also results in better generalization on the adversarial SQuAD datasets with gains of 7.14 and 6.11 F1.

4.2 Natural Language Inference

We report the performance of our model on MultiNLI and the adversarial test set from Glockner et al. (2018) in Table 5. We outperform the

---

[5] Like in `word2vec`, subsampling reduces the size of the dataset and speeds up training. For this, we define the word pair probability as the product of unigram probabilities.

Model	Accuracy
Rule-based Models	
WordNet Baseline	85.8
Models with GloVe	
ESIM (Chen et al., 2017)	77.0
KIM (Chen et al., 2018)	87.7
ESIM + `pair2vec`	**92.9**
Models with ELMo	
ESIM (Peters et al., 2018)	84.6
ESIM + `pair2vec`	**93.4**

Table 5: Performance on the adversarial NLI test set of Glockner et al. (2018).

Model	EM (Δ)	F1 (Δ)
`pair2vec` (Full Model)	69.20	72.68
Composition: 2 Layers	68.35 (-0.85)	71.65 (-1.03)
Composition: Multiply	67.10 (-2.20)	70.20 (-2.48)
Objective: Bivariate NS	68.63 (-0.57)	71.98 (-0.70)
Unsupervised: Pair Dist	67.07 (-2.13)	70.24 (-2.44)
No `pair2vec` (BiDAF)	66.66 (-2.54)	69.90 (-2.78)

Table 6: Ablations on the Squad 2.0 development set show that argument sampling as well as using a deeper composition function are useful.

ESIM + ELMo baseline by 1.3% on the matched and mismatched portions of the dataset.

We also record a gain of 8.8% absolute over ESIM on the Glockner et al. (2018) dataset, setting a new state of the art. Following standard practice (Glockner et al., 2018), we train all models on a combination of SNLI (Bowman et al., 2015) and MultiNLI. Glockner et al. (2018) show that with the exception of KIM (Chen et al., 2018), which uses WordNet features, several NLI models fail to generalize to this setting which involves lexical inference. For a fair comparison with KIM on the Glockner test set, we replace ELMo with GLoVE embeddings, and still outperform KIM by almost halving the error rate.

4.3 Ablations

Ablating parts of `pair2vec` shows that all components of the model (Section 2) are useful. We ablate each component and report the EM and F1 on the development set of SQuAD 2.0 (Table 6). The full model, which uses a 4-layer MLP for $R(x, y)$ and trains with multivariate negative sampling, achieves the highest F1 of 72.68.

We experiment with two alternative composition functions, a 2-layer MLP (*Composition: 2 Layers*) and element-wise multiplication (*Composition: Multiply*), which yield significantly smaller gains over the baseline BiDAF++ model. This demonstrates the need for a deep composition function. Eliminating sampling of target words (x, y) from the objective (*Objective: Bivariate NS*) results in a drop of 0.7 F1, accounting for about a quarter of the overall gain. This suggests that while the bulk of the signal is mined from the pair-context interactions, there is also valuable information in other interactions as well.

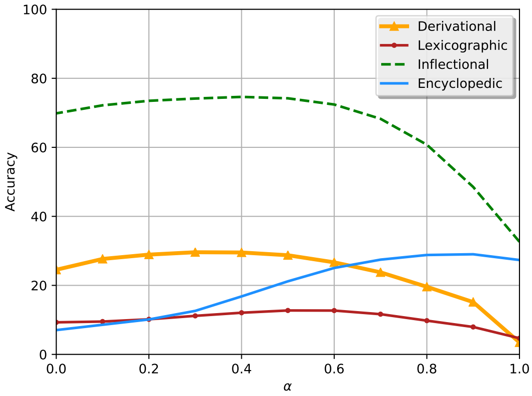

Figure 2: Accuracy as a function of the interpolation parameter α (see Eq. (16)). The α=0 configuration relies only on fastText (Bojanowski et al., 2017), while α=1 reflects `pair2vec`.

We also test whether specific pre-training of word *pair* representations is useful by replacing `pair2vec` embeddings with the vector offsets of pre-trained word embeddings (*Unsupervised: Pair Dist*). We follow the PairDistance method for word analogies (Mikolov et al., 2013b), and represent the pair (x, y) as the L2 normalized difference of single-word vectors: $(\mathbf{x} - \mathbf{y})/\|\mathbf{x} - \mathbf{y}\|$. We use the same fastText (Bojanowski et al., 2017) word vectors with which we initialized `pair2vec` before training. We observe a gain of only 0.34 F1 over the baseline.

5 Analysis

In Section 4, we showed that `pair2vec` adds information complementary to single-word representations like ELMo. Here, we ask what this extra information is, and try to characterize which word relations are better captured by `pair2vec`. To that end, we evaluate performance on a word analogy dataset with over 40 different relation types (Section 5.1), and observe how `pair2vec` fills hand-crafted relation patterns (Section 5.2).

Relation	`3CosAdd`	`+pair2vec`	α^*
Country:Capital	1.2	86.1	0.9
Name:Occupation	1.8	44.6	0.8
Name:Nationality	0.1	42.0	0.9
UK City:County	0.7	31.7	1.0
Country:Language	4.0	28.4	0.8
Verb 3pSg:Ved	49.1	61.7	0.6
Verb Ving:Ved	61.1	73.3	0.5
Verb Inf:Ved	58.5	70.1	0.5
Noun+less	4.8	16.0	0.2
Substance Meronym	3.8	14.5	0.6

Table 7: The top 10 analogy relations for which interpolating with `pair2vec` improves performance. α^* is the optimal interpolation parameter for each relation.

5.1 Quantitative Analysis: Word Analogies

Word Analogy Dataset Given a word pair (a, b) and word x, the word analogy task involves predicting a word y such that $a : b :: x : y$. We use the Bigger Analogy Test Set (BATS, Gladkova et al., 2016) which contains four groups of relations: encyclopedic semantics (e.g., person-profession as in *Einstein-physicist*), lexicographic semantics (e.g., antonymy as in *cheap-expensive*), derivational morphology (e.g., noun forms as in *oblige-obligation*), and inflectional morphology (e.g., noun-plural as in *bird-birds*). Each group contains 10 sub-relations.

Method We interpolate `pair2vec` and `3CosAdd` (Mikolov et al., 2013b; Levy et al., 2014) scores on fastText embeddings, as follows:

$$\begin{aligned}\text{score}(y) = {} & \alpha \cdot \cos(\mathbf{r}_{a,b}, \mathbf{r}_{x,y}) \\ & + (1-\alpha) \cdot \cos(\mathbf{b} - \mathbf{a} + \mathbf{x}, \mathbf{y}) \end{aligned} \quad (16)$$

where $\mathbf{a}$, $\mathbf{b}$, $\mathbf{x}$, and $\mathbf{y}$ represent fastText embeddings[6] and $\mathbf{r}_{a,b}$, $\mathbf{r}_{x,y}$ represent the `pair2vec` embedding for the word pairs (a, b) and (x, y), respectively; α is the linear interpolation parameter. Following prior work (Mikolov et al., 2013b), we return the highest-scoring y in the entire vocabulary, excluding the given words a, b, and x.

Results Figure 2 shows how the accuracy on each category of relations varies with α. For all four groups, adding `pair2vec` to `3CosAdd` results in significant gains. In particular, the biggest relative improvements are observed for encyclopedic (356%) and lexicographic (51%) relations.

Table 7 shows the specific relations in which `pair2vec` made the largest absolute impact. The gains are particularly significant for relations where fastText embeddings provide limited signal. For example, the accuracy for *substance meronyms* goes from 3.8% to 14.5%. In some cases, there is also a synergistic effect; for instance, in *noun+less*, `pair2vec` alone scored 0% accuracy, but mixing it with `3CosAdd`, which got 4.8% on its own, yielded 16% accuracy.

These results, alongside our experiments in Section 4, strongly suggest that `pair2vec` encodes information complementary to that in single-word embedding methods such as fastText and ELMo.

5.2 Qualitative Analysis: Slot Filling

To further explore how `pair2vec` encodes such complementary information, we consider a setting similar to that of knowledge base completion: given a Hearst-like context pattern c and a single word x, predict the other word y from the entire vocabulary. We rank candidate words y based on the scoring function in our training objective: $R(x, y) \cdot C(c)$. We use a fixed set of example relations and manually define their predictive context patterns and a small set of candidate words x.

Table 8 shows the top three y words. The model embeds (x, y) pairs close to contexts that reflect their relationship. For example, substituting *Portland* in the city-state pattern ("*in X, Y.*"), the top two words are *Oregon* and *Maine*, both US states with cities named Portland. When used with the city-city pattern ("*from X to Y.*"), the top two words are *Salem* and *Astoria*, both cities in Oregon. The word-context interaction often captures multiple relations; for example, *Monet* is used to refer to the painter (*profession*) as well as his paintings.

As intended, `pair2vec` captures the three-way word-word-context interaction, and not just the two-way word-context interaction (as in single-word embeddings). This profound difference allows `pair2vec` to complement single-word embeddings with additional information.

6 Related Work

Pretrained Word Embeddings Many state-of-the-art models initialize their word representations using pretrained embeddings such as `word2vec` (Mikolov et al., 2013a) or ELMo (Peters et al., 2018). These representations are typically trained using an interpretation of the Distributional Hy-

---

[6] The fastText embeddings in the analysis were retrained using the same Wikipedia corpus used to train `pair2vec` to control for the corpus when comparing the two methods.

Relation	**Context**	**X**	**Y (Top 3)**
Antonymy/Exclusion	either X or Y	accept hard	*reject*, *refuse*, recognise *soft*, *brittle*, *polished*

Table 8: Given a context c and a word x, we select the top 3 words y from the entire vocabulary using our scoring function $R(x, y) \cdot C(c)$. The analysis suggests that the model tends to rank correct matches (italics) over others.

pothesis (Harris, 1954) in which the bivariate distribution of target words and contexts is modeled. Our work deviates from the word embedding literature in two major aspects. First, our goal is to represent word *pairs*, not individual words. Second, our new PMI formulation models the *trivariate* word-word-context distribution. Experiments show that our pair embeddings can complement single-word embeddings.

Mining Textual Patterns There is extensive literature on mining textual patterns to predict relations between words (Hearst, 1992; Snow et al., 2005; Turney, 2005; Riedel et al., 2013; Van de Cruys, 2014; Toutanova et al., 2015; Shwartz and Dagan, 2016). These approaches focus mostly on relations between pairs of nouns (perhaps with the exception of VerbOcean (Chklovski and Pantel, 2004)). More recently, they have been expanded to predict relations between unrestricted pairs of words (Jameel et al., 2018; Espinosa Anke and Schockaert, 2018), assuming that each word-pair was observed together during pretraining. Washio and Kato (2018a,b) relax this assumption with a compositional model that can represent any pair, as long as each word appeared (individually) in the corpus.

These methods are evaluated on either intrinsic relation prediction tasks, such as BLESS (Baroni and Lenci, 2011) and CogALex (Santus et al., 2016), or knowledge-base population benchmarks, e.g. FB15 (Bordes et al., 2013). To the best of our knowledge, our work is the first to integrate pattern-based methods into modern high-performing semantic models and evaluate their impact on complex end-tasks like QA and NLI.

Integrating Knowledge in Complex Models Ahn et al. (2016) integrate Freebase facts into a language model using a copying mechanism over fact attributes. Yang and Mitchell (2017) modify the LSTM cell to incorporate WordNet and NELL knowledge for event and entity extraction. For cross-sentence inference tasks, Weissenborn et al. (2017), Bauer et al. (2018), and Mihaylov and Frank (2018) dynamically refine word representations by reading assertions from ConceptNet and Wikipedia abstracts. Our approach, on the other hand, relies on a relatively simple extension of existing cross-sentence inference models. Furthermore, we do not need to dynamically retrieve and process knowledge base facts or Wikipedia texts, and just pretrain our pair vectors in advance.

KIM (Chen et al., 2017) integrates word-pair vectors into the ESIM model for NLI in a very similar way to ours. However, KIM's word-pair vectors contain only hand-engineered word-relation indicators from WordNet, whereas our word-pair vectors are automatically learned from unlabeled text. Our vectors can therefore reflect relation types that do not exist in WordNet (such as *profession*) as well as word pairs that do not have a direct link in WordNet (e.g. *bronze* and *statue*); see Table 8 for additional examples.

7 Conclusion and Future Work

We presented new methods for training and using word *pair* embeddings that implicitly represent background knowledge. Our pair embeddings are computed as a compositional function of the individual word representations, which is learned by maximizing a variant of the PMI with the contexts in which the the two words co-occur. Experiments on cross-sentence inference benchmarks demonstrated that adding these representations to existing models results in sizable improvements for both in-domain and adversarial settings.

Published concurrently with this paper, BERT (Devlin et al., 2018), which uses a masked language model objective, has reported dramatic gains on multiple semantic benchmarks including question-answering, natural language inference, and named entity recognition. Potential avenues for future work include multitasking BERT with `pair2vec` in order to more directly incorporate reasoning about word pair relations into the BERT objective.

Acknowledgments

We would like to thank Anna Rogers (Gladkova), Qian Chen, Koki Washio, Pranav Rajpurkar, and Robin Jia for their help with the evaluation. We are also grateful to members of the UW and FAIR NLP groups, and anonymous reviewers for their thoughtful comments and suggestions.

A Implementation Details

Hyperparameters For both word pairs and contexts, we use 300-dimensional word embeddings initialized with FastText (Bojanowski et al., 2017). The context representation uses a single-layer BiLSTM with a hidden layer size of 100. We use 2 negative context samples and 3 negative argument samples for each pair-context tuple.

For pre-training, we used stochastic gradient descent with an initial learning rate of 0.01. We reduce the learning rate by a factor of 0.9 if the loss does not decrease for 300K steps. We use a batch size of 600, and train for 12 epochs.[7]

For both end-task models, we use AllenNLP's implementations (Gardner et al., 2018) with default hyperparameters; we did not change any setting before or after injecting `pair2vec`. We use 0.15 dropout on our pretrained pair embeddings.

B Multivariate Negative Sampling

B.1 Relation to Multivariate PMI

In this appendix, we elaborate on mathematical details of multivariate negative sampling to support our claims in Section 2.2, and also discuss its relation to other PMI multivariate formulations (Table 9).

B.2 Global Objective

Equation (Table 2, J_{3NS}) in Section 2.2 characterizes the local objective for each data instance. To understand the mathematical properties of this objective, we must first describe the global objective in terms of the entire dataset. However, this

---

[7] On Titan X GPUs, the training takes about a week.

(Van de Cruys, 2011)	$SI_1(x,y,c)$	$\log \frac{P(x,y,\cdot)P(x,\cdot,c)P(\cdot,y,c)}{P(x,\cdot,\cdot)P(\cdot,y,\cdot)P(\cdot,\cdot,c)P(x,y,c)}$
	$SI_2(x,y,c)$	$\log \frac{P(x,y,c)}{P(x,\cdot,\cdot)P(\cdot,y,\cdot)P(\cdot,\cdot,c)}$
(Jameel et al., 2018)	$SI_3(x,y,c)$	$\log \frac{P(x,y,c)}{P(x,y,\cdot)P(\cdot,\cdot,c)}$
	$SI_4(x,y,c)$	$\log \frac{P(x,y,c)P(\cdot,\cdot,c)}{P(x,\cdot,c)P(\cdot,y,c)}$
(This Work)	$MVPMI(x,y,c)$	$\log \frac{P(x,y,c)}{k_c P(\cdot,\cdot,c)P(x,y,\cdot)+k_x P(x,\cdot,\cdot)P(\cdot,y,c)+k_y P(\cdot,y,\cdot)P(x,\cdot,c)}$

Table 9: Multivariate generalizations of PMI.

cannot be done by simply summing the local objective for each (x, y, c), since each such example may appear multiple times in our dataset. Moreover, due to the nature of negative sampling, the number of times an (x, y, c) triplet appears as a positive example will almost always be different from the number of times it appears as a negative one. Therefore, we must determine the frequency in which each triplet appears in each role.

We first denote the number of times the example (x, y, c) appears in the dataset as $\#(x, y, c)$; this is also the number of times (x, y, c) is used as a positive example. We observe that the expected number of times (x, y, c) is used as a corrupt x example is $k_x P(x, \cdot, \cdot)\#(\cdot, y, c)$, since (x, y, c) can only be created as a corrupt x example by randomly sampling x from an example that already contained y and c. The number of times (x, y, c) is used as a corrupt y or c example can be derived analogously. Therefore, the global objective of our trenary negative sampling approach is:

$$J_{3NS}^{\text{Global}} = \sum_{(x,y,c)} J_{3NS}^{x,y,c} \tag{17}$$

$$\begin{aligned} J_{3NS}^{x,y,c} &= \#(x,y,c) \cdot \log \sigma\left(S_{x,y,c}\right) \\ &+ Z'_{x,y,c} \cdot \log \sigma\left(-S_{x,y,c}\right) \end{aligned} \tag{18}$$

$$\begin{aligned} Z'_{x,y,c} &= k_x P(x,\cdot,\cdot)\#(\cdot,y,c) J_{-}^{x,y,c} \\ &+ k_y P(\cdot,y,\cdot)\#(x,\cdot,c) J_{-}^{x,y,c} \\ &+ k_c P(\cdot,\cdot,c)\#(x,y,\cdot) J_{-}^{x,y,c} \end{aligned} \tag{19}$$

$$S_{x,y,c} = R(x,y) \cdot C(c) \tag{20}$$

With the global objective, we can now ask what is the optimal value of $S_{x,y,c}$ (20) by comparing the partial derivative of (17) to zero. This derivative is in fact equal to the partial derivative of (18), since it is the only component of the global objective in which $R(x, y) \cdot C(c)$ appears:

$$0 = \frac{\partial J_{3NS}^{\text{Global}}}{\partial S_{x,y,c}} = \frac{\partial J_{3NS}^{x,y,c}}{\partial S_{x,y,c}}$$

The partial derivative of (18) can be expressed as:

$$0 = \#(x,y,c) \cdot \sigma\left(-S_{x,y,c}\right) - Z'_{x,y,c} \cdot \sigma\left(S_{x,y,c}\right)$$

which can be reformulated as:

$$S_{x,y,c} = \log \frac{\#(x,y,c)}{Z'_{x,y,c}}$$

By expanding the fraction by $1/\#(\cdot,\cdot,\cdot)$ (i.e. dividing by the size of the dataset), we essentially convert all the frequency counts (e.g. $\#(x, y, z)$) to empirical probabilities (e.g. $P(x, y, z)$), and arrive at Equation (1) in Section 2.2.

B.3 Other Multivariate PMI Formulations

Previous work has proposed different multivariate formulations of PMI, shown in Table 9. Van de Cruys (2011) presented specific interaction information (SI_1) and specific correlation (SI_2). In addition to those metrics, Jameel et al. (2018) experimented with SI_3, which is the bivariate PMI between (x, y) and c, and with SI_4. Our formulation deviates from previous work, and, to the best of our knowledge, cannot be trivially expressed by one of the existing metrics.

Submodular Optimization-based Diverse Paraphrasing and its Effectiveness in Data Augmentation

Abstract

Inducing diversity in the task of paraphrasing is an important problem in NLP with applications in data augmentation and conversational agents. Previous paraphrasing approaches have mainly focused on the issue of generating semantically similar paraphrases, while paying little attention towards diversity. In fact, most of the methods rely solely on top-k beam search sequences to obtain a set of paraphrases. The resulting set, however, contains many structurally similar sentences. In this work, we focus on the task of obtaining highly diverse paraphrases while not compromising on paraphrasing quality. We provide a novel formulation of the problem in terms of monotone submodular function maximization, specifically targeted towards the task of paraphrasing. Additionally, we demonstrate the effectiveness of our method for data augmentation on multiple tasks such as intent classification and paraphrase recognition. In order to drive further research, we have made the source code available.

1 Introduction

Paraphrasing is the task of rephrasing a given text in multiple ways such that the semantics of the generated sentences remain unaltered. Paraphrasing *Quality* can be attributed to two key characteristics - *fidelity* which measures the semantic similarity between the input text and generated text, and *diversity*, which measures the lexical dissimilarity between generated sentences.

Many previous works (Prakash et al., 2016; Gupta et al., 2018; Li et al., 2018) address the task of obtaining semantically similar paraphrases. While it is essential to produce paraphrases with high fidelity, it is equally important, and in many cases desirable, to produce lexically diverse ones. Diversity in paraphrase generation finds applications in text simplification (Nisioi et al., 2017; Xu et al., 2015), document summarization (Li et al., 2009; Nema et al., 2017), QA systems (Fader et al., 2013; Bernhard and Gurevych, 2008), data augmentation (Zhang et al., 2015; Wang and Yang, 2015), conversational agents (Li et al., 2016) and information retrieval (Anick and Tipirneni, 1999).

Table 1: Sample paraphrases generated by beam search and DiPS (our method). DiPS offers lexically diverse paraphrases without compromising on fidelity.

To obtain a set of multiple paraphrases, most of the current paraphrasing models rely solely on top-k beam search sequences. The resulting set, however, contains many structurally similar sentences with only minor, word level changes. There have been some prior works (Li and Jurafsky, 2016; Elhamifar et al., 2012) which address the notion of diversity in NLP, including in sequence learning frameworks (Song et al., 2018; Vijayakumar et al., 2018). Although Song et al. (2018) address the issue of diversity in the scenario of neural conversation models using determinantal point processes (DPP), it could be naturally used for paraphrasing. On similar lines, subset selection based on Simultaneous Sparse Recovery (SSR) (Elhamifar et al., 2012) can also be easily adapted for the same task.

Though these methods are helpful in maximizing diversity, they are restrictive in terms of re-

taining fidelity with respect to the source sentence. Addressing the task of diverse paraphrasing through the lens of monotone submodular function maximization (Fujishige, 2005; Krause and Golovin; Bach et al., 2013) alleviates this problem and also provides a few additional benefits. Firstly, the submodular objective offers better flexibility in terms of controlling diversity as well as fidelity. Secondly, there exists a simple greedy algorithm for solving monotone submodular function maximization (Nemhauser et al., 1978), which guarantees the diverse solution to be almost as good as the optimal solution. Finally, many submodular programs are fast and scalable to large datasets.

Below, we list the main contributions of our paper.

1. We introduce **Di**verse **P**araphraser using **S**ubmodularity (DiPS). DiPS maximizes a novel submodular objective function specifically targeted towards paraphrasing.
2. We perform extensive experiments to show the effectiveness of our method in generating structurally diverse paraphrases without compromising on fidelity. We also compare against several possible diversity inducing schemes.
3. We demonstrate the utility of diverse paraphrases generated via DiPS as data augmentation schemes on multiple tasks such as intent and question classification.

We have made DiPS's source code available at https://github.com/malllabiisc/DiPS

2 Related Work

Paraphrasing a given sentence is an important problem and numerous approaches have been proposed to address it. Recently *sequence-to-sequence* based data-driven deep learning models have been proposed, which try to address the limitations of earlier traditional rule-based (McKeown, 1983) methods. Prakash et al. (2016) employ residual connections in LSTM to enhance the traditional sequence-to-sequence model. Gupta et al. (2018) provide a VAE (Kingma and Welling, 2013) based framework to improve the quality of generated paraphrases. Li et al. (2018) propose a reinforcement learning based model which uses pointer-generator (See et al., 2017) for generating paraphrases and an evaluator based on (Parikh et al., 2016) to penalize non-paraphrastic generations. Several other works (Cao et al., 2017; Iyyer et al., 2018) exist for paraphrasing, though they have either been superseded by newer models or are not-directly applicable to our settings. However, most of these methods focus on the issue of generating semantically similar paraphrases, while paying little attention towards diversity.

Diversity in paraphrasing models was first explored by (Gupta et al., 2018) where they propose to generate variations based on different samples from the latent space in a deep generative framework. Although diversity in paraphrasing models has not been explored extensively, methods have been proposed to address diversity in other NLP tasks (Li et al., 2016, 2015; Gimpel et al., 2013). Diverse beam search proposed by (Vijayakumar et al., 2018) generates k-diverse sequences by dividing the candidate subsequences at each time step into several groups and penalizing subsequences which are similar to prior groups. The most relevant to our approach is the method proposed by (Song et al., 2018) for neural conversation models where they incorporate diversity by using DPP to select diverse subsequences at each time step. Although their work is addressed in the scenario of neural conversation models, it could be naturally adapted to paraphrasing models and thus we use it as a baseline.

Submodular functions have been applied to a wide variety of problems in machine learning (Iyer and Bilmes, 2013; Jegelka and Bilmes, 2011; Krause and Guestrin, 2011; Kolmogorov and Zabih, 2002) and have recently attracted much attention in several NLP tasks including document summarization (Lin and Bilmes, 2011), data selection in machine translation (Kirchhoff and Bilmes, 2014) and goal-oriented chatbot training (Dimovski et al., 2018). However, their application to sequence generation is largely unexplored.

Data augmentation is a technique for increasing the size of labeled training sets by leveraging task specific transformations which preserve class labels. While the technique is ubiquitous in the vision community (Krizhevsky et al., 2012; Ratner et al., 2017), data-augmentation in NLP is largely under-explored. Most current augmentation schemes involve thesaurus based synonym replacement (Zhang et al., 2015; Wang and Yang, 2015), and replacement by words with paradigmatic relations (Kobayashi, 2018). Both of these

    $P \leftarrow$ Select $k$ based on $\text{argmax}_{X \subseteq V^{(t)}} \mathcal{F}(X)$
      using Algorithm 1
    $t = t + 1$
end
return $P$
```

approaches try to boost the generalization abilities of downstream classification models through word-level substitutions. However, they are inherently restrictive in terms of the diversity they can offer. Our work offers a data-augmentation scheme via high quality paraphrases.

3 Background: Submodularity

Let V = $\{v_1, \ldots, v_n\}$ be a set of objects, which we refer to as the ground set, and $\mathcal{F} : 2^V \rightarrow \mathbb{R}$ be a set function which works on subsets S of V to return a real value. The task is to find a subset S of bounded cardinality say $|S| \leq k$ that maximizes the function $\mathcal{F}$, i.e., $\text{argmax}_{S \subseteq V} \mathcal{F}(S)$. In general, solving this problem is intractable. However, if the function $\mathcal{F}$ is monotone non-decreasing submodular, then although the problem is still NP-complete, there exists a greedy algorithm (Algorithm 1) (Nemhauser et al., 1978) that finds an approximate solution which is guaranteed to be within 0.632 of the optimal solution.

Submodular functions are set functions $\mathcal{F} : 2^V \rightarrow \mathbb{R}$, where 2^V denotes the power set of ground set V. Submodular functions satisfy the following equivalent properties of *diminishing returns*: $\forall X, Y \subseteq V$ with $X \subseteq Y$, and $\forall s \in V \setminus Y$, we have the following.

$$\mathcal{F}(X \cup \{s\}) - \mathcal{F}(X) \geq \mathcal{F}(Y \cup \{s\}) - \mathcal{F}(Y) \quad (1)$$

In other words, the *value* addition due to incorporation of s decreases as the subset grows from X to Y. Equivalently, $\forall X, Y \subseteq V$, we have,

$$\mathcal{F}(X) + \mathcal{F}(Y) \geq \mathcal{F}(X \cup Y) + \mathcal{F}(X \cap Y)$$

In case the above inequalities are equalities, the function $\mathcal{F}$ is said to be modular. Let $\mathcal{F}(s|X) \triangleq \mathcal{F}(X \cup \{s\}) - \mathcal{F}(X)$. Therefore, $\mathcal{F}$ is submodular if $\mathcal{F}(s|X) \geq \mathcal{F}(s|Y)$ for $X \subseteq Y$.

The second criteria which the function needs to satisfy for Algorithm 1 to be applicable is of monotonicity. A set function $\mathcal{F}$ is said to be monotone non-decreasing if $\forall X \subseteq Y, \mathcal{F}(X) \leq \mathcal{F}(Y)$.

Submodular functions are relevant in a large class of real-world applications, therefore making them extremely useful in practice. Additionally, submodular functions share many commonalities with convex functions, in the sense that they are closed under a number of standard operations like mixtures (non-negative weighted sum of submodular functions), truncation and some restricted compositions.

The above properties will be useful when defining the submodular objective for obtaining high quality paraphrases.

4 Methodology

Similar to Prakash et al. (2016); Gupta et al. (2018); Li et al. (2018), we formulate the task of paraphrase generation as a sequence-to-sequence learning problem. Previous SEQ2SEQ based approaches depend entirely on the standard cross-entropy loss to produce semantically similar sentences and greedy decoding during generation. However, this does not guarantee lexical variety in the generated paraphrases. To incorporate some form of diversity, most prior approaches rely solely on top-k beam search sequences. The k-best list generated by standard beam search are a poor surrogate for the entire search space (Finkel et al., 2006). In fact, most of the sentences in the resulting set are structurally similar, differing only by punctuations or minor morphological variations.

While being similar in the encoding scheme, our work adopts a different approach for the final decoding. We propose a framework which organi-

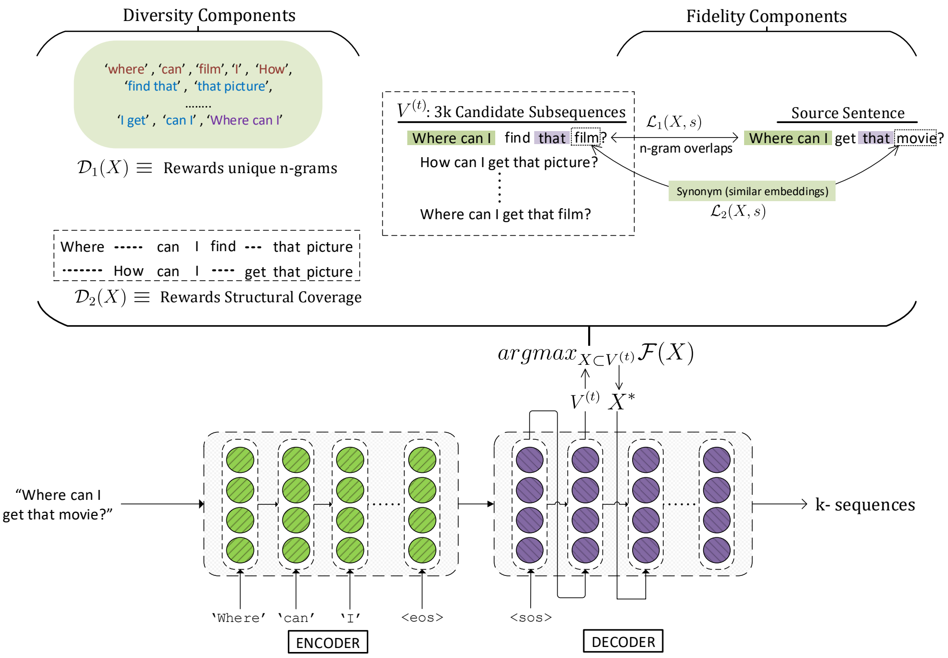

Figure 1: Overview of DiPS during decoding to generate k paraphrases. At each time step, a set of N sequences ($V^{(t)}$) is used to determine $k < N$ sequences (X^*) via submodular maximization . The above figure illustrates the motivation behind each submodular component. Please see Section 4 for details.

cally combines a sentence encoder with a diversity inducing decoder.

4.1 Overview

Our approach is built upon SEQ2SEQ framework. We first feed the tokenized source sentence to the encoder. The task of the decoder is to take as input the encoded representation and produce the respective paraphrase. To achieve this, we train the model using standard cross entropy loss between the generated sequence and the target paraphrase. Upon completion of training, instead of using greedy decoding or standard beam search, we use a modified decoder where we incorporate a submodular objective to obtain high quality paraphrases. Please refer to Figure 1 for an overview of the proposed method.

During the generation phase, the encoder takes the source sentence as input and feeds its representation to the decoder to initiate the decoding process. At each time-step t, we consider N most probable subsequences since they are likely to be well-formed. Based on optimization of our submodular objective, a subset of size $k < N$ are selected and sent as input to the next time step $t + 1$ for further generation. The process is repeated until desired output length T or <eos> token, whichever comes first.

4.2 Monotone Submodular Objectives

We design a parameterized class of submodular functions tailored towards the task of paraphrase generation. Let $V^{(t)}$ be the ground set of possible subsequences at time step t. We aim to determine a set $X \subseteq V^{(t)}$ that retains certain *fidelity* as well as *diversity*. Hence, we model our submodular objective function as follows:

$$X^* = \underset{X \subseteq V^{(t)}}{\operatorname{argmax}} \mathcal{F}(X) \quad s.t. \; |X| \leq k \qquad (2)$$

where k is our budget (desired number of paraphrases) and $\mathcal{F}$ is defined as:

$$\mathcal{F}(X) = \lambda \mathcal{L}(X, s) + (1 - \lambda)\mathcal{D}(X) \qquad (3)$$

Here s is the source sentence, $\mathcal{L}(X, s)$ and $\mathcal{D}(X)$ measure *fidelity* and *diversity*, respectively. $\lambda \in [0, 1]$ is the trade-off coefficient. This formulation clearly brings out the trade-off between the two key characteristics.

Fidelity

It is imperative to design functions that exploit the decoder search space to maximize the semantic similarity between the generated and the source sentence. To achieve this we build upon a known class of monotone submodular functions (Stobbe and Krause, 2010)

$$f(X) = \sum_{i \in U} \mu_i \phi_i(m_i(X)) \tag{4}$$

where U is the set of features to be defined later, $\mu_i \geq 0$ is the feature weight, $m_i(X) = \sum_{x \in X} m_i(x)$ is non-negative modular function and ϕ_i is a non-negative non-decreasing concave function. Based on the analysis of concave functions in (Kirchhoff and Bilmes, 2014), we use the simple square root function as ϕ ($\phi(a) = \sqrt{a}$) in both of our fidelity objectives defined below.

We consider two complementary notions of sentence similarity namely syntactic and semantic. To capture syntactic information we define the following function:

$$\mathcal{L}_1(X, s) = \mu_1 \sqrt{\sum_{x \in X} \sum_{n=1}^{N} \beta^n \left| x_{\text{n-gram}} \cap s_{\text{n-gram}} \right|} \tag{5}$$

where $|x_{\text{n-gram}} \cap s_{\text{n-gram}}|$ represents the number of overlapping n-grams between the source and the candidate sequence x for different values of $n \in \{1, \ldots, N\}$(we use $N = 3$). Since longer n-gram overlaps are more valuable, we set $\beta > 1$. This function inherently increases the BLEU score between the source and the generated sentences.

We address the semantic aspect of fidelity by devising a function based on the word embeddings of source and generated sentences. We define embedding based similarity between two sentences as,

$$\mathcal{S}(x, s) = \frac{1}{|x|} \sum_{w_i \in x} \underset{w_j \in s}{\text{argmax}} \ \psi(\mathbf{v}_{w_i}, \mathbf{v}_{w_j}) \tag{6}$$

where $\mathbf{v}_{w_i}$ is the word embedding for token w_i and $\psi(\mathbf{v}_{w_i}, \mathbf{v}_{w_j})$ is the gaussian radial basis function (rbf)[1]. For each word in the candidate sequence x, we find the best matching word in the source sentence using word level similarity. Using the above mentioned measure for embedding similarity we use the following submodular function:

$$\mathcal{L}_2(X, s) = \mu_2 \sqrt{\sum_{x \in X} \mathcal{S}(x, s)} \tag{7}$$

This function helps increase the semantic homogeneity between the source and generated sequences. The above defined functions (Equation 5,7) are compositions of non-decreasing concave functions and modular functions. Thus, staying in the realm of the class of monotone submodular functions mentioned in Equation 4, we define fidelity function $\mathcal{L}(X, s) = \mathcal{L}_1(X, s) + \mathcal{L}_2(X, s)$

Diversity

Ensuring high fidelity often comes at the cost of producing sequences that only slightly differ from each other. To encourage diversity in the generation process it is desirable to reward sequences with higher number of distinct n-grams as compared to others in the ground set $V^{(t)}$. Accordingly, we propose to use the following function:

$$\mathcal{D}_1(X) = \mu_3 \sum_{n=1}^{N} \beta^n \left| \bigcup_{x \in X} x_{n-gram} \right| \tag{8}$$

For $\beta = 1$, $\mathcal{D}_1(X)$ denotes the number of distinct n-grams present in the set X. Since shorter n-grams contribute more towards diversity, we set $\beta < 1$, thereby giving more value to shorter n-grams. It is easy to see that this function is monotone non-decreasing as the number of distinct n-grams can only increase with the addition of more sequences. To see that $\mathcal{D}_1(X)$ is submodular, consider adding a new sequence to two sets of sequences, one a subset of the other. Intuitively, the increment in the number of distinct n-grams when adding a new sequence to the smaller set should be larger than the increment when adding it to the larger set, as the distinct n-grams in the new sequence might have already been covered by the sequences in the larger set.

Apart from distinct n-gram overlaps, we also wish to obtain sequence candidates that are not only diverse, but also cover all major structural variations. It is reasonable to expect sentences that are structurally different to have lower degree of word/phrase alignment as compared to sentences with minor lexical variations. Edit distance (Levenshtein) is a widely accepted measure to determine such dissimilarities between two sentences. To incorporate this notion of diversity, a formulation in terms of edit distance seems like a natural fit for the problem. To do so, we use the coverage function which measures the similarity of the candidate sequences X with the ground set $V^{(t)}$. The

---

[1] We find gaussian rbf to work better than other similarity metrics such as cosine similarity

coverage function is naturally monotone submodular and is defined as:

$$\mathcal{D}_2(X) = \mu_4 \sum_{x_i \in V^{(t)}} \sum_{x_j \in X} \mathcal{R}(x_i, x_j) \tag{9}$$

where $\mathcal{R}(x_i, x_j)$ is an alignment based similarity measure between two sequences x_i and x_j given by:

$$\mathcal{R}(x_i, x_j) = 1 - \frac{\texttt{EditDistance}(x_i, x_j)}{|x_i| + |x_j|} \tag{10}$$

Note that $\mathcal{R}(x_i, x_j)$ will always lie in the range $[0, 1]$.

Evidently, this method allows flexibility in terms of controlling diversity and fidelity. Our goal is to strike a balance between these two to obtain high-quality generations.

5 Experiments

5.1 Datasets

In this section we outline the datasets used for evaluating our proposed method. We specify the actual splits in Table 2. Based on the task, we categorize them into the following:

1. **Intrinsic evaluation**: To demonstrate the efficacy of our method on fidelity and diversity, we use the standard *Quora question pair*[2] dataset and the *Twitter URL paraphrasing* (Lan et al., 2017) dataset.

   We train and evaluate the paraphrase generation model on a subset of *Quora question pair* dataset which we refer to as *Quora-Div*. This subset comprises only positive examples (pairs which have been annotated as paraphrases).

   We additionally perform in-domain data augmentation for the task of paraphrase recognition. For that, we augment sentences generated through different paraphrasing model as positive samples to the *Quora-PR* dataset. *Quora-PR* is a subset of *Quora question pair* dataset which contains positive as well as negative examples.

2. **Data-augmentation**: We exhibit the importance of samples generated through our method on the task of Data-augmentation using three primary datasets. *SNIPS (Coucke et al., 2018)*, *Yahoo-L31*[3] is used for intent-classification and *TREC* (Li and Roth, 2002) is used for question classification. Each dataset is balanced in terms of the number of samples per classes.

Dataset	Task	Train	Val.	Test	Classes
Quora-Div	Intrinsic	120K	20K	5K	N/A
Twitter	Intrinsic	100K	15K	3K	N/A
Quora-PR	Intrinsic	40K	10K	40K	2
DATA-AUGMENTATION					
SNIPS	Intent	10k	1k	700	7
Yahoo-L31	Intent	4K	1K	1K	2
TREC	Question	1K	200	500	6

Table 2: Dataset Statistics

5.2 Baseline

Several models have sought to increase diversity, albeit with different goals and techniques. However, majority of the prior works in this area have focused on the task of producing diverse responses in dialog systems (Li et al., 2016; Ritter et al., 2011) and not paraphrasing. Given the lack of relevant baselines, we compare our model against the following methods:

1. **SBS**: Decoder which performs standard beam search during generation.
2. **DBS**: An alternative of beam search to incorporate diversity. (Vijayakumar et al., 2018)
3. **DPP**: Decoder based on Determinantal Point Processes (Kulesza et al., 2012)
4. **SSR**[4]: Decoder based on Subset Selection using Simultaneous Sparse Recovery (Elhamifar et al., 2016)

   We additionally, evaluate against the following paraphrase generation models:

5. **VAE-SVG**: VAE based generative framework for paraphrase generation. (Gupta et al., 2018)
6. **RbM**: Deep Reinforcement learning based paraphrase generation model. (Li et al., 2018)

Note that the first four baselines are trained using the same SEQ2SEQ network and differ only in the decoding phase.

---

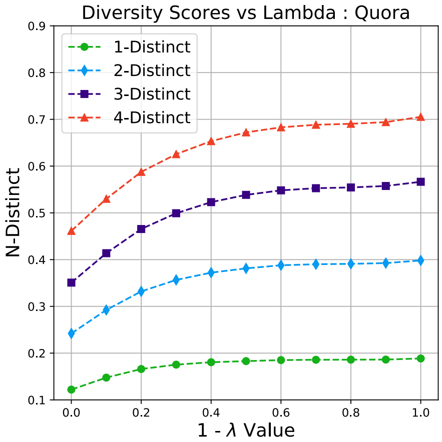

Figure 2: Effect of varying the trade-off coefficient λ in DiPS on various diversity metrics on the Quora dataset.

5.3 Intrinsic Evaluation

1. **Fidelity**: To evaluate our method for fidelity of generated paraphrases, we use three machine translation metrics which have been shown to be suitable for paraphrase evaluation task (Wubben et al., 2010): BLEU (Papineni et al., 2002)(upto bigrams), METEOR (Banerjee and Lavie, 2005) and TERPlus (Snover et al., 2009).
2. **Diversity**: We report degree of diversity by calculating the number of distinct n-grams (n $\in \{1, 2, 3, 4\}$). The value is scaled by the number of generated tokens to avoid favoring long sequences.

In addition to fidelity and diversity, we evaluate the efficacy of our method by using the generated paraphrases as augmented samples in the task of paraphrase recognition on the *Quora-PR* dataset. We perform experiments with multiple augmentation settings for the following classifiers:

1. **LogReg**: Simple Logistic Regression model. We use a set of hand-crafted features, the details of which can be found in the supplementary.
2. **SiameseLSTM**: Siamese adaptation of LSTM to measure quality between two sentences (Mueller and Thyagarajan, 2016)

We also perform ablation testing to highlight the importance of each submodular component. Details can be found in the supplementary section.

5.4 Data-Augmentation

We evaluate the importance of using high quality paraphrases in two downstream classification tasks namely intent-classification and question-classification. Our original generation model is trained on *Quora-Div* question pairs. Since intent-classification and question-classification contain questions, this setting seems like a good fit to perform transfer learning. We perform experiments on the following standard classifier models:

1. **LogRegDA**: Simple logistic regression model trained using hand-crafted features. For details, please refer to the supplementary section.
2. **LSTM**: Single layered LSTM classification model.

In addition to SBS and DBS, we use the following data-augmentation baselines for comparison:

1. **SynRep** : Simple synonym replacement
2. **ContAug**: Data-augmentation scheme based on replacement of words with similar paradigmatic relations. (Kobayashi, 2018)

5.5 Setup

We train our SEQ2SEQ model with attention (Bahdanau et al., 2014) for up to 50 epochs using the adam optimizer (Kingma and Ba, 2014) with initial learning rate set to 2e-4. During the generation phase, we follow standard beam search till

the number of generated tokens is nearly half the source sequence length (token level) to avoid possibly erroneous sentences. We then apply submodular maximization stochastically with probability p at each time step. Since each candidate subsequence is extended by a single token at every time-step, information added might not necessarily be useful as our submodular components work on sentence level. This approach is time efficient and avoids redundant computations.

For each augmentation setting, we randomly select sentences from the training data and generate its paraphrases. We then add them in the training data with the same label as that of the source sentence. We evaluate the performance on different classification models in terms of accuracy.

Based on the formulation of the objective function, it should be clear that diversity would attain maximum value at (or around) $\lambda = 0$ albeit at the cost of fidelity. This is certainly not a desirable property for paraphrasing systems. To address this, we perform hyperparameter tuning for λ value by analyzing the trade-off between diversity and fidelity based on varying λ values. In practice, diversity metric attains saturation at certain λ range (usually 0.2 - 0.5). This behaviour can be seen in Figure 2. Corresponding plot for Twitter, the effect of λ on fidelity and additional details about the hyperparameters can be found in the supplementary.

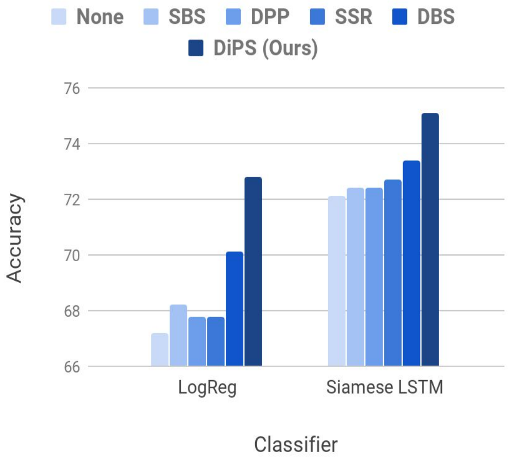

Figure 3: Comparison of accuracy scores of two paraphrase recognition models using different augmentation schemes (Quora-PR). Both LogReg and SiameseLSTM achieve the highest boost in performance when augmented with samples generated using DiPS

6 Results

Our experiments were geared towards answering the following primary questions:

Q1. Is DiPS able to generate diverse paraphrases without compromising on fidelity? (Section 6.1)

Q2. Are paraphrase generated by DiPS useful in data-augmentation? (Section 6.2)

6.1 Intrinsic Evaluation

We compare our method against recent paraphrasing models as well as multiple diversity inducing schemes. DiPS outperforms these baseline models in terms of fidelity metrics namely BLEU, METEOR and TERp. A high METEOR score and a low TERp score indicate the presence of not only exact words but also synonyms and semantically similar phrases. Notably, our model is not only able to achieve substantial gains over other diversity inducing schemes but is also able to do so without compromising on fidelity. Diversity and fidelity scores are reported in Table 4 and Table 3, respectively.

As described in Section 5.3, we evaluate the accuracy of paraphrase recognition models when provided with training data augmented using different schemes. It is reasonable to expect that high quality paraphrases would tend to yield better results on in-domain paraphrase recognition task. We observe that using the paraphrases generated by DiPS helps in achieving substantial gains in accuracy over other baseline schemes. Figure 3 showcases the effect of using paraphrases generated by our method as compared to other competitive paraphrasing methods.

6.2 Data-augmentation

Data Augmentation results for intent and question classification are shown in Table 5. While, SBS does not offer much lexical variability, DBS offers high diversity at the cost of fidelity. SynRep and ContAug are augmentation schemes which are limited by the amount of structural variations they can offer. DiPS on the other hand provides generation having high structural variations without compromising on fidelity. The boost in accuracy scores on both the types of classification models is indicative of the importance of using high quality paraphrases for data-augmentation.

7 Conclusion

In this paper, we have proposed DiPS, a model which generates high quality paraphrases by maximizing a novel submodular objective function designed specifically for paraphrasing. In contrast to prior works which focus exclusively either on fidelity or diversity, a submodular function based approach offers a large degree of freedom to control fidelity and diversity. Through extensive experiments on multiple standard datasets, we have demonstrated the effectiveness of our approach over numerous baselines. We observe that the diverse paraphrases generated are not only interesting and meaning preserving, but are also helpful in data augmentation. We showcase that using multiple settings on the task of intent and question classification. We hope that our approach will be useful not only for paraphrase generation and data augmentation, but also for other NLG problems in conversational agents and text summarization.

Let's Make Your Request More Persuasive: Modeling Persuasive Strategies via Semi-Supervised Neural Nets on Crowdfunding Platforms

Abstract

Modeling what makes a request persuasive—eliciting the desired response from a reader—is critical to the study of propaganda, behavioral economics, and advertising. Yet current models can't quantify the persuasiveness of requests or extract successful persuasive strategies. Building on theories of persuasion, we propose a neural network to quantify persuasiveness and identify the persuasive strategies in advocacy requests. Our semi-supervised hierarchical neural network model is supervised by the number of people persuaded to take actions and partially supervised at the sentence level with human-labeled rhetorical strategies. Our method outperforms several baselines, uncovers persuasive strategies—offering increased interpretability of persuasive speech—and has applications for other situations with document-level supervision but only partial sentence supervision.

1 Introduction

Crowdfunding platforms are a popular way to raise funds for projects. For example, Kiva, a peer-to-peer lending platform, has crowd-funded more than a million loans, totaling over $1 billion since 2005. Kickstarter, another online crowdfunding platform, successfully funded 110,270 projects with a total of over 2 billion dollars. Yet most projects still suffer from low success rates. How can we help requesters craft persuasive and successful pitches to convince others to take actions?

Persuasive communication has the potential to shape and change people's attitudes and behaviors (Hovland et al., 1953), and has been widely researched in various fields such as social psychology, marketing, behavioral economics, and political campaigning (Shrum et al., 2012). One of the most influential theories in the advertising literature is Chaiken's systematic-heuristic dual processing theory, which suggests that people process persuasive communication by evaluating the quality of arguments or by relying on inferential rules. Some such heuristic rules are commonly used in consumer behaviors; commercial websites may highlight the limited availability of their items "*In high demand - only 2 left on our site!*" or emphasize the person in authority "*Speak to our head of sales—he has over 15 years' experience selling properties*" to attract potential consumers. Although numerous studies on persuasion have been conducted (Chaiken, 1980), we still know little about the way how persuasion functions in the wild and how it can be modeled computationally.

In this work, we utilize neural-network based methods to computationally model persuasion in requests from crowdfunding websites. We build on theoretical models of persuasion to operationalize persuasive strategies and ensure generalizability. We propose to identify the persuasive strategy employed in each sentence in each request. However, constructing a large dataset with persuasion strategies labeled at the sentence level is time-consuming and expensive. Instead, we propose to use a small amount of hand-labeled sentences together with a large number of requests automatically labeled at the document level by the number of persuaded support actions. Our model is a semi-supervised hierarchical neural network that identifies the persuasive strategies employed in each sentence, where the supervision comes from the overall persuasiveness of the request. We propose that the success of requests could have substantive explanatory power to uncover their persuasive strategies. We also introduce an annotated corpus with sentence-level persuasion strategy labels and document-level persuasiveness labels, to facilitate future work on persuasion. Experiments

Minneapolis, Minnesota, June 2 - June 7, 2019.

show that our semi-supervised model outperforms several baselines. We then apply this automated model to unseen requests from different domains and obtain nuanced findings of the importance of different strategies on persuasion success. Our model can be useful in any situation in which we have exogenous document-level supervision, but only small amounts of expensive human-annotated sentence labels.

2 Related Work

Computational argumentation has received much recent attention (Ghosh et al., 2016; Stab and Gurevych, 2017; Peldszus and Stede, 2013; Stab et al., 2018; Ghosh et al., 2014). Most work has either identified the arguments in news articles (Sardianos et al., 2015) or user-generated web content (Habernal and Gurevych, 2017; Musi et al., 2018), or classified argument components (Zhang and Litman, 2015) into claims and premises, supporting and opposing claims, or backings, rebuttals and refutations . For example, Stab and Gurevych (2014) proposed structural, lexical, syntactic and contextual features to identify convincing components of Web arguments including claim, major claim, and premise. Similarly, Zhang and Litman (2015) studied student essay revisions and classified a set of argumentative actions associated with successful writing such as warrant/reasoning/backing, rebuttal/reservation, and claims/ideas. Habernal and Gurevych (2016) investigated the persuasiveness of arguments in any given argument pair using bidirectional LSTM. Hidey et al., (2017) utilized the persuasive modes—ethos, logos, pathos—to model premises and the semantic types of argument components in an online persuasive forum.

While most computational argumentation focuses on the relational support structures and factual evidence to make claims, **persuasion** focuses more on language cues aimed at shaping, reinforcing and changing people's opinions and beliefs. How language changes people's attitudes and behaviors have received less attention from the computational community than argumentation, although there have been important preliminary work (Persing and Ng, 2017; Carlile et al., 2018). Farra et al., (2015) built regression models to predict essay scores based on features extracted from opinion expressions and topical elements. Chatterjee et al., (2014) used verbal descriptors and para-verbal markers of hesitation to predict speakers' persuasiveness on website housing videos of product reviews. When looking at persuasion in the context of online forum discussions (Wei et al., 2016), Tan et al., (2016) found that on the Change My View subreddit, interaction dynamics such as the language interplay between opinion holders and other participants provides highly predictive cues for persuasiveness. Using the same dataset, Wel et al., (2016) extracted a set of textual information and social interaction features to identify persuasive posts.

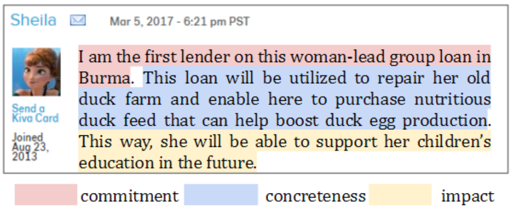
Recently, Pryzant et al., (2017) introduced a neural network with an adversarial objective to select text features that are predictive of some outcomes but decorrelated with others and further analyzed the narratives highlighted by such text features. Further work extended the model to induce narrative persuasion lexicons predictive of enrollment from course descriptions and sales from product descriptions (Pryzant et al., 2018a), and the efficacy of search advertisements (Pryzant et al., 2018b). Similar to their settings, we use the outcomes of a persuasive description to supervise the learning of persuasion tactics, and our model can similarly induce lexicons associated with successful narrative persuasion by examining highly attentional words associated with persuasion outcomes. Our work differs both in our semi-supervised method and also because we explicitly draw on the theoretical literature to model the persuasion strategy for each sentence in requests, allowing requests to have multiple persuasion strategies; our induced lexicons can thus be very specific to different persuasion strategies.

Other lines of persuasion work predict the success of requests on peer-to-peer lending or crowdfunding platforms, and mainly exploit request attributes like project description (Greenberg et al., 2013), project videos (Dey et al., 2017), and social predictors such as the number of backers (Etter et al., 2013) or specific types of project updates (Xu et al., 2014). Among them, only a few investigated the effect of language on the success of requests. Althoff et al., (2014) studied donations in Random Acts of Pizza on Reddit, using the social relations between recipient and donor plus linguistic factors to predict the success of these altruistic requests. Based on a corpus of 45K crowd-funded projects, Mitra and Gilbert (2014) found that 9M phrases commonly present in crowd-funding have reasonable predictive power in accounting for variance around successful funding, suggesting that language does exhibit some general principles of persuasion. Although this prior work offers predictive and insightful models, most studies chose their persuasion labels or variables without reference to a taxonomy of persuasion techniques nor to a principled method of choosing them. Some exceptions include Yang and Kraut (2017), Dey et al., (2017), and Rosenthal and McKeown (2017). For example, Yang and Kraut (2017) looked at the effectiveness of a set of persuasive cues in Kiva requests and found that certain heuristic cues are positively correlated with lenders' contribution.

Inspired by these prior work, we operationalize persuasive strategies based on theories of persuasion and aim to learn local structures/labels of sentences based on the global labels of paragraphs/requests. Our task is different from most previous work on semi-supervised learning for NLP (Liang, 2005; Yang et al., 2017) that focuses on the setting with partial data labels. While in computer vision, there is a lot of prior work in using image global labels to uncover local pixel level labels and bounding boxes of objects (Oquab et al., 2015; Pinheiro and Collobert, 2015), the investigation of this task in NLP, to the best of our knowledge, is novel and could potentially have much broader applications.

3 Research Context

We situate this research within the team forums of Kiva[1], the largest peer-to-peer lending website. These self-organized lending teams are built around common interests, school affiliation or location. In such teams, members can post messages in their team discussion board to persuade other members to lend to a particular borrower. One such message is shown in Figure 1. A borrower, Sheila, posted a message on Kiva to request loans for woman-led group. As highlighted in the figure, she made use of several persuasion strategies such as commitment, concreteness, and impact to render her request more persuasive. We define the *persuasiveness* score of a request message as the number of team members (in log-scale) who read the message and make loans to the mentioned borrower. We then regard this overall persuasiveness of messages as high-level supervision for training our model to determine which persuasion strategy is used in each sentence inside each message.



I am the first lender on this woman-lead group loan in Burma. This loan will be utilized to repair her old duck farm and enable here to purchase nutritious duck feed that can help boost duck egg production. This way, she will be able to support her children's education in the future.

Figure 1: An anonymized advocating message that persuaded 5 members to lend to the mentioned borrower. Persuasion strategies are highlighted.

4 Persuasion Strategies

Numerous studies have investigated the basic principles that govern getting compliance from people (Cialdini and Garde, 1987; Petty et al., 1983). In this work, we utilized Chiaken's 1980 systemic-heuristic model of social information processing, which suggests that people process persuasive requests by assessing the quality of arguments (systematic processing) or by relying on heuristic rules (heuristic processing). Building on that, we first borrow several commonly used heuristic principles (Cialdini and Garde, 1987) that are also suitable for our context as below.

- **Scarcity** states that people tend to value an item more as soon as it becomes rare, distinct or limited. For example, take the use of 'expire'in this message: *"This loan is going to expire in 35 mins..."*.
- The principle of **Emotion** says that making messages full of emotional valence and arousal affect (e.g., describing a miserable situation or a happy moment) can make people care and act, e.g., "*The picture of widow Bunisia holding one of her children in front of her meager home brings tears to my eyes..*", similar to *Sentiment* and *Politeness* used by Althoff et al., (2014) and Tan et al., (2016), and *Pathos* used by Hidey et al., (2017).
- **Commitment** states that once we make a choice, we will encounter pressures that cause us to respond in ways that justify our earlier decision, and to convince others that we have made the correct choice. Here it could be mentioning their contribution in the message, e.g., *"I loaned to her already."*
- **Social Identity** refers to people's self-concept of their membership in a social

---

[1] `https://www.kiva.org/`

group, and people have an affinity for their groups over others, similar to *name mentions* in Rosenthal and McKeown (2017). Thus if a loan request comes from their own groups, they are more likely to contribute, such as *"For those of you in our team who love bread, here is a loan about bakery."*

- **Concreteness** refers to providing concrete facts or evidence, such as "*She wishes to have a septic tank and toilet, and is 51% raised and needs $825*", similar to *Claim* and *Evidence* (Zhang et al., 2016; Stab and Gurevych, 2014)), *Evidentiality* (Althoff et al., 2014), and *Logos* (Hidey et al., 2017).

We also propose a new strategy to capture importance or impact on these requests:

- **Impact and Value** emphasizes the importance or bigger impact of this loan, such as *"... to grow organic rice. Then, she can provide better education for her daughter"*.

Note that other persuasion tactics such as *Reciprocity* — "feel obligated to return something after receiving something of value from another" — and *Authority* — "comply with the requests of authority in an unthinking way to guide their decisions"— are also widely used in persuasive communication. However, in this context, we did not observe enough instances of them.

5 Semi-supervised Neural Net

Given a message $M = \{S_0, S_1, ..., S_L\}$ consisting of L sentences that the author posted to advocate for a loan, our task is to predict the persuasion strategies p_i employed in each sentence S_i, $i \in [0, L]$. However, purely constructing a large-scale dataset that contains such labels of sentence-level persuasion strategy is often time-consuming and expensive. Instead, we propose to utilize a small amount of labeled and a large amount of unlabeled data. We design a semi-supervised hierarchical neural network to identify the persuasive strategies employed in each sentence, where the supervision comes from the sentence-level labels g in a small portion of data and the overall persuasiveness scores y of messages. The overall architecture of our method is shown in Figure 2.

5.1 Sentence Encoder

Given a sentence S_i with words $w_{i,j}$, $j \in [0, l]$ and l is the sentence length, a GRU (Bahdanau et al., 2014) is used to incorporate contextual cues of words into hidden state $h_{i,j}$. This GRU reads the sentence S_i from $w_{i,1}$ to $w_{i,l}$ and encodes each word $w_{i,j}$ with its context into hidden state $h_{i,j}$:

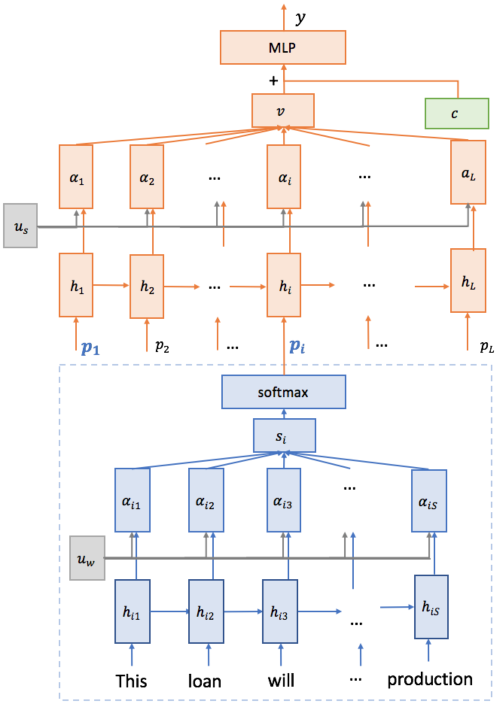


Figure 2: The overall model architecture. The blue part describes the sentence encoder. Sentences with labels of persuasion strategies are highlighted with dark blue like p_1. The orange part shows the document encoder.

$$h_{i,j} = \text{GRU}(W_e w_{i,j}, h_{i,j-1}), j \in [0, l]. \quad (1)$$

where W_e is the word embedding matrix. To learn the characteristic words associated with the persuasive strategy in a sentence, we apply an attention mechanism (Bahdanau et al., 2014; Yang et al., 2016). The representation of those words are then aggregated to form the sentence vector s_i. We formulated this word level attention as follows:

$$u_{i,j} = \tanh(W_w h_{i,j} + b_w) \quad (2)$$

$$\alpha_{i,j} = \frac{\exp(u_{i,j}^\intercal u_w)}{\sum_k \exp(u_{i,k}^\intercal u_w)} \quad (3)$$

$$s_i = \sum_j \alpha_{i,j} h_{i,j} \quad (4)$$

where u_w is a context vector that queries the characteristic words associated with different persuasion strategies. It is randomly initialized and jointly learned from data.

5.2 Latent Persuasive Strategies

We assume that each sentence instantiates only one type of persuasion strategy. For example, a sentence *"She is 51% raised and needs $825 in 3 days"* employs *Scarcity*, trying to emphasize limited time availability. We propose to use the high level representation of each sentence to predict the latent variable:

$$p_i = \text{softmax}(W_v s_i + b_v) \tag{5}$$

5.3 Document Encoder

After obtaining the sentence vector p_i, we can get a document vector in a similar way:

$$h_i = \text{GRU}(p_i, h_{i-1}), i \in [0, L] \tag{6}$$

where L denotes the number of sentences in a message. Similarly, we introduce an attention mechanism to measure the importance of each sentence and its persuasion strategy via a context vector u_s:

$$u_i = \tanh(W_s h_i + b_s) \tag{7}$$

$$\alpha_i = \frac{\exp(u_i^\intercal u_s)}{\sum_k \exp(u_k^\intercal u_s)} \tag{8}$$

$$v = \sum_i \alpha_i h_i \tag{9}$$

5.4 Semi-Supervised Learning Objective

The document vector v is a high-level representation of the document and can be used as a set of features for predicting $\tilde{y}$, the persuasiveness of a message, i.e., how many team members will make loans to the project mentioned in this message. We also include a context vector c to further assist the prediction of making loans. For instance, c could represent the number of team members in a team, the total amount of money contributed by this team in the past, etc.

$$\tilde{y} = W_f[v, c] + b_f \tag{10}$$

We then can use the mean squared error between the predicted and ground truth persuasiveness as training loss. To take advantage of the labeled subset that has sentence level annotation of persuasive strategies, we reformulate this problem as a semi-supervised learning task:

$$l = \gamma \sum_{d \in C_L} (y_d - \tilde{y_d})^2 - \beta \sum -g_i \log p_i \tag{11}$$

$$+ (1-\gamma) \sum_{d' \in C_U} (y_{d'} - \tilde{y_{d'}})^2 \tag{12}$$

Here, C_L refers to the document corpus with sentence level persuasion labels. C_U denotes those without any sentence labels. g_i refers to the persuasion strategy in sentence S_i, and p_i is predicted by our model. γ and β are used as re-weight factors to trade off the penalization and reward introduced by different components.

6 Experiment

6.1 Dataset

Our collaboration with Kiva provided us access to all public data dumps of the team discussion forums on Kiva. Here we only focused on messages that have explicit links because in most cases, members need to include the loan link to better direct others to a specific loan or borrower. After removing messages that do not contain any links, we obtained 41,666 messages that contain loan advocacy. We used Amazon's Mechanical Turk (MTurk) to construct a reliable, hand-coded dataset to obtain the persuasion strategy label for each sentence. To increase annotation quality, we required Turkers to have a United States location with 98% approval rate for their previous work on MTurk. Since messages often contain different numbers of sentences, which might be associated with different sets of persuasion strategies, we sampled 200 messages for each fixed message length ranging from one sentence to six sentences, in order to guarantee that our hand-coded dataset reasonably represents the data. Messages with at most six sentences accounted for 89% percentages among all messages in our corpus. Each sentence in a message was labeled by two Mechanical Turk Master Workers [2]. To assess the reliability of the judges' ratings, we computed the intra-class correlation (ICC), and obtained an overall ICC score of 0.524, indicating moderate agreement among annotators (Cicchetti, 1994). The distribution for each persuasion strategy in the annotated corpus is described in the blue line in Figure 3. We assigned a persuasion label to a sentence if two annotators gave consistent labels for it, and filtered out sentences that annotators disagreed on the label.

In the final annotated corpus, there were 1200 messages, with 2898 sentences. The average number of sentences is 2.4 and the average number of words per sentence is 17.3. For predicting the persuasive strategy in each sentence, we randomly

---

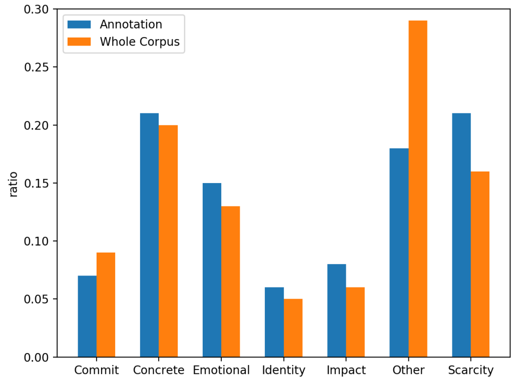

Figure 3: The distribution of each persuasion strategy in the annotation corpus and in the whole unlabeled corpus after prediction.

split 80% of this annotated corpus as the training set (2271 sentences in 1060 messages), 10% as the validation set (322 sentences in 70 messages), and 10% as the testing set (305 sentences in 70 messages). To further utilize supervision from the persuasiveness score of each message, we merged 1060 documents with sentence labels and 40,466 unlabeled messages, using it as the final training set for training semi-supervised models.

6.2 Model Setup and Baselines

We split documents into sentences and tokenize each sentence using Stanford's CoreNLP (Manning et al., 2014). Words appearing less than 5 times were replaced with a special UNK token. We trained the hyperparameters of the models on the validation set using Adam (Kingma and Ba, 2014). Specifically, we set the word embedding dimension to be 128, where the word embeddings are initialized randomly, and GRU dimension to be 256. The learning rate is set to be 5e-5. The balancer γ is the ratio of labeled data in a batch of training data. The balancer β is selected via grid search, searching in a set of (5, 10, 20, 50, 100), resulting in β=10.

We propose several baselines to predict the sentence level persuasion strategies for comparison with our model. (1) ***SVM + BoW*** is a *SVM* classifier with *RBF* kernel using bag-of-words features (one-hot). (2) ***GRU*** uses the hidden state at the last word as features to classify persuasive strategies, a special case of our *SH Net* model without the supervision from the overall persuasiveness scores. (3) ***bi-GRU*** uses bi-directional GRU.

H Net is a hierarchical GRU for classifying strategies with the supervision from the overall persuasiveness scores as shown in Figure 2, but it only adopts all the annotated messages. We denote our semi-supervised hierarchical model as **SH Net** (Semi Hierarchical Net), which utilizes both annotated messages and unlabeled corpus. **Semi-Att Net** builds on **SH Net** by incorporating both word-level and sentence-level attention. In addition to the textual cues in the advocation message, persuasive requests also depend on the context. We introduced a set of contextual descriptors into our semi-supervised hierarchical network, denoted as *SH-Att Plus Net*. Such features include the number of borrowers in this message, the number of team members in a team, the total amount of money contributed by this team, the number of messages ever posted in the discussion board of this team, and the amount of money requested in this loan.

6.3 Results

We evaluated the baselines and our hierarchical neural network models using accuracy, macro-averaged F1 score, macro-averaged precision and macro-averaged recall, as well as RMSE for evaluating the message level persuasiveness score prediction. As we can see in Table 1, when predicting the persuasive strategies (6 types of persuasive strategies plus an *Other* strategy), BoW + SVM gives a performance of 0.347 and a macro F1 of 0.229. A direct neural network *GRU* boosted the accuracy to 0.518, demonstrating the effectiveness of neural networks for sentence classification. When bi-directional contextual information is used, the sentence level prediction performance is 52.1%. Our hierarchical neural network achieved an accuracy of 48.2% and a macro F1 of 0.432. When incorporating the whole corpus of unlabeled messages, our semi-supervised neural network achieved an accuracy of 56.1% (16.4% improvement over *H Net*). This indicates that our semi-supervised model effectively takes advantage of the supervision from the small amount of labeled data and the overall persuasiveness scores. Moreover, we noticed that this semi-supervised neural network not only helps predict the sentence level persuasion strategies, but also assist the prediction of messages' overall persuasiveness with a 9% RMSE decrease. *Semi-Att* outperformed *SH Net* with an accuracy of 56.9%, and a macro F1 score of 0.518. Although the improvement from attention is minor (but significant), it's important for visualizing associations between words, persuasion strategies and persua-

	Evaluating Sentence Level Strategies				Doc Level
Model	**Accuracy**	**Macro F1**	**Macro Precision**	**Macro Recall**	**RMSE**
SVM (RBF) + BoW	0.347	0.229	0.364	0.167	-
GRU	0.518	0.479	0.479	0.479	-
bi-GRU	0.521	0.440	0.445	0.436	-
Hierarchical Net (H Net)	0.482	0.432	0.430	0.432	1.15
Semi Net (SH Net)*	0.561	0.513	0.504	0.522	1.05
Semi-Att Net*	**0.569**	**0.518**	**0.512**	**0.534**	1.04
Semi-Att Plus Net	0.552	0.513	0.515	0.512	**0.87**

Table 1: Results of different models. * indicates that the model is significantly better than the one above it.

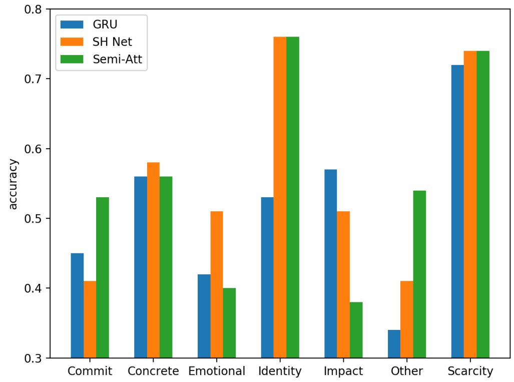

Figure 4: The accuracy for each persuasion strategy evaluated via *GRU*, *SH Net* and *Semi-Att*.

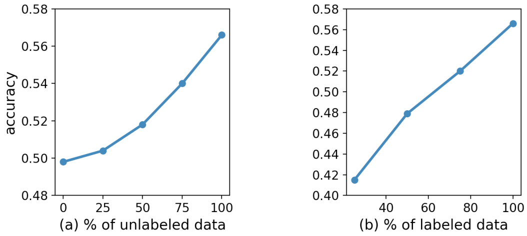

Figure 5: Model performances with different portion of unlabeled data (a) and labeled data (b).

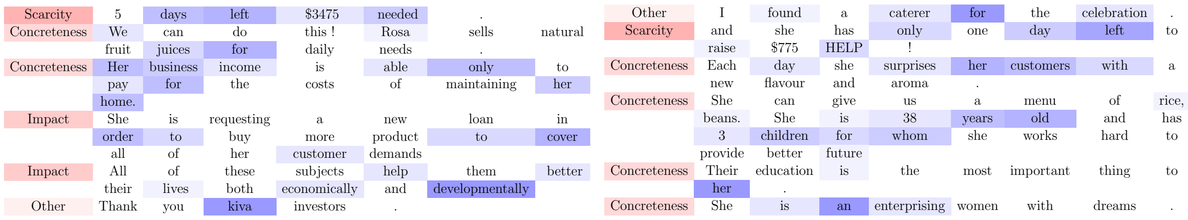
sion outcomes. Interestingly, incorporating contextual descriptors did not help the prediction of persuasion strategies. However, such contextual information strongly predicted the overall persuasiveness, decreasing RMSE to 0.84 from 1.04.

Strategy-Level Performance: We also report the accuracy per persuasion strategy category via *Semi-Att*, *SH Net* and simple *GRU* in Figure 4. It seems that overall neural models are better at capturing persuasion strategies such as concreteness, identity and scarcity. This might be because people are concrete by using specific terms such as numbers or entities that are easy to model. Similar principles might also occur for social identity and scarcity where the use of words such as "*we*", "*our*" and "*expire*", "*left*" can reveal a lot about the persuasion strategies.

Strategy	**Top Ranked Keywords**
Commitment	joined, lenders, loaning, lend, loan just, join, loaned, made, lent
Concreteness	women, married, old, heads, year-old money, sells, years, business, number
Emotion	hard, thank, better, grief, great maybe, help, please, thanks, happy
Identity	promotion, shall, captain, form, number spirits, lenders, member, team
Impact	improve, new, better, products, money to, use, business, more, order
Scarcity	minutes, there's, now, soon, go expire, hours, days, number, left

Table 2: Top ranked keywords for persuasion strategies

Different Percentage of Labeled Data: To figure out the importance of supervision from massages' overall persuasiveness scores, we experiment on *SH Net* with all the labeled messages. To this end, we include all the labeled messages, and vary the percentage of unlabeled corpus from 0%, 25%, 50%, 75%, to 100%, in Figure 5 (a). We found that as the amount of unlabeled messages increases, the accuracy of sentence level prediction increases as well, which further validates the effectiveness of the semi-supervised setting for persuasion strategy prediction. Similarly, to investigate the predictive power introduced by the sentence level labels, we also vary the percentage of labeled messages from 25%, 50%, 75%, to 100% when including the whole unlabeled corpus, as shown in Figure 5 (b). As expected, having more training data about sentence-level annotation increases the prediction performance. Overall, these experiments demonstrate the effectiveness of semi-supervised models for predicting sentence level persuasion strategies. This enables us



Scarcity	5	days	left	$3475	needed	.

Figure 6: Attention Visualization. Left-most columns in red represent sentence-level attention and the remaining columns in blue are word-level attention.

to obtain sentence level labels for any given paragraphs by using a small amount of labeled data.

6.4 Visualization

To validate whether our semi-supervised model captures characteristic words and sentences in requests, we visualize the attention in a sentence in Figure 6. We show the predicted persuasion label for each sentence in a message in red (left-most columns in Figure 6(a) and 6(b)), with the color scale indicating its learned attention weight. Word-level attention is highlighted in blue (remaining columns). As we can see in Figure 6(b), our model places emphasis on *Scarcity*, and highlights words such as "*left*" and "*day*" that carry the scarcity meaning. Similarly, in the second message— *5 days left* 3475 *needed*—our model first labeled the sentence as *Scarcity*, and then picked words such as "*days*" and "*left*". Sentences predicted as *Concreteness* seem to contain specific entities and concepts such as "*business*", "*her*", and "*home*". For *Impact*, our model accurately localizes words like "*in order to*" and "*cover*".

To demonstrate that our model can learn representative words associated with different persuasion strategies, we show the 10 highest-scoring words from sentences with different labels in Table 2. Interestingly, *Commitment* is highly associated with words such as "*made*" and "*loan*". Explicit mentions of "*thanks*" and "*hard*" were found in sentences with *Emotional* labels. Sentences that emphasize their "*team*" as a whole were labeled as *Identity*. Overall, this validates that our model is able to select informative words associated with different persuasion strategies.

For further illustration, we visualized the attention weight distributions of different persuasion strategies. Since the number of sentences inside each message is intertwined with attention weights, we only plotted the distributions for messages with two or three sentences in Figure 7. We observed that *Scarcity*, *Identity*, and *Impact* seem to play a relatively more important role for influencing the success of requests, whereas *Emotional* language, *Commitment* and *Concreteness* seem to concentrate more on the lower weight ranges.

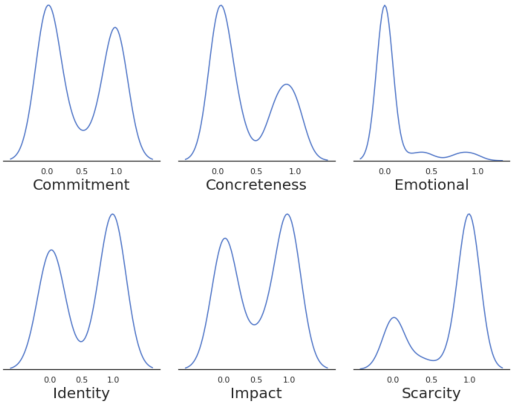

Figure 7: Attention weight distributions of persuasion strategies in requests with 2-3 sentences.

7 Importance of Persuasive Strategies

After applying the semi-supervised hierarchical neural network to the unlabeled 40552 messages, we obtained their sentence-level persuasive strategies usages. We showed the distribution of each persuasive strategy in the whole corpus in Figure 3, as described by the orange line. To further investigate how important each persuasive strategy is for convincing others to make loans, in this section, we present results on which of them are predictive via linear regression. All variables are standardized before entering the regression model. We controlled for the number of team members in a team, the total amount of money contributed by this team, the number of messages posted in the discussion board of this team. Since those variables are highly correlated with each other, we av-

Persuasion Strategy	**Kiva** (Coef.)	**RAOP** (Odds ratio)
Concreteness	0.041***	1.111***
Commitment	-0.015**	1.062
Emotional	0.030***	1.145***
Identity	0.087***	1.104**
Impact/Value	0.024***	1.084*
Scarcity	-0.076***	1.118***

Table 3: The influences of different persuasive strategies on request success on Kiva and RAOP. Here, p<0.001:***; p<0.01:**; p<0.05:*.

eraged them into a single variable to capture these team level attributes. We also controlled for the amount of money the borrower requested. We represented each message as a 6-dimensional vector to capture the amount of each persuasive strategy, which is calculated by selecting the maximum probability associated with each strategy from all sentences in this message. The persuasive strategy features significantly improve the model fit, as indicated by a 11.8% improvement in adjusted R-squared from 0.152 to 0.170. To demonstrate the generalizability of our persuasion strategies and the resulted semi-supervised model, we also applied our *Semi-Att* model to 5671 textual requests for pizza from the Reddit community "Random Acts of Pizza" (RAOP). Specifically, we used the data released by Althoff et al., (2014) where each request asked for a free pizza and the outcome whether its author received a pizza or not was provided in the dataset. Via *Semi-Att*, we were able to obtain the persuasive strategy used in each sentence of each request. Similarly, we built a logistic regression model to predict whether a request will receive the pizza or not, controlling for the community age of the requester, the number of subreddits the requester participated in, his/her number of posts as well as the votes (upvotes - downvotes) this requester had received.

As shown in the column of *RAOP* in Table 3, concreteness is significantly correlated with success on both datasets. This demonstrated that providing more evidence might help readers know the situation better, consistent with the effect of *Evidentiality* in Althoff et al., (2014). Similarly, making the request full of emotions (β=0.030, Odds ratio (OR) =1.145), mentioning the similarity between potential readers and the requester (β=0.087, *OR*=1.104), and talking about the potential impact and value for others (β=0.024, *OR*=1.084) are all significantly associated with increases in the persuasiveness of these requests across two contexts. In contrast, highlighting the urgency of the requests and emphasizing existing contribution to loans (β=-0.015) negatively correlate with request success (β=-0.076) on Kiva, confirming prior work (Yang and Kraut, 2017). This communicates to us that some of those loans might have expired before others read the request and took action given the limited time available, or it could be that members thought their actions might not help if the remaining money needed is high and the time left is low, different from the "limited-time offer" tactics widely used in commercial advertising. To sum up, the two analyses demonstrated that certain persuasive strategies such as *Identity* and *Impact* are consistently effective across two datasets, whereas *Scarcity* and *Commitment* contribute differently and need to be used with caution for different contexts.

8 Conclusion

In this work, we operationalized a set of persuasive strategies widely used in micro-lending platforms based on theories of persuasion, and developed an annotated corpus for identifying persuasion strategies. We designed a semi-supervised hierarchical neural network to identify the persuasive strategies contained in loan requests. Results show that our model improves accuracy considerably. We also showed how different persuasive strategies contribute to request success. In the future, we plan to build a richer taxonomy of persuasion strategies and incorporate additional neural architectures such as variational autoencoders to better represent sentences in each message to further assist the modeling of persuasiveness. Beyond the text, images and even audios may provide additional insights on the successes of persuasive requests. Our model also has important applications to other domains, such as in computational advertisements, micro-funding platforms and political campaigns.

Abstract

We introduce Recursive Routing Networks (RRNs), which are modular, adaptable models that learn effectively in diverse environments. RRNs consist of a set of functions, typically organized into a grid, and a meta-learner decision-making component called the *router*. The model jointly optimizes the parameters of the functions and the meta-learner's policy for routing inputs through those functions. RRNs can be incorporated into existing architectures in a number of ways; we explore adding them to word representation layers, recurrent network hidden layers, and classifier layers. Our evaluation task is natural language inference (NLI). Using the MULTINLI corpus, we show that an RRN's routing decisions reflect the high-level genre structure of that corpus. To show that RRNs can learn to specialize to more fine-grained semantic distinctions, we introduce a new corpus of NLI examples involving implicative predicates, and show that the model components become fine-tuned to the inferential signatures that are characteristic of these predicates.

1 Introduction

Human cognition has an extraordinary ability to modularize, decomposing problems and solving them by re-composing elements from prior solutions, and this ability is nowhere more evident than in language understanding (Partee, 1984; Janssen, 1997). Most machine learning architectures lack this modularity, which limits their ability to generalize and leaves them susceptible to *catastrophic interference* (McCloskey and Cohen, 1989) – forgetting past skills when acquiring new ones.

We propose to address this need for modularity by applying Routing Networks (Rosenbaum et al., 2017) to natural language understanding. Routing Networks are self-organizing networks with two components (Figure 1): a set of function blocks which can be applied to transform the input, and a router which makes decisions about which function block to apply next. Here we introduce Recursive Routing Networks (RRNs), in which there is a single set of composable functions, recursively chosen by the router. RRNs can be applied to different components of modern language understanding architectures with full end-to-end training. The model jointly optimizes the parameters of selected sub-functions and the meta-learner's policy for how to route inputs through those functions. As a result, individual sub-functions specialize to specific inputs, and paths through the grid of sub-functions can similarly be trained to reflect specific concepts and capabilities.

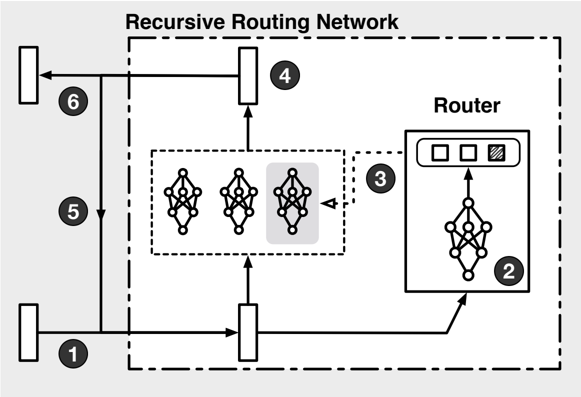

Figure 1: Given a premise–hypothesis pair x, e.g., *t managed to do s* and *t did s* (1), the model needs to learn to predict *entails* (6). The router (2) estimates the value of applying each of the available sub-functions to the input. Given that *manage* has certain semantic properties, the router may select (3) a function f_1 specialized to them. The module is then applied (4), yielding $f_1(x)$. This process repeats (5), now using $f_1(x)$, selecting and applying another sub-function, and so on, until the router is confident in its prediction (6).

RRNs share many intuitions with other modular methods like: Neural Module Networks (Andreas et al., 2015, 2016; Hu et al., 2017), which learn to construct a neural network from pre-defined modules; the Compositional Recursive Learner (Chang et al., 2018), a closely related approach that uti-

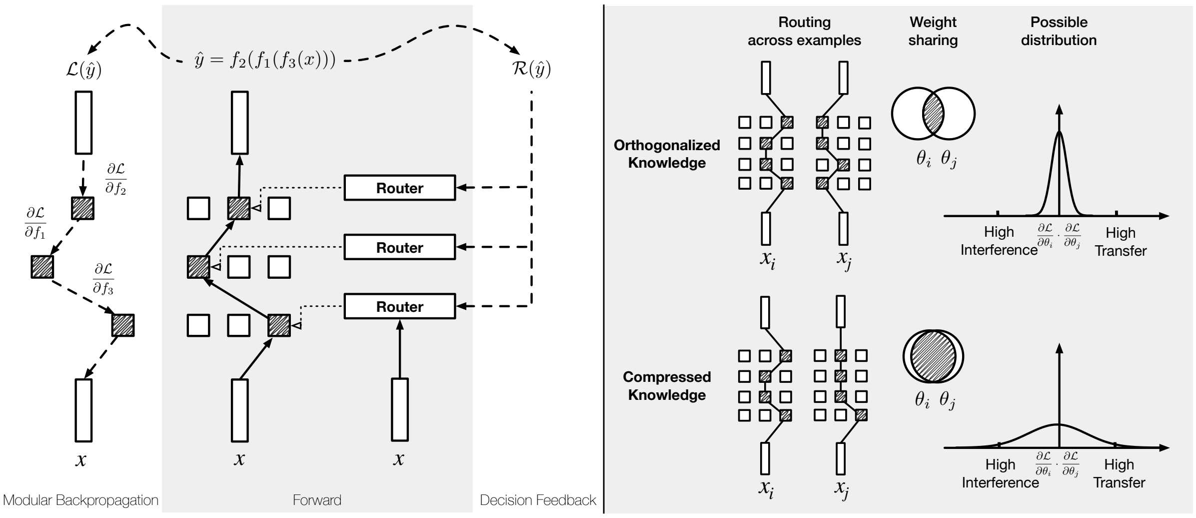

Figure 2: Left: **RRN learning.** Forward (grey background) and backward passes (white background) during the training of a rollout of an RRN with three blocks (width) and limited to depth three (height). In this unrolled version, a *path* is the sequence of function blocks selected by the router. Right: **The dilemma of weight sharing and the transfer–interference trade-off.** When examples are learned using largely separate weights, there is a thin possible distribution of gradient dot products that limits interference, which unfortunately also limits transfer. This is beneficial for unrelated examples, but frustrates the learning of related ones. Conversely, when examples are learned using largely shared weights, there is a wide possible distribution of gradient dot products that allows for both high magnitude transfer and interference. This is beneficial for related examples, but maximizes interference when examples are unrelated. With RRNs, we provide our network with an unprecedented degree of leverage to learn to navigate this trade-off.

lizes curriculum learning to solve arithmetic and vision problems; and ModularNetworks (Kirsch et al., 2018), which extend Routing Networks with an EM-like training approach.

We show how to incorporate RRNs into different neural components (word representation layers, recurrent network hidden layers, classifier layers), and we study their application to natural language inference (NLI), in which premise–hypothesis pairs are labeled for whether the premise entails, contradicts, or is neutral with respect to the hypothesis. We chose this task because reasoning in natural language involves context-sensitive interpretation of words and sentences as well as compositional structure. We make use of the MULTINLI corpus (Williams et al., 2018), which includes text from multiple genres that we expect to condition linguistic senses in complex ways. Our experiments show that RRNs learn policies and components that reflect this genre structure, which leads to superior performance.

We also introduce a new corpus of NLI examples involving implicative constructions like *manage to*, *be able to*, and *fail to* (Karttunen, 1971, 2012). This corpus follows the design of many recent NLI corpora, but with the added challenges of reasoning about implicatives, which have logical *signatures* that interact compositionally with each other and with surrounding semantic operators. Our experiments show that trained RRN model components become fine-tuned to these signatures. Finally, we introduce an extension of the framework which leverages a *Dispatcher* for situations where meta-information is not available at test time, obtaining very promising results.

2 Background and Motivation

RRNs are a natural extension of the Routing Networks introduced by Rosenbaum et al. (2017), themselves part of a larger class of conditional computation models (Bengio et al., 2015). Routing Networks combine trainable modules with a meta-learner called a *router*, which is typically trained using reinforcement learning, though any hard-decision making algorithm could be used. Given an example, the router selects a module and applies it, yielding an activation that can be the input to another routing iteration. As Rosenbaum et al. observe, this can be modelled as a recursive process where the router is applied repeatedly to define complex paths through the modules. The final routed output is passed to additional layers or interpreted as the output of the network (Figure 1).

We are motivated to consider Routing Networks, and in particular recursive variants, in order to address the transfer–interference trade-off

(Riemer et al., 2019). Vanilla neural networks latently attempt to solve a very difficult problem of deciding when to orthogonalize and compress knowledge (Figure 2, right). When two examples are learned with the same weights, there is high potential for transfer as well as interference. This is good for related examples because it maximizes the potential for transfer. However, weight sharing is bad for unrelated examples, as it increases the likelihood of interference. In contrast, when two examples are learned using different weights, there is low potential for transfer and interference. This is beneficial for unrelated examples, but limits the potential for learning about commonalities between related ones. RRNs extend vanilla neural networks by granting them the leverage to navigate this trade-off by making global functional decisions at the module level. As a result, RRNs explicitly make decisions to compress or orthogonalize knowledge between examples by deciding whether to share specific weights.

Thus far, hard-selection routing has not been applied to language domains. Zaremoodi et al. (2018) introduced a *soft* version of routing that falls within a larger class of Mixtures of Experts (MoE) models (Jacobs et al., 1991). However, MoE models differ from RRNs in two crucial ways. First, MoE models generally do not consider the recursive application of functions. The promise is that we can compose functions to reflect the compositional aspects of a problem. Imagine we have a sentence encoding and we want to answer a particular question. We can now condition the router on the question, so that it applies exactly the functions required that translate the encoding to extract the answer. Second, MoE models do not allow for nearly the level of specialization as those based on routing, because they do not eliminate weight sharing across modules and instead only gate the sharing. In practice, this still leads to significant interference across tasks.

Composition of modules has been widely explored for question answering, starting with Andreas et al. (2015). Andreas et al. (2016) learn to assemble a deep neural network on-the-fly from a pre-specified inventory of neural modules using tree-structured layouts based on linguistic analysis. Chang et al. (2018) also explore routing, but with problems described in pseudo-language rather than natural language.

3 Recursive Routing Networks

We now provide a formal presentation of RRNs and show how to incorporate them into existing neural architectures.

3.1 The Routing Paradigm

Formally, the router bases its decision on the tuple $\langle \mathfrak{f}(x), m \rangle$, where x is the sample, $\mathfrak{f}(x) = f_i \circ \cdots \circ f_k(x)$ is the composition of all applied functions from the set of all available functions $\mathcal{F} = \{f_1, \ldots, f_b\}$, and m is a vector that contains meta-information that can be utilized by the router – for example, an embedding for its genre or semantic classification. The router consists of a policy $\pi(\mathcal{F} | \langle \mathfrak{f}(x), m \rangle)$ that determines which of the functions in $\mathcal{F}$ to apply for a given state $\langle \mathfrak{f}(x), m \rangle$. Once a new function f_k is selected, the latest activation (and, thereby, the state) gets updated to $f_k \circ \mathfrak{f}(x)$, and the process repeats.[1]

We focus on the recursive case where the set $\mathcal{F}$ is generally the same for each decision. Apart from being the more general formulation, this form of recursivity allows more weight sharing and better compositional generalization. While there is no necessary upper limit to the number of selections, we found that limiting the number to a maximum of d makes the learning more stable. Consequently, the total number of possible routing paths available is b^d.

Decision Making One of the most important design choices for the router concerns the meta-learning algorithm. Routing is limited to *hard* decision-making algorithms, in particular a stochastic reparameterization using the Gumbel-Softmax function (Jang et al., 2016; Maddison et al., 2016) and reinforcement learning (RL) algorithms. As with other recent approaches to compositional architectures with hard selections (Bengio et al., 2015; Shazeer et al., 2017; Kirsch et al., 2018), routing networks can suffer from *module collapse*, a lack of diversity in the router's decision making. This general problem, common in architectures that jointly train decision making and functions, stems from an early over-estimation of the value of specific functions. This leads to these functions being selected and trained more than others, until these functions are indeed so good

---

[1] Some architectures have constraints that prevent repeated selection of the same functions in $\mathcal{F}$. In these cases, the router has to be restricted to select from only a compatible subset of $\mathcal{F}$.

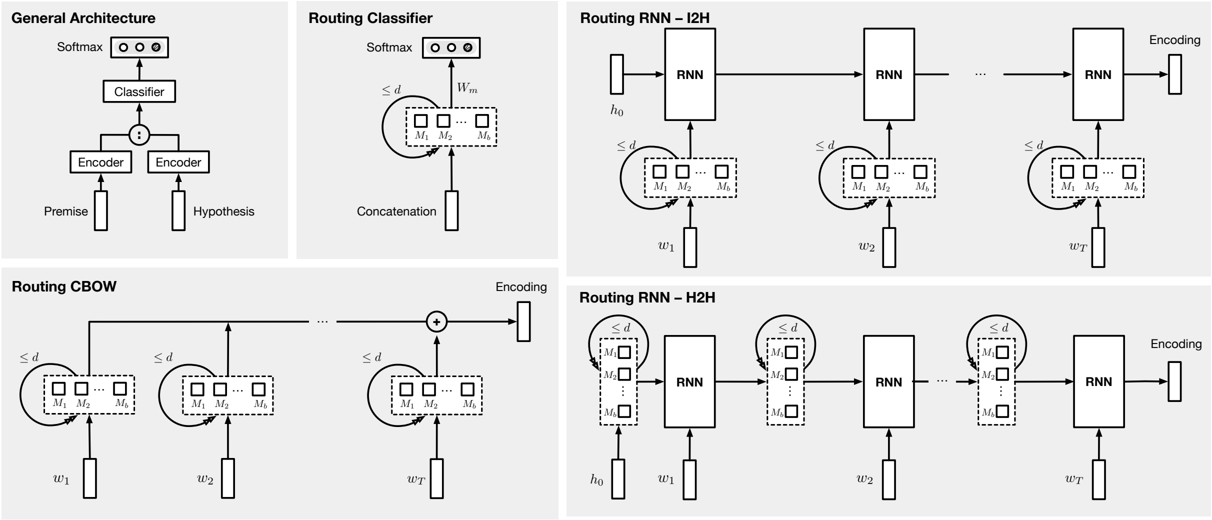

Figure 3: Top left: Our general NLI architecture. Top center: Routing the classifier. Lower left: Word representation routing of a CBOW encoder. Top right: Routing an RNN input transformation. Bottom right: Routing an RNN hidden transformation.

that others are not considered. To mitigate this, we start with a strategy proposed by Rosenbaum et al. (2017): exclusively conditioning the router on meta-information provided by the datasets and storing the router's policy in a table. We found that this stabilizes early training. During later training, we can replace the meta-information hard assignment rule with a meta-information "guesser". We implement this guesser with what Rosenbaum et al. call a *Dispatcher*, an approximation-based sub-policy that estimates the meta-information for each sample and passes it to the corresponding policies (Section 5).

Losses and Training Once the routing procedure terminates, the selected modules are trained using standard optimization techniques, such as backpropagation with stochastic gradient descent (SGD). The decision-making algorithm is either also trained with SGD (Gumbel reparameterization) or trained using reinforcement learning. As we focus on classification problems, our core loss function $\mathcal{L}_{class}(y, \hat{y})$ is the standard cross-entropy loss. We backpropagate this loss along the function path chosen by the router for input x.

Reinforcement Learning Rewards For RL training of the router, we define the reward r for the reinforcement learner to be the sum of the negative classification loss and an additional regularization reward that encourages diversity in the selection of modules:

$$r = -\mathcal{L}_{class}(y, \hat{y}) + r_{reg} \tag{1}$$

For discussion of this reward, see Appendix A.1.

3.2 Architectures

If not otherwise mentioned, we assume that the routed modules are all fully connected layers with the same input and output dimensions. We furthermore assume that the router is always selecting from the same set of functions when defining paths through the routing layers, as this straightforwardly allows recursion in the relevant sense.

Routing Classifiers The simplest method we explore involves routing the layers of a classifier. To do this, we define a fixed set of b fully connected layers (FC), each of the same dimensionality, and we allow the router to choose any path through this set up to a maximum length d (Figure 3, top center). The final activation produced by the chosen path is then densely connected to a non-routed output layer. To further model each example's dependence on its class, we hard-select this output layer based on the meta-information label m for x:

$$W_m \left(\mathrm{FC}_{k_1} \circ \cdots \circ \mathrm{FC}_{k_d}(x)\right) + b_m \tag{2}$$

Routing RNN Encoders In routing RNNs we focus on their two core transformations: from the hidden state at time step t_k to time step t_{k+1}, and from the input to the hidden state. We have designed routing architectures for both of them. In this paper, we start with LSTMs, but the techniques are straightforward to adapt to other cell types.

Figure 3, top right, shows an architecture where we route the input-to-hidden (I2H) transformation. Similarly, Figure 3, bottom right, shows an architecture where we route the hidden-to-hidden

(H2H) transformation. While these transformations are often designed as single fully connected layers, we allow a recursive application of d steps from a selection of b modules to be applied. The selections for the transformations f, i, o, c are tied to be the same. The corresponding transformation (in form of their weight matrices $W_{f/i/o/c}$ for I2H and $U_{f/i/o/c}$ for H2H) becomes:

$$\begin{aligned} &K = \mathrm{FC}_k \circ \cdots \circ \mathrm{FC}_m(x_t), \\ &\forall K \in \{W_f, W_i, W_o, W_c, U_f, U_i, U_o, U_c\} \end{aligned} \tag{3}$$

Routing CBOW Encoders We also experiment with routing a continuous bag of words (CBOW) encoding. As routing after the main addition is just routing the classifier, we instead add a word-level transformation before the addition (Figure 3, bottom left). This transformation can again be routed recursively (with up to d steps through b modules). The entire CBOW model can be defined as (with $w_1, \ldots, w_t$ as premise or hypothesis):

$$\begin{aligned} \mathrm{CBOW}_R(w_1, \ldots, w_t) = \\ \textstyle\sum_{i=1}^{t} \mathrm{FC}_{k_1} \circ \cdots \circ \mathrm{FC}_{k_d}(w_i) \end{aligned} \tag{4}$$

Routing Transformers The Transformers model (Vaswani et al., 2017) was recently pretrained as a language model (Radford et al., 2018) achieving impressive results on several NLI datasets. Since the corpus for pretraining is not available, we instead use the parameter-files distributed by the authors.[2] The encoding consists of twelve Transformer-blocks. Each block consists of a convolutional attention layer followed by two convolutional layers (along with several dropout and layer-norm layers). This allows routing at different levels of granularity, of which we investigate two: routing entire blocks and routing the attention step within each block. As we use pre-defined parameters, we cannot apply the blocks or the attention layers recursively. Furthermore, we have to add routing in the fine-tuning phase of using Transformers by creating b copies of each routed module (the depth is necessarily $d = 12$). When fine-tuning, the router then diversifies the initially identical modules.

4 Experiments

We now evaluate the routing architectures introduced in the previous section, along with minimally different non-routing baselines. Our experiments focus on NLI, using the MULTINLI corpus (Williams et al., 2018) and a new English Corpus of Implicatives, the *Stanford Corpus of Implicatives* (SCI). In both, each example is a premise/hypothesis pair labeled with one of *entails*, *contradicts*, or *permits*. What is special about MULTINLI and SCI in the current context is that the examples also have meta-information that can be used to guide the router: a genre label for MULTINLI and an implicative signature for SCI. We expect our routing models to leverage this information during policy and parameter learning.

For all models (except Transformers), we adopt the architecture in Figure 3, top left, in which the premise and hypothesis are processed separately, and the final representations of each are concatenated and fed into the classifier layers. We explore two methods for input processing: (i) pretrained word representations (GloVe; Pennington et al. 2014) and (ii) pretrained contextualized representations (ELMo; Peters et al. 2018). For all non-routed models, we provide explicit access to the genre label via special keywords put in front of each sentence before encoding. The routed models use this label as meta-information.

Unless otherwise specified, we used embedding and hidden dimensions of 300. The classifier consists of three fully connected layers with input and output dimensions of 600 (also when routed). The final layer projects from 600 to the output dimension, 3. The classifier nonlinearities are ReLUs. We train the modules using Adam (Kingma and Ba, 2014) with a learning rate of $1e{-}3$ and the router using SGD with a learning rate of $3e{-}4$ (for additional details, see Appendix A.5). For Transformers, all hyperparameters are determined by the published parameter files.

In experiments with different decision making algorithms (see Appendix A.5), we found that the Gumbel-Softmax reparameterization performed 10% worse on average, with *much* higher variance. QLearning was consistently as good as other more complex RL algorithms, so we report only our QLearning experiments. As Routing Networks have more parameters than their non-routed counterparts, we ran experiments with larger non-routed networks. We found that this did not affect performance, only resulting in more overfitting.

Table 1: Results for MULTINLI and SCI with different baselines and their routed versions. We report average accuracy with confidence intervals over five runs with different seeds. For Transformers, we found that finetuning was highly volatile. We therefore report test results from the best-of-5 train models. *All results for nested SCI were computed by fine-tuning the same network previously trained on joint. 'WP' stands for Word Projection, '+D' for Dispatching, 'I2H' for Input-to-Hidden routing, and 'H2H' for Hidden-to-Hidden routing. Italics mark scores whose confidence intervals overlap with the best scores.

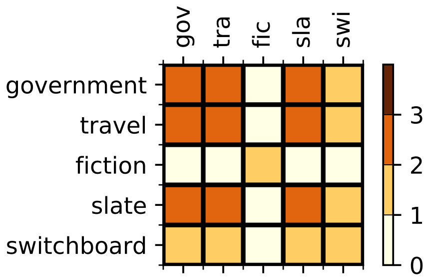

Figure 4: Path (module selection) overlap for MULTINLI between genres with the CBOW GloVe WP model. The diagonal represents the number of function blocks applied for a genre. A maximum of three means that two genres would be routed through the exact same functions.

4.1 Experiments with MULTINLI

The MULTINLI corpus contains 392,702 training examples, 10K dev examples, and 10K test examples. The examples come from 5 genres: fiction, government reports, the *Slate* website, the Switchboard corpus (Godfrey and Holliman, 1997), and Berlitz travel guides. We treat these genre labels as meta-information for the model (Section 3.1).

Our MULTINLI results are given in Table 1, and the learning dynamics in Figure 5. The best model combines the Transformer base model with routing in the attentional layers. Our methods for routing the RNN seem to be less successful, but word-representation routing offers clear benefits with the CBOW base model. Interestingly, the baseline (non-routed) models perform at the same level as the very similar models without genre labels evaluated by Williams et al. (2018). It seems that these models are not able to take advantage of the meta-information. In contrast, RRNs seem to provide the space needed to condition linguistic senses on these labels.

Our hypothesis is that routing will not only lead to better performance on diverse tasks like MULTINLI, but also that the paths – i.e., the sequence of functions selected by the router – followed by the network will reflect high-level task structure. Figure 4 suggests that this is the case for MULTINLI. Here we show the degree of path-overlap for all pairs of genres. As we might expect, government (the 9/11 report), Slate (current affairs), and travel cluster together, as distinct from the two more isolated genres (Switchboard; spoken language) and fiction (mostly from the 20th century).

4.2 Experiments with Implicatives

Karttunen (1971) discovered that implicative constructions, such as *manage* and *waste chance* (e.g. *They wasted their chance to win*), have *signatures*, which characterize the inferences they support in positive and negative contexts. This makes them

the order compelled him to appear as a witness	**entails**	he appeared as a witness
we have missed an opportunity to examine the art market today	**contradicts**	we have examined the art market today
Mr Odinga had not been forced to change his plans	**permits**	Mr Odinga had changed his plans

Table 2: Examples from SCI randomly chosen from the validation set. Each row contains a triplet formed by a premise (left column), a hypothesis (right column), and a label specifying one of the three possible relations (*entails*, *contradicts*, *permits*) holding between premise and hypothesis. The last row contains an example of a probabilistic implicative (see the main text).

particularly informative for NLI predictions.

For instance, the positive sentence *Joan managed to solve the problem* entails *Joan solved the problem*, and the negative sentence *Joan didn't manage to solve the problem* contradicts *Joan solved the problem*, so we say that the verb *manage* has the signature + | − (MacCartney and Manning, 2009; Karttunen, 2016). In contrast, *waste chance* has the opposite signature, since *they wasted the chance to befriend him* contradicts *they befriended him*, and *they didn't waste the chance to befriend him* entails *they befriended him*. There are seven implicative signatures: six were previously known (Karttunen, 1971, 2012), and we found an additional one (+ | +; e.g. *take no time to*). See Appendix C for additional details.

Signatures are compositional: when two or more implicative constructions are composed in a sentence, they create a *nested implicative construction* whose signature is determined by the signatures of the individual verbs (Nairn et al., 2006). For example, *John managed to remember to get the keys* entails *John got the keys*, where the nested implicative *manage to remember* has the overall signature + | −. We also see a more limited form of compositionality inside phrasal implicatures; their signatures are often largely determined by the lexical semantic family of their constituent words. Therefore, signatures make implicatives ideal for evaluating different degrees of compositional generalization with RRNs, as they provide valuable meta-information (Section 3.1).

4.2.1 A Corpus of Implicative Constructions

Our SCI dataset contains ≈10K premise–hypothesis pairs. All seven signature types are represented, in addition to pragmatic signatures, which have inferential biases (see Appendix C).

We provide SCI[3] in three versions for all single and phrasal implicatives.[4] In the *joint* version, the underlying distribution of implicatives is shared across train, validation, and test splits. In the *disjoint* version, a different subset of implicatives is used in train from those used in validation and test. This allows us to test generalization to unseen constructions. Although disjoint with respect to constructions, the constructions are carefully distributed so that all the underlying signatures and most lexical items are represented in all splits. The lexical items that make up implicative constructions overlap between the splits. For example, *take vow* appears only in training and validation, while *make vow* only appears in test. The last version is *mismatch*, where different subsets of the signatures are present in training/validation and test (see appendix C for more details).

Data collection for SCI proceeded as follows: we collected at least 12, and most often 20, seed premises from examples found in Google Books and on the web. For each example, six hypotheses were created by expert annotators.[5] These six examples were constructed in two steps: first, the premise was taken to be the seed sentence, and three hypotheses were created to exhaust the label space in relation to the premise. Second, the premise was taken to be the *negation* of the seed sentence, and a different set of three hypotheses was created to also exhaust the label space with respect to this negated sentence. For example, one of the seeds for *manage* was *I managed to see who it was*. From this, annotators produced by hand a

---

[3] https://nlp.stanford.edu/projects/sci/

[4] We provide nested constructions as a separate extension, with the exception of a few nested implicatives that were used in the development version of this corpus, for which the results are presented here. In the final version of the corpus, single and phrasal implicatives will be separated from nested implicatives. See the Appendix for more details.

[5] Native speakers of English trained in semantics at the undergraduate level, with expertise in implicatives.

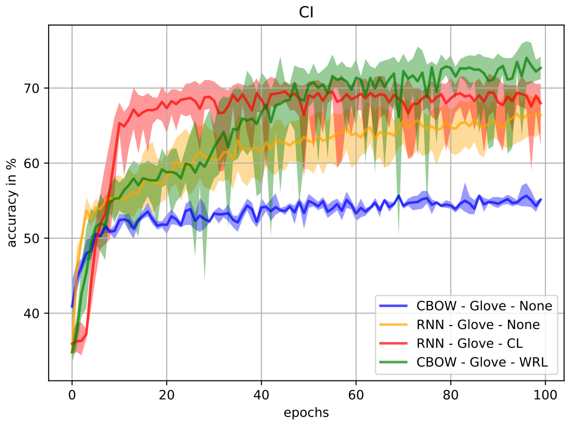

Figure 7: Learning on SCI (joint) with GloVe inputs.

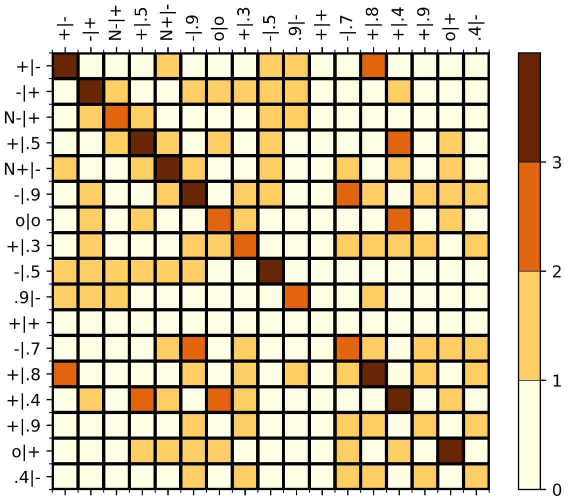

Figure 6: The path-overlap between different signatures on SCI, using the CBOW GloVe WP model, for $b = 4$, $d = 3$. N+|− and N−|+ are nested signatures.

negated seed, *I did not manage to see who it was.* Then three hypotheses were generated for each of these two premises. Finally, each example was labeled by the author of the hypothesis examples.

Validation was performed on a randomly selected subset of constructions. Two additional votes were cast by different linguists, resulting in three label votes for each example in the subset. The gold label was then defined to be the majority class from this set of votes. The Fleiss κ shows high inter-annotator agreement (Table 3).

4.2.2 Implicatives Results and Analysis

For each example in SCI, we use its associated implicative signature as the meta-information label. This serves as a subtler kind of semantic information than genre. The learning dynamics of different models are shown in Figure 7. As Table 1 shows, RRNs lead to considerable gains in performance over most benchmarks. Recursive routing of the classifier helps consistently with all models. Even simple word-level routing yields major improvements for CBOW. As with MULTINLI, we believe that the modules allow the conditioning of linguistic senses. Routing at the word-level for sequential models seems suboptimal here. The training accuracies ($> 99.5\%$) suggest that the problem is overfitting. Intuitively, routing can assign too many exclusive parameters to each class; and as the samples within these classes are similar to begin with, remembering them can be easier for the network than for non-routed networks.

We expect examples with similar signatures to be routed along similar paths. Figure 6 summarizes the path-overlap between different signatures. Some similar paths involve reversals of polarity, which calls for further scrutiny. However, many of these similarities make intuitive sense. For example, `+|.4` and `+|.5` are highly similar, as are `-|.7` and `-|.9`. In addition, the isolation of the unusual signature `+|+` (limited to just two constructions) seems expected, as does the affinity of the nested signatures `N+|-` and `N-|+` to their unnested counterparts. However, as shown in Table A3, some signatures only contain very few samples, resulting in highly noisy routing paths.

4.3 Navigating the Transfer–Interference Trade-off

We now seek to provide intuitive explanation for how RRNs help in navigating the transfer–interference trade-off. We have characterized the trade-off in terms of controlling weight sharing between examples. While baseline networks can learn to navigate this trade-off if they are optimized for the appropriate objective (Riemer et al., 2019), in general these models do not have available supervision on how to do this and so optimize greedily for the current example. As such, early experiments with the baseline, non-routed models show that examples with neutral signatures, such as ○ | ○ and ○ | +, are the first to be learned. We noticed that baseline sequence models learned to classify *take vow* much earlier in the training process, as the word *vow* is lexicalized through training on *make vow* examples. However, its performance decreases over time as *take* is lexicalized through training on examples of other implicatives with different signatures, such as *take chance*. This behavior is the characteristic outcome of catastrophic interference: learning *take chance* results in decreased performance on *take vow* as the two examples interfere. This is a particularly revealing instance as these two phrasal verbs are similar on the surface, but have quite different semantic properties, as reflected by their signatures. However, given that RRNs are able to route them differently (Figure 6), interference is less likely. It is also possible that routing helps with the transfer related to similar examples, an avenue we want to explore in the future.

5 Prediction without Meta-Information

We have shown that high-quality meta-information can be extremely useful. Unfortunately, it is often not available at test-time. To compensate, we evaluated an RRN extension in which an additional neural network module is trained to assign examples to meta-information classes (genres for MULTINLI; signatures for SCI). When we trained this model jointly, we found that it was unstable and did not perform well. However, if this model is introduced after RRN training on examples with known meta-information, then the results are extremely promising. We call this *Dispatcher Training* ('+D'), borrowing similar terminology from Rosenbaum et al. (2017). Table 1 includes an initial evaluation of this variant with a CBOW base model and WP routing. As we can see, accuracy actually *increases* by a small amount over WP alone.

Additionally, having +D allows the network to generalize better to unseen examples and unseen patterns. Consider the relative performance drop for CBOW WP+D from the full joint SCI dataset (75.56%) to disjoint (−0.69%) and from disjoint (74.87%) to mismatch (−3.79%), and compare this to the plain WP version: full (74.95%) to disjoint (−1.04%), and disjoint (73.91%) to mismatch (−5.22%)

6 Conclusion

This paper introduced Recursive Routing Networks and showed how to incorporate them into a variety of different neural architectures; we explored a range of possibilities for this, and the techniques generalize to other options straightforwardly. Our evaluations focused on NLI. We showed in particular that our RRNs can effectively leverage the meta-information in the MULTINLI corpus and in our new corpus focused on implicatives; not only do RRNs use this information to achieve superior accuracy, but they also learn sub-structure that reflects this high-level information, and our Dispatcher variant extends the framework to situations where the relevant meta-information is not available for testing. We believe exploring more powerful variants of dispatching is an interesting avenue for future work, as is pretraining routing models on language model tasks using large corpora. It is our hope that these lessons extend to other richly compositional, context-sensitive language understanding tasks.

Appendices

A Architecture Details

A.1 The reward design

Rosenbaum et al. (2017) found that it was helpful in incentivizing different routing strategies to add a regularization reward to each action made. This reward is constructed by computing the average count of choosing a particular module, multiplied by a scaling factor. We also use a similar reward. In particular, we compute it for module m_k and action a as follows:

$$r_c(m_k) = \begin{cases} (1-\alpha) * r'_c(m_k) + \alpha & \text{if } k = a \\ r'_c(m), & \text{otherwise} \end{cases}$$

As we want this reward to sum to 1 over all modules, we normalize. Additionally, we want to scale this reward to stay constant even for larger routing depths. The result is therefore scaled as such:

$$r_c = \frac{r_c}{d \sum r_c}$$

A.2 Losses

To make the backpropagation step to train the network more efficient, we combine the losses

$$\mathcal{L}_{total}(x, \hat{y}) = \mathcal{L}_{class}(x, \hat{y}) + \mathcal{L}_{RL}(x, r) \qquad (5)$$

where $\mathcal{L}_{RL}(x, r)$ is the loss defined by the chosen RL algorithm.

A.3 Routing RNNs

We modify LSTMs as originally defined by Hochreiter and Schmidhuber (1997):

$$f_t = \sigma_g(W_f x_t + U_f h_{t-1} + b_f) \qquad (6)$$

$$i_t = \sigma_g(W_i x_t + U_i h_{t-1} + b_i) \qquad (7)$$

$$o_t = \sigma_g(W_o x_t + U_o h_{t-1} + b_o) \qquad (8)$$

$$\begin{aligned} c_t = {} & f_t \circ c_{t-1} + i_t \circ \\ & \sigma_c(W_c x_t + U_c h_{t-1} + b_c) \end{aligned} \qquad (9)$$

$$h_t = o_t \circ \sigma_h(c_t) \qquad (10)$$

However, analogous architectures can be implemented for GRUs or different LSTMs. Here, either architecture has two core transformations – one from the hidden state at time step t_k to time step t_{k+1}, and one from the input (in our case, word embeddings) to the hidden state. We have designed architectures that route either.

The resulting equations (6), (7), and (8) for the input-to-hidden routing model illustrated in Figure 3, top right, become (with g being a placeholder for f, i, o):

$$\begin{aligned} g_t = {} & \sigma_g(\text{FC}_{g,k_d} \circ \text{FC}_{g,k_{d-1}} \circ \cdots \text{FC}_{g,k_d} x_t \\ & + U_g h_{t-1} + b_g) \end{aligned} \qquad (11)$$

Similarly, the equations (6), (7), and (8) for the hidden-to-hidden routing model in Figure 3, bottom right, become (with g being a placeholder for f, i, o):

$$\begin{aligned} g_t = {} & \sigma_g(W_g x_t + \text{FC}_{g,k_d} \circ \text{FC}_{g,k_{d-1}} \circ \cdots \\ & \text{FC}_{g,k_d} h_{t-1} + b_g) \end{aligned} \qquad (12)$$

A.4 Routing Transformers

The following describes the two different approaches for routing transformers. When routing entire transformer blocks (TB), we have:

$$\mathcal{F}_{k_t} = \{\text{TB}_{t,1}, \text{TB}_{t,2}, \ldots, \text{TB}_{t,b}\} \qquad (13)$$

However, as the routing functions for routing the attention layers are interleaved with the other block-layers (BL), the basic routing chain changes to:

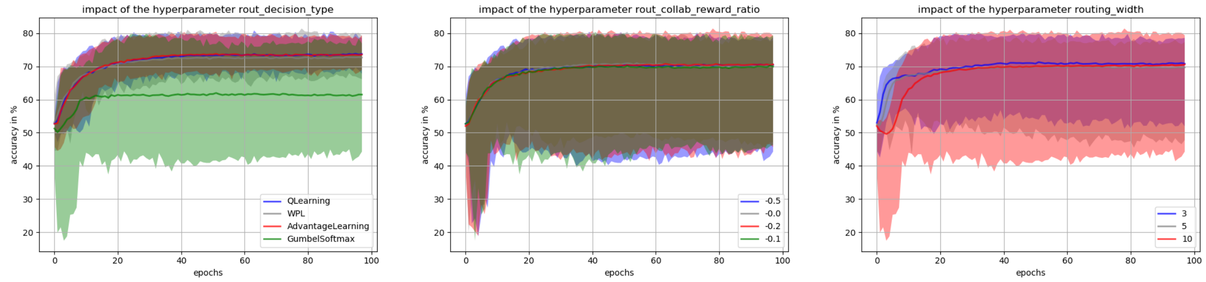
$$f_R(x) = f_{k_1} \circ \text{BL} \circ \ldots \circ \text{BL} \circ f_{k_d}(x) \circ \text{BL} \qquad (14)$$

and the routing module sets are (with AL as attention layers):

$$\mathcal{F}_{k_t} = \{\text{AL}_{t,1}, \text{AL}_{t,2}, \ldots, \text{AL}_{t,b}\} \qquad (15)$$

A.5 Hyperparameter Search

We found that training the router with Adam can become unstable and stay at random baseline performance. In contrast, we found that using Adam for the modules increased performance by around 1%. When training a routing utilizing the Gumbel-Softmax reparameterization, we tested Adam and SGD exclusively, and settled for Adam. We found the module learning rate of $1e{-}3$ and the router learning rate of $3e{-}4$ by performing sweeps over the learning rate from $1e{-}2$ to $1e{-}4$ for the module training and from $1e{-}2$ to $1e{-}5$ for the router training, roughly by decrements of factor 3. In general, we found a branching size of $b = 3$ to work best (although performance for $b = 5$ was nearly identical), after sweeps for $b \in \{2, 3, 5, 10, 15, 20\}$. As we also specify the maximum recursion depth, we generally allow up to $d = 3$ recursive steps. Higher ds add to training time, but neither increase nor decrease performance significantly, as the router (nearly) never learns to apply more than three transformations anyway. Figure A1 shows the effects of the value of the decision making algorithm, the value of the regularization reward, and of the routing width. Most notably, Gumbel-Softmax routing performs



(a) Effect of the decision-making algorithm.

(b) Effect of the regularization reward value.

(c) Effect of the routing width.

Figure A1: Encoder Routing Strategies.

on average 10% worse than RL algorithms, with variance that is nearly an order of magnitude larger. Also, larger routing width has similar expected performance but increases the variance. The value of the regularization reward has little effect on expected performance.

B Implicatives Experiments

Routed models that achieve good performance on SCI show a strong indication of proper learning of entailment and contradiction, and some difficulties with neutral cases, as indicated by the confusion matrix in Table A1. An inspection of common errors of the CBOW WP model shows a number of cases related to the probabilistic component of the signature. For example, *Jerry got a chance to pitch* was marked as contradicting *Jerry did not manage to pitch*, when the gold label is indeed *permits*. In this case, if the premise is true then there is a small chance that the author would regard the hypothesis as false and therefore predict *contradicts* as the model did. Other errors involve coreference, such as the prediction of entailment between *you took the time to review my presentation* and *you reviewed his presentation*.

Relation	entailment	contradiction	neutral	Totals
entailment	35	2	10	47
contradiction	2	33	5	40
neutral	7	6	28	41
Totals:	44	41	43	128

Table A1: Confusion Matrix.

C Implicatives Corpus

Implicative constructions yield a judgment about the truth of their complement clause under at least one polarity. Some are simple verbs like *manage* and *fail*, while some are phrasal constructions like *meet one's duty* and *waste a chance*.

C.1 Signatures

The signature of an implicative indicates the relation between the matrix clause and complement clause. The symbol + indicates an entailment of the complement clause, the symbol − indicates an entailment of the negation of the complement clause, and the symbol *o* indicates no entailment relation to the complement clause. A signature consists of a left symbol, which indicates the entailment relation to the complement clause when the matrix clause is in a positive environment, and the right symbol, which indicates the entailment relation to the complement clause when the matrix clause is in a negative environment.

For example, in the notation of MacCartney and Manning (2009) and Karttunen (2016), the signature of *manage* is + | −. This means a sentence with *manage* entails its complement in positive contexts, and contradicts its complement in negative contexts. As such, *Joan didn't manage to solve the problem* contradicts *Joan solved the problem.*

Fail and *lack foresight* have the implicative signature − | +. *NP failed/lacked the foresight to VP* contradicts *NP VPed* and entails *NP didn't VP*. This is negative entailment under positive polarity (−), positive entailment under negative polarity (+).

Two-way implicatives like *manage* and *fail* yield an entailment under positive and negative polarity. One-way implicatives such as *force* (+ | ○), *prevent* (− | ○), *be able* (○ | −), and *hesitate* (○ | +) yield an entailment, + or −, only under one polarity and no entailment (○) under the other.[6]

---

[6] In addition to the entailment properties that we focus on in this study, most implicative constructions also have another component of meaning, sometimes called *presupposition* (Karttunen, 1971; Baglini and Francez, 2016), some-

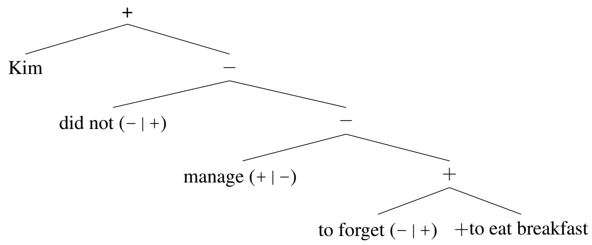


Figure A2: Computation of the inference *Kim ate breakfast* entailed by the premise *Kim did not manage to forget to eat breakfast*.

There are seven known implicative signatures, six of them documented earlier (Karttunen, 1971, 2012). In the course of collecting data for this study, we came across a new implicative construction that had been missed in all previous studies. We code *take no time* and *waste no time* as + | + because, in the vast majority of cases we looked at, the presence or absence of negation makes no difference. *I wasted no time to jump on board* and *I didn't waste no time to jump on board* both mean that I jumped on board quickly.

C.2 Pragmatic Implicatives

In cases where there is no logical entailment, one-way implicatives may give rise to an *invited inference* (Geis and Zwicky, 1971). *I was able to speak but just didn't know what to say* is not a contradiction. But if the speaker leaves out the *but*-clause, she probably means that not only was she able to speak, but she in fact did speak. There is no invited inference in cases like *Bill Clinton had a chance to kill Bin Laden before the September 11 attacks*, because it is common knowledge that the attempt to do so failed. Insofar as these cases depend on an encyclopedic knowledge about the world, as opposed to a dictionary/lexical knowledge, we use the terminology *pragmatic implicatives* for this type of verbs.

The likelihood of invited inferences varies greatly depending on the construction. They are very likely with *be able*, less likely with *have chance*, and very unlikely with *hesitate*. To better match actual usage, we assign to *be able* not the semantically correct ○ | − signature but `.9` | −, reflecting our estimation that there is a `.9` probability that the author is using the construction as if it were a two-way + | − implicative. We code *have chance* as `.4` | − and *hesitate* as ○ | +.

C.3 Nested Implicatives

Implicative constructions can be nested inside of other implicative constructions, as in *Stan managed to fail to propose to Carol*. The meaning of nested implicatives is compositional; the signature of a nested implicative can be determined algorithmically by the signatures of the single implicatives that compose it (Nairn et al. 2006; see Figure A2). Since *manage* has the signature + | − and *fail* is − | +, the nested constructions *manage to fail* and *fail to manage* are both − | +. Thus, the example above entails that Stan did not propose to Carol, as does *Stan failed to manage to propose to Carol*. The entailments are the same, but the implications associated with *manage* and *fail* differ depending on the nesting.

Some implicative constructions – e.g., *manage* and *fail*, *remember*, and *forget* – can be nested in one another. In many cases, only one order makes sense. It is easy to find examples of *happen to turn out* – e.g., *it happened to turn out to be a success* – but a search for *turn out to happen* sentences does not turn up any. One can even find triply nested implicative constructions, such as *don't forget to remember not to forget to watch the finale of series 2 tonight*, but they are rare.

The single-word, phrasal implicatives, and (a few) nested implicatives used in our data set are listed in Table A3. The release version of SCI will contain additional doubly-nested constructions (the complete list is in Table A4), and will have additional splits.

C.4 Corpus Versions and Extension

The three different versions of the dataset described in the article are *joint*, *disjoint*, and *mismatch*. The *disjoint* test set contains the implicatives listed in Table A2, and thus the implicatives listed there are not contained in train and validation.

The *mismatch* version of the SCI corpus contains all signatures in validation and test, but only a restricted set for train. Table A5 contains the subsets available on each split.

---

times *conventional implicature* (Karttunen and Peters, 1979). For example, *Marco failed to show up for work* implicates that Marco tried or was expected to show up for work. The *NatLog* system (MacCartney and Manning, 2009) computes entailments of implicatives but no presuppositions. No current NLP system does. The difference between entailment and presupposition/conventional implicature can be made with the question *Did Marco fail to show up for work?* This question asks whether Marco showed up for work or not; *fail* indicates that the speaker thinks that Marco tried or was expected to come to work.

In addition to the versions, we included all the nested constructions as a separate extension to the dataset using the same format. This expansion can then be easily used as a test set for generalization to longer sequences.

Figure A3 show the distribution of lengths, counted in word tokens, for premises and hypotheses. Figure A4 shows the distribution of lengths for both premises and hypotheses.

Structural Neural Encoders for AMR-to-text Generation

Marco Damonte **Shay B. Cohen**

`m.damonte@sms.ed.ac.uk`
`scohen@inf.ed.ac.uk`

Abstract

AMR-to-text generation is a problem recently introduced to the NLP community, in which the goal is to generate sentences from Abstract Meaning Representation (AMR) graphs. Sequence-to-sequence models can be used to this end by converting the AMR graphs to strings. Approaching the problem while working directly with graphs requires the use of graph-to-sequence models that encode the AMR graph into a vector representation. Such encoding has been shown to be beneficial in the past, and unlike sequential encoding, it allows us to explicitly capture reentrant structures in the AMR graphs. We investigate the extent to which reentrancies (nodes with multiple parents) have an impact on AMR-to-text generation by comparing graph encoders to tree encoders, where reentrancies are not preserved. We show that improvements in the treatment of reentrancies and long-range dependencies contribute to higher overall scores for graph encoders. Our best model achieves 24.40 BLEU on LDC2015E86, outperforming the state of the art by 1.1 points and 24.54 BLEU on LDC2017T10, outperforming the state of the art by 1.24 points.

1 Introduction

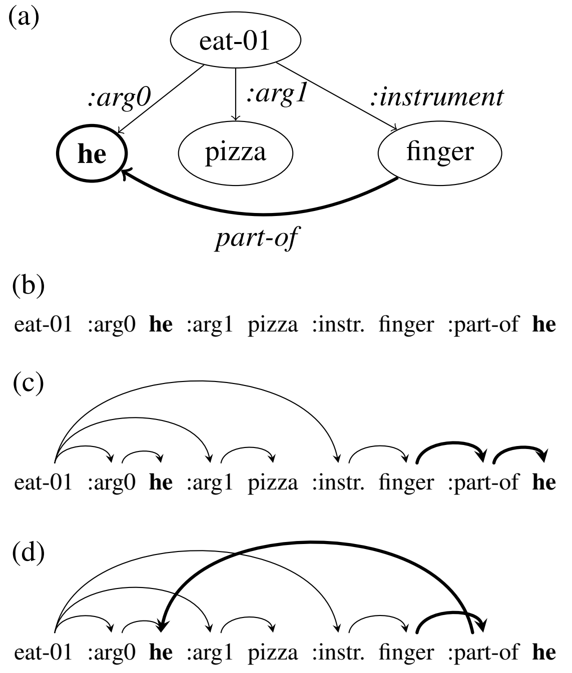

Figure 1: (a) AMR for the sentence *He ate the pizza with his fingers* and different input representations: (b) sequential; (c) tree-structured; (d) graph-structured. The nodes and edges in bold highlight a reentrancy.

Abstract Meaning Representation (AMR; Banarescu et al. 2013) is a semantic graph representation that abstracts away from the syntactic realization of a sentence, where nodes in the graph represent concepts and edges represent semantic relations between them. AMRs are graphs, rather than trees, because co-references and control structures result in nodes with multiple parents, called reentrancies. For instance, the AMR of Figure 1(a) contains a reentrancy between *finger* and *he*, caused by the possessive pronoun *his*. AMR-to-text generation is the task of automatically generating natural language from AMR graphs.

Attentive encoder/decoder architectures, commonly used for Neural Machine Translation (NMT), have been explored for this task (Konstas et al., 2017; Song et al., 2018; Beck et al., 2018). In order to use sequence-to-sequence models, Konstas et al. (2017) reduce the AMR graphs to sequences, while Song et al. (2018) and Beck et al. (2018) directly encode them as graphs. Graph encoding allows the model to explicitly encode reentrant structures present in the AMR graphs. While central to AMR, reentrancies are often hard to treat both in parsing and in generation. Previous work either removed them from the graphs, hence obtaining sequential (Konstas et al.,

Proceedings of NAACL-HLT 2019, pages 3649–3658
Minneapolis, Minnesota, June 2 - June 7, 2019.

2017) or tree-structured (Liu et al., 2015; Takase et al., 2016) data, while other work maintained them but did not analyze their impact on performance (e.g., Song et al., 2018; Beck et al., 2018). Damonte et al. (2017) showed that state-of-the-art parsers do not perform well in predicting reentrant structures, while van Noord and Bos (2017) compared different pre- and post-processing techniques to improve the performance of sequence-to-sequence parsers with respect to reentrancies. It is not yet clear whether explicit encoding of reentrancies is beneficial for generation.

In this paper, we compare three types of encoders for AMR: 1) sequential encoders, which reduce AMR graphs to sequences; 2) tree encoders, which ignore reentrancies; and 3) graph encoders. We pay particular attention to two phenomena: reentrancies, which mark co-reference and control structures, and long-range dependencies in the AMR graphs, which are expected to benefit from structural encoding. The contributions of the paper are two-fold:

- We present structural encoders for the encoder/decoder framework and show the benefits of graph encoders not only compared to sequential encoders but also compared to tree encoders, which have not been studied so far for AMR-to-text generation.
- We show that better treatment of reentrancies and long-range dependencies contributes to improvements in the graph encoders.

Our best model, based on a graph encoder, achieves state-of-the-art results for both the LDC2015E86 dataset (24.40 on BLEU and 23.79 on Meteor) and the LDC2017T10 dataset (24.54 on BLEU and 24.07 on Meteor).

2 Input Representations

Graph-structured AMRs AMRs are normally represented as rooted and directed graphs:

$$\begin{aligned}&G_0 = (V_0, E_0, L),\\ &V_0 = \{v_1, v_2, \ldots, v_n\},\\ &root \in V_0,\end{aligned}$$

where V_0 are the graph vertices (or nodes) and $root$ is a designated root node in V_0. The edges in the AMR are labeled:

$$\begin{aligned}&E_0 \subseteq V_0 \times L \times V_0,\\ &L = \{\ell_1, \ell_2, \ldots, \ell_{n'}\}.\end{aligned}$$

Each edge $e \in E_0$ is a triple: $e = (i, label, j)$, where $i \in V_0$ is the parent node, $label \in L$ is the edge label and $j \in V_0$ is the child node.

In order to obtain unlabeled edges, thus decreasing the total number of parameters required by the models, we replace each labeled edge $e = (i, label, j)$ with two unlabeled edges: $e_1 = (i, label), e_2 = (label, j)$:

$$\begin{aligned}&G = (V, E),\\ &V = V_0 \cup L = \{v_1, \ldots, v_n, \ell_1, \ldots, \ell_{n'}\},\\ &E \subseteq (V_0 \times L) \cup (L \times V_0).\end{aligned}$$

Each unlabeled edge $e \in E$ is a pair: $e = (i, j)$, where one of the following holds:

1. $i \in V_0$ and $j \in L$;
2. $i \in L$ and $j \in V_0$.

For instance, the edge between *eat-01* and *he* with label *:arg0* of Figure 1(a) is replaced by two edges in Figure 1(d): an edge between *eat-01* and *:arg0* and another one between *:arg0* and *he*. The process, also used in Beck et al. (2018), tranforms the input graph into its equivalent Levi graph (Levi, 1942).

Tree-structured AMRs In order to obtain tree structures, it is necessary to discard the reentrancies from the AMR graphs. Similarly to Takase et al. (2016), we replace nodes with $n > 1$ incoming edges with n identically labeled nodes, each with a single incoming edge.

Sequential AMRs Following Konstas et al. (2017), the input sequence is a linearized and anonymized AMR graph. Linearization is used to convert the graph into a sequence:

$$\begin{aligned}&x = x_1, \ldots, x_N,\\ &x_i \in V.\end{aligned}$$

The depth-first traversal of the graph defines the indexing between nodes and tokens in the sequence. For instance, the root node is x_1, its leftmost child is x_2 and so on. Nodes with multiple parents are visited more than once. At each visit, their labels are repeated in the sequence, effectively losing reentrancy information, as shown in Figure 1(b).

Anonymization removes names and rare words with coarse categories to reduce data sparsity. An alternative to anonymization is to employ a copy mechanism (Gulcehre et al., 2016), where the models learn to copy rare words from the input itself. In this paper, we follow the anonymization approach.

3 Encoders

In this section, we review the encoders adopted as building blocks for our tree and graph encoders.

3.1 Recurrent Neural Network Encoders

We reimplement the encoder of Konstas et al. (2017), where the sequential linearization is the input to a bidirectional LSTM (BiLSTM; Graves et al. 2013) network. The hidden state of the BiLSTM at step i is used as a context-aware word representation of the i-th token in the sequence:

$$e_{1:N} = \mathrm{BiLSTM}(x_{1:N}),$$

where $e_i \in \mathbb{R}^d$, d is the size of the output embeddings.

3.2 TreeLSTM Encoders

Tree-Structured Long Short-Term Memory Networks (TreeLSTM; Tai et al. 2015) have been introduced primarily as a way to encode the hierarchical structure of syntactic trees (Tai et al., 2015), but they have also been applied to AMR for the task of headline generation (Takase et al., 2016). TreeLSTMs assume tree-structured input, so AMR graphs must be preprocessed to respect this constraint: reentrancies, which play an essential role in AMR, must be removed, thereby transforming the graphs into trees.

We use the Child-Sum variant introduced by Tai et al. (2015), which processes the tree in a bottom-up pass. When visiting a node, the hidden states of its children are summed up in a single vector which is then passed into recurrent gates.

In order to use information from both incoming and outgoing edges (parents and children), we employ bidirectional TreeLSTMs (Eriguchi et al., 2016), where the bottom-up pass is followed by a top-down pass. The top-down state of the root node is obtained by feeding the bottom-up state of the root node through a feed-forward layer:

$$h^{\downarrow}_{\text{root}} = \tanh(W_r h^{\uparrow}_{\text{root}} + b),$$

where $h^{\uparrow}_i$ is the hidden state of node $x_i \in V$ for the bottom-up pass and $h^{\downarrow}_i$ is the hidden state of node x_i for the top-down pass.

The bottom up states for all other nodes are computed with an LSTM, with the cell state given by their parent nodes:

$$h^{\downarrow}_i = \mathrm{LSTM}(h^{\uparrow}_{p(i)}, h^{\uparrow}_i),$$

where $p(i)$ is the parent of node x_i in the tree. The final hidden states are obtained by concatenating the states from the bottom-up pass and the top-down pass:

$$h_i = \left[h^{\downarrow}_i; h^{\uparrow}_i\right].$$

The hidden state of the root node is usually used as a representation for the entire tree. In order to use attention over all nodes, as in traditional NMT (Bahdanau et al., 2015), we can however build node embeddings by extracting the hidden states of each node in the tree:

$$e_{1:N} = h_{1:N},$$

where $e_i \in \mathbb{R}^d$, d is the size of the output embeddings.

The encoder is related to the TreeLSTM encoder of Takase et al. (2016), which however encodes labeled trees and does not use a top-down pass.

3.3 Graph Convolutional Network Encoders

Graph Convolutional Network (GCN; Duvenaud et al. 2015; Kipf and Welling 2016) is a neural network architecture that learns embeddings of nodes in a graph by looking at its nearby nodes. In Natural Language Processing, GCNs have been used for Semantic Role Labeling (Marcheggiani and Titov, 2017), NMT (Bastings et al., 2017), Named Entity Recognition (Cetoli et al., 2017) and text generation (Marcheggiani and Perez-Beltrachini, 2018).

A graph-to-sequence neural network was first introduced by Xu et al. (2018). The authors review the similarities between their approach, GCN and another approach, based on GRUs (Li et al., 2015). The latter recently inspired a graph-to-sequence architecture for AMR-to-text generation (Beck et al., 2018). Simultaneously, Song et al. (2018) proposed a graph encoder based on LSTMs.

The architectures of Song et al. (2018) and Beck et al. (2018) are both based on the same core computation of a GCN, which sums over the embeddings of the immediate neighborhood of each node:

$$h_i^{(k+1)} = \sigma\left(\sum_{j \in \mathcal{N}(i)} W_{(j,i)}^{(k)} h_j^{(k)} + b^{(k)}\right),$$

where $h_i^{(k)}$ is the embeddings of node $x_i \in V$ at layer k, σ is a non-linear activation function, $\mathcal{N}(i)$ is the set of the immediate neighbors of x_i, $W_{(j,i)}^{(k)} \in \mathbb{R}^{m \times m}$ and $b^{(k)} \in \mathbb{R}^m$, with m being the size of the embeddings.

It is possible to use recurrent networks to model the update of the node embeddings. Specifically, Beck et al. (2018) uses a GRU layer where the gates are modeled as GCN layers. Song et al. (2018) did not use the activation function σ and perform an LSTM update instead.

The systems of Song et al. (2018) and Beck et al. (2018) further differ in design and implementation decisions such as in the use of edge label and edge directionality. Throughout the rest of the paper, we follow the traditional, non-recurrent, implementation of GCN also adopted in other NLP tasks (Marcheggiani and Titov, 2017; Bastings et al., 2017; Cetoli et al., 2017). In our experiments, the node embeddings are computed as follows:

$$h_i^{(k+1)} = \sigma\left(\sum_{j \in \mathcal{N}(i)} W_{\mathrm{dir}(j,i)}^{(k)} h_j^{(k)} + b^{(k)}\right), \quad (1)$$

where $\mathrm{dir}(j,i)$ indicates the direction of the edge between x_j and x_i (i.e., outgoing or incoming edge). The hidden vectors from the last layer of the GCN network are finally used to represent each node in the graph:

$$e_{1:N} = h_1^{(K)}, \ldots, h_N^{(K)},$$

where K is the number of GCN layers used, $e_i \in \mathbb{R}^d$, d is the size of the output embeddings.

To regularize the models we apply dropout (Srivastava et al., 2014) as well as edge dropout (Marcheggiani and Titov, 2017). We also include highway connections (Srivastava et al., 2015) between GCN layers.

While GCN can naturally be used to encode graphs, they can also be applied to trees by removing reentrancies from the input graphs. In the experiments of Section 5, we explore GCN-based models both as graph encoders (reentrancies are maintained) as well as tree encoders (reentrancies are ignored).

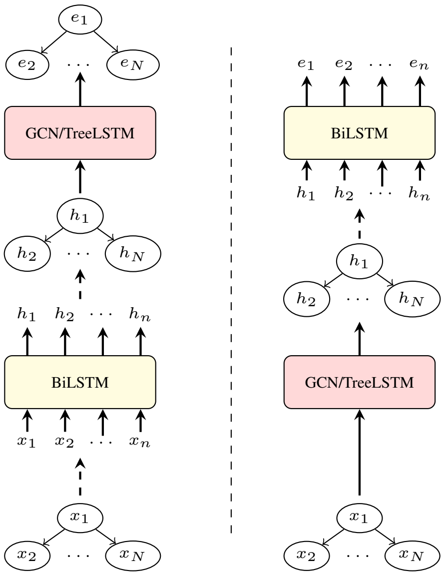

Figure 2: Two ways of stacking recurrent and structural models. Left side: structure on top of sequence, where the structural encoders are applied to the hidden vectors computed by the BiLSTM. Right side: sequence on top of structure, where the structural encoder is used to create better embeddings which are then fed to the BiLSTM. The dotted lines refer to the process of converting the graph into a sequence or vice-versa.

4 Stacking Encoders

We aimed at stacking the explicit source of structural information provided by TreeLSTMs and GCNs with the sequential information which BiLSTMs extract well. This was shown to be effective for other tasks with both TreeLSTMs (Eriguchi et al., 2016; Chen et al., 2017) and GCNs (Marcheggiani and Titov, 2017; Cetoli et al., 2017; Bastings et al., 2017). In previous work, the structural encoders (tree or graph) were used on top of the BiLSTM network: first, the input is passed through the sequential encoder, the output of which is then fed into the structural encoder. While we experiment with this approach, we also propose an alternative solution where the BiLSTM network is used on top of the structural encoder: the input embeddings are refined by exploiting the explicit structural information given by the graph. The refined embeddings are then fed into the BiLSTM networks. See Figure 2 for a graphical representation of the two approaches. In our experiments, we found this approach to be more effective. Compared to models that interleave structural and recurrent components such as the systems of Song et al. (2018) and Beck et al. (2018), stacking the components allows us to test for their contributions more easily.

4.1 Structure on Top of Sequence

In this setup, BiLSTMs are used as in Section 3.1 to encode the linearized and anonymized AMR. The context provided by the BiLSTM is a sequential one. We then apply either GCN or TreeLSTM on the output of the BiLSTM, by initializing the GCN or TreeLSTM embeddings with the BiLSTM hidden states. We call these models SeqGCN and SeqTreeLSTM.

4.2 Sequence on Top of Structure

We also propose a different approach for integrating graph information into the encoder, by swapping the order of the BiLSTM and the structural encoder: we aim at using the structured information provided by the AMR graph as a way to refine the original word representations. We first apply the structural encoder to the input graphs. The GCN or TreeLSTM representations are then fed into the BiLSTM. We call these models GCNSeq and TreeLSTMSeq.

The motivation behind this approach is that we know that BiLSTMs, given appropriate input embeddings, are very effective at encoding the input sequences. In order to exploit their strength, we do not amend their output but rather provide them with better input embeddings to start with, by explicitly taking the graph relations into account.

5 Experiments

We use both BLEU (Papineni et al., 2002) and Meteor (Banerjee and Lavie, 2005) as evaluation metrics.[1] We report results on the AMR dataset LDC2015E86 and LDC2017T10. All systems are implemented in PyTorch (Paszke et al., 2017) using the framework OpenNMT-py (Klein et al., 2017). Hyperparameters of each model were tuned on the development set of LDC2015E86. For the GCN components, we use two layers, ReLU activations, and tanh highway layers. We use single layer LSTMs. We train with SGD with the initial learning rate set to 1 and decay to 0.8. Batch size is set to 100.[2]

We first evaluate the overall performance of the models, after which we focus on two phenomena that we expect to benefit most from structural encoders: reentrancies and long-range dependencies. Table 1 shows the comparison on the development split of the LDC2015E86 dataset between sequential, tree and graph encoders. The sequential encoder (Seq) is a re-implementation of Konstas et al. (2017). We test both approaches of stacking structural and sequential components: structure on top of sequence (SeqTreeLSTM and SeqGCN), and sequence on top of structure (TreeLSTMSeq and GCNSeq). To inspect the effect of the sequential component, we run ablation tests by removing the RNNs altogether (TreeLSTM and GCN). GCN-based models are used both as tree encoders (reentrancies are removed) and graph encoders (reentrancies are maintained).

Input	Model	BLEU	Meteor
Seq	Seq	21.40	22.00
Tree	SeqTreeLSTM	21.84	22.34
	TreeLSTMSeq	22.26	22.87
	TreeLSTM	22.07	22.57
	SeqGCN	21.84	22.21
	GCNSeq	**23.62**	**23.77**
	GCN	15.83	17.76
Graph	SeqGCN	22.06	22.18
	GCNSeq	**23.95**	**24.00**
	GCN	15.94	17.76

Table 1: BLEU and Meteor (%) scores on the development split of LDC2015E86.

For both TreeLSTM-based and GCN-based models, our proposed approach of applying the structural encoder before the RNN achieves better scores. This is especially true for GCN-based models, for which we also note a drastic drop in performance when the RNN is removed, highlighting the importance of a sequential component. On the other hand, RNN layers seem to have less impact on TreeLSTM-based models. This outcome is not unexpected, as TreeLSTMs already use LSTM gates in their computation.

The results show a clear advantage of tree and graph encoders over the sequential encoder. The best performing model is GCNSeq, both as a tree and as a graph encoder, with the latter obtaining the highest results.

Table 2 shows the comparison between our best sequential (Seq), tree (GCNSeq without reentrancies, henceforth called Tree) and graph en-

coders (GCNSEQ with reentrancies, henceforth called GRAPH) on the test set of LDC2015E86 and LDC2017T10. We also include state-of-the-art results reported on these datasets for sequential encoding (Konstas et al., 2017) and graph encoding (Song et al., 2018; Beck et al., 2018).[3] In order to mitigate the effects of random seeds, we train five models with different random seeds and report the results of the median model, according to their BLEU score on the development set (Beck et al., 2018). We achieve state-of-the-art results with both tree and graph encoders, demonstrating the efficacy of our GCNSeq approach. The graph encoder outperforms the other systems and previous work on both datasets. These results demonstrate the benefit of structural encoders over purely sequential ones as well as the advantage of explicitly including reentrancies. The differences between our graph encoder and that of Song et al. (2018) and Beck et al. (2018) were discussed in Section 3.3.

Table 4: Differences, with respect to the sequential baseline, in the Meteor score of the test split of LDC2017T10 as a function of the number of reentrancies.

5.1 Reentrancies

Overall scores show an advantage of graph encoder over tree and sequential encoders, but they do not shed light into how this is achieved. Because graph encoders are the only ones to model reentrancies explicitly, we expect them to deal better with these structures. It is, however, possible that the other models are capable of handling these structures implicitly. Moreover, the dataset contains a large number of examples that do not involve any reentrancies, as shown in Table 3, so that the overall scores may not be representative of the ability of models to capture reentrancies. It is expected that the benefit of the graph models will be more evident for those examples containing more reentrancies. To test this hypothesis, we evaluate the various scenarios as a function of the number of reentrancies in each example, using the Meteor score as a metric.[4]

Table 4 shows that the gap between the graph encoder and the other encoders is widest for examples with more than six reentrancies. The Meteor score of the graph encoder for these cases is 3.1% higher than the one for the sequential encoder and 2.3% higher than the score achieved by the tree encoder, demonstrating that explicitly encoding reentrancies is more beneficial than the overall scores suggest. Interestingly, it can also be observed that the graph model outperforms the tree model also for examples with no reentrancies, where tree and graph structures are identical. This suggests that preserving reentrancies in the training data has other beneficial effects. In Section 5.2 we explore one: better handling of long-range dependencies.

---

[3] We run comparisons on systems without ensembling nor additional data.

[4] For this analysis we use Meteor instead of BLEU because it is a sentence-level metric, unlike BLEU, which is a corpus-level metric.

5.1.1 Manual Inspection

In order to further explore how the graph model handles reentrancies differently from the other models, we performed a manual inspection of the models' output. We selected examples containing reentrancies, where the graph model performs better than the other models. These are shown in Table 5. In Example (1), we note that the graph model is the only one that correctly predicts the phrase *he finds out*. The wrong verb tense is due to the lack of tense information in AMR graphs. In the sequential model, the pronoun is chosen correctly, but the wrong verb is predicted, while in the tree model the pronoun is missing. In Example (2), only the graph model correctly generates the phrase *you tell them*, while none of the models use *people* as the subject of the predicate *can*. In Example (3), both the graph and the sequential models deal well with the control structure caused by the *recommend* predicate. The sequential model, however, overgenerates a wh-clause. Finally, in Example (4) the tree and graph models deal correctly with the possessive pronoun to generate the phrase *tell your ex*, while the sequential model does not. Overall, we note that the graph model produces a more accurate output than sequential and tree models by generating the correct pronouns and mentions when control verbs and co-references are involved.

5.1.2 Contrastive Pairs

For a quantitative analysis of how the different models handle pronouns, we use a method to inspect NMT output for specific linguistic analysis based on contrastive pairs (Sennrich, 2017). Given a reference output sentence, a contrastive sentence is generated by introducing a mistake related to the phenomenon we are interested in evaluating. The probability that the model assigns to the reference sentence is then compared to that of the contrastive sentence. The accuracy of a model is determined by the percentage of examples in which the reference sentence has a higher probability than the contrastive sentence.

We produce contrastive examples by running CoreNLP (Manning et al., 2014) to identify co-references, which are the primary cause of reentrancies, and introducing a mistake. When an expression has multiple mentions, the antecedent is repeated in the linearized AMR. For instance, the linearization of Figure 1(b) contains the token *he* twice, which instead appears only once in the sentence. This repetition may result in generating the token *he* twice, rather than using a pronoun to refer back to it. To investigate this possible mistake, we replace one of the mentions with the antecedent (e.g., *John ate the pizza with his fingers* is replaced with *John ate the pizza with John fingers*, which is ungrammatical and as such should be less likely).

An alternative hypothesis is that even when the generation system correctly decides to predict a pronoun, it selects the wrong one. To test for this, we produce contrastive examples where a pronoun is replaced by either a different type of pronoun (e.g., *John ate the pizza with his fingers* is replaced with *John ate the pizza with him fingers*) or by the same type of pronoun but for a different number (*John ate the pizza with their fingers*) or different gender (*John ate the pizza with her fingers*). Note from Figure 1 that the graph-structured AMR is the one that more directly captures the relation between *finger* and *he*, and as such it is expected to deal better with this type of mistakes.

From the test split of LDC2017T10, we generated 251 contrastive examples due to antecedent replacements, 912 due to pronoun type replacements, 1840 due to number replacements and 95 due to gender replacements.[5] The results are shown in Table 6. The sequential encoder performs surprisingly well at this task, with better or on par performance with respect to the tree encoder. The graph encoder outperforms the sequential encoder only for pronoun number and gender replacements. Future work is required to more precisely analyze if the different models cope with pronomial mentions in significantly different ways. Other approaches to inspect phenomena of co-reference and control verbs can also be explored, for instance by devising specific training objectives (Linzen et al., 2016).

5.2 Long-range Dependencies

When we encode a long sequence, interactions between items that appear distant from each other in the sequence are difficult to capture. The problem of long-range dependencies in natural language is well known for RNN architectures (Bengio et al., 1994). Indeed, the need to solve this problem motivated the introduction of LSTM models, which are known to model long-range dependencies better than traditional RNNs.

Table 8: Differences, with respect to the sequential baseline, in the Meteor score of the test split of LDC2017T10 as a function of the maximum dependency length.

Because the nodes in the graphs are not aligned with words in the sentence, AMR has no notion of distance between the nodes taking part in an edge. In order to define the length of an AMR edge, we resort to the AMR linearization discussed in Section 2. Given the linearization of the AMR $x_1, \ldots, x_N$, as discussed in Section 2, and an edge between two nodes x_i and x_j, the length of the edge is defined as $|j - i|$. For instance, in the AMR of Figure 1, the edge between *eat-01* and *:instrument* is a dependency of length five, because of the distance between the two words in the linearization *eat-01 :arg0 he :arg1 pizza :instrument*. We then compute the maximum dependency length for each AMR graph.

To verify the hypothesis that long-range dependencies contribute to the improvements of graph models, we compare the models as a function of the maximum dependency length in each example. Longer dependencies are sometimes caused by reentrancies, as in the dependency between *:part-of* and *he* in Figure 1. To verify that the contribution in terms of longer dependencies is complementary to that of reentrancies, we exclude sentences with reentrancies from this analysis. Table 7 shows the statistics for this measure. Results are shown in Table 8. The graph encoder always outperforms both the sequential and the tree encoder. The gap with the sequential encoder increases for longer dependencies. This indicates that longer dependencies are an important factor in improving results for both tree and graph encoders, especially for the latter.

6 Conclusions

We introduced models for AMR-to-text generation with the purpose of investigating the difference between sequential, tree and graph encoders. We showed that encoding reentrancies improves overall performance. We observed bigger benefits when the input AMR graphs have a larger number of reentrant structures and longer dependencies. Our best graph encoder, which consists of a GCN wired to a BiLSTM network, improves over the state of the art on all tested datasets. We inspected the differences between the models, especially in terms of co-references and control structures. Further exploration of graph encoders is left to future work, which may result crucial to improve performance further.

Abstract

There is growing evidence that changes in speech and language may be early markers of dementia, but much of the previous NLP work in this area has been limited by the size of the available datasets. Here, we compare several methods of domain adaptation to augment a small French dataset of picture descriptions ($n = 57$) with a much larger English dataset ($n = 550$), for the task of automatically distinguishing participants with dementia from controls. The first challenge is to identify a set of features that transfer across languages; in addition to previously used features based on *information units*, we introduce a new set of features to model the order in which information units are produced by dementia patients and controls. These concept-based language model features improve classification performance in both English and French separately, and the best result (AUC = 0.89) is achieved using the multilingual training set with a combination of information and language model features.

1 Introduction

According to the World Health Organisation, the largest global challenge facing the world today is the rapid increase of the population aged over 65 years. It is projected to increase from 524 million in 2010 to 1.5 billion in 2050, with the largest increase in the developing world (Suzman and Beard, 2011). This demographic trend has profound societal implications; for example, the number of persons affected by dementia will increase worldwide from 46 million in 2015 to 131.5 million in 2050 (Prince et al., 2015). The most common underlying condition causing dementia is Alzheimer's disease (AD). Although no cure to this neurodegenerative disease has been found, experts agree that intervention in early stages is crucial to delay onset (Dubois et al., 2016).

AD is characterised by a global impairment of cognitive functioning, with specific deficits in episodic memory, executive functioning, perceptual speed and language (Bäckman et al., 2005; Weiner et al., 2008).

Machine learning experiments using speech and language for the detection of dementia or related disorders have been conducted in many languages, including English (Roark et al., 2011; Mirheidari et al., 2016; Fraser et al., 2016; Asgari et al., 2017), French (Tröger et al., 2017; König et al., 2018), German (Weiner et al., 2016), Hungarian (Szatloczki et al., 2015; Vincze et al., 2016), Spanish (Meilán et al., 2014), Greek (Satt et al., 2013), Swedish (Lundholm Fors et al., 2018; Fraser et al., 2018a), Japanese (Shibata et al., 2016), Portuguese (Aluísio et al., 2016), and Mandarin Chinese (Lai et al., 2009). Most studies acknowledge that small data sets are a limitation and describe the difficulties in gathering more data, including the challenges in patient recruitment, the expense of running clinically-based studies, and the manual effort required for transcription and annotation.

Here, we consider whether it could be possible to increase the amount of available data by augmenting a corpus in one language with data from another language, and thus improve predictive per-

Minneapolis, Minnesota, June 2 - June 7, 2019.

formance without the need for new data collection. Specifically, we consider augmenting a relatively small French dataset with a much larger English one. The two aims of this study are: (1) to identify a set of features that are both useful for the detection of dementia and that we expect to transfer across different languages, and (2) to improve classification results on the French dataset by augmenting the training set with English data.

2 Background and Related Work

2.1 Narrative Analysis in AD

One way to assess language is through narrative speech, such as that elicited by the *Cookie Theft Picture* (CTP) task (Goodglass et al., 2000). In this task, participants are asked to describe the content of a line drawing of a kitchen scene, where a boy can be seen standing on a stool, trying to reach a cookie jar, while a woman is preoccupied washing dishes. In this study, we analyse CTP narratives, due to the widespread use of the task in multiple languages.

Narrative speech can be analysed on a number of levels, including phonology, morphology, syntax, semantics, and pragmatics. Here, our goal is to extract features that both predict AD and are likely to transfer across different languages. Although other studies have used acoustic features for this task (Meilán et al., 2014; König et al., 2018), there are well-documented differences in the phonology and prosody of French and English (Bertrán, 1999; Vaissière, 2002). Syntax and morphology also differ across languages, and the degree to which they are impaired in mild to moderate AD is unclear (Taler and Phillips, 2008). Pragmatic ability in AD may be disrupted (Chapman et al., 1998; Boschi et al., 2017); however, the CTP is not ideally suited for assessing pragmatics.

Instead, we focus on the semantic level, with the assumption that while the specific vocabulary will be different across languages, the underlying meanings or semantic concepts expressed should be the same. Features relating to semantic content are also motivated by the AD literature. Cuetos et al. (2007) reported a significant reduction in semantic units produced by pre-clinical AD participants, relative to controls, on the CTP task. Croisile et al. (1996) studied CTP descriptions from French participants, and found that the AD descriptions were shorter and less informative than the control descriptions. They measured information content by scoring the narratives against a gold standard list of 23 expected "information units", which have been widely used in subsequent research.

2.2 NLP for AD Classification

Several recent studies have used NLP and machine learning to analyse speech samples from people with dementia and other cognitive disorders. Most relevant here, are those which focus on picture description tasks in English or French.

DementiaBank[1] is a large database of CTP narratives from AD patients and controls, containing primarily English data. A number of recent papers report classification results on this corpus (Prud'hommeaux and Roark, 2015; Fraser et al., 2016; Al-Hameed et al., 2016; Yancheva and Rudzicz, 2016; Sirts et al., 2017). Language analysis of English-language CTP data from other sources has also been used to differentiate between different underlying pathologies in AD (Rentoumi et al., 2014), and variants of frontotemporal lobar degeneration (Pakhomov et al., 2010).

In French, picture description was one of multiple tasks used to elicit speech for the classification of participants with mild cognitive impairment and AD reported by König et al. (2015) and König et al. (2018), although only acoustic processing was used.

2.3 Multi- and Cross-Lingual NLP

There has been very little prior work on multilingual or cross-lingual dementia classification. Rentoumi et al. (2018) presented preliminary results suggesting that some language features from CTP samples could transfer across Greek and English, but did not report classification results. Fraser et al. (2018b) studied a related task of detecting mild cognitive impairment (MCI), and found that classification results could be improved in both English and Swedish by incorporating multilingual topic modelling into the feature extraction pipeline; however, they did not consider multilingual classification directly.

More generally, multilingual NLP is an active and growing area of research. Some approaches to improving classifier performance on a resource-poor *target* language by leveraging a resource-rich *source* language include: translate the target language to the source language (or vice versa) and

---

[1] `https://dementia.talkbank.org/`

train a unilingual classifier (Wan, 2009); extract features from the two languages separately and then use domain adaptation techniques to train a classifier for the target language (Blitzer et al., 2006; Prettenhofer and Stein, 2010); or determine a common representation for both languages and then extract features from the combined corpus to train a multilingual classifier (Ammar et al., 2016). In the extreme case, one can also consider purely cross-lingual classification, in which the classifier is trained solely on the source language, but tested on the target language.

We use a supervised domain adaptation approach, similar to that of Daumé III (2007), by considering each language to be a different domain. In related (though not multilingual) work, Masrani et al. (2017) also used this approach to adapt a dataset of AD narratives to their MCI classification task.

2.4 Class-Based Language Modelling

In contrast to the previous work on AD classification, we measure not only which information units are mentioned, but also the order in which they are mentioned. Our approach has some similarity to class-based language models (Brown et al., 1992), in which words are first grouped into classes (or clusters), and then the language model is trained on the classes rather than the individual words. One benefit to this approach is improved generalisability (Hoidekr et al., 2006), and another is the ability of classes to span different languages (Täckström et al., 2012).

3 Methodology

3.1 Data

Data were taken from two corpora: a small French dataset ($n = 57$), collected at the Memory Clinic and Research Centre of the University Hospital Nice, and the Pitt subcorpus of DementiaBank, containing 550 English samples[2]. Detailed information about the protocols for each study can be found in Tröger et al. (2017) and Becker et al. (1994). In both cases, ethics approval for the data collection was obtained from the local governing bodies.

The demographics for the participants in each language are shown in Table 1. In both studies, the participants were asked to perform the CTP task in their respective languages. In English, the image was shown on paper and speech was digitally recorded, while in the French study, the image was displayed on a tablet and speech was recorded via the tablet microphone.

	English		French	
	HC	AD	HC	AD
N	241	309	25	33
Gender	154F/87M	189F/120M	19F/6M	22F/11M
Age	64.8 (7.7)	71.4 (8.4)	75.4 (7.0)	79.2 (6.6)
Education	14.2 (2.6)	12.8 (3.0)	14.0 (2.6)	11.3 (4.0)
MMSE (/30)	29.1 (1.1)	19.8 (5.7)	28.6 (1.4)	18.9 (3.9)

Table 1: Demographics of participants, where AD indicates Alzheimer's disease, and HC indicates healthy control. The Mini Mental State Examination (MMSE) is global measure of cognitive status.

3.2 Features

The English and French audio samples were manually transcribed using the CHAT protocol (MacWhinney, 2014). A set of pre-defined information units found in the CTP was determined as an extension to Croisile et al. (1996), and is given in Table 2a. Mentions of information units were determined using keyword-spotting (based on manually-constructed word lists specific to each language), and used to translate the full narratives to sequences of information units. As an example, the English *A boy is standing on a stool* and French *Le garçon est sur un tabouret* would both be mapped to the sequence BOY STOOL.

Features relating to the occurrence of each distinct information unit comprise the *info* feature set, described in Table 2b. Additionally, new features are derived from language models build on the sequence of information units. To this end, concept-based language models are trained for English and French in a leave-one-out fashion, using the `kenlm` framework (Heafield, 2011). Models up to 5-grams were constructed. For each participant, two language models are constructed for each n: one trained on the healthy control (HC) population and one trained on the AD population. The participant is left out of the model built on their associated diagnostic group. The trained language models are then applied to the held-out participant's sequence of information units and various language model (*LM*) features are extracted (Table 2c).

---

[2] In this analysis, we included all participants in the Dementia subfolder, regardless of specific diagnosis, to maximize the size of the source data.

Actions STEAL, FALL, WASH, OVERFLOW, GIRL'S ACTION, WOMAN'S INDIFFERENCE

(a) Information units.

has_*unit* Binary feature indicating presence or absence of each information unit (23 features)
ratio_*unit* For each information unit, the number of times that unit was mentioned, divided by the total number of words in the original narrative (23 features)
unique_concept_density Total number of information units which were mentioned at least once, divided by the total number of words in the original narrative (1 feature)
unique_concept_efficiency Total number of information units which were mentioned at least once, divided by the duration of the sample in seconds (1 feature)
total_concept_density Total number of words referring to information units, divided by the total number of words in the original narrative (1 feature)
total_concept_efficiency Total number of words referring to information units, divided by the duration of the sample in seconds (1 feature)

(b) *info* features

perplexity_*class*_*n*-gram The perplexity assigned to the sample by each of the eight language models, where $n = 2, 3, 4, 5$, and the models are trained on data from either the AD or HC class. (8 features)
score_*class*_*n*-gram The log probability assigned to the sample by each of the eight language models. (8 features)
max_perplexity_*class*_*n*-gram The maximum perplexity, computed over all *n*-grams in a sample, for each of the eight language models. (8 features)
min_score_*class*_*n*-gram The minimum log probability, computed over all *n*-grams in a sample, for each of the eight language models. (8 features)

(c) *LM* features

Table 2: Top, the information units extracted from CTP narratives. Bottom, the *info* and *LM* features that are computed from the resulting sequence of information units.

3.3 Unilingual Classification

To evaluate the performance of the three proposed feature sets (*info*, *LM*, and *info*+*LM*), we first train classifiers to distinguish between HC and AD participants within a given language. To examine the importance of certain features, we restrict ourselves to more explainable linear models, namely logistic regression (LR) and linear support vector machines (SVM) (Pedregosa et al., 2011). In both cases, we use L_1 regularisation to promote sparsity in the feature weights.

Area under the Receiver-Operator curve (AUC) is reported as the evaluation parameter. Due to the small size of the French dataset, we use leave-pair-out cross validation (LPO-CV), which has been shown to produce an unbiased estimate for AUC on small datasets (Airola et al., 2009), and has also been used in related work (Roark et al., 2011). However, since LPO-CV is computationally very costly, we instead use 10-fold cross-validation (10-CV) for English, making sure that any samples for a given participant occur in either the training set or the test set, but not both. For LPO-CV we compute AUC and its standard deviation as described by Roark et al. (2011); for 10-CV we compute the AUC in each test fold and then report the average and standard deviation over folds.

Feature scaling and hyper-parameter optimisation is done on the training set in each fold. Features are scaled using Maximum-Absolute Scaling to preserve the binary nature of the *info* features. For both SVMs and LR, C was optimised between $C \in [10^{-4}, ..., 10^{4}]$ using a grid search.

3.4 Multilingual Classification

Our goal is to improve classification in French, by incorporating training data from English. To this end, we examine multiple ways to combine data from both English and French in the training set.

We first consider *domain adaptation*, where we treat French as the target domain and English as the source domain. We implement the AUGMENT method of Daumé III (2007), which involves augmenting the feature space with source-specific, target-specific, and combined versions of all the original features, allowing the classifier to assign a higher weight to the combined version when that feature transfers well across domains, while also retaining source- and target-specific information where appropriate.

We consider as well as the baseline methods described in Daumé III (2007): WEIGHT, in which the samples from the source domain are assigned reduced weights in the model; PRED, in which the prediction made by the source classifier is used as an additional feature in the target model; LININT, in which the predictions from the source and target models are linearly interpolated; and ALL, in which target and source data are simply combined in a single training set. Due to the limited size of our data, we do not optimise the weighting factors in WEIGHT and LININT, but rather assume the two languages should be given equal importance, and use a weighting factor of 0.1 in WEIGHT (since the English data is 10 times the size of the French data), and 0.5 in LININT.

Another option is to combine the French

and English datasets before extracting features. Specifically, we first replace the word-level transcripts with the sequence of information units, and then combine the two datasets and train the language models over the multilingual corpus, thus generating *multilingual language models*.

3.5 Cross-Lingual Classification

To understand how well a trained classification model in one language could be applied to another, we also perform cross-lingual experiments. For this, we train language and classification models in one language and test it on the other.

4 Results

The results of the classification experiments are presented in Figure 1.

4.1 Unilingual Classification

In French, for both LR and SVM, using *LM* features leads to higher AUC than the *info* features, and the combination of features is more effective than either feature set alone. In the English case, the *LM* and *info* features lead to equivalent performance individually, but the AUC is again marginally improved when the feature sets are combined, suggesting that they are capturing at least somewhat complementary information.

4.2 Domain Adaptation Results

For French, the *LM* features generally do not benefit from domain adaptation, with equivalent or poorer AUC relative to the unilingual case. The best result with the *LM* features is achieved in the AUGMENT scenario, where the classifier can select the French *LM* features only (although this result holds only for the SVM classifier). In contrast, the *info* features do benefit from the additional data available through domain adaptation, and lead to better results than the unilingual baseline. The best overall result of AUC = 0.89 is achieved by combining the feature types in the ALL configuration.

For English, we do not expect to see much benefit from including the (much smaller) French dataset. The WEIGHT adaptation technique is not feasible when the source data is smaller than the target data, and the LININT technique performs poorly, as it assigns too much importance the smaller and out-of-domain dataset. However, we do see marginal improvements using ALL and AUGMENT, reflecting the value of increasing the training set size by roughly 10%. The best result of AUC = 0.84 is achieved in the ALL condition, using the combined feature set.

4.3 Multilingual LM Results

Using the multilingual LM does not affect the *info* features, and therefore Figure 1 shows only the *LM* and *info+LM* results. Clearly, the multilingual LM approach does not work well here. Unlike in domain adaptation, combining the datasets using this method assumes that information units will be produced in the same order in the two languages. While French and English are similar in this respect, there are many possible counter-examples, such as *cookie jar* (COOKIE JAR) versus *boîte à biscuits* (JAR COOKIE).

4.4 Cross-Lingual Classification

When training entirely on English data and testing on French, the results using *info* and *info+LM* features are significantly improved over the unilingual baseline, while the *LM* results are reduced, once again indicating that the *info* features transfer better across languages. The results are very similar to those using the ALL technique for domain adaptation, suggesting that in that case, model training is dominated by the English data.

To further explore the similarity in performance in the ALL and cross-lingual cases, we examine the effect of incrementally increasing the amount of English data in the training set, when testing on French data. Figure 2 displays the classification performance of SVM and LR classifiers trained either using the ALL method of domain adaptation or cross-lingually with increasing amounts (10% at a time) of the English data. Considering first the ALL method (red and blue), at $x = 0$ there is no English data, and so we recover the French unilingual baseline. As we increase the amount of English data in the training set, performance slowly increases, eventually reaching the values reported in Figure 1. Considering next the cross-lingual case (yellow and green), we see that training on only 10% of the English data (55 samples) results in much poorer AUC values. However, each further 10% increases the classification performance. At 80% of English data (440 samples) the multi- and cross-lingual cases converge in performance. Thus, it would appear that domain adaptation is more data-efficient, as we achieve close to optimal results with a smaller proportion of English data,

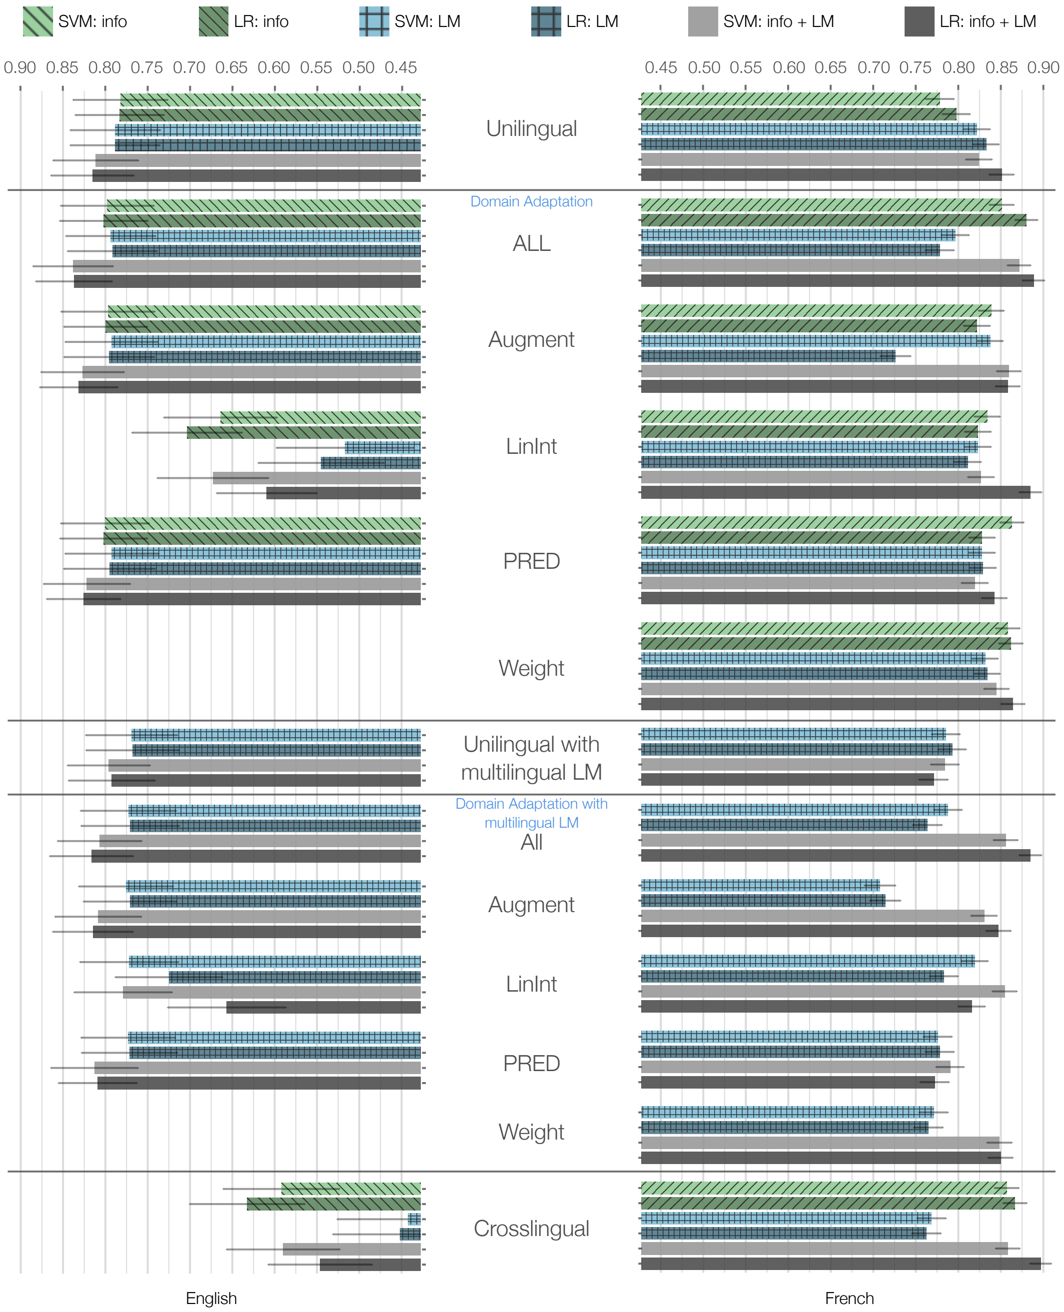

Figure 1: Results of uni-, multi- and cross-lingual classification experiments. Left panel displays results for English, right panel for French. Labels in the middle indicate the classification scenario and method of domain adaptation. Colours indicate the feature set and classifier. Bars indicate the AUC; error bars represent standard deviation.

but that the cross-lingual approach can be equally effective, given a large enough corpus.

4.5 Feature Analysis

Finally, we examine the features to determine which features are most useful to the task of dementia detection, and to compare the selected features in the unilingual and multilingual cases. Figure 3 shows the median absolute value of the weights assigned to each feature, for English and French, in the unilingual and multilingual ALL condition. The L_1 regularisation serves to set many feature weights to zero.

As a high-level observation, in both the uni- and multilingual cases, relatively more *info* features are selected, and relatively fewer *LM* features. Of the *LM* features that are selected, those which relate to the maximum perplexity or minimum probability appear to be more useful. These features

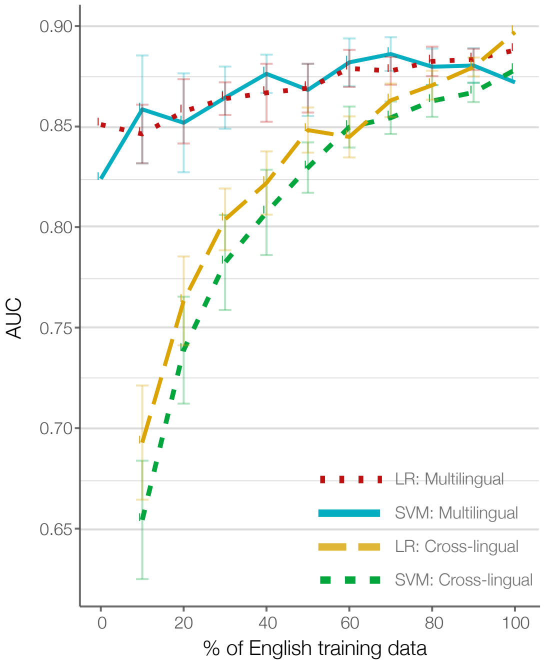

Figure 2: *AUC* as a function of the amount of English data used in the training set, for both multi- and cross-lingual cases. Error bars indicate 95% confidence intervals.

capture locally anomalous speech patterns, relative to either the AD or control language models.

In the unilingual case, the French models show a preference for the binary "has" features (indicating whether or not an information unit has been mentioned). Only 4 of the "ratio" features and none of the density or efficiency features have a median value greater than zero. However, these features *are* relevant to the task, and potentially more generalisable (e.g., total concept efficiency differs between the French AD and HC groups with $p < 0.001$ on a t-test, and represents an aggregate score rather than depending on the presence or absence of a single information unit). Such features are selected more often in the multilingual case, and lead to improved performance. One explanation for this could be that in the small French training set, spurious correlations due to noise can overpower the real signal, and lead to less relevant features being assigned high weights, while correlated (but perhaps actually more relevant) features are suppressed. By increasing the size of the training set with English data, the signal-to-noise ratio is improved, and a better set of features is selected.

Generally, the feature values (not shown) support the intuition that controls mention more of the information units in the image (higher "has" feature values), convey information more efficiently, with fewer off-topic words (higher density and efficiency scores), and organize the narrative in a more predictable way (narratives have lower perplexity and higher probability) than the AD participants. Again, these trends are more apparent in the English data than the French data, likely due to the relatively larger number of samples.

5 Discussion

One perhaps surprising result of this study was that naively combining features in the ALL condition led to better results than the AUGMENT algorithm. However, this is in line with the original findings of Daumé III (2007), where he identified a set of tasks where AUGMENT performed sub-optimally: specifically, those cases where training on source-only data was better than training on target-only data. This is precisely the case we have here, as training cross-lingually (on English source data) leads to better results than training unilingually (on French target data). The explanation offered by Daumé III is, "If the domains are so similar that a large amount of source data outperforms a small amount of target data, then it is unlikely that blowing up the feature space will help." In some sense, then, these results are confirmation that we have indeed identified a set of features over which the two languages (i.e. domains) are very similar.

The fact that the ALL configuration is optimal in both French and English has an added practical benefit: since there is no distinction between source and target features, the resulting classifier is language-agnostic. This means that test data could come from either language, in a hypothesized future screening application.

While our goal in this paper was not to push the state-of-the-art on the DementiaBank dataset, we do find that our best English result (AUC=0.84, which corresponds to an accuracy of 75% and F_1 score of 0.77) is comparable to the other published results on this dataset (Prud'hommeaux and Roark, 2015; Yancheva and Rudzicz, 2016; Sirts et al., 2017; Fraser et al., 2016; Hernández-Domínguez et al., 2018). There are no previously published results on the French dataset.

6 Conclusion and Future Work

In this work, we have shown that there are features which can both distinguish AD patients from healthy controls with a high degree of accuracy,

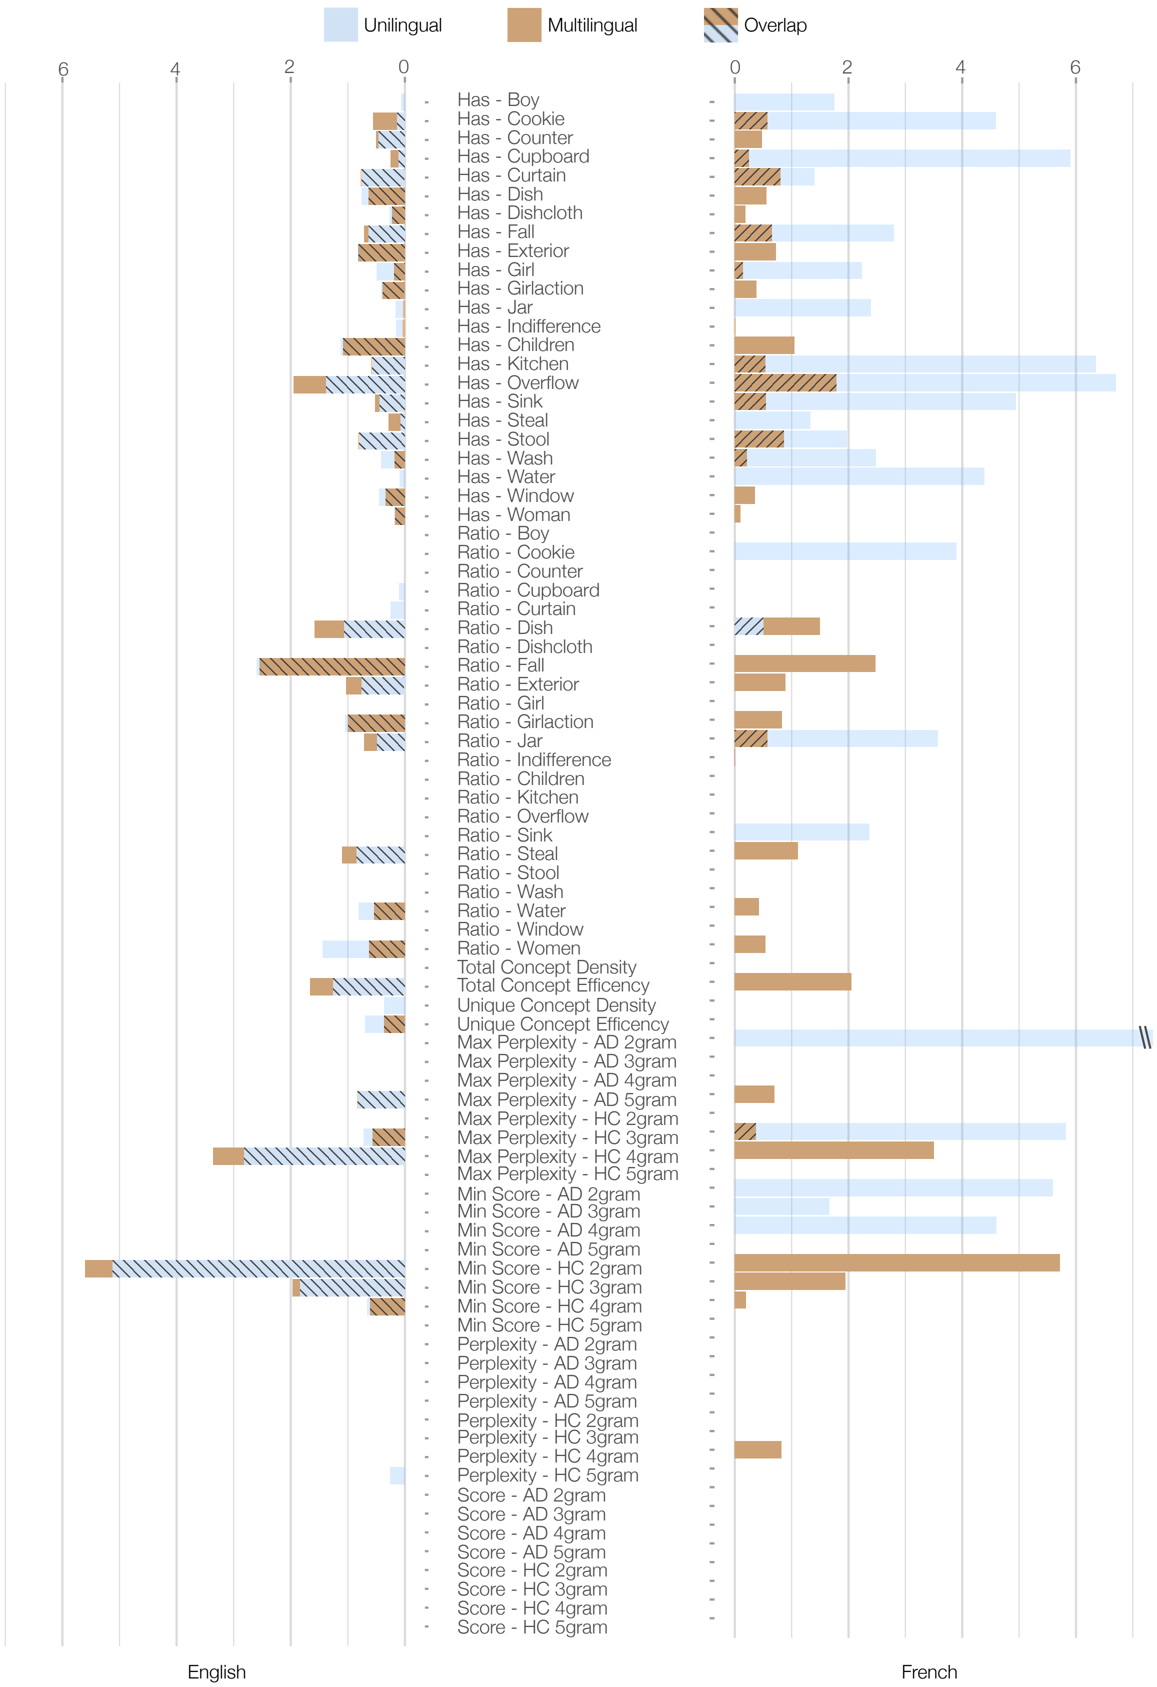

Figure 3: Visualisation of feature weights for uni- and multilingual experiments. Median feature importances over LPO- and 10-CV are displayed. The left panel displays the English and the right panel the French data sets. Unilingual experiments are given in blue and multilingual in yellow.

and also generalize across languages. By incorporating a large English dataset, we were able to improve the AUC on the French dataset from 0.85 to 0.89. We also developed a new set of features for this task, using concept-based language modelling, which improved AUC from 0.80 to 0.85 in the unilingual case, and 0.88 to 0.89 in the multilingual case.

Future work will involve extending the set of features involved, incorporating data from other languages, and testing whether similar techniques can be effective for detecting earlier stages of cognitive decline, such as MCI. Other work from our group has also begun to explore the use of unsupervised methods and out-of-domain data sources (Li et al., 2019).

Technical challenges aside, collaborations of this nature can be difficult due to the sensitive nature of the data, and the need to respect ethical guidelines and participant consent when sharing and storing data. With this in mind, we recommend to other researchers working in similar domains to consider from the outset whether their data could eventually be shared, and to make suitable provisions in their ethics protocols and participant consent forms. We look to DementiaBank as a model for this kind of data-sharing and openness, and hope that researchers can continue to find ways to share resources of this nature.

Abstract

To make machines better understand sentiments, research needs to move from polarity identification to understanding the reasons that underlie the expression of sentiment. Categorizing the goals or needs of humans is one way to explain the expression of sentiment in text. Humans are good at understanding situations described in natural language and can easily connect them to the character's psychological needs using commonsense knowledge. We present a novel method to extract, rank, filter and select multi-hop relation paths from a commonsense knowledge resource to interpret the expression of sentiment in terms of their underlying human needs. We efficiently integrate the acquired knowledge paths in a neural model that interfaces context representations with knowledge using a gated attention mechanism. We assess the model's performance on a recently published dataset for categorizing human needs. Selectively integrating knowledge paths boosts performance and establishes a new state-of-the-art. Our model offers interpretability through the learned attention map over commonsense knowledge paths. Human evaluation highlights the relevance of the encoded knowledge.

1 Introduction

Sentiment analysis and emotion detection are essential tasks in human-computer interaction. Due to its broad practical applications, there has been rapid growth in the field of sentiment analysis (Zhang et al., 2018). Although state-of-the-art sentiment analysis can detect the polarity of text units (Hamilton et al., 2016; Socher et al., 2013), there has been limited work towards explaining the reasons for the expression of sentiment and emotions in texts (Li and Hovy, 2017). In our work, we aim to go beyond the detection of sentiment, toward explaining sentiments. Such explanations can range from detecting overtly expressed explanations or reasons for sentiments towards specific aspects of, e.g., products or films, as in user reviews to the explanation of the underlying reasons for emotional reactions of characters in a narrative story. The latter requires understanding of stories and modeling the mental state of characters. Recently, Ding and Riloff (2018) proposed to categorize affective events with categories based on human needs, to provide explanations of people's attitudes towards such events. Given an expression such as *I broke my leg*, they categorize the reason for the expressed negative sentiment as being related to a need concerning 'health'.

In this paper we focus on the *Modelling Naive Psychology of Characters in Simple Commonsense Stories* dataset of Rashkin et al. (2018), which contains annotations of a fully-specified chain of motivations and emotional reactions of characters for a collection of narrative stories. The stories are annotated with labels from multiple theories of psychology (Reiss, 2004; Maslow, 1943; Plutchik, 1980) to provide explanations for the emotional reactions of characters.

Similar to Ding and Riloff (2018), we hypothesize that emotional reactions (joy, trust, fear, etc.) of characters can be explained by (dis)satisfaction of their psychological needs. However, predicting categories of human needs that underlie the expression of sentiment is a difficult task for a computational model. It requires not only detecting surface patterns from the text, but also requires commonsense knowledge about how a given situation may or may not satisfy specific human needs of a character. Such knowledge can be diverse and complex, and will typically be implicit in the text. In contrast, human readers can make use of relevant information from the story and associate it with their knowledge about human interaction, desires and human needs, and thus will be able

Proceedings of NAACL-HLT 2019, pages 3671–3681
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

to infer underlying reasons for emotions indicated in the text. In this work, we propose a computational model that aims to categorize human needs of story characters by integrating commonsense knowledge from ConceptNet (Speer and Havasi, 2012). Our model aims to imitate human understanding of a story, by (i) learning to select relevant words from the text, (ii) extracting pieces of knowledge from the commonsense inventory and (iii) associating them with human need categories put forth by psychological theories. Our assumption is that by integrating commonsense knowledge in our model we will be able to overcome the lack of textual evidence in establishing relations between expressed emotions in specific situations and the inferable human needs of story characters. In order to provide such missing associations, we leverage the graph structure of the knowledge source. Since these connections can be diverse and complex, we develop a novel approach to extract and rank multi-hop relation paths from ConceptNet using graph-based methods.

Our contributions are: (i) We propose a novel approach to extract and rank multi-hop relation paths from a commonsense knowledge resource using graph-based features and algorithms. (ii) We present an end-to-end model enhanced with attention and a gated knowledge integration component to predict human needs in a given context. To the best of our knowledge, our model is the first to advance commonsense knowledge for this task. (iii) We conduct experiments that demonstrate the effectiveness of the extracted knowledge paths and show significant performance improvements over the prior state-of-the-art. (iv) Our model provides interpretability in two ways: by selecting relevant words from the input text and by choosing relevant knowledge paths from the imported knowledge. In both cases, the degree of relevance is indicated via an attention map. (v) A small-scale human evaluation demonstrates that the extracted multi-hop knowledge paths are indeed relevant. Our code is made publicly available.[1]

2 Related Work

Sentiment Analysis and Beyond. Starting with Pang et al. (2002), sentiment analysis and emotion detection has grown to a wide research field. Researchers have investigated polarity classification, sentiment and emotion detection and classification (Tang et al., 2015; Yin et al., 2017; Li et al., 2017) on various levels (tokens, phrases, sentences or documents), as well as structured prediction tasks such as the identification of holders and targets (Deng and Wiebe, 2015) or sentiment inference (Choi et al., 2016). Our work goes beyond the analysis of overtly expressed sentiment and aims at identifying goals, desires or needs underlying the expression of sentiment. Li and Hovy (2017) argued that the goals of an opinion holder can be categorized by human needs. There has been work related to goals, desires, wish detection (Goldberg et al., 2009; Rahimtoroghi et al., 2017). Most recently, Ding and Riloff (2018) propose to categorize affective events into physiological needs to explain people's motivations and desires. Rashkin et al. (2018) published a dataset for tracking emotional reactions and motivations of characters in stories. In this work, we use this dataset to develop a knowledge-enhanced system that 'explains' sentiment in terms of human needs.

Integrating Structured Knowledge into Neural NLU Systems. Neural models aimed at solving NLU tasks have been shown to profit from the integration of knowledge, using different methods: Xu et al. (2017) show that injecting loosely structured knowledge with a recall-gate mechanism is beneficial for conversation modeling; Mihaylov and Frank (2018) and Weissenborn et al. (2017) propose integration of commonsense knowledge for reading comprehension: the former explicitly encode selected triples from ConceptNet using attention mechanisms, the latter enriches question and context embeddings by encoding triples as mapped statements extracted from ConceptNet. Concurrently to our work, Bauer et al. (2018) proposed a heuristic method to extract multi-hop paths from ConceptNet for a reading comprehension task. They construct paths starting from concepts appearing in the question to concepts appearing in the context, aiming to emulate multi-hop reasoning. Tamilselvam et al. (2017) use ConceptNet relations for aspect-based sentiment analysis. Similar to our approach, Bordes et al. (2014) make use of knowledge bases to obtain longer paths connecting entities appearing in questions to answers in a QA task. They also provide a richer representation of answers by building subgraphs of entities appearing in answers. In contrast, our work aims to provide information about missing links

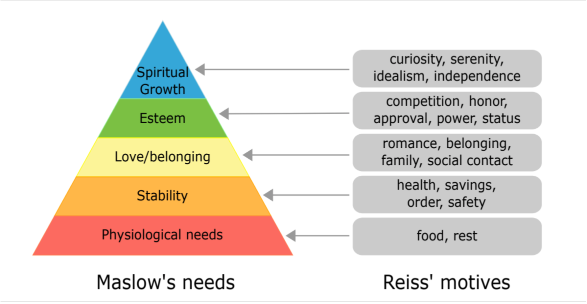

Figure 1: Maslow and Reiss: Theories of Psychology as presented in Rashkin et al. (2018).

between sentiment words in a text and underlying human needs by extracting relevant multi-hop paths from structured knowledge bases.

3 Selecting and Ranking Commonsense Knowledge to Predict Human Needs

Our task is to automatically predict human needs of story characters given a story context. In this task, following the setup of Rashkin et al. (2018), we *explain* the probable reasons for the expression of emotions by predicting appropriate categories from two theories of psychology: *Hierarchy of needs* (Maslow, 1943) and *basic motives* (Reiss, 2002). The task is defined as a multi-label classification problem with five coarse-grained (Maslow) and 19 fine-grained (Reiss) categories, respectively (see Fig. 1).[1] We start with a Bi-LSTM encoder with self-attention as a baseline model, to efficiently categorize human needs. We then show how to select and rank multi-hop commonsense knowledge paths from ConceptNet that connect textual expressions with human need categories. Finally, we extend our model with a gated knowledge integration mechanism to incorporate relevant multi-hop commonsense knowledge paths for predicting human needs. An overview of the model is given in Figure 2. We now describe each component in detail.

3.1 A Bi-LSTM Encoder with Attention to Predict Human Needs

Our Bi-LSTM encoder takes as input a sentence S consisting of a sequence of tokens, denoted as $w_1^s, w_2^s, ..., w_n^s$, or $w_{1:n}^s$ and its preceding context Cxt, denoted as $w_1^{cxt}, w_2^{cxt}, ..., w_m^{cxt}$, or $w_{1:m}^{cxt}$. As further input we read the name of a story character, which is concatenated to the input sentence. For this input the model is tasked to predict appropriate human need category labels $z \in Z$, according to a predefined inventory.

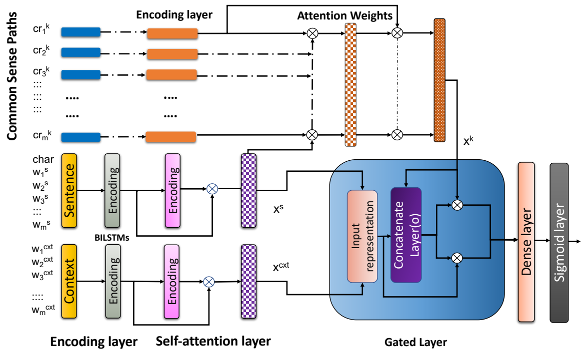

Figure 2: Attention over multi-hop knowledge paths.

Embedding Layer: We embed each word from the sentence and the context with a contextualized word representation using character-based word representations (ELMo) (Peters et al., 2018). The embedding of each word w_i in the sentence and context is represented as e_i^s and e_i^{cxt}, respectively.

Encoding Layer: We use a single-layer Bi-LSTM (Hochreiter and Schmidhuber, 1997) to obtain sentence and context representations h^s and h^{cxt}, which we form by concatenating the final states of the forward and backward encoders.

$$h^s = BiLSTM(e_{1:n}^s); h^{cxt} = BiLSTM(e_{1:m}^{cxt}) \tag{1}$$

A Self-Attention Layer allows the model to dynamically control how much each token contributes to the sentence and context representation. We use a modified version of self-attention proposed by Rei and Søgaard (2018), where both input representations are passed through a feedforward layer to generate scalar values for each word in context v_i^{cxt} and sentence v_i^s (cf. (2-5)).

$$a_i^s = ReLU(W_i^s h_i^s + b_i^s), \tag{2}$$

$$a_i^{cxt} = ReLU(W_i^{cxt} h_i^{cxt} + b_i^{cxt}) \tag{3}$$

$$v_i^s = W_v^s{}_i a_i^s + b_{vi}^s \tag{4}$$

$$v_i^{cxt} = W_v^{cxt}{}_i a_i^{cxt} + b_v^{cxt}{}_i \tag{5}$$

where, $W^s, b^s, W^{cxt}, b^{cxt}, W_v^s, W_v^{cxt}$ are trainable parameters. We calculate the soft attention weights for both sentence and context:

$$\widetilde{v_i} = \frac{1}{1 + exp(-v_i)}; \quad \hat{v}_i = \frac{\widetilde{v_i}}{\sum_{k=1}^{N} \widetilde{v}_k} \tag{6}$$

---

[1] Details about the labels are given in the Supplement.

where, $\widetilde{v}_i$ is the output of the sigmoid function, therefore $\widetilde{v}_i$ is in the range [0,1] and $\hat{v}_i$ is the normalized version of $\widetilde{v}_i$. Values $\hat{v}_i$ are used as attention weights to obtain the final sentence and context representations x^s and x^{cxt}, respectively:

$$x^s = \sum_{i=1}^{N} \hat{v}_i{}^s h_i^s \tag{7}$$

$$x^{cxt} = \sum_{i=1}^{M} \hat{v}_i{}^{cxt} h_i^{cxt} \tag{8}$$

with N and M the number of tokens in S and Cxt. The output of the self-attention layer is generated by concatenating x^s and x^{cxt}. We pass this representation through a FF layer of dimension Z:

$$y = ReLU(W_y[x^s; x^{cxt}] + b_y) \tag{9}$$

where W_y, b_y are trainable parameters and ';' denotes concatenation of two vectors. Finally, we feed the output layer y to a logistic regression layer to predict a binary label for each class $z \in Z$, where Z is the set of category labels for a particular psychological theory (Maslow/Reiss, Fig. 1).

3.2 Extracting Commonsense Knowledge

To improve the prediction capacity of our model, we aim to leverage external commonsense knowledge that connects expressions from the sentence and context to human need categories. For this purpose we extract multi-hop commonsense knowledge paths that connect words in the textual inputs with the offered human need categories, using as resource ConceptNet (Speer and Havasi, 2012), a large commonsense knowledge inventory. Identifying contextually relevant information from such a large knowledge base is a non-trivial task. We propose an effective two-step method to extract multi-hop knowledge paths that associate concepts from the text with human need categories: (i) collect all potentially relevant knowledge relations among concepts and human needs in a subgraph for each input sentence; (ii) rank, filter and select high-quality paths using graph-based local measures and graph centrality algorithms.

3.2.1 Construction of Sub-graphs

ConceptNet is a graph $G = (V, E)$ whose nodes are concepts and edges are relations between concepts (e.g. CAUSES, MOTIVATEDBY). For each sentence S we induce a subgraph $G' = (V', E')$ where V' comprises all concepts $c \in V$ that appear in S and the directly preceding sentence in context Cxt. V' also includes all concepts $c \in V$ that correspond to one of the human need categories in our label set Z. Fig. 3 shows an example. The sub-graph is constructed as follows:

Shortest Paths: In a first step, we find all shortest paths p' from ConceptNet that connect any concept $c_i \in V'$ to any other concept $c_j \in V'$ and to each human needs concept $z \in Z$. We further include in V' all the concepts $c \in V$ which are contained in the above shortest paths p'.

Neighbours: To better represent the meaning of the concepts in V', we further include in V' all concepts $c \in V$ that are directly connected to any $c \in V'$ that is not already included in V'.

Sub-graph: We finally construct a connected sub-graph $G' = (V', E')$ from V' by defining E' as the set of all ConceptNet edges $e \in E$ that directly connect any pair of concepts $(c_i, c_j) \in V'$.

Overall, we obtain a sub-graph that contains relations and concepts which are supposed to be useful to "explain" *why* and *how strongly* concepts c_i that appear in the sentence and context are associated with any of the human needs $z \in Z$.

3.2.2 Ranking and Selecting Multi-hop Paths

We could use all possible paths p contained in the sub-graph G', connecting concepts c_i from the text and human needs concepts z contained in G', as additional evidence to predict suitable human need categories. But not all of them may be relevant. In order to select the most relevant paths, we propose a two-step method: (i) we score each vertex with a score (*Vscore*) that reflects its importance in the sub-graph and on the basis of the vertices' *Vscores* we determine a path score *Pscore*, as shown in Figure 3; (ii) we select the top-k paths with respect to the computed path score (*Pscore*) .

(i) Vertex Scores and Path Scores: We hypothesize that the most useful commonsense relation paths should include vertices that are *important* with respect to the entire extracted subgraph. We measure the importance of a vertex using different local graph measures: the *closeness centrality measure, page rank* or *personalized page rank*.

Closeness Centrality (CC) (Bavelas, 1950) reflects how close a vertex is to all other vertices in the given graph. It measures the average length of the shortest paths between a given vertex v_i and all other vertices in the given graph G'. In a connected graph, the closeness centrality $CC(v_i)$ of a vertex $v_i \in G'$ is computed as

$$Vscore_{CC}(v_i) = \frac{\mid V' \mid}{\sum_j d\left(v_j, v_i\right)} \tag{10}$$

where $\mid V' \mid$ represents the number of vertices in the graph G' and $d(v_j, v_i)$ represents the length of the shortest path between v_i and v_j. For each path we compute the normalized sum of $Vscore_X$ of all vertices v_j contained in the path, for any measure $X \in \{CC, PR, PPR\}$.

$$Pscore_X = \frac{\sum_j Vscore_X(v_j)}{N} \tag{11}$$

We rank the paths according to their $Pscore_{CC}$, assuming that relevant paths will contain vertices that are close to the center of the sub-graph G'.

PageRank (PR) (Brin and Page, 1998) is a graph centrality algorithm that measures the relative importance of a vertex in a graph. The PageRank score of a vertex $v_i \in G'$ is computed as:

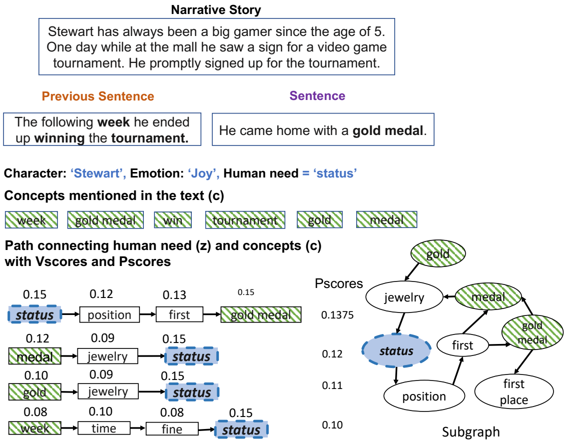
$$Vscore_{PR}(v_i) = \alpha \sum_j u_{ji} \frac{v_j}{L_j} + \frac{1-\alpha}{n} \tag{12}$$

where $L_j = \sum_i u_{ji}$ is the number of neighbors of vertex j, α is a damping factor representing the probability of jumping from a given vertex v_i to another random vertex in the graph and n represents the number of vertices in G'. We calculate $Pscore_{PR}$ using Eq. 11 and order the paths according to their $Pscore_{PR}$, assuming that relevant paths will contain vertices with high relevance, as reflected by a high number of incoming edges.

Personalized PageRank (PPR) (Haveliwala, 2002) is used to determine the importance of a vertex with respect to a certain topic (set of vertices). Instead of assigning equal probability for a random jump $\frac{1-\alpha}{n}$, PPR assigns stronger probability to certain vertices to prefer topical vertices. The PPR score of a vertex $v \in G'$ is computed as:

$$Vscore_{PPR}(v_i) = \alpha \sum_j u_{ji} \frac{v_j}{L_j} + (1-\alpha)\, T \tag{13}$$

where $T = \frac{1}{|T_j|}$ if nodes v_i belongs to topic T_j and otherwise $T = 0$. In our setting, T_j will contain concepts from the text and human needs, to assign them higher probabilities. We calculate $Pscore_{PPR}$ using Eq. 11 and order the paths according to their scores, assuming that relevant paths should contain vertices holding importance with respect to vertices representing concepts from the text and human needs.



Stewart has always been a big gamer since the age of 5. One day while at the mall he saw a sign for a video game tournament. He promptly signed up for the tournament.

The following **week** he ended up **winning** the **tournament.**

He came home with a **gold medal**.

Figure 3: Illustration of commonsense path selection. Top: Context and sentence, Bottom: Selected knowledge paths with *Vscores* and *Pscores* (left) and the corresponding subgraph. Concepts from the text are marked with green dashed lines; blue boxes show the human need label *status* assigned to *Stewart*.

(ii) Path Selection: We rank knowledge paths based on their *Pscore* using the above relevance measures, and construct ranked lists of paths of two types: (i) paths connecting a human needs concept $z \in Z$ to a concept mentioned in the text (p_{c-z}) [2] and (ii) paths connecting concepts in the text (p_{c-c}) [3]. Ranked lists of paths are constructed individually for concepts that constitute the start or endpoint of a path: a human needs concept for p_{c-z} or any concept from the text for p_{c-c}.

Figure 3 illustrates an example where the character *Stewart* felt *joy* after winning a gold medal. The annotated human need label is *status*. We show the paths selected by our algorithm that connect concepts from the text and the human need *status*. We select the top-k paths of type p_{c-z} for each human need to capture relevant knowledge about human needs in relation to concepts in the text. Similarly, we select the top-k paths of type p_{c-c} for each c_i to capture relevant knowledge about the text (not shown in Fig. 3).

3.3 Extending the Model with Knowledge

We have seen how to obtain a ranked list of commonsense knowledge paths from a subgraph extracted from ConceptNet that connect concepts from the textual input and possible human needs categories that are the system's classification tar-

---

[2] p_{c-z} denotes path connecting a human needs concept $z \in Z$ and a concept c mentioned in the text.

[3] p_{c-c} denotes path connecting a concept c and another concept c mentioned in the text.

gets. Our intuition is that the extracted commonsense knowledge paths will provide useful evidence for our model to *link the content expressed in the text to appropriate human need categories*. Paths that are selected by the model as a relevant connection between the input text and the labeled human needs concept can thus provide *explanations* for emotions or goals expressed in the text *in view of a human needs category*. We thus integrate these knowledge paths into our model, (i) to help the model making correct predictions and (ii) to provide explanations of emotions expressed in the text in view of different human needs categories. For each input, we represent the extracted ranked list of n commonsense knowledge paths p as a list $cr^{k,1}, cr^{k,2}, ..., cr^{k,n}$, where each $cr^{k,i}_{1:l}$ represents a path consisting of concepts and relations, with l the length of the path. We embed all concepts and relations in $cr^{k,i}_{1:l}$ with pretrained GloVe (Pennington et al., 2014) embeddings.

Encoding Layer: We use a single-layer BiLSTM to obtain encodings ($h^{k,i}$) for each knowledge path

$$h^{k,i} = BiLSTM(e^{k,i}_{1:n}) \tag{14}$$

where h^k represents the output of the BiLSTM for the knowledge path and i its the ranking index.

Attention Layer: We use an attention layer, where each encoded commonsense knowledge path interacts with the sentence representation x^s to receive attention weights ($\hat{h}^{k,i}$):

$$\widetilde{h}^{k,i} = \sigma(x^s h^{k,i}), \quad \hat{h}^{k,i} = \frac{\widetilde{h}^{k,i}}{\sum_{i=1}^{N} \widetilde{h}^{k,i}} \tag{15}$$

In Eq. 15, we use sigmoid to calculate the attention weights, similar to Eq. 6. However, this time we compute attention to highlight which knowledge paths are important for a given input representation (x^s being the final state hidden representation over the input sentence, Eq. 7). To obtain the sentence-aware commonsense knowledge representation x^k, we pass the output of the attention layer through a feedforward layer. W_k, b_k are trainable parameters.

$$x^k = ReLU(W_k(\sum_{i=1}^{N} \hat{h}^{k,i} h^{k,i}) + b_k) \tag{16}$$

3.4 Distilling Knowledge into the Model

In order to incorporate the selected and weighted knowledge into the model, we concatenate the sentence x^s, context x^{cxt} and knowledge x^k representation and pass it through a FF layer.

$$o_i = ReLU(W_z[x^s_i; x^{cxt}_i; x^k_i] + b_z) \tag{17}$$

Classification	**Train**	**Dev**	**Test**
Reiss	5432	1469	5368
Reiss without *belonging* class	5431	1469	5366
Maslow	6873	1882	6821

Table 1: Dataset Statistics: nb. of instances (sentences with annotated characters and human need labels).

We employ a gating mechanism to allow the model to selectively incorporate relevant information from commonsense knowledge x^k and from the joint input representation y_i (see Eq. 9) *separately*. We finally pass it to a logistic regression classifier to predict a binary label for each class z in the set Z of category labels

$$z_i = \sigma(W_{\widetilde{y}_z}(o_i \odot y_i + o_i \odot x^k_i) + b_{\widetilde{y}_z}) \tag{18}$$

where $\odot$ represents element-wise multiplication, $b_{\widetilde{y}_z}$, $W_{\widetilde{y}_z}$ are trainable parameters.

4 Experimental Setup

Dataset: We evaluate our model on the *Modeling Naive Psychology of Characters in Simple Commonsense Stories (MNPCSCS)* dataset (Rashkin et al., 2018). It contains narrative stories where each sentence is annotated with a character and a set of human need categories from two inventories: Maslow's (with five coarse-grained) and Reiss's (with 19 fine-grained) categories (Reiss's labels are considered as subcategories of Maslow's). The data contains the original worker annotations. Following prior work we select the annotations that display the "majority label" i.e., categories voted on by ≥ 2 workers. Since no training data is available, similar to prior work we use a portion of the devset as training data, by performing a random split, using 80% of the data to train the classifier, and 20% to tune parameters. Data statistics is reported in Table 1.

Rashkin et al. (2018) report that there is low annotator agreement i.a. between the *belonging* and the *approval* class. We also find high co-occurrence of the *belonging, approval* and *social contact* classes, where *belonging* and *social contact* both pertain to the Maslow class *Love/belonging* while *approval* belongs to the

Maslow class *Esteem*. This indicates that *belonging* interacts with *Love/belonging* and *Esteem* in relation to social contact. We further observed during our study that in the Reiss dataset the number of instances annotated with the *belonging* class is very low (no. of instances in training is 24, and in dev 5). The performance for this class is thus severely hampered, with 4.7 F_1 score for BiLSTM+Self-Attention and 7.1 F_1 score for BiLSTM+Self-Attention+Knowledge. After establishing benchmark results with prior work (cf. Table 2, including *belonging*), we perform all further experiments with a reduced Reiss dataset, by eliminating the *belonging* class from all instances. This impacts the overall number of instances only slightly: by *one* instance for training and *two* instances for test, as shown in Table 1.

Training: During training we minimize the weighted binary cross entropy loss,

$$L = \sum_{z=1}^{Z} w_z y_z log\widetilde{y}_z + (1 - w_z)(1 - y_z)log(1 - \widetilde{y}_z) \tag{19}$$

$$w_z = \frac{1}{1 - exp^{-\sqrt{P(y_z)}}} \tag{20}$$

where Z is the number of class labels in the classification tasks and w_z is the weight. $P(y_z)$ is the marginal class probability of a positive label for z in the training set.

Embeddings: To compare our model with prior work we experiment with pretrained GloVe (100d) embeddings (Pennington et al., 2014). Otherwise we used GloVe (300d) and pretrained ELMo embeddings (Peters et al., 2018) to train our model.

Hyperparameters for Knowledge Inclusion: We compute ranked lists of knowledge paths of two types: p_{c-z} and p_{c-c}. We use the top-3 p_{c-z} paths for each z using our best ranking strategy (Closeness Centrality + Personalized PageRank) in our best system results (Tables 2, 3, 5), and also considered paths p_{c-c} (top-3 per pair) when evaluating different path selection strategies (Table 4).

Evaluation Metrics: We predict a binary label for each class using a binary classifier so the prediction of each label is conditionally independent of the other classes given a context representation of the sentence. In all prediction tasks we report the micro-averaged Precision (P), Recall (R) and F_1 scores by counting the number of positive instances across all of the categories. All reported results are averaged over five runs. More information on the dataset, metrics and all other training details are given in the Supplement.

5 Results

Our experiment results are summarized in Table 2. We benchmark our baseline BiLSTM+Self-Attention model (BM, BM w/ knowledge) against the models proposed in Rashkin et al. (2018): a BiLSTM and a CNN model, and models based on the recurrent entity network (REN) (Henaff et al., 2016) and neural process networks (NPN) (Bosselut et al., 2017). The latter differ from the basic encoding models (BiLSTM, CNN) and our own models by explicitly modeling entities. We find that our baseline model BM outperforms all prior work, achieving new state-of-the-art results. For Maslow we show improvement of 21.02 pp. F_1 score. For BM+K this yields a boost of 6.39 and 3.15 pp. F_1 score for Reiss and Maslow, respectively. When using ELMo with BM we see an improvement in recall. However, adding knowledge on top improves the precision by 2.24 and 4.04 pp. for Reiss and Maslow. In all cases, injecting knowledge improves the model's precision and F_1 score.

Table 2 (bottom) presents results for the reduced dataset, after eliminating Reiss' label *belonging*. Since *belonging* is a rare class, we observe further improvements. We see the same trend: adding knowledge improves the precision of the model.

5.1 Model Ablations

To obtain better insight into the contributions of individual components of our models, we perform an ablation study (Table 3). Here and in all later experiments we use richer (300d) GloVe embeddings and the dataset w/o *belonging*. We show results including and not including self-attention

and knowledge components. We find that using self-attention over sentences and contexts is highly effective, which indicates that learning how much each token contributes helps the model to improve performance. We observe that integrating knowledge improves the overall F_1 score and yields a gain in precision with ELMo. Further, integrating knowledge using the gating mechanism we see a considerable increase of 3.58 and 1.74 pp. F_1 score improvement over our baseline model for GloVe and ELMo representations respectively.

5.2 Commonsense Path Selection

We further examine model performance for (i) different variants of selecting commonsense knowledge, including (ii) the effectiveness of the relevance ranking strategies discussed in §3.2.2. In Table 4, rows 3-4 use our best ranking method: CC+PPR; rows 5-8 show results when using the top-3 ranked p_{c-z} paths for each human need z with different ranking measures. *None* shows results when no selection is applied to the set of extracted knowledge paths (i.e., using all possible paths from p_{c-z} and p_{c-c}). *Random* randomly selects 3 paths for each human need from the set of paths used in *None*. This yields only a slight drop in performance. This suggests that not every path is relevant. We evaluate the performance when only considering single-hop paths (now top-3 ranked using CC+PPR) *(Single-Hop)*. We see an improvement over random paths and no selection, but not important enough. In contrast, using both single and multi-hop paths in conjunction with relevance ranking improves the performance considerably (rows 4-8). This demonstrates that multi-hop paths are informative. We also experimented with p_{c-c}+p_{c-z}. We find improvement in recall, however the overall performance decreases by 0.2 F_1 score compared to paths p_{c-z} ranked using CC + PPR. Among different ranking measures *precision* for Personalized PageRank performs best in comparison with CC and PR in isolation, and recall for CC in isolation is highest. Combining CC and PPR yields the best results among the different ranking strategies (rows 5-8).

6 Analysis

6.1 Performance per Human Need Categories

We examined the model performance on each category (cf. Figure 4). The model performs well for basic needs like *food*, *safety*, *health*, *romance*, etc. We note that inclusion of knowledge improves the performance for most classes (only 5 classes do not profit from knowledge compared to only using ELMo), especially for labels which are rare like *honor, idealism, power.* We also found that the annotated labels can be subjective. For instance, *Tom lost his job* is annotated with *order* while our model predicts *savings*, which we consider to be correct. Similar to Rashkin et al. (2018) we observe that preceding context helps the model to better predict the characters' needs, e.g., *Context: Erica's [..] class had a reading challenge [..]. If she was able to read 50 books [..] she won a pizza party!; Sentence: She read a book every day for the entire semester* is annotated with *competition*. Without context the predicted label is *curiosity*, however when including context, the model predicts *competition, curiosity*. We measure the models performance when applying it only to the first sentence of each story (i.e., without the context). As shown in Table 5, also in this setting the inclusion of knowledge improves the performance.

Model	WE	P	R	F1

Context: Timmy had to renew his driver's license. He went to his local DMV. He waited in line for nearly 2 hours. He took a new picture for his driver's license.
Sentence: He drove back home after an exhausting day.
True Label: *rest*
Predicted Label (BM): *status, approval, order*
Predicted Label (BM+K): *rest*

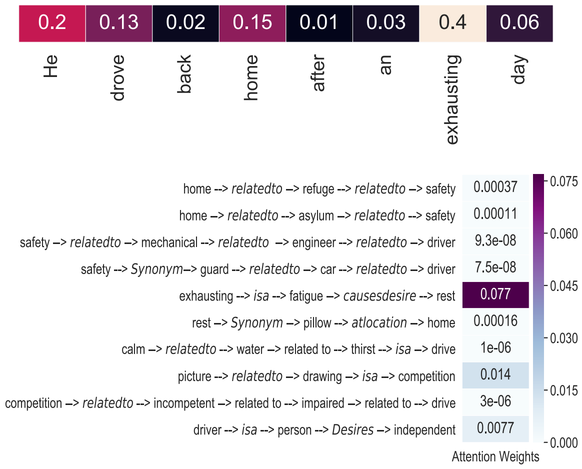

Figure 5: Interpreting the attention weights on sentence representation and selected commonsense paths.

6.2 Human Evaluation of Extracted Paths

We conduct human evaluation to test the effectiveness and relevance of the extracted commonsense knowledge paths. We randomly selected 50 sentence-context pairs with their gold labels from the devset and extracted knowledge paths that contain the gold label (using CC+PPR for ranking). We asked three expert evaluators to decide whether the paths are relevant to provide information about the missing links between the concepts in the sentence and the human need (gold label). The inter-annotator agreement had a Fleiss' κ= 0.76. The result for this evaluation shows that in 34% of the cases computed on the basis of majority agreement, our algorithm was able to select a relevant commonsense path. More details about the human evaluation are given in the Supplement.

6.3 Interpretabilty

Finally we study the learned attention distributions of the interactions between sentence representation and knowledge paths, in order to interpret how knowledge is employed to make predictions. Visualization of the attention maps gives evidence of the ability of the model to capture relevant knowledge that connects human needs to the input text. The model provides interpretability in two ways: by selecting tokens from the input text using Eq.6 and by choosing knowledge paths from the imported knowledge using Eq.15 as shown in Figure 5. Figure 5 shows an example where including knowledge paths helped the model to predict the correct human need category. The attention map depicts which exact paths are selected to make the prediction. In this example, the model correctly picks up the token *"exhausting"* from the input sentence and the knowledge path *"exhausting is a fatigue causes desire rest"*. We present more examples of extracted knowledge and its attention visualization in the Supplement.

7 Conclusion

We have introduced an effective new method to rank multi-hop relation paths from a commonsense knowledge resource using graph-based algorithms. Our end-to-end model incorporates multi-hop knowledge paths to predict human needs. Due to the attention mechanism we can analyze the knowledge paths that the model considers in prediction. This enhances transparency and interpretability of the model. We provide quantitative and qualitative evidence of the effectiveness of the extracted knowledge paths. We believe our relevance ranking strategy to select multi-hop knowledge paths can be beneficial for other NLU tasks. In future work, we will investigate structured and unstructured knowledge sources to find explanations for sentiments and emotions.

Abstract

Incorporating domain knowledge is vital in building successful natural language processing (NLP) applications. Many times, cross-domain application of a tool results in poor performance as the tool does not account for domain-specific attributes. The clinical domain is challenging in this aspect due to specialized medical terms and nomenclature, shorthand notation, fragmented text, and a variety of writing styles used by different medical units. Temporal resolution is an NLP task that, in general, is domain-agnostic because temporal information is represented using a limited lexicon. However, domain-specific aspects of temporal resolution are present in clinical texts. Here we explore parsing issues that arose when running our system, a tool built on Newswire text, on clinical notes in the THYME corpus. Many parsing issues were straightforward to correct; however, a few code changes resulted in a cascading series of parsing errors that had to be resolved before an improvement in performance was observed, revealing the complexity of temporal resolution and rule-based parsing. Our system now outperforms current state-of-the-art systems on the THYME corpus with little change in its performance on Newswire texts.

1 Introduction

Temporal resolution is required for comprehending many types of communication, including written texts. This is especially true in clinical texts as patient narratives revolve around when an event happened, such as when a symptom occurred or the frequency a drug was administered (Lee et al., 2017; Sun et al., 2013b). Understanding the temporal component in texts is vital for many NLP systems (Tissot et al., 2015) to accurately interpret a patient narrative (Sun et al., 2013b).

Some temporal expressions could be considered domain agnostic as there are limited ways to represent information about time, such as formatted dates or days of the week. However, there are many lexical variations of these standard tokens. Additionally, vague temporal expressions, relative times, and event durations require contextual or implicit knowledge of the subject area for resolution (Sun et al., 2013b). Clinical texts include all these types of temporal expressions, and also contain domain-specific challenges to temporal expression identification and normalization, such as differentiating between dosage and time. Additionally, clinical texts frequently use repeated phrases such as "At this time" that are infrequently used in the general domain. These phrases are vague, relative, and require contextual knowledge of the subject area and the time of events to be resolved (Sun et al., 2013b).

In this work we focus on identification of temporal expressions in clinical texts using Chrono– a hybrid system that normalizes temporal expressions into the SCATE Schema (Bethard and Parker, 2016). Originally designed on general domain Newswire texts, we evaluate Chrono's performance on the clinical THYME corpus (Styler et al., 2014) "out-of-the-box" with no modifications, perform an error analysis, algorithm updates, and then re-evaluate on THYME. This analysis reveals six aspects of temporal expression extraction that should be considered when using a general domain tool in the clinical domain.

2 Related Work

State-of-the-art temporal expression extraction and normalization tools have emerged from temporal parsing challenges such as TempEval (Verhagen et al., 2007, 2010; UzZaman et al., 2013) and i2b2 (Sun et al., 2013a). Strategies utilized by these tools range from rule-based (SUTime (Chang and Manning, 2012), HeidelTime

Proceedings of NAACL-HLT 2019, pages 3682–3692
Minneapolis, Minnesota, June 2 - June 7, 2019.

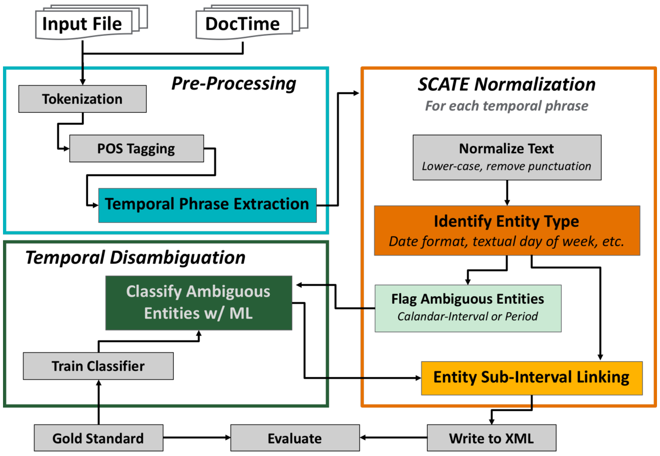

Figure 1: Overview of Chrono Workflow

(Strötgen and Gertz, 2010), NavyTime (Chambers, 2013), GUTime (Verhagen et al., 2005)) to machine learning (TRIPS and TRIOS (UzZaman and Allen, 2010), ClearTK (Bethard, 2013)) and hybrid approaches (ManTIME (Filannino et al., 2013)). For general domain texts, machine learning systems like ClearTK perform well at identifying temporal expression spans; however, rule-based and hybrid systems have better performance when taking temporal expression normalization into account (UzZaman et al., 2013).

When applied to clinical text in the 2012 i2b2 Challenge, high-ranking general domain systems SUTime, GUTime, and HeidelTime had reduced performance (Sun et al., 2013a) as compared to systems built specifically for this data (Sohn et al., 2013; Kovaevi et al., 2013; Xu et al., 2013). Regardless of the performance on general domain texts, modifications had to be made to the state-of-the-art systems to recognize clinical temporal expressions and achieve improved performance. For example, three teams utilized HeidelTime with two teams incorporating additional rules and machine learning modules on top of the default system, which achieved better performance in the 2012 i2b2 Challenge than HeidelTime with no modifications.

In addition to temporal challenges, other systems have been developed for general domain temporal parsing that utilize machine learning and complex grammars (Lee et al., 2014; Angeli et al., 2012) and rule-based methods referencing a central knowledge base (Llorens et al., 2012). SynTime (Zhong et al., 2017) takes a simplistic approach by defining a layer of syntactic token types that rules are applied to instead of processing the raw tokens. For temporal expression extraction, SynTime out-performs HeidelTime and SUTime, however, it does not attempt normalization. All these systems were built and trained on general domain texts, such as TimeBank (Pustejovsky et al., 2003) and WikiWars (Mazur and Dale, 2010) and may require adjustments to accurately capture clinical temporal expressions. In addition, these systems normalize expressions into the ISO-TimeML (Pustejovsky et al., 2010) representation, which is unable to represent expressions that don't map to a single calendar unit or are relative to an event instead of a temporal unit–both of which are frequent in clinical texts. The SCATE schema is able to faithfully represent these types of expressions, but normalization requires a more detailed approach to annotate fine-grained temporal components that are not captured by TimeML (Bethard and Parker, 2016). In this work we adapt Chrono, a novel SCATE normalization system, to the clinical domain and describe the challenges encountered when normalizing to the SCATE Schema.

3 Methods

Chrono is a hybrid rule-based and machine learning system built to identify temporal expressions in the AQUAINT corpus of Newswire texts (Graff, 2002) followed by normalization into the SCATE Schema for SemEval 2018 Task 6 (Laparra et al., 2018). Chrono consists of 3 main modules: 1) Temporal Phrase Extraction, 2) SCATE Normalization, and 3) Temporal Disambiguation (Figure 1). Briefly, the Temporal Phrase Extraction module identifies temporal/numeric tokens using a series of hierarchical rules and regular expressions. Temporal phrases are extracted based on consecutive tagged temporal/numeric tokens. Next, the SCATE Normalization module normalizes temporal phrases into the SCATE Schema using additional rule-based logic and regular expressions to identify specific temporal entities within each phrase, and links related sub-intervals. Finally, machine learning is used in the Temporal Disambiguation module as a sub-module of SCATE Normalization to disambiguate certain SCATE entities. Details on the specific rules implemented by Chrono for SemEval 2018 can be found in the systems description paper (Olex et al., 2018), and Chrono can be downloaded from https://github.com/AmyOlex/Chrono.

4 THYME Corpus

The THYME corpus consists of de-identified clinical notes and pathology reports for colon and brain cancer patients. For this work, we utilized the subset of the THYME colon cancer documents that have associated SCATE annotations in the Anafora XML format from SemEval 2018 Task 6 (Laparra et al., 2018). The Training Corpus includes 22 clinical notes and 13 pathology reports along with their gold standard Anafora XML annotations. The Evaluation Corpus includes 92 clinical notes and 49 pathology reports with the annotations withheld. In this work, Chrono is first run on the THYME Evaluation Corpus before modifications are made, then the THYME Training Corpus is used to identify problem areas in need of improvement. Finally, Chrono is run on the Evaluation Corpus again after making improvements. Data in the Evaluation Corpus remained hidden through the entire process.

5 Evaluation

Evaluation of Chrono's performance on the Training Corpus utilized python scripts provided by AnaforaTools[†] that compare Anafora XML (Chen and Styler, 2013) annotation files. All metrics reported exclude the "Event" entity because event identification is currently not implemented by Chrono, and was not included in the SemEval Task. Chrono's annotation of the Evaluation Corpus was uploaded to the Post-Evaluation submission system for SemEval 2018 Task 6, and overall Precision, Recall, and F1 measures are reported in Tables 1 and 3.

6 Results and Discussion

This section first discusses Chrono's "out-of-the-box" performance on the THYME Evaluation Corpus prior to any code changes. The next section presents parsing issues encountered using the Training Corpus that fall into six main categories: 1) lexical, 2) entity frequency, 3) numeric disambiguation, 4) machine learning training data, 5) writing style, and 6) document structure. While fixing some of these issues was straightforward, more complex issues resulted in debugging an error cascade before performance increased. Finally, a discussion of Chrono's improved performance on the THYME Evaluation Corpus is presented.

6.1 Out-of-the-Box Performance on THYME

Chrono's performance decreased significantly on the THYME Evaluation Corpus out-of-the-box with an F1 of 0.35, precision of 0.49, and recall of 0.27 (Table 1). This is due to Chrono having only been trained on Newswire text, thus, it saw a limited number of temporal expression examples.

Chrono's performance on the THYME Training Corpus resulted in an F1 of 0.314 when considering all entity properties (100% Correct Entity), and an F1 of 0.468 when only considering correct token span (Span Only). The higher Span Only result indicates that Chrono is identifying more correct entities than the 100% Correct Entity score indicates, but it is not assigning all the properties correctly. With the AnaforaTools evaluation script we are able to look at the performance on each SCATE entity individually to identify specific entities that significantly impact performance.

Dataset	System	Precision	Recall	F1
THYME Eval	Chrono	0.49	0.27	0.35
THYME Eval	Laparra et. al.	0.52	0.63	0.57
Newswire Eval	Chrono	0.61	0.50	0.55
Newswire Eval	Laparra et. al.	0.58	0.46	0.51
THYME Train	Chrono 100%	0.439	0.244	0.314
THYME Train	Chrono Span Only	0.696	0.352	0.468

Table 1: Baseline performance, excluding "Event", on THYME Training and Evaluation corpora using SVM.

6.2 NLP Whack-A-Mole - Resolving Cross-Domain NLP Challenges

Addressing cross-domain parsing issues felt synonymous to playing the arcade game of Whack-A-Mole, where as one issue was fixed another popped up. Several code improvements resulted

---

[†] https://github.com/bethard/anaforatools

in a cascading series of other code bugs and/or logical issues that needed resolution prior to realizing a performance improvement. This section describes these adventures in code improvement, which identify six primary challenges encountered in cross-domain application of temporal expression extraction. The following examples relay how complex and interconnected temporal expression extraction can be, and demonstrate the need to go beyond basic pattern identification and dictionary look-up strategies to including contextual and semantic information in order to capture all types of temporal expressions.

6.2.1 Lexical Diversity

Different domains are expected to differ in their lexicon. For example, the clinical domain contains many specialized medical terms and clinical jargon that is not encountered in general domain texts (Meystre et al., 2008). This is also true for a temporal lexicon. Originally trained on the Newswire corpus, Chrono's lexicon was limited to examples found in this domain; however, by expanding Chrono's temporal lexicon the performance on several SCATE entities increased.

Performance on the SCATE entity "Modifier" improved after refining the lexicon to include missed terms such as "nearly", "almost", "mid", "over", "early", and "beginning", and removing terms that should be annotated with other entities such as "this", "next", and "last". These descriptive temporal tokens are commonly used in clinical texts to describe various events in the patient narrative such as when symptoms occur or patient histories. The PartOfDay entity was also augmented with the terms "bedtime", "eve", and "midnight" as these, and similar terms, are frequently utilized in clinical notes for medication instructions, such as "take one pill at bedtime". Significant improvement in performance was observed after these additions, with an F1 increase of 0.117 for PartOfDay, and an F1 increase of 0.241 for Modifier.

Patient records revolve around temporal information, such as conveying medication instructions, describing symptom time lines, and outlining patients' histories. We found that temporal phrases associated with these events, like "at that time", "take one-time daily", "in four weeks time", "since that time", etc., were ubiquitous. All of these expressions include the token "time", which is annotated as a Period entity in the SCATE Schema. This token, along with others found frequently in clinical text such as "/min" and "/week" that are most commonly used as short-hand for conveying medication frequency, were not included in Chrono's temporal lexicon. This resulted in poor performance for the CalendarInterval and Period SCATE entities. The addition of 15 terms that were not present in the Newswire corpus significantly improved performance for these phrases. This result indicates that commonly used tokens have domain-specific frequencies. For example, the token "time" was used on average 0.32 times per document in the Newswire corpus and just over 4 times per document in the THYME corpus (Table 2).

6.2.2 Frequent Frequency

The frequency for some lexical terms, like "time", in clinical texts is understandable as certain concepts that convey a patient's narrative may be utilized over and over again. However, it is interesting that this observation also applies at the temporal entity level. For example, the initial build of Chrono excluded the SCATE entity Frequency because it is highly complex to parse and did not appear regularly in the Newswire corpus (0.12 times per document on average, Table 2). However, in the THYME corpus, the Frequency entity appeared on average 8.9 times per document–a 72-fold increase–which had a major impact on Chrono's performance. In clinical texts, phrases specifying frequency such as "2 time per day" or "once a day" are abundant as they are routinely used for specifying medication or symptom frequency. This increase in clinical usage extends to all but two temporal entities, with Frequency having the second highest fold change next to Event (Table 2).

6.2.3 Disambiguating Dosage

Clinical text commonly contains non-temporal numerical information representing lab test results or medication dosage along with their frequency. The majority of these instances in the THYME corpus were not identified as temporal because their values and formats were distinct. However, Chrono confused a few occurrences of medication dosage with a 24-hour time instance. For example, in the phrase "Vitamin D-3 1000 unit tablet" the "1000" was incorrectly assigned the 24-hour time value of 10am. In the current implementation of Chrono, if a 4-digit dose falls within the correct year range (1500 to 2050) or 24-hour time it will

Entity	Chrono Implements	Newswire Avg Freq	Clinical Avg Freq

Table 2: The average frequency per document of each SCATE Entity for the Newswire (81 documents) and THYME (35 documents) training corpora. The "Chrono Implements" column indicates whether or not Chrono identifies a given entity (Y=yes, N=no).

be annotated as such. A fix for this issue has yet to be implemented in Chrono, as it has a low rate of occurrence, but may include rules to identify dosage amounts such as "mg" and machine learning methods to disambiguate 4-digit numbers.

Another example of the need to disambiguate numerical values is found in the clinical phrase "Carotid pulses are 4/4". Without context, the "4/4" could be interpreted as the date "April 4th". This instance did not cause an issue with Chrono because a 2- or 4-digit year is required for a phrase to be identified as a formatted date. While this strategy worked for this example, it could become a problem when parsing files that contain year-less formatted dates. Thus, future improvements will include a numerical disambiguation module to aid in determining if a numerical phrase is temporal.

6.2.4 Cross-Domain Machine Learning Training Data

Supervised machine learning (ML) methods require the use of annotated training data in order to generate a predictive model. Naturally, training data is chosen from the domain of the task as it is the most relevant. Chrono utilizes ML to disambiguate the SCATE entities Period and CalendarInterval. First, rule-based logic identifies if an entity is a possible Period or CalendarInterval, but it is hard to tell which one without considering context. Then the ML module decides which class the entity should be labeled. The training data for this task was initially from the Newswire corpus, but this performed poorly on clinical texts with an overall F1 of 0.544. To incorporate domain-specific contextual elements, Chrono was re-trained using just the THYME corpus, which improved performance to an F1 of 0.577. We then generated a model that utilized both the Newswire and THYME data, which performed slightly better, giving an F1 of 0.578. As temporal expressions can be domain-agnostic, it makes sense that training on cross-domain data would generate a more robust and generalizable model; therefore, we chose to use the cross-domain model.

6.2.5 Lexical Variation

An advantage of processing clinical texts is that you are introduced to a variety of writing styles and preferences from different departments and medical personnel, where each may represent the same temporal concept differently. This results in lexical variations of concepts, for example, the concept of "Monday" can be represented as "M", "Mon.", or, "monday", and a temporal reasoning system must be able to identify that these all refer to the same day. The following sub-sections discuss issues associated with variation in formatted dates, times, and long temporal phrases.

Variation in Formatted Dates/Times: There are a number of standard formats to convey dates and times, of which only a few were identified in the Newswire corpus and implemented in Chrono. Clinical texts introduced additional variability in date and time formats that Chrono was unable to handle correctly. For example, the date format "21-SEP-2009" contains a mixture of letters and numbers needing to be interpreted. Chrono uses regular expressions to identify formatted dates and times; however, the expression restricted all components to be digits, so dates with alphanumeric characters were not captured. Editing the regular expression to allow for alphanumeric characters fixed the capturing issue, but resulted in an error downstream where other methods expected a numeric month to be returned. Ultimately, a custom function was written to convert months represented as text to integers as existing conversion packages were not versatile enough to accommodate all lexical variations of these entities.

Similarly, hour and minute formats such as "5:45 PM" were not being recognized correctly because Chrono's regular expression looked specifically for the format found in the Newswire corpus that contained seconds (hh:mm:ss). Debugging formatted time expressions proved to be a challenge because Chrono utilizes three different modules to parse out this data. First, a module to identify the hours, minutes, and seconds, followed by a module to identify AMPM entities, and finally, a module to link sub-intervals where both MinuteOfHour and AMPM entities are sub-intervals of HourOfDay. Interestingly, the performance of HourOfDay for the Span Only evaluation had an F1 score of 0.941 both before and after improvements, indicating that Chrono was actually identifying most of the hours correctly, but was missing specific SCATE properties.

Punctuation - To Include or Not to Include? Part of the HourOfDay parsing issue stemmed from temporal phrases at the end of a sentence, such as "2:04 AM.", where the period ended up being part of the "AM" string. Initially, Chrono looked for AMPM entities without considering punctuation unlike the MonthOfYear parsing, which specifically accounts for punctuation such as "Dec.". Thus, the "AM." in the example was never identified, so the HourOfDay entity "2" would be lacking the subinterval link to the AMPM entity. To resolve this, Chrono was modified to utilize regular expressions in parsing out AMPM entities with and without surrounding punctuation.

One dilemma arose when considering the variants of an AMPM entity. For example, valid AMPM entity strings include "AM", "am", "A.M.", and "a.m."; however, "AM." may not be considered a valid representation of an AMPM entity. Thus, Chrono specifically includes the period in the span only if there is a period after each letter in strings (e.g. "A.M."), otherwise, the period is not included in the span. Implementing this fix resulted in a significant performance improvement for the AMPM entity and, oddly, a decrease in HourOfDay performance.

Where have the Minutes Gone? While the HourOfDay entity was performing well in the Span Only evaluation, the MinuteOfHour entity performed poorly in both Span Only and 100% Correct Entity evaluations. This was a result of Chrono looking for an HourOfDay in two different methods–one that identified formatted times and another that first looked for an AMPM entity and, if found, searched for an upstream HourOfDay. The majority of time expressions in THYME were formatted as "hh:mm" followed by an "AM" or "PM" which resulted in HourOfDay being identified by AMPM parsing and not the formatted time method. The AMPM method was designed to identify the pattern found frequently in Newswire texts (e.g. "5 PM"), which doesn't include second or minute parsing. To fix this issue the formatted time method was adjusted to allow for the "hh:mm" format, so now the HourOfDay and MinuteOfHour entities are being identified and appropriate sub-intervals are annotated. However, this code improvement resulted in another decrease in performance of the HourOfDay entity.

Too Many Hours of the Day! The expected result of fixing the AMPM entity and formatted time parsing was increased performance on AMPM, MinuteOfHour, and HourOfDay entity parsing because the AMPM and MinuteOfHour sub-interval links were now identified correctly. However, HourOfDay performance actually became worse due to predicting too many HourOfDay entities. Further investigation revealed that every temporal phrase that included an AMPM entity had duplicate HourOfDay entities annotated (the same hour was annotated twice), one with the correct AMPM and MinuteOfHour sub-interval links and the other with no sub-interval links. This issue stemmed from a combination of the hierarchical parsing of formatted dates/times and inadvertently excluding a check to see if an HourOfDay entity already existed when parsing AMPM entities.

In Chrono, all temporal phrases are interrogated by all modules. To ensure only one entity of each type is identified in each temporal phrase Chrono implements a flag system. For example, in the phrase “Monday at 3:05 PM.” there is one DayOfWeek, one HourOfDay, one MinuteOfHour, and one AMPM entity. This phrase is first parsed by the formatted date/time module to identify the HourOfDay “3” and the MinuteOfHour “05” entity. Following is the identification of the “PM” AMPM entity; however, if this module finds an AMPM entity it then proceeds to look for an HourOfDay entity preceeding the AMPM substring. However, an HourOfDay had already been identified, and the AMPM module neglected checking this. Fixing this double parsing issue was straightforward as the AMPM module just needed to check if the HourOfDay flag had been set for the given temporal phrase. This error resulted in some initially puzzling results where the HourOfDay performance kept decreasing with every “improvement”, and ended up identifying twice as many HourOfDay entities as it should have. Different modules may be required for parsing different date/time formats, so it is important to ensure that all modules are consistently coded. It is also important to keep in mind that some formats are more frequent in one domain than another. This issue had not appeared when using the Newswire corpus because the majority of the AMPM entities were accompanied by the shorter format of “5 PM”, or contained the full “hh:mm:ss” format, whereas in the clinical domain the specification of hour and minutes, such as “3:05 PM”, was ubiquitous throughout the corpus.

Stop words splitting temporal phrases: Chrono was initially unable to handle stop words that connected temporal entities into a single phrase, which limited its performance on the THYME corpus due to the use of long temporal expressions in clinical texts. Chrono identified temporal phrases by looking for consecutive temporal and/or numeric tokens. If a stop word was identified (e.g. “is”, “of”, “at”, etc), the temporal phrase would be terminated–in some cases prematurely. For example, the phrase “beginning of this month on September 1” was originally separated into 3 temporal phrases: “beginning”, “this month”, and “September 1”. Other examples of temporal phrases that were incorrectly split include “2005 in April” and “October 14, 2010 at 02:07 PM”, which were both separated into two phrases. While individual temporal entities were identified correctly, the correct sub-intervals for each entity were unable to be assigned because Chrono only links sub-intervals within a single phrase. To fix this, code was added to tag “linking” words in the temporal phrase extraction module. Now, if a linking token is identified while constructing a temporal phrase it is ignored and the phrase is extended. This allows Chrono to correctly identify longer temporal phrases and results in correct assignment of sub-intervals, which brought the 100% Entity performance closer to Span Only.

Unexpected Effects of Longer Temporal Phrases: The inclusion of stop words in temporal phrases was a major upgrade to Chrono resulting in sub-intervals of longer phrases being correctly assigned. However, this had an unintended result that initially lowered the overall F1 scores for Calendar-Interval and Period entities. Investigating changes in performance revealed Calendar-Interval and Period entities that were correct were now incorrectly annotated with a link to a Number entity. This happened for phrases like “four times a day” or “one time a day”, which are highly frequent expressions in clinical notes as they are part of instructions for taking medications. This behavior resulted from Chrono’s parsing strategy for identifying associated numbers with SCATE entities where Chrono naively looked for a number token in the sub-string of characters preceding an annotated entity. This parsing strategy worked well for Newswire text as the majority of associated numbers appeared in formats similar to “2 weeks ago”, or “5 days”. Previously, Chrono assigned expressions like “four times a day” to two temporal phrases: “four times” and “day”. Thus, the Calendar-Interval “day” was correctly identified with no Number link. After including the stop words in the temporal phrases the first number in the phrase (e.g. “four”) was incorrectly associated with the Period or Calendar-Interval entity. Chrono’s number parsing strategy also became an issue with other frequent clinical phrases such as “one-time daily” where the number “one” was incorrectly associated with the Calendar-Interval “daily”. To fix this issue, Chrono’s definition of where a number had to be located in order to be linked to a SCATE entity was restricted to the immediately preceding token instead of the full preceding sub-string. This restriction works well for the THYME and Newswire corpora; however, may not work well with expressions such as “2 full weeks from now” where the Period “weeks” should be annotated with the Number “2”.

6.2.6 Document Design

Sentence Boundaries: An interesting temporal parsing issue appears in clinical texts regarding sentence tokenization due to item lists in the clinical record. Initially, Chrono did not tokenize on sentences as temporal phrases spanning sentence boundaries were not an issue in the Newswire corpus. However, clinical records in the THYME corpus contained entries like the following:

> “...my notes from December.
>
> 2. Ulcerative colitis...”

Where the top sentence ends with the temporal entity “December” followed by a numbered list item. Since Chrono did not consider sentence boundaries, this line break was removed in the preprocessing phase and the “2” that numbers the list item was parsed as a DayOfMonth associated with “December”. To resolve this issue, Chrono was updated to identify sentence boundaries. In Temporal Phrase Extraction, Chrono no longer allows a single temporal phrase to span sentence boundaries; however, the Temporal Disambiguation module still ignores these boundaries.

Metadata: Domain agnostic rules and procedures can be developed to identify many temporal expressions in written text, but metadata presents additional challenges in that it is inherently domain-specific, and can even be document type specific within the same domain. For example, pathology reports and clinical encounters with a physician can have their metadata formatted in different ways. In dealing with metadata the first question is if one wants to parse the metadata at all. A good reason to do so would be to gather contextual information that is not explicitly written in the text, like identifying the document creation date to disambiguate references to days of the week, etc. The gold standard SCATE annotations do contain dates from the metadata sections, so it is necessary for Chrono to identify these entities. Two issues arose when working on this problem: 1) How to identify a temporal token using whitespace tokenization when the metadata line contains little whitespace, and 2) whether or not to include the word “date” as a temporal token.

In the THYME corpus metadata is formatted as “[start_date=12/02/2010, rev_date=12/02/2010]”. Using whitespace tokenization this line is split into two tokens–both marked as temporal as they contain formatted date strings. However, in the Temporal Phrase Extraction module this line is considered a single phrase because it is composed of two consecutive temporal tokens. This causes an issue as Chrono assumes there is only one of each SCATE entity type in a phrase; thus, initially Chrono only annotated one of the two dates in the metadata line. To resolve this, Chrono now converts all equal signs to spaces prior to whitespace tokenization, thereby separating the metadata text to four tokens. While this fix resolved the issue of parsing metadata dates, an equal sign could be useful information, so a more sophisticated approach will be required in the future.

The second issue with parsing metadata information arose when updating the lexicon of known temporal tokens. The word “date” is temporal, but had not been included in the initial lexicon of Chrono. Including “date” as a temporal token resulted in identifying the metadata line as a single temporal phrase again as it was now a consecutive sequence of four temporal tokens: “start_date”, “12/02/2010”, “rev_date”, and “12/02/2010”. As “start_date” and “rev_date” are just labels they should not be considered temporal entities. Some mentions of “date” were valid temporal expressions, but there were few of them. Thus, we decided to continue to exclude this token. To be applicable to different domains, more sophisticated methods to parse metadata will need to be implemented to resolve issues with temporal labels and other special characters seen in metadata text.

6.3 Improved Performance

Improvements made to Chrono using the THYME Training Corpus lead to a 0.27 and 0.24 increase in precision and recall, respectively, with a 0.26 increase in F1 measure for the Evaluation Corpus (Table 3). This resulted in Chrono being the top performing system for SCATE Normalization. Chrono’s performance on the Training Corpus improved similarly with a precision of 0.881 in the Span Only evaluation and 0.729 for the 100% Correct Entity. This indicates that Chrono is identifying the correct location of many entities, but it is having trouble setting all the properties correctly.

When designing a rule-base system it is possible to develop rules that overfit or are tailored to the training corpus (i.e. Newswire texts). Overfitting rules results in good performance on the

Dataset	System	Precision	Recall	F1
THYME Eval	Chrono	0.76	0.51	0.61
THYME Eval	Laparra et. al.	0.52	0.63	0.57
Newswire Eval	Chrono	0.57	0.54	0.55
Newswire Eval	Laparra et. al.	0.58	0.46	0.51
THYME Train	Chrono 100%	0.729	0.478	0.578
THYME Train	Chrono Span Only	0.881	0.575	0.696

Table 3: Improved performance on THYME Corpora using SVM, excluding "Event".

training domain and poor performance on the testing domain, similar to Chrono's performance on the THYME corpus. However, when rules are adjusted to incorporate another domain it is expected that the performance in the training domain go down, indicating that it was overfitting the training domain. To see if this happened with Chrono, we re-evaluated our final model on the Newswire corpus. The results showed an insignificant 0.01 drop in F1 due to a 0.05 drop in Precision and a 0.04 increase in Recall, which indicates that Chrono is now more compatible with cross-domain application. Since we do not see a major drop in performance on the Newswire corpus we can conclude the original rules did not overfit the Newswire domain, but rather they were incomplete and required expansion to improve performance in the clinical domain.

7 Conclusions and Future Work

In conclusion, clinical domain texts posed additional challenges that were either not present in the Newswire corpus, or not frequent enough to prioritize highly when initially building Chrono. Application to the THMYE Training Corpus brought these limitations to light, such as the consistent use of temporal expressions that utilize frequency, highly repeated temporal phrases, dosage values being annotated as temporal expressions, and additional lexical elements. As temporal information is relatively domain agnostic, improvements made to Chrono for THYME should improve performance on other domains. An advantage of utilizing clinical texts is that it encounters a variety of writing styles from different practitioners who may prefer specifying temporal information in different ways. Additionally, different medical forms, such as pathology reports versus clinical notes, have specific ways to convey dates. Thus, the range of temporal expressions Chrono now identifies has been significantly expanded due to the variety incorporated in the clinical texts.

While Chrono's performance on SCATE Normalization has improved, there are still many areas for further development. These include identifying frequency, disambiguating dosage versus 4-digit year or 24-hour time, implementing more sophisticated approaches to parsing metadata, and performing a more detailed investigation at the entity level to identify which SCATE properties are being missed or incorrectly assigned in order to bring the 100% Correct Entity performance closer to the Span Only performance. These updates will require the implementation of additional rule-sets as well as the addition of machine learning modules and more complex contextual parsing. One approach to augmenting current rule sets is the automated generation of regular expressions (Redd et al., 2015) based on annotated gold standards, which has the potential to expand Chrono's capabilities without time-consuming human review of missed expressions. Finally, Chrono outputs normalized temporal expressions in the SCATE schema format, which limits our ability to evaluate its performance on corpora in other domains. Currently, only select subsets of the AQUAINT and THYME corpora are annotated with SCATE, and the complete conversion of TimeML to the SCATE schema is difficult as TimeML lacks details required by SCATE. Thus, implementation of a method to convert SCATE XML to the standard TimeML format will allow Chrono to be evaluated on additional cross-domain corpora and classic benchmark temporal corpora such as i2b2 (Sun et al., 2013a), TempEval (Verhagen et al., 2007, 2010; UzZaman et al., 2013), and Clinical TempEval (Bethard et al., 2015).

The process of improving Chrono brought to light several aspects of cross-domain application of temporal parsing: 1) lexical differences, 2) the frequency of temporal entity usage, 3) disambiguating numerical phrases, 4) appropriate machine learning data, 5) lexical variation of concepts, and 6) differences in document structure. While the concept of time is the same regardless of the domain, its representation can vary. Thus, temporal parsing provides a good backdrop for determining the challenges of cross-domain application, which is difficult for many NLP applications. The aspects of cross-domain application discussed herein provide a foundation for designing adaptable NLP tools that can be utilized across domains.

Abstract

Most information extraction methods focus on binary relations expressed within single sentences. In high-value domains, however, n-ary relations are of great demand (e.g., drug-gene-mutation interactions in precision oncology). Such relations often involve entity mentions that are far apart in the document, yet existing work on cross-sentence relation extraction is generally confined to small text spans (e.g., three consecutive sentences), which severely limits recall. In this paper, we propose a novel multiscale neural architecture for document-level n-ary relation extraction. Our system combines representations learned over various text spans throughout the document and across the subrelation hierarchy. Widening the system's purview to the entire document maximizes potential recall. Moreover, by integrating weak signals across the document, multiscale modeling increases precision, even in the presence of noisy labels from distant supervision. Experiments on biomedical machine reading show that our approach substantially outperforms previous n-ary relation extraction methods.

1 Introduction

Knowledge acquisition is a perennial challenge in AI. In high-value domains, it has acquired new urgency in recent years due to the advent of big data. For example, the dramatic drop in genome sequencing cost has created unprecedented opportunities for tailoring cancer treatment to a tumor's genetic composition (Bahcall, 2015). Despite this potential, operationalizing personalized medicine is difficult, in part because it requires painstaking curation of precision oncology knowledge from biomedical literature. With tens of millions of papers on PubMed, and thousands more added every day,[1] we are sorely in need of automated methods to accelerate manual curation.

> "*We next expressed ALK F1174L, ALK F1174L/L1198P, ALK F1174L/G1123S, and ALK F1174L/G1123D in the original SH-SY5Y cell line.*"

> "*The 2 mutations that were only found in the neuroblastoma resistance screen (G1123S/D) are located in the glycine-rich loop, which is known to be crucial for ATP and ligand binding and are the first mutations described that induce resistance to TAE684, but not to PF02341066.*"

Figure 1: Two examples of drug-gene-mutation relations from a biomedical journal paper. The relations are expressed across multiple paragraphs, requiring document-level extraction.

Prior work in machine reading has made great strides in sentence-level binary relation extraction. However, generalizing extraction to n-ary relations poses new challenges. Higher-order relations often involve entity mentions that are far away in the document. Recent work on n-ary relation extraction has begun to explore cross-sentence extraction (Peng et al., 2017; Wang and Poon, 2018), but the scope is still confined to short text spans (e.g., three consecutive sentences), even though a document may contain hundreds of sentences and tens of thousands of words. While this already increases the yield compared to sentence-level extraction, it still misses many relations. For example, in Figure 1, the drug-gene-mutation relations between `PF02341066`, `ALK`, `G1123S(D)` (`PF02341066` can treat cancers with mutation `G1123S(D)` in gene `ALK`) can only be extracted by substantially expanding the scope. High-value information, such as latest medical findings, might only be mentioned once in the corpus. Maximiz-

Minneapolis, Minnesota, June 2 - June 7, 2019.

ing recall is thus of paramount importance.

In this paper, we propose a novel multiscale neural architecture for document-level n-ary relation extraction. By expanding extraction scope to the entire document, rather than restricting relation candidates to co-occurring entities in a short text span, we ensure maximum potential recall. To combat the ensuing difficulties in document-level extraction, such as low precision, we introduce multiscale learning, which combines representations learned over text spans of varying scales and for various subrelations (Figure 2). This approach deviates from past methods in several key regards.

First, we adopt an entity-centric formulation by making a single prediction for each entity tuple occurring in a document. Previous n-ary relation extraction methods typically classify individual mention tuples, but this approach scales poorly to whole documents. Since each entity can be mentioned many times in the same document, applying mention-level methods leads to a combinatorial explosion of mention tuples. This creates not only computational challenges but also learning challenges, as the vast majority of these tuples do not express the relation. Our entity-centric formulation alleviates both of these problems.

Second, for each candidate tuple, prior methods typically take as input the contiguous text span encompassing the mentions. For document-level extraction, the resulting text span could become untenably large, even though most of it is unrelated to the relation of interest. Instead, we allow discontiguous input formed by multiple discourse units (e.g., sentence or paragraph) containing the given entity mentions.

Finally, while an n-ary relation might not reside within a discourse unit, its subrelations might. In Figure 1, the paper first mentions a gene-mutation subrelation, then discusses a drug-mutation subrelation in a later paragraph. By including subrelations in our modeling, we can predict n-ary relations even when all n entities never co-occur in the same discourse unit.

With multiscale learning, we turn the document view from a challenge into an advantage by combining weak signals across text spans and subrelations. Following recent work in cross-sentence relation extraction, we conduct thorough evaluation in biomedical machine reading. Our approach substantially outperforms prior n-ary relation extraction methods, attaining state-of-the-art results on a large benchmark dataset recently released by a major cancer center. Ablation studies show that multiscale modeling is the key to these gains.[2]

2 Document-Level N-ary Relation Extraction

Prior work on relation extraction typically formulates it as a mention-level classification problem. Let $e_1, \ldots, e_n$ be entity mentions that co-occur in a text span T. Relation extraction amounts to classifying whether a relation R holds for $e_1, \ldots, e_n$ in T. For the well-studied case of binary relations within single sentences, $n = 2$ and T is a sentence.

In high-value domains, however, there is increasing demand for document-level n-ary relation extraction, where $n > 2$ and T is a full document that may contain hundreds of sentences. For example, a molecular tumor board needs to know if a drug is relevant for treating cancer patients with a certain mutation in a given gene. We can help the tumor board by extracting such ternary interactions from biomedical articles. The mention-centric view of relation extraction does not scale well to this general setting. Each of the n entities may be mentioned many times in a document, resulting in a large number of candidate mention tuples, even though the vast majority of them are irrelevant to the extraction task.

In this paper, we adopt an *entity-centric* formulation for document-level n-ary relation extraction. We use upper case for entities ($E_1, \cdots, E_n$) and lower case for mentions ($e_1, \cdots, e_n$). We define an n-ary relation candidate to be an $(n+1)$-tuple $(E_1, \ldots, E_n, T)$, where each entity E_i is mentioned at least once in the text span T. The relation extraction model is given a candidate $(E_1, \ldots, E_n, T)$ and outputs whether or not the tuple expresses the relation R.[3] Deciding what information to use from the various entity mentions within T is now a modeling question, which we address in the next section.

3 Our Approach: Multiscale Representation Learning

We present a general framework for document-level n-ary relation extraction using multiscale

---

[2] Our code and data will be available at `hanover.azurewebsites.net`

[3] It is easy to extend our approach to situations where k mutually exclusive relations $R_1, \ldots, R_k$ must be distinguished, resulting in a $(k+1)$-way classification problem.

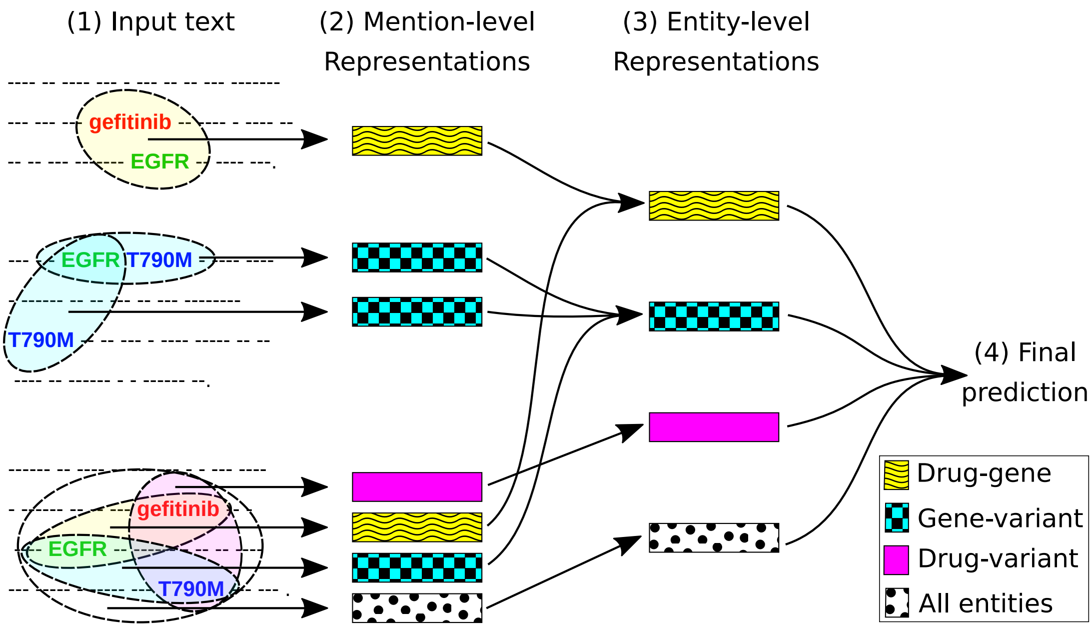

Figure 2: Multiscale representation learning for document-level n-ary relation extraction, an entity-centric approach that combines mention-level representations learned across text spans and subrelation hierarchy. (1) Entity mentions (e.g., gefitinib, a drug; EGFR, a gene; T790M, a variant) are identified from text, and mentions that co-occur within a discourse unit (e.g., paragraph) are isolated. (2) Within each discourse unit, mention-level representations are computed for each tuple of entity mentions. These representations may correspond to the entire n-ary relation or subrelations over subsets of entities (drug-variant, drug-gene, gene-variant). (3) At the document scale, mention-level representations for both the n-ary relation and its subrelations are combined into entity-level representations. (4) Entity-level representations are used to predict the relation.

representation learning. Given a document with text T and entities $E_1, \ldots, E_n$, we first build mention-level representations for groups of these entities whenever they co-occur within the same discourse unit. We then aggregate these representations across the whole document, yielding entity-level representations for each subset of entities. Finally, we predict whether $E_1, \ldots, E_n$ participate in the relation based on the concatenation of these entity-level representations. These steps are depicted in Figure 2.

3.1 Mention-level Representation

Let the full document T be composed of discourse units $T_1, \ldots, T_m$ (e.g., different paragraphs). Let T_j be one such discourse unit, and suppose $e_1, \ldots, e_n$ are entity mentions of $E_1, \ldots, E_n$ that co-occur in T_j. We construct a contextualized representation for mention tuple $(e_1, \ldots, e_n)$ in T_j. In this paper, we use a standard approach by applying a bi-directional LSTM (BiLSTM) to T_j, concatenating the hidden states for each mention, and feeding this through a single-layer neural network. We denote the resulting vector as $r(R, e_1, \ldots, e_n, T_j)$ for the relation R.

3.2 Entity-level Representation

Let $M(R, E_1, \ldots, E_n, T)$ denote the set of all mention tuples $(e_1, \ldots, e_n)$ and discourse units T_j within T such that each e_i appears in T_j. We can create an entity-level representation $r(R, E_1, \ldots, E_n, T)$ of the n entities by combining mention-level representations using an aggregation operator $\mathcal{C}$:

$$\underset{(e_1,\ldots,e_n,T_j)\in M(R,E_1,\ldots,E_n,T)}{\mathcal{C}} r(R, e_1, \ldots, e_n, T_j)$$

A standard choice for $\mathcal{C}$ is max pooling, which works well if it is pretty clear-cut whether a mention tuple expresses a relation. In practice, however, the mention tuples could be ambiguous and less than certain individually, yet collectively express a relation in the document. This motivates us to experiment with logsumexp, the smooth version of max, where

$$\mathrm{logsumexp}(x_1, \ldots, x_k) = \log \sum_{i=1}^{k} \exp(x_i).$$

This facilitates accumulating weak signals from individual mention tuples, and our experiments show that it substantially improves extraction accuracy compared to max pooling.

3.3 Subrelations

For higher-order relations (i.e., larger n), it is less likely that they will be completely contained within a discourse unit. Often, the relation can be decomposed into subrelations over subsets of entities, each of which is more likely to be expressed in a single discourse unit. This motivates us to construct entity-level representations for subrelations as well. The process is straightforward. Let R_S be the $|S|$-ary subrelation over entities $E_{S_1}, \cdots, E_{S_{|S|}}$, where $S \subseteq \{1, \dots, n\}$ and $|S|$ denotes its size. We first construct mention-level representations $r(R_S, e_{S_1}, \cdots, e_{S_{|S|}}, T)$ for R_S and its relevant entity mentions, then combine them into an entity-level representation $r(R_S, E_{S_1}, \cdots, E_{S_{|S|}}, D)$ using the chosen aggregation operator $\mathcal{C}$. We do this for every $S \subseteq \{1, \dots, n\}$ with $|S| \geq 2$ (including the whole set, which corresponds to the full relation R). This gives us an entity-level representation for each subrelation of arity at least 2, or equivalently, each subset of entities of size at least 2.

3.4 Relation Prediction

To make a final prediction, we first concatenate all of the entity-level representations $r(R_S, E_{S_1}, \dots, E_{S_{|S|}}, D)$ for all $S \subseteq \{1, \dots, n\}$ with $|S| \geq 2$. The concatenated representation is fed through a two-layer feedforward neural network followed by a softmax function to predict the relation type.

It is possible that for some subrelations R_S, all $|S|$ entities do not co-occur in any discourse unit. When this happens, we set $r(R_S, E_{S_1}, \dots, E_{S_{|S|}})$ to a bias vector which is learned separately for each R_S. This ensures that the concatenation is done over a fixed number of vectors, e.g., 4 for a tenary relation (three binary subrelations and the main relation). Importantly, this strategy enables us to make meaningful predictions for relation candidates even if all n entities never co-occur in the same discourse unit; such candidates would never be generated by a system that only looks at single discourse units in isolation.

3.5 Document Model

Our document model is actually a family of representation learning methods, conditioned on the choice of discourse units, subrelations, and aggregation operators. In this paper, we consider sentences and paragraphs as possible discourse units. We explore $\max$ and $\operatorname{logsumexp}$ as aggregation operators. Moreover, we explore ensemble prediction as an additional aggregation method. Specifically, we learn a restricted multiscale model by limiting the text span to a single discourse unit (e.g., a paragraph); the model still combines representations across mentions and subrelations. At test time, given a full document with m discourse units, we obtain independent predictions $p_1, \dots, p_m$ for each discourse unit. We then combine these probabilities using an ensemble operator $\mathcal{P}$. A natural choice for $\mathcal{P}$ is max, though we also experiment with noisy-or:

$$\mathcal{P}(p_1, \cdots, p_k) = 1 - \prod_{i=1}^{k} (1 - p_i).$$

It is also possible to ensemble multiple models that operate on different discourse units, using this same operator.

Our model can be trained using standard supervised or indirectly supervised methods. In this paper, we focus on distant supervision, as it is a particularly potent learning paradigm for high-value domains. Our entity-centric formulation is particularly well aligned with distant supervision, as distant supervision at the entity level is significantly less noisy compared to the mention level, so we don't need to deploy sophisticated denoising strategies such as multi-instance learning (Hoffmann et al., 2011).

	Sentence level	Paragraph level	Document level
Text Units	2,326	3,687	3,362
Pos. Examples	2,222	4,906	8,514
Neg. Examples	2,849	13,371	323,584

Table 1: Statistics of our training corpus using PMC-OA articles and distant supervision from CIVIC, GDKD, and OncoKB. "Text Units" refers to the number of distinct sentences, paragraphs, and documents that contain a candidate triple of drug, gene, mutation.

	Development	Test
Documents	118	225
Annotated facts	701	1,324
Paragraphs per document	101	105
Sentences per document	314	320
Words per document	6,871	7,010

4 Experiments

4.1 Biomedical Machine Reading

We validate our approach on a standard biomedical machine reading task: extracting drug-gene-mutation interactions from biomedical articles (Peng et al., 2017; Wang and Poon, 2018). We cast this task as binary classification: given a drug, gene, mutation, and document in which they are mentioned, determine whether the document asserts that the mutation in the gene affects response to the drug. For training, we use documents from the PubMed Central Open Access Subset (PMC-OA)[4]. For distant supervision, we use three existing knowledgebases (KBs) with hand-curated drug-gene-mutation facts: CIVIC,[5] GDKD (Dienstmann et al., 2015), and OncoKB (Chakravarty et al., 2017). Table 1 shows basic statistics of this training data. Past methods using distant supervision often need to up-weight positive examples, due to the large proportion of negative candidates. Interestingly, we found that our document model was robust to this imbalance, as re-weighting had little effect and we didn't use it in our final results.

Evaluating distant supervision methods is challenging, as there is often no gold-standard test set, especially at the mention level. Prior work thus resorts to reporting sample precision (estimated proportion of correct system extractions) and absolute recall (estimated number of correct system extractions). This requires subsampling extraction results and manually annotating them. Subsampling variance also introduces noise in the estimate.

Instead, we used CKB CORE™, a public subset of the Clinical Knowledgebase (CKB)[6] (Patterson et al., 2016), as our gold-standard test set. CKB CORE™ contains document-level annotation of drug-gene-mutation interactions manually curated by The Jackson Laboratory (JAX), an NCI-designated cancer center. It is a high-quality KB containing facts from a few hundred PubMed articles for 86 genes, with minimal overlap with the three KBs we used for distant supervision. To avoid contamination, we removed CKB entries whose documents were used in our training data, and split the rest into a development and test set. See Table 2 for statistics. We tuned hyperparameters and thresholds on the development set, and report results on the test set.

4.2 Implementation Details

We conducted standard preprocessing and entity linking, similar to Wang and Poon (2018) (see Section A.1). Following standard practice, we masked all entities of the same type with a dummy token, to prevent the classifier from simply memorizing the facts in distant supervision. Wang and Poon (2018) observed that many errors stemmed from incorrect gene-mutation association. We therefore developed a simple rule-based system that predicts which gene-mutation pairs are valid (see Section A.2). We removed candidates that contained a gene-mutation pair that was not predicted by the rule-based system.

4.3 Main Results

We evaluate primarily on area under the precision recall curve (AUC).[7] We also report maximum recall, which is the fraction of true facts for which a candidate was generated. Finally, we report precision, recall, and F1, using a threshold tuned to maximize F1 on the CKB development set.

We compared our multiscale system (MULTISCALE) with three restricted variants (SENTLEVEL, PARALEVEL, DOCLEVEL). SENTLEVEL and PARALEVEL restricted training and prediction to single discourse units (i.e., sentences and paragraphs), and produced a document-level prediction by applying the ensemble operator over individual discourse units. DOCLEVEL takes the whole document as input, with each paragraph as a discourse unit. MULTISCALE further combined SENTLEVEL, PARALEVEL, and DOCLEVEL using the ensemble operator. For additional details about the models, see Section A.3. We also compared MULTISCALE with DPL (Wang and Poon, 2018), the prior state of the art in cross-sentence n-ary relation extraction. DPL classifies drug-gene-mutation interactions within three consecutive sentences using the same model architecture as Peng et al. (2017), but incorporates additional indirect supervision such as data programming and joint inference. We used the DPL code from the authors and produced a document-level prediction similarly using the ensemble operator. In the base version, we used max as the ensemble operator. We also evaluated the effect when we

Table 3: Comparison of our multiscale system with restricted variants and DPL (Wang and Poon, 2018) on CKB.

used noisy-or as the ensemble operator, as well as when we applied the gene-mutation filter during postprocessing.

Table 3 shows the results on the CKB test set. In all scenarios, our full model (MultiScale) substantially outperforms the prior state-of-the-art system (DPL). For example, in the best setting, using both noisy-or and the gene-mutation filter, the full model improves over DPL by 8.4 AUC points. Multiscale learning is the key to this performance gain, with MultiScale substantially outperforming more restricted variants. Not surprisingly, expanding extraction scope from sentences to paragraphs resulted in the biggest gain, already surpassing DPL. Conducting end-to-end learning over a document-level representation, as in DocLevel, is beneficial compared to ensembling over predictions for individual discourse units (SentLevel, ParaLevel), especially in the base version. Interestingly, MultiScale still attained significant gain over DocLevel with an ensemble over SentLevel and ParaLevel, suggesting that the document-level representation can still be improved. In addition to prediction accuracy, the document-level models also have much more room to grow, as maximum recall is about 20 absolute points higher in MultiScale and DocLevel, compared to ParaLevel or DPL.[8]

The ensemble operator had a surprisingly large effect, as shown by the gain when it was changed from max (base version) to noisy-or. This suggests that combining weak signals across multiple scales can be quite beneficial. Our handcrafted gene-mutation filter also improved all systems substantially, corroborating the analysis of Wang and Poon (2018). In particular, without the filter, it is hard for the document-level models to achieve high precision, so they sacrifice a lot of recall to get good F1 scores. Using the filter helps them attain significantly higher recall while maintaining respectable precision.

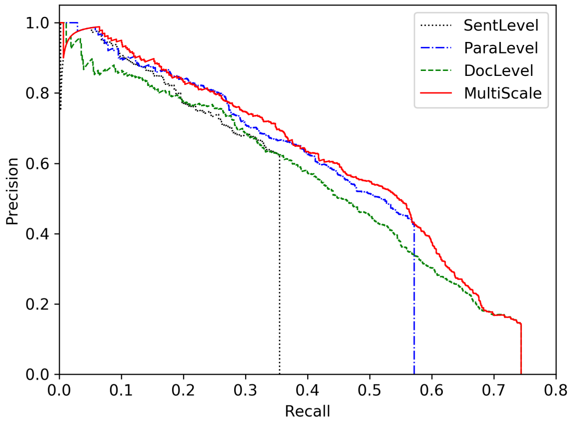

Figure 3: Precision-recall curves on CKB (with noisy-or and gene-mutation filter). MultiScale attained generally better precision than ParaLevel, and higher maximum recall like DocLevel.

Figure 3 shows the precision-recall curves for the four models (with noisy-or and gene-mutation filter). DocLevel has higher maximum recall than ParaLevel, but generally lower precision at the same recall level. By ensembling all three variants, MultiScale achieves the best combi-

---

[8] The difference in actual recall is less pronounced, as we chose thresholds to maximize F1 score. We expect actual recall to increase significantly as document-level models improve, whereas the other models are closer to their ceiling.

System	AUC	MR	P	R	F1
MultiScale	**47.5**	74.4	52.6	53.0	**52.8**
– SentLevel	47.0	74.4	43.0	55.8	48.6

– DocLevel	42.4	57.2	59.6	44.4	50.9

Table 4: Results on CKB when removing either SentLevel, ParaLevel, or DocLevel from the ensemble computed by MultiScale. MR=max recall, P=precision, R=recall.

System	AUC	P	R	F1
SentLevel	28.3	62.7	35.1	45.0
ParaLevel	38.1	47.4	52.2	49.7
DocLevel	41.1	48.2	45.6	46.9
MultiScale	43.7	45.7	51.2	48.3

Table 5: Results on CKB after replacing `logsumexp` with max (with noisy-or and gene-mutation filter). P=precision, R=recall. Max recall same as in Table 3.

nation: it generally improves precision while capturing more cross-paragraph relations. This can also be seen in Table 4, where we ablate each of the three variants used by MultiScale. All three variants in the ensemble contributed to overall performance.

We use logsumexp as the aggregation operator to combine mention-level representations into an entity-level one. If we replace it with max pooling, the performance drops substantially across the board, as shown in Table 5. For example, MultiScale lost 3.8 absolute points in AUC. Such difference is also observed in Verga et al. (2018). As in comparing ensemble operators, this demonstrates the benefit of combining weak signals using a multiscale representation.

4.4 Cross-sentence and Cross-paragraph Extractions

Compared to standard sentence-level extraction, our method can extract relations among entities that never co-occur in the same sentence or even paragraph. Figure 4 shows the proportion of correctly predicted facts by MultiScale that are expressed across paragraph or sentence boundaries. MultiScale can substantially improve the recall by making additional cross-sentence and cross-paragraph extractions. We manually inspected twenty correct cross-paragraph extractions (with the chosen threshold for the precision/recall numbers in Table 3) and found that our model was able to handle some interesting linguistic phenomena. Often, a paper would first describe the mutations present in a patient cohort, and later describe the effects of drug treatment. There are also instances of bridging anaphora, for example via cell lines. One paper first stated the gene and mutation for a cell line "*The **FLT3**-inhibitor resistant cells Ba/F3-ITD+691, Ba/F3-ITD+842, . . . , which harbored FLT-ITD plus F691L, **Y842C**, . . . mutations. . .*", and later stated the drug effect on the cell line "***E6201** also demonstrated strong anti-proliferative effects in **FLT3**-inhibitor resistant cells. . . such as Ba/F3-ITD+691, Ba/F3-ITD+842 . . .*".

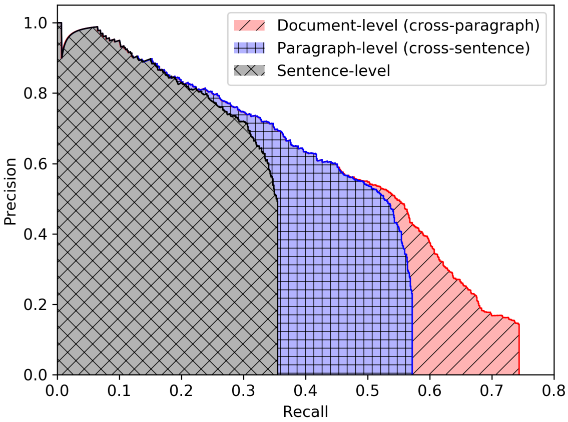

Figure 4: Breakdown of MultiScale recall based on whether entities in a correctly extracted fact occurred within a single sentence, cross-sentence but within a single paragraph, or only cross-paragraph. Adding cross-sentence and cross-paragraph extractions is important for high recall.

System	AUC	MR	P	R	F1
Base version					
SentDrugMut	31.0	40.8	60.0	40.7	48.5

ParaDrugGene	26.1	68.9	46.1	29.5	36.0

Table 6: Results of subrelation decomposition baselines on CKB, with the gene-mutation filter. MR=max recall, P=precision, R=recall.

4.5 Subrelation Decomposition

As a baseline, we also consider a different document-level strategy where we decompose the n-ary relation into subrelations of lower arity, train independent classifiers for them, then join the subrelation predictions into one for the n-ary relation. We found that with distant supervision, the gene-mutation subrelation classifier was too noisy. Therefore, we focused on training drug-gene and drug-mutation classifiers, and joined each with the rule-based gene-mutation predictions to make ternary predictions. Table 6 shows the results on CKB. The paragraph-level drug-mutation model is quite competitive, which benefits from the fact that the gene-mutation associations in a document are unique. This is not true in general n-ary relations. Still, it trails MULTISCALE by a large margin in predictive accuracy, and with an even larger gap in the potential upside (i.e., maximum recall). The drug-gene model has higher maximum recall, but much worse precision. This low precision is expected, as it is usually not valid to assume that if a drug and gene interact, then all possible mutations in the gene will have an effect on the drug response.

4.6 Error Analysis

While much higher compared to other systems, the maximum recall for MULTISCALE is still far from 100%. For over 20% of the relations, we can't find all three entities in the document. In many cases, the missing entities are in figures or supplements, beyond the scope of our extraction. Some mutations are indirectly referenced by well-known cell lines. There are also remaining entity linking errors (e.g., due to missing drug synonyms).

We next manually analyzed some sample prediction errors. Among 50 false positive errors, we found a significant portion of them were actually true mentions in the paper but were excluded by curators due to additional curation criteria. For example, CKB does not curate a fact referenced in related work, or if they deem the empirical evidence as insufficient. This suggests the need for even higher-order relation extraction to cover these aspects. We also inspected 50 sample false negative errors. In 40% of the cases, the textual evidence is vague and requires corroboration from a table or figure. In most of the remaining cases, there is direct textual evidence, though they require cross-paragraph reasoning (e.g., bridging anaphora). While MULTISCALE was able to process such phenomena sometimes, there is clearly much room to improve.

5 Related Work

N-ary relation extraction Prior work on n-ary relation extraction generally follows Davidsonian semantics by reducing the n-ary relation to n binary relations between the reified relation and its arguments, a.k.a. *slot filling*. For example, early work on the Message Understanding Conference (MUC) dataset aims to identify event participants in news articles (Chinchor, 1998). More recently, there has been much work in extracting semantic roles for verbs, as in semantic role labeling (Palmer et al., 2010), as well as properties for popular entities, as in Wikipedia Infobox (Wu and Weld, 2007) and TAC KBP[9]. In biomedicine, the BioNLP Event Extraction Shared Task aims to extract genetic events such as expression and regulation (Kim et al., 2009). These approaches typically assume that the whole document refers to a single coherent event, or require an event anchor (e.g., verb in semantic role labeling and trigger word in event extraction). We instead follow recent work in cross-sentence n-ary relation extraction (Peng et al., 2017; Wang and Poon, 2018; Song et al., 2018), which does not have these restrictions.

Document-level relation extraction Most information extraction work focuses on modeling and prediction within sentences (Surdeanu and Ji, 2014). Duan et al. (2017) introduces a pre-trained document embedding to aid event detection, but their extraction is still at the sentence level. Past work on cross-sentence extraction often relies on explicit coreference annotations or the assumption of a single event in the document (Wick et al., 2006; Gerber and Chai, 2010; Swampillai and Stevenson, 2011; Yoshikawa et al., 2011; Koch et al., 2014; Yang and Mitchell, 2016). Recently, there has been increasing interest in general cross-sentence relation extraction (Quirk and Poon, 2017; Peng et al., 2017; Wang and Poon, 2018), but their scope is still limited to short text spans of a few consecutive sentences. These methods all extract relations at the mention level, which does not scale to whole documents due to the combinatorial explosion of relation candidates. Wu et al. (2018b) applies manually crafted rules to heavily filter the candidates. We instead adopt an entity-centric approach and combine mention-level representations to create an entity-level representation for extraction. Mintz et al. (2009) aggregates mention-level features into entity-level ones within a document, but they only consider

---

[9] `http://www.nist.gov/tac/2016/KBP/ColdStart/index.html`

binary relations within single sentences. Kilicoglu (2016) used hand-crafted features to improve cross-sentence extraction, but they focus on binary relations, and their documents are limited to abstracts, which are substantially shorter than the full-text articles we consider. Verga et al. (2018) applies self-attention to combine the representations of all mention pairs into an entity pair representation, which can be viewed a special case of our framework. Their work is also limited to binary relations and abstracts, rather than full documents.

Multiscale modeling Deep learning on long sequences can benefit from multiscale modeling that accounts for varying scales in the discourse structure. Prior work focuses on generative learning such as language modeling (Chung et al., 2017). We instead apply multiscale modeling to discriminative learning for relation extraction. In addition to modeling various scales of discourse units (sentence, paragraph, document), we also combine mention-level representations into an entity-level one, as well as sub-relations of the n-ary relation. McDonald et al. (2005) learn $\binom{n}{2}$ pairwise relation classifiers, then construct maximal cliques of related entities, which also bears resemblance to our subrelation modeling. However, our approach incorporates the entire subrelation hierarchy, provides a principled end-to-end learning framework, and extracts relations from the whole document rather than within single sentences.

Distant supervision Distant supervision has emerged as a powerful paradigm to generate large but potentially noisy labeled datasets (Craven et al., 1999; Mintz et al., 2009). A common denoising strategy applies multi-instance learning by treating mention-level labels as latent variables (Hoffmann et al., 2011). Noise from distant supervision increases as extraction scope expands beyond single sentences, motivating a variety of indirect supervision approaches (Quirk and Poon, 2017; Peng et al., 2017; Wang and Poon, 2018). Our entity-centric representation and multiscale modeling provide an orthogonal approach to combat noise by combining weak signals spanning various text spans and subrelations.

6 Conclusion

We propose a multiscale, entity-centric approach for document-level n-ary relation extraction. We vastly increase maximum recall by scoring document-level candidates. Meanwhile, we preserve precision with a multiscale approach that combines representations learned across the subrelation hierarchy and text spans of various scales. Our method substantially outperforms prior cross-sentence n-ary relation extraction approaches in the high-value domain of precision oncology.

Our document-level view opens opportunities for multimodal learning by integrating information from tables and figures (Wu et al., 2018a). We used the ternary drug-gene-mutation relation as a running example in this paper, but knowledge bases often store additional fields such as effect (sensitive or resistance), cancer type (solid tumor or leukemia), and evidence (human trial or cell line experiment). It is straightforward to apply our method to such higher-order relations. Finally, it will be interesting to validate our approach in a real-world assisted-curation setting, where a machine reading system proposes candidate facts to be verified by human curators.

A Appendices

A.1 Preprocessing

Full-text documents in this study were obtained from PMC. The text was first tokenized using NLTK[10], then entities were extracted using a combination of regular expressions and dictionary lookups. To identify mutation mentions, we applied a regular expression rule for missense mutations. To identify gene mentions, we used dictionary lookup from the HUGO Gene Nomenclature Committee (HGNC)[11] dataset. To identify drug mentions, we used dictionary lookup from a curated list of drugs and their synonyms. For our training set, our list of drugs consists of all the drugs present in the distant supervision knowledge bases and selected cancer-related drugs from DrugBank[12] (770 drugs total). For our test set, our drug dictionary consists of all the drugs in CKB (1119 drugs).

A.2 Gene-mutation Rule-based System

Here we describe our rule-based system for linking mutations and genes within a document. We first generate a global mapping of mutations to sets of genes by combining publicly-available mutation-gene datasets (COSMIC[13], COSMIC Cell Lines Project[14], CIViC[15], and OncoKB[16]). We then augment this mapping by finding the gene that most frequently co-occurs with each mutation in all of PubMed Central (PMC) full-text articles based on three high-precision rules:

1. Gene and mutation are in the same token (e.g., ”EGFR-T790M”)
2. Gene token is followed by mutation token (e.g., ”EGFR T790M”)
3. Gene token is followed by a token of any single character and then followed by mutation token (e.g., ”EGFR - T790M”)

For each mutation, we start with the first rule, and find all text matches for a gene with that mutation and rule. If we found at least one match, we add the gene that occurred in the most matches to the global map. Otherwise, we repeat with the next rule.

Each mutation in the global mutation-gene map is mapped to more than 20 genes on average. However, within the context of a document, each mutation is (usually) associated with just a single gene. Given a document containing a mutation, we associate that mutation with the gene that (1) is in the global mutation-gene map for that mutation, and (2) appears closest to any mutation mention in the document.

To associate genes for the remaining mutations, we apply two recall-friendly regular expression rules within that document:

4. Mutation is in same sentence as “*GENE* mut”
5. Mutation is in same paragraph as “*GENE* mutation”

We choose the first gene in the document that satisfies one of the two rules, in the above order. If there is still no matching gene at this point, the most frequent gene in the document is selected for that mutation.

A.3 Model Details

We used 200-dimensional word vectors, initialized with word2vec vectors trained on a biomedical text corpus (Pyysalo et al., 2013). We updated

these vectors during training. At each step, our BiLSTM received as input a concatenation of the word vectors and a 100-dimensional embedding of the index of the current discourse unit within the document. Following Vaswani et al. (2017), we used sinusoidal embeddings to represent these indices. We used a single-layer bidirectional LSTM with a 200-dimensional hidden state. Mention-level representations were 400-dimensional and computed from BiLSTM hidden states using a single linear layer followed by the $\tanh$ activation function. For the final prediction layer, we used a two-layer feedforward network with 400 hidden units and ReLU activation function. We train using the Adam optimizer (Kingma and Ba, 2014) with learning rate of 1×10^{-5}. During training, we consider each document to be a single batch, which allows us to reuse computation for different relation candidates in the same document.

Inferring Which Medical Treatments Work from Reports of Clinical Trials

Abstract

How do we know if a particular medical treatment actually works? Ideally one would consult all available evidence from relevant clinical trials. Unfortunately, such results are primarily disseminated in natural language scientific articles, imposing substantial burden on those trying to make sense of them. In this paper, we present a new task and corpus for making this unstructured evidence actionable. The task entails inferring reported findings from a full-text article describing a randomized controlled trial (RCT) with respect to a given intervention, comparator, and outcome of interest, e.g., inferring if an article provides evidence supporting the use of *aspirin* to reduce *risk of stroke*, as compared to *placebo*.

We present a new corpus for this task comprising 10,000+ prompts coupled with full-text articles describing RCTs. Results using a suite of models — ranging from heuristic (rule-based) approaches to attentive neural architectures — demonstrate the difficulty of the task, which we believe largely owes to the lengthy, technical input texts. To facilitate further work on this important, challenging problem we make the corpus, documentation, a website and leaderboard, and code for baselines and evaluation available at `http://evidence-inference.ebm-nlp.com/`.

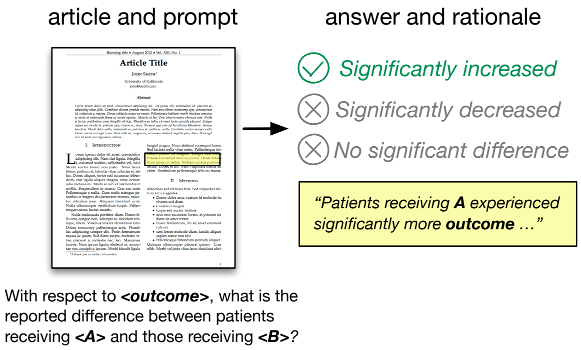

Figure 1: The task. Given a treatment **A**, a comparator **B**, and an **outcome**, infer the reported relationship between **A** and **B** with respect to **outcome**, and provide evidence supporting this from the text.

1 Introduction

Biomedical evidence is predominantly disseminated in unstructured, natural language scientific manuscripts that describe the conduct and results of randomized control trials (RCTs). The published evidence base is vast and expanding (Bastian et al., 2010): at present more than 100 reports of RCTs are published every day, on average. It is thus time-consuming, and often practically impossible, to sort through all of the relevant published literature to robustly answer questions such as: *Does infliximab reduce dysmenorrhea (pain) scores, relative to placebo*?

Given the critical role published reports of trials play in informing evidence-based care, organizations such as the Cochrane collaboration and groups at evidence-based practice centers (EPCs) are dedicated to manually synthesizing findings, but struggle to keep up with the literature (Tsafnat et al., 2013). NLP can play a key role in automating this process, thereby mitigating costs and keeping treatment recommendations up-to-date with the evidence as it is published.

In this paper, we consider the task of inferring whether a given treatment is effective with respect to a specified outcome. Typically, this assessment is done relative to other treatment options (i.e., comparators). We assume the model is provided with a *prompt* that specifies an intervention, a comparator, and an outcome, along with a full-text article. The model is then to infer the reported findings with respect to this prompt (Figure 1). From a healthcare perspective, this inference task is an essential step for automating extraction of actionable evidence from trial reports.

Proceedings of NAACL-HLT 2019, pages 3705–3717
Minneapolis, Minnesota, June 2 - June 7, 2019.

From an NLP standpoint, the proposed task can be seen as an instance of natural language inference (Bowman et al., 2015), viewing the article and prompt as the premise and hypothesis, respectively. However, the problem differs in a few important ways from existing NLP formulations. First, the inputs: prompts are brief (∼13.5 words on average), but articles are long (∼4200 words). Further, only a few snippets of the article will be relevant to the label for a given prompt. Second, prompts in this domain are structured, and include only a few types of key information: interventions, comparators, and outcomes. Methods that exploit this regularity are likely to be more accurate than generic inference algorithms.

Another interesting property of this task is that the target for an article depends on the interventions and outcome specified by a given prompt. Most articles report results for multiple interventions and outcomes: 67% of articles in our corpus are associated with two or more prompts that have *different* labels, e.g., indicating that a specific treatment was comparatively effective for one outcome but not for another. As a concrete example from our corpus, *infliximab* was reported as realizing *no significant difference* with respect to *dysmenorrhea*, compared to a *placebo*. But *infliximab* was associated with a *significant increase* in *pain killer intake*, again compared to *placebo*. Generally positive words in an article (e.g., "improved") will confuse inference models that fail to account for this. One may view these as built-in "adversarial" examples (Jia and Liang, 2016) for the task.

A key sub-problem is thus identifying snippet(s) of evidence in an article *relevant to a given input prompt*. Attention mechanisms (Bahdanau et al., 2014) conditioned on prompts would seem a natural means to achieve this, and we do find that these achieve predictive gains, but they are modest. Existing attention variants seem to struggle to consistently attend to relevant evidence, even when explicitly pretrained using marked rationales. This corpus can facilitate further research in attention variants designed for lengthy inputs (Choi et al., 2017; Yang et al., 2016).

In sum, our contributions are threefold. We: (1) formulate a novel task (*evidence inference*) that is both practically important and technically challenging; (2) Provide a new publicly-available corpus comprising 10,000+ evidence "prompts", answers, supporting evidence spans, and associated full-text articles (`http://evidence-inference.ebm-nlp.com`) all manually annotated by medical doctors; (3) Develop baseline algorithms to establish state-of-the-art performance and highlight modeling challenges posed by this new task.

2 Annotation

The specialized nature of this task necessitates adequate domain knowledge. We thus recruited medical doctors (MDs) via the Upwork platform to perform annotation. Annotators were assigned to one of three mutually exclusive groups, responsible for: (1) prompt generation, (2) prompt and article annotation, and (3) verification. Figure 2 depicts the annotation process schematically; we describe these steps in more detail below.

It is important to note that annotation was performed on full-texts, not just abstracts. Evidence relevant to a particular clinical question is quite often only available in the full text. Indeed, in our dataset, the relevant evidence span was marked in the abstract only 40.5% of the time.

2.1 Prompt Generation

This first task entails generating questions (or "prompts") that are answerable on the basis of a corresponding full-text article describing an RCT. Such prompts concern the comparison of specific interventions with respect to a particular outcome. Specifically, these questions ask whether an article reports that the specified intervention was found (in the described trial) to be significantly more effective than a comparator treatment, with respect to the outcome of interest.

Prompt creators were instructed to identify a snippet, in a given full-text article, that reports a relationship between an intervention, comparator, and outcome. Generators were also asked to provide answers and accompanying rationales to the prompts that they provided; such supporting evidence is important for this task and domain.

As a concrete example, an example generated prompt for a trial described in (Marre et al., 2009) specifies *Proinsulin : insulin ratio* as the outcome of interest, *liraglutide (1.8 mg) plus glimepiride* as the intervention, and *rosiglitazone plus glimepiride* as the comparator. Liraglutide and rosiglitazone are both drugs that can be used to treat type 2 diabetes. In this case, use of the intervention (liraglutide) was reported to *signifi-*

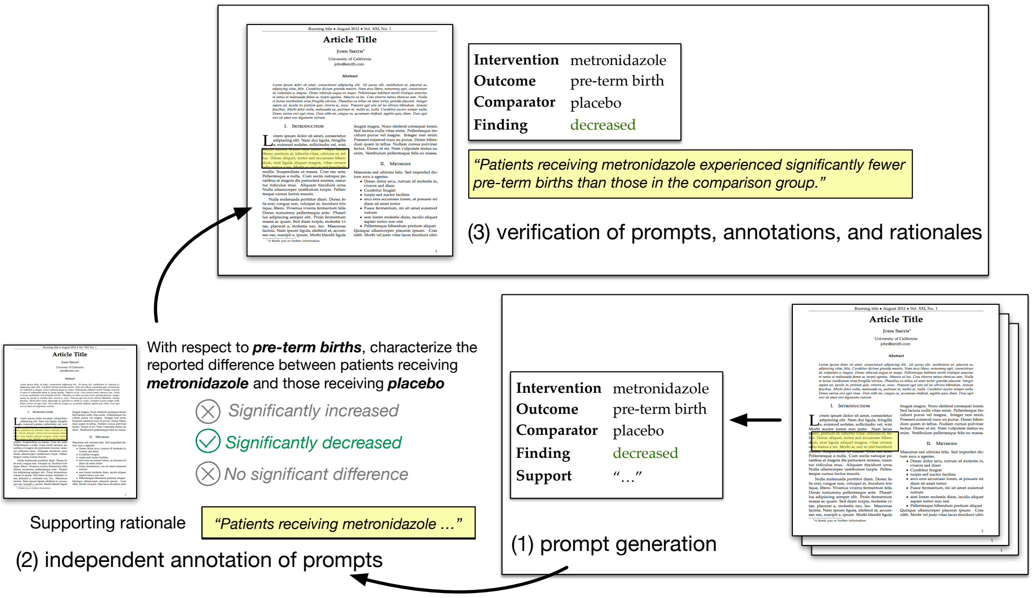

Figure 2: Schematic of the annotation process, performed by qualified (MD) annotators for all articles and prompts.

cantly decrease the proinsulin to insulin ratio, as supported by the following evidence snippet extracted by the prompt creator: "Reductions in the proinsulin : insulin ratio were greater with both liraglutide 1.2 and 1.8 mg compared with either rosiglitazone or placebo."

Trials typically report results for multiple outcomes, and often for more than two interventions. As discussed above, results for these will often differ. For instance, *postprandial plasma glucose* was another outcome reported in the aforementioned trial report, and *placebo plus glimepeiride* was considered as another comparator. Therefore, we instructed prompt generators to create multiple prompts for each full-text article. On average, this yielded 4.19 distinct prompts per article.[1]

Articles may be deemed *invalid* for a few reasons, chiefly for not describing RCTs.[2] Of 3525 articles considered, 1106 were marked invalid (31.4%). The prompt generators provided valid answers and rationales in 95.9% and 97.8% of cases, respectively, as per the verifier.

To summarize: prompt creation entails specifying answerable clinical questions, along with answers to these and supporting rationales (evidence snippets from the text). This task is the most laborious step in the annotation process.

2.2 Prompt Annotation

For this task, annotators were asked to answer prompts on the basis of a particular article. More specifically, given an evidence prompt articulating an intervention, comparator, and outcome (generated as described above), the task was to determine whether the associated article reports results indicating that the intervention *significantly increased*, *significantly decreased*, or realized *no significant difference*, relative to the comparator and with respect to the outcome. The annotator was also asked to mark a snippet of text supporting their response. Annotators also had the option to mark prompts as *invalid*, e.g., if the prompt did not seem answerable on the basis of the article.

Annotations collected in this step are redundant with the classification and rationale independently provided by the prompt generator in the preceding step; this is by design to ensure robust, high-quality annotations.

2.3 Verification

The final task in our annotation process entails a worker verifying the prompts and responses generated in the previous two steps. The verifier is here responsible for checking both whether the prompt (i.e., question) is valid and can be answered from the text, and whether the responses provided are accurate. Verifiers also assess whether the associated supporting evidence provided is reasonable.

Verification is a relatively easy task, because the verifier is directly provided all information rele-

---

[1] We restricted generators to creating at most five prompts for a given article; prior to imposing this constraint, annotators would sometimes generate >10 prompts per article.

[2] We used the RobotReviewer RCT classifier, which improves upon the standard MEDLINE RCT filter (Marshall et al., 2018), but some false positives remain.

vant to making a quality judgment. Nonetheless, this step decidedly improved data quality: 3.8% of prompts, 6.7% of answers, and 7.1% of rationales (supporting evidence snippets) were marked as invalid. All invalid prompts were removed from the corpus; so too were all prompts for which the verifier rejected all answers or all rationales.

2.4 Task Refinement

In an initial pilot round, we acquired annotations on 10 articles, yielding 93 prompts. Three medical doctors (MDs) were tasked with answering these prompts, achieving an agreement of 0.58 (Krippendorf's α). To improve this poor agreement, we provided personalized feedback that addressed systematic issues we observed. Following this feedback, the MDs were asked to re-examine the same set of prompts and update their responses if they felt it appropriate to do so. This resulted in a much improved agreement of α=0.84.

To verify that this agreement held beyond the specific set with respect to which we provided feedback, we subsequently assigned an additional 113 prompts to the annotators. As measured over these 113 prompts, the three annotators exhibited relatively high agreement between themselves and with the prompt generator (Krippendorf's α of 0.75 and 0.80, respectively).

3 Dataset Statistics

We hired 16 doctors from Upwork and split them at random into groups: 10 for prompt generation, 3 for annotation, and 3 for verification.[3] In total, we have acquired 10,137 annotated prompts for 2,419 unique articles. For each of these prompts, we have at least two independent sets of labels and associated rationales (supporting snippets).

We additionally calculated agreement between prompt generators, annotators and verifiers using Krippendorf's α. To calculate this, we converted the verifier's binary labels of valid or not to the label with which they agreed. This yields $\alpha = 0.88$. Removing the verifier annotations from the calculation results in $\alpha = 0.86$.

Intervention, outcome, and comparator strings contain on average 5.1, 5.3, and 3.4 tokens, respectively. Articles comprise a mean of 4.2k tokens.

We provide additional details concerning the dataset in the Appendix.

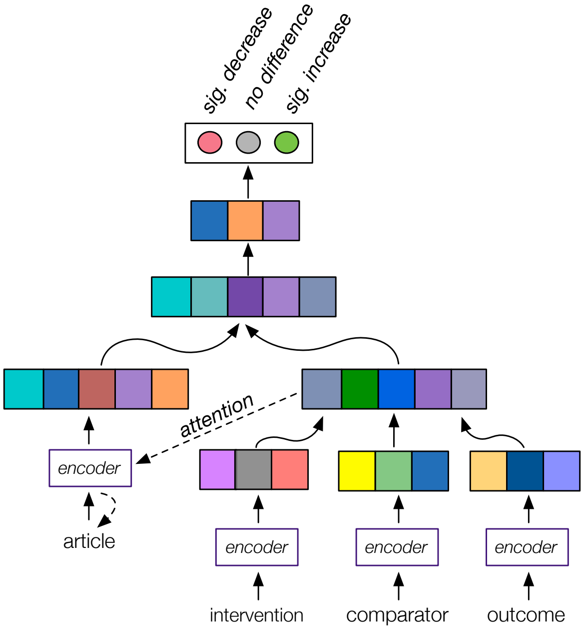

Figure 3: A generalized illustration of the neural network we propose for evidence inference.

4 Models

We experimented with a suite of models to establish performance on this task, which we explain below in increasing order of complexity.

4.1 Baselines

Majority. Predict the most common class, i.e., *no significant difference*.

Heuristics. This entails two parts: (1) finding the sentence that contains the answer, and (2) interpreting the sentence that possesses the evidence. The first step of this process is achieved through locating the sentence that has the most overlap with words in the outcome, intervention, and comparator. Afterwards, we search for reported p-values within the identified sentence, and evaluate whether they seem significant. We provide a detailed description of the heuristics model in Section A of the Appendix.

Logistic Regression. A standard logistic regression model trained on top of binary bag-of-words representations of articles and intervention, comprator and outcome (ICO) frames — these are concatenated to form inputs. We use a vocabulary size of 20k (based on frequency of occurrence), thus yielding an input size of 80k.

Neural Network Variants. We encode the intervention, comparator, and outcome strings accompanying a prompt into vectors i, c, and o, respec-

---

[3] One doctor from verification was moved to annotation in order to increase productivity.

	Train	Dev	Test	Total
Number of prompts	8168	1004	965	10137
Number of articles	1931	248	240	2419
Label counts (-1 / 0 / 1)	1981 / 3619 / 2568	232 / 448 / 324	215 / 403 / 347	2428 / 4470 / 3239

Table 1: Corpus statistics. Labels -1, 0, 1 indicate *significantly decreased*, *no significant difference* and *significantly increased*, respectively.

tively. Similarly, we encode the article itself into a vector a. We experimented with several encoder options, including simple bag-of-words style encoding (i.e., averaging constituent word vectors) and RNNs. For the latter, we specifically pass a Gated Recurrent Unit (Cho et al., 2014), or GRU, over inputs, yielding hidden states for each article token.

In preliminary experiments we found that simple averages over token embeddings worked well for encoding prompts (i, c and o), likely because they tend to be quite short. But this encoding works terribly for articles, due to their length. Therefore, we use a GRU to encode articles (uni-directional, as bi-directional added complexity without improving results).

In the simplest neural model variant, we simply concatenate the encoded article and ICO frame into a vector $[a; i; c; o]$ which is then passed through a feedforward network with a single hidden layer to allow interactions between the prompt and article text.[4] As discussed in detail below, we experiment with a variety of attention mechanisms imposed over article tokens.

4.2 Finding the Evidence

Exploiting the spans of evidence marked as supporting assessments should improve the predictive performance of models. An additional advantage of modeling this explicitly is that models will then be able to provide *rationales* for decisions (Lei et al., 2016; Zhang et al., 2016; Zaidan et al., 2007), i.e., snippets of text that support predictions. We therefore experiment with model variants that classify input tokens as being relevant evidence (or not) prior to performing inference.

We consider both *pipeline* and *joint* instantiations of such models. In the former type, the model first identifies spans in the text and then passes these forward to an independent component that makes predictions on the basis of these. In models of the latter type, evidence span tagging and document-level inference is performed end-to-end. Evidence snippets are not restricted to sentence boundaries (i.e., are token-wise), but we also consider model variants that relax evidence span tagging to a sentence labeling task (classifying sentences as containing *any* evidence tokens, or not). In either case, which spans are relevant will depend on the prompt assessed. Thus, we consider and contrast variants that condition evidence span prediction on the input prompt.

We consider both linear and neural models. For the former, we train two logistic regression models over bag-of-words input representations. The first predicts whether or not a given sentence contains any evidence tokens. Document predictions are then made via a second (independent) logistic regression model that consumes aggregate bag-of-words representations of only those sentences predicted to contain evidence. This is a linear model, and thus does not accommodate interactions; we therefore consider only an unconditioned version.

For our pipeline neural model, we first induce vector representations of article sentences via a GRU, and these are then passed through a binary classification layer. To allow interactions between the input prompt and the sentence being classified, we also consider a conditioned variant in which the sentence classification model is provided the induced vector representations of the prompt elements alongside the sentence vector.

For end-to-end models, we capitalize on attention mechanisms that learn to focus on (contextualized hidden representations of) individual article tokens prior to making a prediction. We consider several variants of attention, and we explore directly pretraining these using the marked evidence spans available in the training data.

The simplest attention module we consider is unconditioned; we simply learn weights W that scores hidden states h_a output from the article encoder. Concretely,

$$\alpha = \text{softmax}\{w_\alpha \cdot H_a\} \qquad (1)$$

where $w_\alpha \in \mathcal{R}^{1\times d}$ and $H_a \in \mathcal{R}^{d\times|a|}$, denoting hidden size by d and article length by $|a|$.[5]

---

[4] We use a linear hidden layer; experiments adding a non-linearity (ReLU) did not affect results.

[5] We have elided bias terms for presentation.

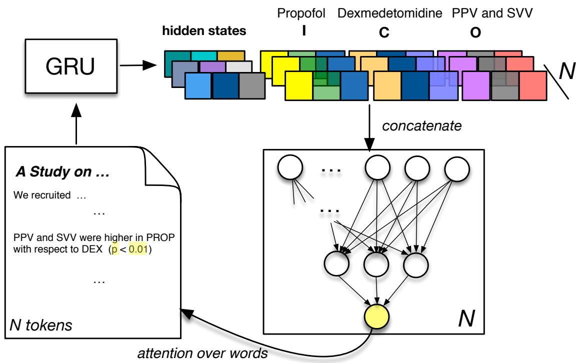

Figure 4: The proposed conditional attention variant. ICO frame embeddings are concatenated to hidden state vectors from the GRU and fed through an MLP to induce attention weights.

However, the text span relevant to a classification will depend on the prompt under consideration. We thus also consider a conditioned variant of attention. In this version we concatenate the i, c, and o vectors induced by our encoders to the hidden states. Abusing notation a bit, denote the matrix in which we concatenate the i, c, and o vectors to each column in H_a by $[H_a; i; c; o]$. We then consider an attention variant that passes this concatenated representation through a single hidden layer to score tokens (Figure 4).

$$\alpha = \text{softmax}\{v_\alpha^t \cdot \tanh(W_\alpha \cdot [H_a; i; c; o])\} \quad (2)$$

We consider two ways of converting the provided evidence spans into targets: (1) Imposing a uniform distribution over marked evidence tokens; (2) Setting the target for all marked evidence tokens as 1. In both cases we treat the absence of annotations on a token as an implicit negative target (0). It is important to note that the model will see the same article multiple times during training with different evidence span targets, one for each prompt in the train set. The snippet of text that supports a particular assessment naturally depends on the prompt under consideration. Unconditioned attention variants will thus, by construction, be unable to attend exclusively to the relevant spans of text for across all prompts.

When training with binary targets, we consider two specifications: one in which the outputs of the attention model are independent (per-token) sigmoids indicating whether or not a word belongs to an evidence span, and another in which attention weights are normalized via a softmax over tokens. The latter is standard, although per-token attention has been previously proposed (Kim et al., 2017).

5 Experimental Details

5.1 Development Setting

During model development, we used 90% of the train set for training, and the remaining 10% as to monitor performance over epochs. To iteratively assess and refine models during this development phase, we used the standardized validation set. All decisions regarding final experiments to run were made using this validation set, prior to evaluating models on the held-out test set of articles. Results reported in this paper are on the final test set. Note that we report averages for neural models (over five runs) to mitigate noise due to random initialization and fitting.

5.2 Training Details and Hyperparameters

All neural variants were trained up to 50 epochs with a patience of 10 epochs. We monitored performance during training on a nested development set and retained the model that achieved the highest F1 score on this. For GRU encoders we used 32 hidden units. All models for the primary task were trained with batch sizes of 32.

We initialized word embeddings to pretrained word vectors induced over a large set of PubMed abstracts (Pyysalo et al., 2013). Given the modest training dataset size, we did not fine-tune these.

5.3 Attention pretraining Details

We use the manually marked supporting snippets as explicit, intermediate supervision for pretraining the attention mechanisms described in 4.2. More specifically, we pretrain the attentional model components for both conditioned and unconditioned attention variants.

Concretely, we minimize token-wise binary cross entropy loss with respect to one of the two token-wise targets delineated in the preceding Section. We normalize loss per batch by the number of constituent tokens, using batch sizes of 16.[6] We monitor token-wise AUC with respect to the reference evidence span annotations marked in the held-out validation set mention in Section 5.1. We retained the model that achieved the best AUC measured over fifty epochs of attention pretraining (again with a patience of ten) and used these weights as initialization values for fine-tuning the end-to-end inference network.[7]

---

[6] Memory constraints precluded larger batches.

[7] We also experimented with 'freezing' attention module parameters during fine-tuning, but this performed poorly.

Model	Precision	Recall	F1	Evidence token AUC / mass
Majority	0.138	0.333	0.195	–
Heuristics	0.431	0.389	0.354	0.682 / 0.025

+ Pretrain conditional attention†	0.531	0.519	0.520	0.836 / 0.125

Table 2: Summary results on the evidence inference task test set, averaged over five independent runs (with independent random initialization values). Metrics are macro-averages over classes. Evidence token AUC and mass (last column) quantify identification of relevant supporting tokens. Models in the top two rows perform no learning; the second two correspond to linear models; the rest are neural model variants. † indicates 'token-wise' attention pretraining; we report results for alternative attention losses in the Appendix.

Class	Precision	Recall	F1
Sig. decreased	0.448	0.334	0.380
No sig. diff.	0.586	0.636	0.610
Sig. increased	0.556	0.585	0.572

Table 3: Average per-class test performance of best overall model (*pretrain conditional attention*).

We trained all models with the Adam optimizer using the parameters suggested by (Kingma and Ba, 2014). We trained using PyTorch (Paszke et al., 2017), `v 1.0.1.post2`.[8] Code for our models and to reproduce our results is available at: `https://github.com/jayded/evidence-inference`.

5.4 Pipeline Model Training Details

Pipeline models first attempt to identify sentences containing evidence. To train these, we generalize token-wise annotations to sentences such that a sentence is labeled 1 if it contains any evidence tokens, and 0 otherwise. We then trained the sentence tagging models described above with these labels, monitoring loss on a nested validation set and retaining the best observed model over 50 epochs. The document-level model subsequently consumes only sentences tagged as relevant.

6 Results

6.1 Main Task Results

Results on the main task for proposed model variants are reported in Table 2. These are averages over five independent runs, to ensure relatively robust measures of model performance.[9] The best performing model exploits pretrained conditional attention. For the leaderboard we assume a single set of model predictions. To generate these we evaluated models on the test set using the versions that realized the strongest observed performance on the validation set over the aforementioned five runs/initializations. The best performing model (and hence current leader) is the variant that uses pretrained, conditional attention, which aligns with the average results in Table 2. Table 4 reports the results here, along with a more standard attentive architecture for context.

Model	Precision	Recall	F1
NN + Attention	0.518	0.503	0.505
NN + pretrain cond. attn.	**0.533**	**0.530**	**0.531**

Table 4: Leaderboard results.

To highlight the importance of identifying relevant spans to inform predictions, we present results achieved when these are provided directly to models via an 'oracle' prior to prediction in Table 6. Access to this oracle yields a 20+ point jump in F1, indicating that accurately extracting the relevant evidence is critical. Below (Section 6.2) we attempt to elucidate how well (or poorly) attention mechanisms fail to find supporting evidence.

A natural question that arises in NLP tasks in which the output depends on both a document and a question (here, a prompt) is: how much does the latter in fact influence model predictions (Kaushik and Lipton, 2018)? We explore this in Table 5. Relying only on the prompt (ignoring the article completely) achieves surprisingly strong performance, outperforming a vanilla neural model (sans attention). This is not entirely unreasonable, as certain intervention types will tend to correlate with significant vs insignificant findings, i.e., the prompt

---

[8] This is a nightly build, used due to a dependence on recently introduced RNN utilities.

[9] These models exhibit a fair amount of variance; we report ranges over the validation set in the Appendix.

- article	0.489	0.468	0.472

Table 5: Average results achieved (macro-averages over five runs) by the neural model when it is provided only the article or only the prompt. We reproduce results for the best model from Table 2 and the vanilla (no attention) end-to-end neural network for context.

Model	Precision	Recall	F1
Heuristics	0.492	0.457	0.453
Logistic regression	0.732	0.734	0.731
Neural network	0.740	0.739	0.739

Table 6: Average results achieved when models are provided directly with the reference evidence spans.

itself contains signal. The neural model without attention is likely simply unable to extract meaningful signal from lengthy articles, and so induced representations merely add noise. By contrast, ignoring the prompt severely degrades performance.

6.2 Analyzing Attention

To provide a sense of how well models are able to identify relevant evidence (i.e., tokens in the supporting snippets marked by annotators), we report token AUCs and *evidence masses* for all models that assign scores to words. The former captures how well models discriminate evidence from non-evidence tokens in general; the latter measures the relative amount of attention payed to evidence tokens. Concretely we calculate attention mass as a sum of the normalized attention scores assigned to words that belong to reference evidence spans. Thus, e.g., if the evidence token mass were 1, this would mean the model attended to *only* relevant evidence, ignoring all other tokens. We also experimented with optimizing for this directly during attention pretraining (see Appendix).

Aside from the *Majority* and *LR* baselines, all of the models explored generate scores encoding token relevance, either explicitly or implicitly. Attentive neural variants induce these by scoring contextualized representations of tokens t, h_t for relevance. Pipelined models score sentences, not tokens. For comparison across models, we assign the probability predicted for a given sentence to all of the words that it contains. Note that the maximum evidence token AUC achievable when selecting a sentence is ~0.92.

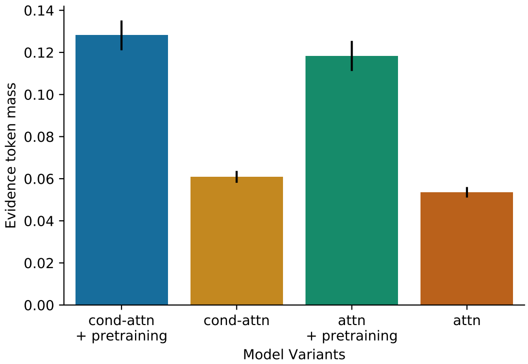

Figure 5: Evidence token masses achieved by models on the validation set, after training.

Qualitatively, we observe that attention weights often, though not always, square with intuition. In a test example wherein the intervention is *propofol*, the comparator *dexmedetomidine*, and the outcome *Stroke Volume Variation (SVV) and Pulse Pressure Variation (PPV)*, the conditioned, pretrained attention model focuses on tokens ‘svv’, ‘versus’ (suggesting comparison), and p-value indicators (‘p’, ‘01’). This is not surprising given the reasonably high evidence token AUC achieved by this model.

Overall, despite conditioning and pretraining attention mechanisms, end-to-end models remain over 20 points behind the oracle variant (Table 6. This suggests that the model is failing to sufficiently attend to the relevant evidence. Figure 5 supports this conjecture. This shows the total evidence mass realized by models on the validation set (after training for the final task of evidence inference). Even pretrained models assign $<$14% of total attention mass to actual evidence tokens.

We also explore how token-level discriminative performance varies between pretrained and end-to-end variants (without explicit attention training), and how this changes as learning progresses. Figure 6 plots evidence token AUC over epochs (on the validation set) for attentive model variants (conditioned and unconditioned). We show curves for the case where we use explicit supervision (pretraining; dotted lines) and where relevance is learned only indirectly via the downstream evidence inference objective (no pretraining; solid lines). Interestingly, evidence token AUC reaches maximum values during pretraining (shown as negative epochs) for supervised attention variants, and declines precipitously when the training objective transitions to the downstream task. This suggests a kind of catastrophic forgetting introduced due to shifting objectives.

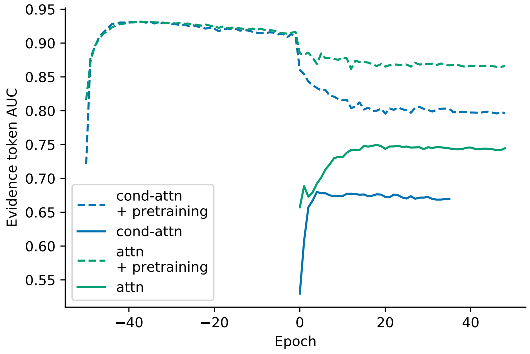

Figure 6: Validation evidence token AUCs during training. 'pretraining' epochs are depicted as 'negative' for the two explicitly supervised attention variants. Note that we use early stopping, so not all models run for the same number of epochs.

7 Related Work

The proposed task is situated at the intersection of information extraction (Cardie, 1997), natural language inference (Bowman et al., 2015), evidence mining (Rinott et al., 2015) and question answering (Harabagiu et al., 2000; Hovy et al., 2000). However, our focus on inferring results from lengthy clinical trial reports pertaining to particular prompts constitutes a unique problem, as discussed in the Introduction.

Prior systems have attempted to extract information from articles describing RCTs. For example, ExaCT (Kiritchenko et al., 2010) attempts to extract variables describing clinical trials from articles, and ACRES (Summerscales et al., 2011) ingests extracts key variables from abstracts. Blake and Lucic (2015; 2012) considered the problem of automatically extracting interventions and outcomes in sentences that report direct comparisons. And Mihaila *et al.* (2013) have proposed annotating and extracting casual statements from biomedical literature. Classifying the *modality* of statements in scientific literature has also been investigated (Thompson et al., 2008); this relates to identifying evidence.

None of these prior efforts attempted to infer the *findings* concerning the extracted interventions and outcomes, as we do here.

8 Conclusions and Future Work

We have presented the task of inferring the polarity of comparative results reported in articles describing clinical trials with respect to interventions and outcomes of interest. Such models would render the unstructured evidence currently buried in manuscripts actionable, in turn potentially informing evidence-based care. In addition to the practical import of this problem, the task poses core NLP challenges related to processing lengthy, technical texts, and performing conditional inference over entities within these.

Our baseline results establish both the feasibility and difficulty of the task. Very simple baselines (e.g., rule-based methods) perform quite poorly, and modern neural architectures achieve the best results, currently. When models are provided with reference evidence spans from an oracle, they achieve dramatically improved performance. This demonstrates that the key challenge concerns conditionally identifying relevant snippets to inform predictions; attention mechanisms would seem to provide a natural means of allowing the model to learn to focus, and we indeed found that (supervised) attention provides some predictive gains, but these are relatively modest.

The gap between the model that directly consumes only relevant evidence snippets (Table 6) and the best performing end-to-end model is over 20 points in F1. Further, ignoring the article entirely (relying only on the prompt) degrades performance by only $\sim$5 points in F1, again suggesting that even the pretrained, conditioned attention variant is not making good use of the relevant evidence contained in articles. The evidence token mass metrics also support this: The best models we have proposed consistently place only $\sim$10-15% of the attention mass on tokens actually marked as containing relevant evidence.

We are simply not learning to attend well, even with explicit pretraining and conditioning. This motivates a key future research direction: designing more sophisticated attention mechanisms that (conditionally) identify spans of evidence pertinent to a given prompt. We hope this corpus and task provides opportunity to pursue such models.

Appendix

A Description of Heuristics Baseline

We describe the heuristics implemented in our rule-based baseline model. These can be broken into two stages: (1) finding the sentence that contains the answer, and (2) interpreting the sentence that possesses the evidence. The variant that consumes the evidence spans directly (thus "cheating") uses only rules defined for (2). In both cases we use a 'points' based approach, where simple rules assign points to potential labels.

As an attempt to identify evidence spans, we first split the article into sentences and tokenize these. Each sentence is then assigned a ranking based on the number of words in the outcome, intervention, and comparator that it contains; each map is associated with one point. The sentence with the highest number of points is then designated as being most likely to contain the evidence of interest.

Once this sentence is selected, we use simple checks to try and identify a reported p-value. In particular we search for the following three distinct forms: "$p = X$", "$p > X$", and "$p < X$"; we use a simple RegEx to find instances of these, ignoring whitespace.

If we identify "$p = X$", we then attempt to identify the comparator and intervention from the prompt in the sentence, as the aim is to extract the p-value closest to the intervention or comparator (sentences may contain multiple p-values). If the p-value found is greater than 0.05, we add a point for a label of *no significant difference*. If the p-value is smaller than 0.05, we add a point for a label of *significant difference* (both significantly increases or significantly decreases). If neither the intervention nor the comparator is found in the selected sentence, then we look at all the p-values that it contains and sum points accordingly.

In the case of "$p > X$", we add a point to the label of *no significant difference*, as a p-value greater than some X likely corresponds to a statistically non-significant result.

In the case of "p < 0.05", we add a point to a label of significant difference, as a p-value smaller than some X likely corresponds to varying effects for both the intervention and comparator with respect to the outcome. If there is a tie between points pointing to a significant difference (in either direction) and *no significant difference*, then we return the latter, because it is the majority category.

Otherwise, we assume the result is significant, and next attempt to infer the reported direction of the effect. To do so, we count occurrences of synonyms of the word "increase" in the sentence and compare that with the number of occurrences of synonyms of "decrease". Synonyms are retrieved using WordNet via NLTK. If there are more synonyms of "increase", we return the label *significantly increase*; if there are more synonyms of "decrease", we return *significantly decrease*. If the number of occurrences is equal, we return *significantly increase*, as this designation is slightly more frequent than *significantly decrease*.

B Annotation Costing Details

Generating each prompt cost an average of 99 cents. We thus paid about $4.14 to complete prompt generation for each article. Doctors hired for prompt generation were paid an average of $19.05 an hour.

Prompts took an average of 2.54 minutes to complete. Annotators (again MDs) were paid an average of $13.88 dollars per hour, with each prompt costing 58 cents.

Verification cost a mere 27 cents per prompt. Verifiers were paid, on average, $16.25 an hour.

C Additional Dataset Details

Each prompt has at least two rows, one of which corresponds to the prompt generator's answer, and the other for an annotator's. These rows can be distinguished using the UserID column, in which prompt generator answers are marked with a value of '0', whereas annotator UserIDs are values greater than '0'. Each row also includes the verifier's response, which denotes the validity of that row's answer and rationale. We additionally include the offsets of where the rationale occurs in the text [10]. These offsets are calculated through FuzzyWuzzy, due to the frequent differences in encoding between rationales and extracted XML text.

D Preprocessing Details

To process the PubMed central XML documents, we iterate through by section, and parse subsequent sub-sections. Afterwards, we use an HTML parser library to remove all tags, as these might distract models. We removed all <p> tags that remained due to malformed XML documents.

E Attention (and Attention Pretraining) Variants

On the validation set we explored several substantiations of attention and associatd objectives, in the case of pre-training. These include:

1. **Tokenwise**. This attention variant aims to maximize per-token evidence predictions independently, i.e., no softmax is imposed over attention activations, and so attention weights may range between 0 and 1. During the forward pass, however, we do normalize these weights prior to inducing the context vector.

2. **Balanced tokenwise attention**. This is the same as above, except that during training we construct samples composed of an equal number of evidence and non-evidence tokens (the latter far outnumbering the former, in general).

3. **Evidence mass attention**. Here we attempt to directly optimize total quantity of attention mass placed on evidence tokens.

During pre-training, we run for some number of epochs over available marked evidence spans (we used a maximum of 50, with an early-stopping criterion using a patience of 10). This requires a metric to determine the 'best' observed set of attention weights during pre-training (as measured on a nested validation set). For this we considered a few options for performance measuring criterion over tokens, including evidence mass and entropy. We ultimately settled on monitoring evidence token AUC as a proxy for attention performance over tokens.

F Validation Results and Variances

For completeness in Table 7 we report means and ranges of all model variants explored on the validation dataset (taken over five runs). We include in these the attention variants explained above.

For pretraining variants, trained on the observed evidence spans for 50 epochs prior to shifting objectives to the downstream evidence inference task. We then must select which set of weights, over these 50 epochs, to use for initialization following pretraining. We considered three metrics to score attentional components during pretraining: token-level AUC (overall discriminatory power of the network, with respect to evidence/not-evidence words); entropy (with the intuition that we seek peaky distributions); and evidence token mass (such that most attention is placed on evidence tokens).

We settled on using the tokenwise pretrained variant along with token AUC as our pretraining criterion for the test experiments, but we report full results on the validation dataset in Table 7.

On the test set, we only considered using AUC as the criterion.

Abstract

To capture salient contextual information for spoken language understanding (SLU) of a dialogue, we propose time-aware models that automatically learn the latent time-decay function of the history without a manual time-decay function. We also propose a method to identify and label the current speaker to improve the SLU accuracy. In experiments on the benchmark dataset used in Dialog State Tracking Challenge 4, the proposed models achieved significantly higher F1 scores than the state-of-the-art contextual models. Finally, we analyze the effectiveness of the introduced models in detail. The analysis demonstrates that the proposed methods were effective to improve SLU accuracy individually.

1 Introduction

Spoken language understanding (SLU) is a component that understands the user's utterance of a dialogue system. Given an utterance, SLU generates a structured meaning representation of the utterance; i.e., a semantic frame. SLU can be decomposed into several subtasks such as domain identification, intent prediction and slot filling; these subtasks can be jointly assigned using a single model (Hakkani-Tür et al., 2016; Liu and Lane, 2016; Chen et al., 2016b). The accuracy of SLU is important for the dialogue system to generate an appropriate response to a user.

To improve the accuracy of SLU, much work has used contextual information of dialogues to alleviate the ambiguity of recognition of the given utterance. In SLU, selecting important history information is crucial, and it directly influences the improvement of SLU accuracy. To summarize this history, content-aware models (Chen et al., 2016a; Kim et al., 2017) similar to attention models in machine translation (Bahdanau et al., 2014) have been proposed. However, content-aware models are likely to select the wrong history when the histories are similar in content. To alleviate this problem, time-aware models (Chen et al., 2017; Su et al., 2018a,b) which pay attention to recent previous utterances by using the temporal distance between a previous utterance and a current utterance are being considered; the models are based on mathematical formulas, time-decay functions, which are formulated by human, and decomposed into trainable parameters.

However, the previous time-aware models may not be sufficiently accurate. In the models, either a single time-decay function is used or a limited number of time-decay functions are linearly combined; these manual functions may not be sufficiently flexible to learn an optimal time-decay function.

In this paper, we propose flexible and effective time-aware attention models to improve SLU accuracy. The proposed models do not need any manual time-decay function, but learn a time-decay tendency directly by introducing a trainable distance vector, and therefore have good SLU accuracy. The proposed models do not use long short-term memory (LSTM) to summarize histories, and therefore use fewer parameters than previous time-aware models. We also propose current-speaker modeling by using a speaker indicator that identifies the current speaker.

To the best of our knowledge, this is the first method that shows improvement by considering the identity of the current speaker. This information may be helpful for modeling multi-party conversations in addition to human-human conversations.

Prediction of the semantic label of the current utterance even using a conventional time-aware model can be difficult. (Figure 1). The nearest utterance is "Right.", but it is not the most rele-

Proceedings of NAACL-HLT 2019, pages 3718–3726
Minneapolis, Minnesota, June 2 - June 7, 2019.

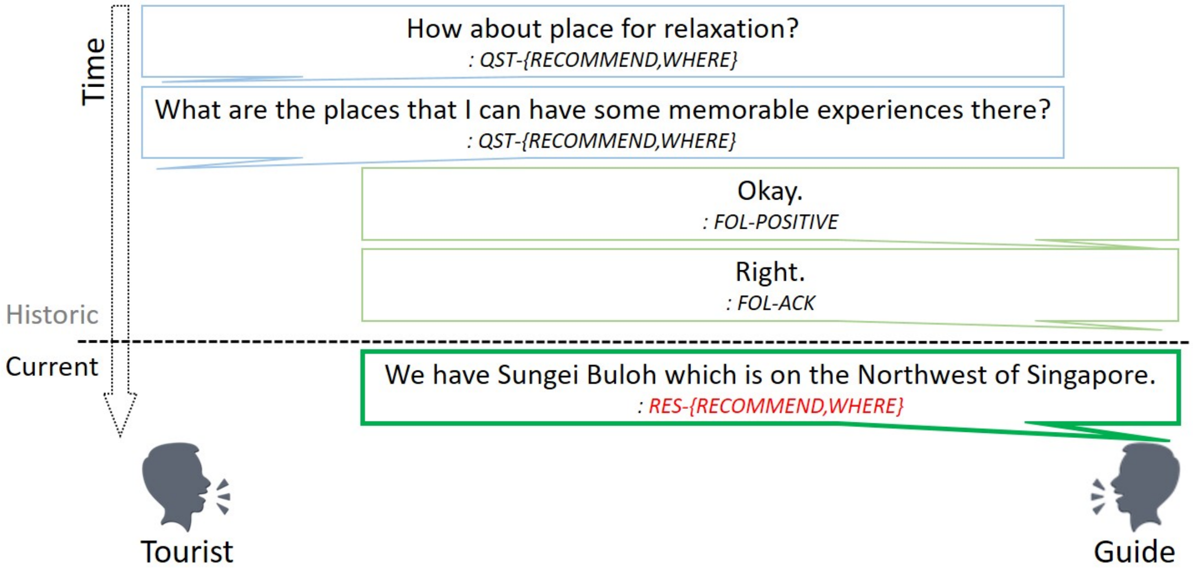

Figure 1: An example of utterances with their semantic labels (speech acts combined with associated attributes) from DSTC 4. The semantic labels are italicized.

vant utterance to the current utterance; the most relevant utterance is "What are the places that I can have some memorable experiences there?". If we do not know the current speaker is *Guide*, we cannot easily assess the relative importance of the nearest histories of the two speakers. We believe that the proposed 'speaker indicator' can help our model to identify such information.

In experiments on the Dialog State Tracking Challenge 4 (DSTC 4) dataset, the proposed models achieved significantly higher accuracy than the state-of-the-art contextual models for SLU. Also, we examine how the proposed methods affect the SLU accuracy in detail. This result shows that the proposed methods were effective to improve SLU accuracy individually. Our contributions are as follows:

- We propose a decay-function-free time-aware attention model that automatically learn the latent time-decay function of the history without a manual time-decay function. The proposed model achieves a new state-of-the-art F1 score.
- We propose a current-speaker modeling method that uses a speaker indicator to identify the current speaker. We present how to incorporate speaker indicator in the proposed attention model for further improvement of SLU accuracy.
- We propose a model that is aware of content as well as time, which also achieved a higher F1 score than the state-of-the-art contextual models.
- We analyze the effectiveness of proposed methods in detail.

Our source code to reproduce the experimental results is available at `https://github.com/jgkimi/Decay-Function-Free-Time-Aware`.

2 Related Work

Joint semantic frame parsing has the goal of learning intent prediction and slot filling jointly. By joint learning, the model learns their shared features, and this ability is expected to improve the accuracy on both tasks. A model based on bidirectional LSTM for joint semantic frame parsing (Hakkani-Tür et al., 2016) is trained on the two tasks in sequence, by adding an intent label to the output of the final time-step of LSTM. Similarly, an attention-based LSTM predicts slot tags for each time-step, then feeds the hidden vectors and their soft-aligned vectors to a fully-connected layer for intent prediction (Liu and Lane, 2016). Knowledge-guided joint semantic frame parsing (Chen et al., 2016b) incorporates syntax or semantics-level parsing information into a model by using a recurrent neural network (RNN) for joint semantic frame parsing.

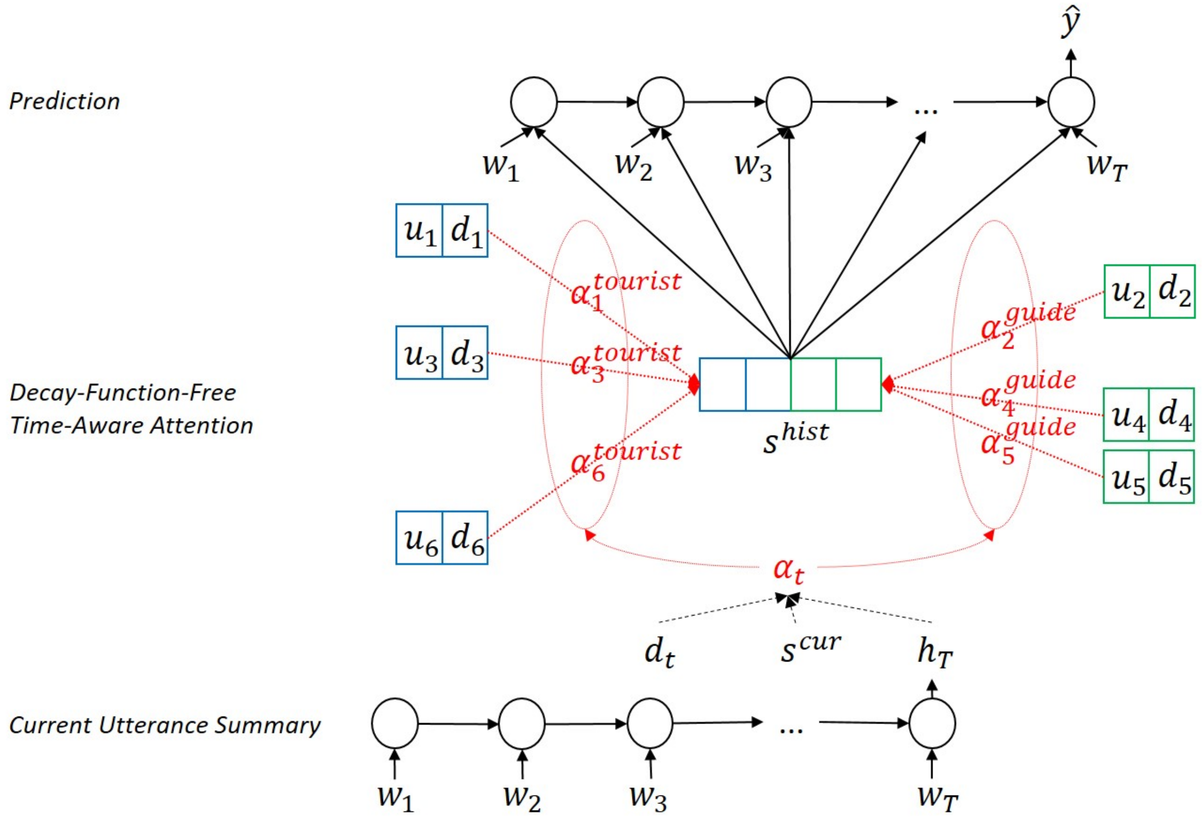

Figure 2: Overall architecture of the decay-function-free time-aware attention with speaker indicator (role-level). $w_1, ..., w_T$ are word vectors of the current utterance, d_t is the t^{th} distance vector, u_t is the t^{th} utterance vector, s^{cur} is the current speaker indicator, h_T is the current utterance summary vector and α_t is the importance of the t^{th} historic utterance. For simplicity, we represent bidirectional LSTM layers as unidirectional LSTM layers.

Other research on SLU uses context information. A model based on support vector machine and a hidden Markov model uses contextual information to show the importance of contextual information in SLU tasks, intent prediction and slot detection (Bhargava et al., 2013). RNN-based models can exploit context to classify domains (Xu and Sarikaya, 2014), and have been combined with previously-estimated intent and slot labels to predict domain and intent (Shi et al., 2015). A memory network that contains historic utterance vectors encoded by RNN has been used to select the most relevant history vector by multiplicative soft-attention (Chen et al., 2016a); the selected vector is fed to an RNN-based slot tagger as context information.

A memory network can be regarded as use of content-based similarity between the current utterance and previous utterances. A memory network can be separated to capture historic utterances for each speaker independently (Kim et al., 2017), and a contextual model can use different LSTM layers to separately encode a history summary for each speaker (Chi et al., 2017). For another task, addressee and response selection in multi-party conversations, a distinct RNN-based encoder for each speaker-role (sender, addressee, or observer) has been used to generate distinct history summaries (Zhang et al., 2018).

Recent work on contextual SLU has introduced time information of contexts into models because content-based attention may cause a wrong choice that introduce noises. The reciprocal of temporal distance between a current utterance and contexts can be used as a time-decay function, and the function can be decomposed into trainable parameters (Chen et al., 2017). Similarly, a universal time-aware attention model (Su et al., 2018a) has been proposed; it is a trainable linear combination of three distinct (convex, linear and concave) time-decay functions . An extension of this model is a context-sensitive time-decay attention (Su et al., 2018b) that generates its parameters from the current utterance by using a fully-connected layer so that the content information of the current utterance is also considered in the attention.

3 Proposed Model

We propose a time-aware model that includes a speaker indicator (Figure 2). In addition, we propose a content-and-time-aware model that includes a speaker indicator. The models are trained in an end-to-end way, in which every model parameter is automatically learned based on a downstream SLU task. The objective of the proposed models are to optimize the conditional probability of labels of SLU, given the current utterance $p(\hat{y}|x)$, by minimizing the cross-entropy loss.

The following description of the proposed model considers three steps: current utterance summary, context summary, and prediction.

3.1 Current Utterance Summary

To select salient parts of contextual histories, the current utterance is used. To summarize a current utterance matrix U that consists of words w_i as a vector (i.e., $U = \{w_1 , w_2,..., w_T\}$), U is fed to bidirectional LSTMs, and the final hidden vector $h_T \in \mathbb{R}^{dim}$ is taken as a current utterance summary.

3.2 Decay-Function-Free Time-Aware Attention

In this subsection, we introduce a decay-function-free time-aware attention model. To summarize contexts, we use a time difference (distance) between a historic utterance and the current utterance; this distance represents the interval between the historic utterance and the current utterance. We use the distance of the t^{th} history from the current utterance as an index to select a dense vector from a distance-embedding matrix $D \in \mathbb{R}^{dim\times|D|}$, then use the vector as the t^{th} distance vector d_t.

To compute the importance α_t of the t^{th} history, both in the sentence-level attention and in the role-level attention, our time-aware attention uses the current utterance summary h_T and the history distance d_t simultaneously and additively:

$$\alpha_t = w_{att}^T \sigma\big(h_T + d_t + b_{att}\big), \qquad (1)$$

where w_{att}^T is the transpose of a trainable weight vector for the attention, b_{att} is a trainable bias vector for the attention, and σ is the hyperbolic tangent function.

Computing a time-aware context summary vector s_{time}^{hist} depends on whether the role-level or sentence-level attention is considered. For the role-level attention, we use the softmax operation applied to all α_t of the same speaker, either a guide or a tourist, to obtain a role-level probabilistic importance α_t^{role} of t^{th} history. We then multiply α_t^{role} by t^{th} history vector, which is a concatenation of the corresponding intent-dense vector u_t and the distance vector d_t. We use the element-wise sum of the vectors of the same speaker to construct two summary vectors s_{time}^{guide} and $s_{time}^{tourist}$. Finally, s_{time}^{guide} and $s_{time}^{tourist}$ are concatenated to form a time-aware history summary vector s_{time}^{hist} as:

$$\alpha_t^{role} = softmax_{role}(\alpha_t), \qquad (2)$$

$$s_{time}^{role} = \sum_t \alpha_t^{role}(u_t \oplus d_t), \qquad (3)$$

$$s_{time}^{hist} = s_{time}^{guide} \oplus s_{time}^{tourist}, \qquad (4)$$

where $\oplus$ represents a concatenation operation.

For the sentence-level attention to obtain a sentence-level probabilistic importance α_t^{sent} of t^{th} history, we use the softmax operation applied to all α_t regardless of the speaker, then multiply α_t^{sent} by the t^{th} history vector, which is a concatenation of the corresponding intent dense vector u_t and the distance vector d_t. We use the element-wise sum of the vectors to construct a time-aware summary vector s_{time}^{hist} as:

$$\alpha_t^{sent} = softmax_{sent}(\alpha_t), \qquad (5)$$

$$s_{time}^{hist} = \sum_t \alpha_t^{sent}(u_t \oplus d_t). \qquad (6)$$

Then, s_{time}^{hist} is used as a context summary s^{hist} in the prediction step.

3.3 Decay-Function-Free Content-and-Time-Aware Attention

Although a time-aware attention model is powerful by itself, content can be considered at the same time to improve accuracy. We propose another contextual attention model that is aware of content, in addition to time. This model is called content-and-time-aware attention. The model uses an importance value β_t for the t^{th} history. To compute β_t, we uses the trainable parameters w_{att} and b_{att} of the time attention as:

$$\beta_t = w_{att}^T \sigma\big(h_T + u_t + b_{att}\big), \qquad (7)$$

where u_t is the intent dense vector of t^{th} history, and σ is the hyperbolic tangent function.

Then, β_t is used in the same way as α_t, but independently. s^{hist}_{time} is computed as in the previous subsection, β_t is used to compute s^{hist}_{cont} for the role-level attention as:

$$\beta^{role}_t = softmax_{role}(\beta_t), \tag{8}$$

$$s^{role}_{cont} = \sum_t \beta^{role}_t (u_t \oplus d_t), \tag{9}$$

$$s^{hist}_{cont} = s^{guide}_{cont} \oplus s^{tourist}_{cont}. \tag{10}$$

To compute s^{hist}_{cont} for the sentence-level attention, β_t is used as:

$$\beta^{sent}_t = softmax_{sent}(\beta_t), \tag{11}$$

$$s^{hist}_{cont} = \sum_t \beta^{sent}_t (u_t \oplus d_t). \tag{12}$$

Finally, the time-aware history summary s^{hist}_{time} and the content-aware history summary s^{hist}_{cont} are concatenated to generate a history summary s^{hist} regardless of the attention level:

$$s^{hist} = s^{hist}_{time} \oplus s^{hist}_{cont}. \tag{13}$$

3.4 Speaker Indicator

Speaker indicator is a trainable vector $s^{cur} \in \mathbb{R}^{dim}$ which indicates the identity of the current speaker; i.e., either a tourist or a guide in DSTC 4. An embedding lookup method is used after a speaker embedding matrix $S \in \mathbb{R}^{dim \times |S|}$ is defined. The speaker embedding matrix is randomly initialized before the model is trained.

To use speaker indicator s^{cur} in the proposed attentions, Eq. 1 is rewritten as:

$$\alpha_t = w^T_{att}\sigma\big(h_T + d_t + s^{cur} + b_{att}\big), \tag{14}$$

and Eq. 7 is rewritten as:

$$\beta_t = w^T_{att}\sigma\big(h_T + u_t + s^{cur} + b_{att}\big). \tag{15}$$

3.5 Prediction

To predict the true label in spoken language understanding, our model consumes the current utterance U again. We use another bidirectional LSTM layer which is distinct from that of the current utterance summary. To prepare for t^{th} input v_t of the LSTM layer, we concatenate t^{th} word vector w_t of the current utterance U with the history summary vector s^{hist}:

$$v_t = w_t \oplus s^{hist}. \tag{16}$$

Then, we feed each v_t to the LSTM layer sequentially, and the final hidden vector of the LSTM layer is used as an input of a feed-forward layer to predict the true label $\hat{y}$.

4 Experiments

To test the proposed models, we conducted language-understanding experiments on a dataset of human-human conversations.

4.1 Dataset and Settings

We conducted experiments on the DSTC 4 dataset which consists of 35 dialogue sessions on touristic information for Singapore; they were collected from Skype calls of three tour guides with 35 tourists. The 35 dialogue sessions total 21 h, and include 31,034 utterances and 273,580 words (Kim et al., 2016). DSTC 4 is a suitable benchmark dataset for evaluation, because all of the dialogues have been manually transcribed and annotated with speech acts and semantic labels at each turn level. a semantic label consists of a speech act and associated attribute(s). The speaker information (guide and tourist) is also provided. Human-human dialogues contain rich and complex human behaviors and bring much difficulty to all tasks that are involved in SLU. We used the same training dataset, the same test dataset and the same validation set as in the DSTC 4 competition: 14 dialogues as the training dataset, 6 dialogues as the validation dataset, and 9 dialogues as the test dataset.

We used Adam (Kingma and Ba, 2015) as the optimizer in training the model. We set the batch size to 256, and used pretrained 200-dimensional word embeddings GloVe (Pennington et al., 2014). We applied 30 training epochs with early stopping. We set the size dim of every hidden layer to 128, and the context length to 7. We used the ground truth intents (semantic labels) to form an intent-dense vector like previous work. To evaluate SLU accuracy, we used the F1 score, which is the harmonic mean of precision and recall. To validate the significance of improvements, we used a one-tailed t-test. We ran each model ten times, and report their average scores.

As baseline models, we used the state-of-the-art contextual models, and most accurate participant of DSTC 4 (DSTC 4 - Best) (Kim et al., 2016). For comparison with our models, we used the scores

Model	F1 score Sent.-Level	 Role-Level
DSTC 4 - Best	*61.4*	
No Context	65.06	
LSTM-Used Context Summary without Attention	72.15	
LSTM-Used Content-Aware Attention	71.27	71.84
Speaker Role Modeling (Chi et al., 2017)	*66.8*	*70.1*
Convex Time-Aware Attention (Chen et al., 2017)	*74.6*	*74.2*
Universal Time-Aware Attention (Su et al., 2018a)	74.22	74.12
Universal Content + Time Attention (Su et al., 2018a)	74.40	74.33
Context-Sensitive Time Attention (Su et al., 2018b)	74.20	73.53
Decay-Function-Free Time-Aware Attention	75.58**	75.58**
with Speaker Indicator	75.95**	**76.56****
Decay-Function-Free Content-and-Time-Aware Attention	75.59**	75.30**
with Speaker Indicator	76.11**	76.14**

Table 1: SLU accuracy on DSTC 4. *: $p < 0.05$; **, $p < 0.01$ compared to all the baseline models. Italicized scores are reported in the references. Model names are described in the text.

reported in the papers[1]. We ran three additional baseline models in which the prediction stage is the same: (1) 'No Context' uses no context summary; (2) 'LSTM-Used Context Summary without Attention' uses the context summary of bidirectional LSTM without an attention mechanism, and (3) 'LSTM-Used Content-Aware Attention' uses context summary of bidirectional LSTM after content-aware attention is applied to histories, as in previous approaches.

4.2 Results

We conducted an experiment to compare the proposed models with the baseline models in the SLU accuracy (Table 1). All of the proposed models achieved significant improvements compared to all the baseline models.

We conducted an experiment to identify details of how possible combinations of the proposed methods affect the SLU accuracy (Table 2). In addition to the combinations of the proposed methods, we tested another content-and-time-aware attention method (Content x Time) which computes attention values using both intent and distance at a time, and shares the values to compare with the proposed content-and-time-aware attention.

5 Discussion

In the first subsection, we analyze the effectiveness of the decay-function-free time-aware attention and decay-function-free content-and-time-aware attention by comparison with others. In the next subsection, we analyze the effectiveness of the proposed methods in their possible combinations. We also analyze the effectiveness of the use of a distance vector in the history representation under the various conditions. Finally, we analyze attention weights of the proposed models in a qualitative way to convince of the effectiveness of them.

We also conducted an experiment to show the effectiveness of the use of a distance vector in the history representation under the same condition as in the role-level attention (Table 3). Although we propose to use both intent and distance by concatenating them as a history representation, intent can be used alone; this approach is more intuitive than using both intent and distance.

5.1 Comparison with Baseline Models

In Table 1, Decay-Function-Free Time-Aware Attention and Decay-Function-Free Content-and-Time-Aware Attention achieved significantly higher F1 scores that all baseline models. Especially, the role-level Decay-Function-Free Time-Aware Attention with speaker indicator achieved an F1 score of 76.56 % (row 11), which is a state-of-the-art SLU accuracy.

---

[1] Su et al. (2018a) and Su et al. (2018b) specified that they used different training/valid/test datasets that had been randomly selected from the whole DSTC 4 data with different rates for the experiments. Therefore, we do not use the reported score in our comparison, but produced the results under the same conditions by using the open-source code.

Attention Type	F1 score Sent.-Level	 Role-Level
no attention	70.49	70.43
Content	73.03	72.87
Content	73.05	72.68
Time	75.58	75.58
Time	75.95**	**76.56****
Content + Time	75.59	75.30
Content + Time	75.83	75.96**
Content + **Time**	75.94*	75.97**

Content x Time	75.03	75.64**

Table 3: SLU accuracy of possible combinations of the proposed methods in role-level attention with different history representations. Int. used intent vector; Dist. used distance vector. *: $p < 0.05$; **, $p < 0.01$ compared to using intent only. Other codes are as in Table 2.

5.2 Detailed Analysis on Proposed Methods

The proposed methods had good SLU accuracy (Table 2). Every time-aware attention with and without speaker indicator (rows 4 to 11) improved the F1 score compared to the content-aware attention with and without speaker indicator (rows 2 and 3) and to no attention (row 1). This result means that the proposed time-aware attention was effective to improve the SLU accuracy. Any of the content-and-time-aware attention with or without speaker indicator (rows 6 to 11) did not improve the F1 score compared to the time-aware attention with and without speaker indicator (rows 4 and 5). This result means that incorporating content could not make further improvement of the accuracy. Also, without speaker indicator, all the time-aware attention (rows 4, 6 and 10) achieved similar F1 scores.

Use of speaker indicator also showed tendencies. It did not significantly improve the SLU accuracy of Decay-Function-Free Content-Aware Attention (rows 2 and 3) or Decay-Function-Free Inseparate Content-and-Time-Aware Attention (rows 10 and 11), but did improve the accuracy of the proposed models, Decay-Function-Free Time-Aware Attention (rows 4 and 5) and Decay-Function-Free Content-and-Time-Aware Attention (rows 6 to 9). Decay-Function-Free Content-and-Time-Aware Attention with speaker indicator (rows 7 to 9) were more accurate than Decay-Function-Free Inseparate Content-and-Time-Aware Attention with speaker indicator (row 11). This result means that using speaker indicator, separation of content and time improved the accuracy. The improvement in the role-level tended to be greater than that in the sentence-level. The improvement was greatest when speaker indicator was involved in the proposed role-level Decay-Function-Free Time-Aware Attention (row 5).

5.3 Effectiveness of Use of Distance in History Representation

In all models, the use of both intent and distance vectors significantly achieved higher F1 than the use of an intent vector only (Table 3). The results indicate that distance embeddings are helpful both for attention and for the history representation. Decay-Function-Free Time-Aware Attention achieved the biggest improvement (row 5) among all the models.

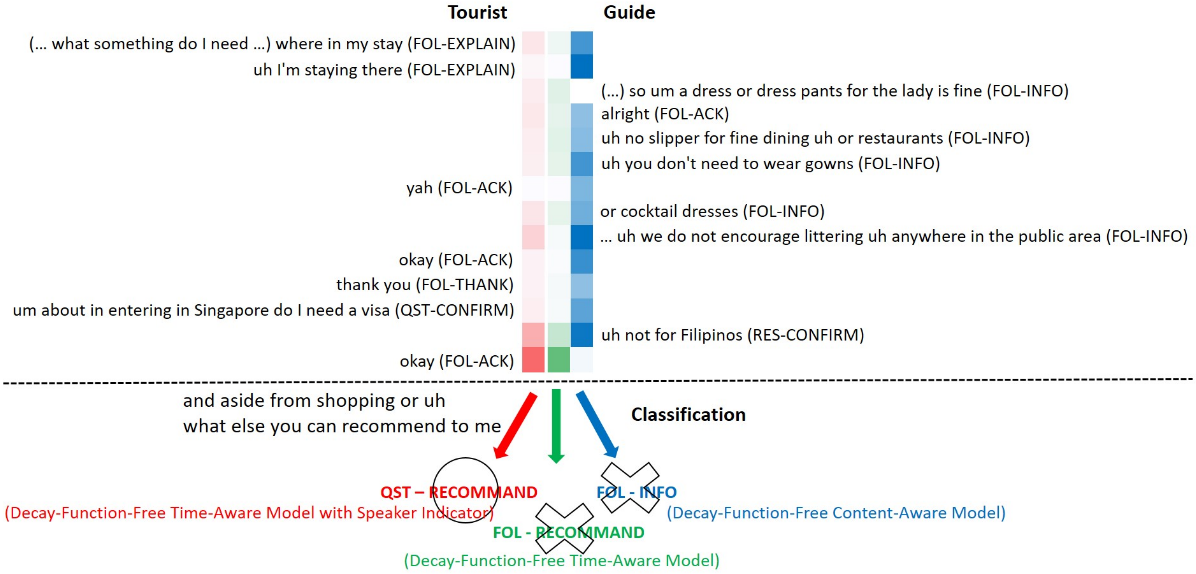

Figure 3: The visualization of the attention weights of the proposed models and the baseline content-aware model. Color gradient indicates intensity given a single datum after training. The color gradient at the left side indicates attention intensities of Decay-Function-Free Time-Aware Model with Speaker Indicator, the color gradient in the center indicates attention intensities of Decay-Function-Free Time-Aware Model without Speaker Indicator, and the color gradient at the right side indicates attention intensities of Decay-Function-Free Content-Aware Model.

5.4 Qualitative Analysis

To assess whether the proposed time-aware attention and speaker indicator can learn a time-decay tendency of the history effectively, we inspected the weights trained in Decay-Function-Free Time-Aware Attention with and without the speaker indicator. We also inspected Decay-Function-Free Content-Aware Attention to compare with them. We observed (Figure 3) that the weights of the proposed models were trained well compared to Decay-Function-Free Content-Aware Attention. The proposed time-aware attention with/without speaker indicator tended to pay attention to recent histories, whereas the content-aware attention does not. As a result, Decay-Function-Free Time-Aware Attention with speaker indicator could generate the true label, *QST-RECOMMEND*, by avoiding noisy contextual information like "uh I'm staying there (FOL-EXPLAIN)" or "... uh we do not encourage littering uh anywhere in the public area (FOL-INFO)".

6 Conclusion

In this paper, we propose decay-function-free time-aware attention models for SLU. These models summarize contextual information by taking advantage of temporal information without a manual time-decay function. We also propose a current-speaker detector that identifies the current speaker. In experiments on the DSTC 4 benchmark dataset, the proposed models achieved a state-of-the-art SLU accuracy. Detailed analysis of effectiveness of the proposed methods demonstrated that the proposed methods increase the accuracy of SLU individually.

Dialogue Act Classification with Context-Aware Self-Attention

Vipul Raheja   **Joel Tetreault**
Grammarly
`firstname.lastname@grammarly.com`

Abstract

Recent work in Dialogue Act classification has treated the task as a sequence labeling problem using hierarchical deep neural networks. We build on this prior work by leveraging the effectiveness of a context-aware self-attention mechanism coupled with a hierarchical recurrent neural network. We conduct extensive evaluations on standard Dialogue Act classification datasets and show significant improvement over state-of-the-art results on the Switchboard Dialogue Act (SwDA) Corpus. We also investigate the impact of different utterance-level representation learning methods and show that our method is effective at capturing utterance-level semantic text representations while maintaining high accuracy.

1 Introduction

Dialogue Acts (DAs) are the functions of utterances in dialogue-based interaction (Austin, 1975). A DA represents the meaning of an utterance at the level of illocutionary force, and hence, constitutes the basic unit of linguistic communication (Searle, 1969). DA classification is an important task in Natural Language Understanding, with applications in question answering, conversational agents, speech recognition, etc. Examples of DAs can be found in Table 1. Here we have a conversation of 7 utterances between two speakers. Each utterance has a corresponding label such as *Question* or *Backchannel*.

Speaker	Utterance	DA label
A	Okay.	Other
A	Um, what did you do this weekend?	Question
B	Well, uh, pretty much spent most of my time in the yard.	Statement
B	[Throat Clearing]	Non Verbal
A	Uh-Huh.	Backchannel
A	What do you have planned for your yard?	Question
B	Well, we’re in the process of, revitalizing it.	Statement

Table 1: A snippet of a conversation sample from the SwDA Corpus. Each utterance has a corresponding dialogue act label.

Early work in this field made use of statistical machine learning methods and approached the task as either a structured prediction or text classification problem (Stolcke et al., 2000; Ang et al., 2005; Zimmermann, 2009; Surendran and Levow, 2006). Many recent studies have proposed deep learning models for the DA classification task with promising results (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Ortega and Vu, 2017). However, most of these approaches treat the task as a text classification problem, treating each utterance in isolation, rendering them unable to leverage the conversation-level contextual dependence among utterances. Knowing the text and/or the DA labels of the previous utterances can assist in predicting the current DA state. For instance, in Table 1, the *Answer* or *Statement* dialog acts often follow *Question* type utterances.

This work draws from recent advances in NLP such as self-attention, hierarchical deep learning models, and contextual dependencies to produce a dialogue act classification model that is effective across multiple domains. Specifically, we propose a hierarchical deep neural network to model different levels of utterance and dialogue act semantics, achieving state-of-the-art performance on the Switchboard Dialogue Act Corpus. We demonstrate how performance can improve by leveraging context at different levels of the model: previous labels for sequence prediction (using a CRF), conversation-level context with self-attention for utterance representation learning, and character embeddings at the word-level. Finally, we explore different ways to learn effective utterance repre-

Proceedings of NAACL-HLT 2019, pages 3727–3733
Minneapolis, Minnesota, June 2 - June 7, 2019.

sentations, which serve as the building blocks of our hierarchical architecture for DA classification.

2 Related Work

A full review of all DA classification methods is outside the scope of the paper, thus we focus on two main classes of approaches which have dominated recent research: those that treat DA classification as a text classification problem, where each utterance is classified in isolation, and those that treat it as a sequence labeling problem.

Text Classification: Lee and Dernoncourt (2016) build a vector representation for each utterance, using either a CNN or RNN, and use the preceding utterance(s) as context to classify it. Their model was extended by Khanpour et al. (2016) and Ortega and Vu (2017). Shen and Lee (2016) used a variant of the attention-based encoder for the task. Ji et al. (2016) use a hybrid architecture, combining an RNN language model with a latent variable model.

Sequence Labeling: Kalchbrenner and Blunsom (2013) used a mixture of sentence-level CNNs and discourse-level RNNS to achieve state-of-the-art results on the task. Recent works (Li and Wu, 2016; Liu et al., 2017) have increasingly employed hierarchical architectures to learn and model multiple levels of utterance and DA dependencies. Kumar et al. (2018), Chen et al. (2018) and Tran et al. (2017) used RNN-based hierarchical neural networks, using different combinations of techniques like last-pooling or attention mechanism to encode sentences, coupled with CRF decoders. Chen et al. (2018) achieved the highest performance to date on the two datasets for this task.

Our work extends these hierarchical models and leverages a combination of techniques proposed across these prior works (CRF decoding, contextual attention, and character-level word embeddings) with self-attentive representation learning, and is able to achieve state-of-the-art performance.

3 Model

The task of DA classification takes a conversation C as input, which is a varying length sequence of utterances $U = \{u_1, u_2, ...u_L\}$. Each utterance $u_i \in U$, in turn, is a sequence of varying lengths of words $\{w_i^1, w_i^2, ..., w_i^{N_i}\}$, and has a corresponding target label $y_i \in Y$. Hence, each conversation (i.e. a sequence of utterances) is mapped to a corresponding sequence of target labels $Y = \{y_1, y_2, ..., y_L\}$, which represents the DAs associated with the corresponding utterances.

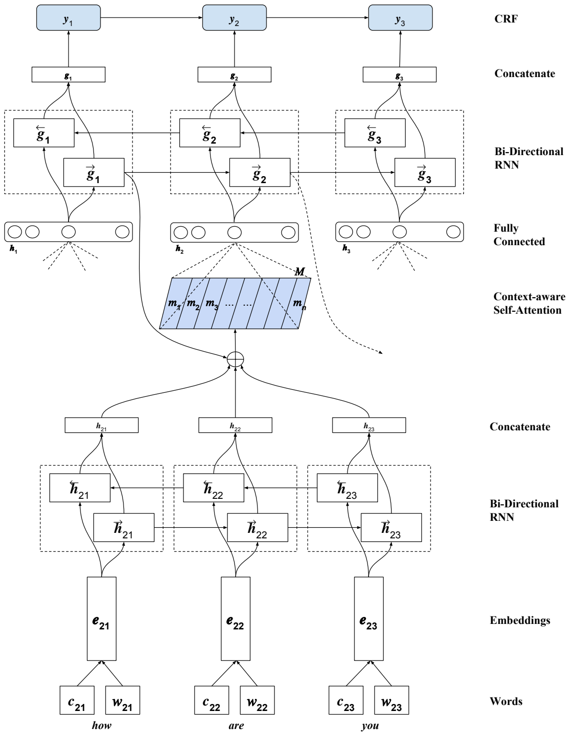

Figure 1: Model Architecture

Figure 1 shows the overall architecture of our model, which involves three main components: (1) an utterance-level RNN that encodes the information within the utterances at the word and character-level; (2) a context-aware self-attention mechanism that aggregates word representations into utterance representations; and (3) a conversation-level RNN that operates on the utterance encoding output of the attention mechanism, followed by a CRF layer to predict utterance labels. We describe them in detail below.

3.1 Utterance-level RNN

For each word in an utterance, we combine two different word embeddings: GloVe (Pennington et al., 2014) and pre-trained ELMo representations (Peters et al., 2018) with fine-tuned task-specific parameters, which have shown superior performance in a wide range of tasks. The word embedding is then concatenated with its CNN-based 50-D character-level embedding (Chiu and Nichols, 2016; Ma and Hovy, 2016) to get the complete word-level representations. The motivation behind incorporating subword-level information is to infer the lexical features of utterances and named entities better.

The word representation layer is followed by a bidirectional GRU (Bi-GRU) layer. Concatenating the forward and backward outputs of the Bi-GRU generates the utterance embedding that serves as input to the utterance-level context-aware self-attention mechanism which learns the final utterance representation.

3.2 Context-aware Self-attention

Self-attentive representations encode a variable-length sequence into a fixed size, using an attention mechanism that considers different positions within the sequence. Inspired by Tran et al. (2017), we use the previous hidden state from the conversation-level RNN (Section 3.3), which provides the context of the conversation so far, and combine it with the hidden states of all the constituent words in an utterance, into a self-attentive encoder (Lin et al., 2017), which computes a $2D$ representation of each input utterance. We follow the notation originally presented in Lin et al. (2017) to explain our modification of their self-attentive sentence representation below.

An utterance u_i, which is a sequence of n words $\{w_i^1, w_i^2, ...w_i^n\}$, is mapped into an embedding layer, resulting in a d-dimensional word embedding for every word. It is then fed into a bidirectional-GRU layer, whose hidden state outputs are concatenated at every time step.

$$\overrightarrow{h_i^j} = \overrightarrow{GRU}(w_i^j, \overrightarrow{h_i^{j-1}}) \qquad (1)$$

$$\overleftarrow{h_i^j} = \overleftarrow{GRU}(w_i^j, \overleftarrow{h_i^{j+1}}) \qquad (2)$$

$$\mathbf{h_i^j} = concat(\overrightarrow{h_i^j}, \overleftarrow{h_i^j}) \qquad (3)$$

$$H_i = \{\mathbf{h_i^1}, \mathbf{h_i^2}, ...\mathbf{h_i^n}\} \qquad (4)$$

H_i represents the n GRU outputs of size $2u$ (u is the number of hidden units in a unidirectional GRU).

The contextual self-attention scores are then computed as follows:

$$S_i = W_{s2}tanh(W_{s1}H_i^T + W_{s3}\overrightarrow{g_{i-1}} + \mathbf{b}) \qquad (5)$$

Here, W_{s1} is a weight matrix with a shape of $d_a \times 2u$, W_{s2} is a matrix of parameters of shape $r \times d_a$, where r and d_a are hyperparameters we can set arbitrarily, and W_{s3} is a parameter matrix of shape $d_a \times k$ for the conversational context, where k is another hyperparameter that is the size of a hidden state in the conversation-level RNN (size of $\overrightarrow{g_{i-1}}$), and $\mathbf{b}$ is a vector representing bias. Equation 5 can then be treated as a 2-layer MLP with bias, with d_a hidden units, W_{s1}, W_{s2} and W_{s3} as weight parameters. The scores S_i are mapped into a probability matrix A_i by means of a softmax function:

$$A_i = softmax(S_i) \qquad (6)$$

which is then used to obtain a 2-d representation M_i of the input utterance, using the GRU hidden states H_i according to the attention weights provided by A_i as follows:

$$M_i = A_iH_i \qquad (7)$$

This 2-d representation is then projected to a 1-d embedding (denoted as $\mathbf{h_i}$), using a fully-connected layer. The conversation-level GRU then operates over this 1-d utterance embedding, and hence, we can represent $\mathbf{g_i}$ as:

$$\overrightarrow{g_i} = \overrightarrow{GRU}(\mathbf{h_i}, \overrightarrow{g_{i-1}}) \qquad (8)$$

$$\overleftarrow{g_i} = \overrightarrow{GRU}(\mathbf{h_i}, \overrightarrow{g_{i+1}}) \qquad (9)$$

$$\mathbf{g_i} = concat(\overrightarrow{g_i}, \overleftarrow{g_i}) \qquad (10)$$

$\mathbf{g_i}$ then provides the conversation-level context used to learn the attention scores and 2-d representation (M_{i+1}) for the next utterance in the conversation ($\mathbf{h_{i+1}}$).

3.3 Conversation-level RNN

The utterance representation $\mathbf{h_i}$ from the previous step is passed on to the conversation-level RNN, which is another bidirectional GRU layer used to encode utterances across a conversation. The hidden states $\overrightarrow{g_i}$ and $\overleftarrow{g_i}$ (Figure 1) are then concatenated to get the final representation $\mathbf{g_i}$ of each utterance, which is further propagated to a linear chain CRF layer. The CRF layer considers the correlations between labels in context and jointly decodes the optimal sequence of utterance labels for a given conversation, instead of decoding each label independently.

4 Data

We evaluate the classification accuracy of our model on the two standard datasets used for DA classification: the Switchboard Dialogue Act Corpus (SwDA) (Jurafsky et al., 1997) consisting of 43 classes, and the 5-class version of the ICSI Meeting Recorder Dialogue Act Corpus (MRDA) introduced in (Ang et al., 2005). For both datasets,

Dataset	|C|	|V|	Train	Validation	Test
MRDA	5	12k	78k	16k	15k
SwDA	43	20k	193k	23k	5k

Table 2: Number of utterances by dataset. |C| denotes number of classes and |V| is the vocabulary size.

we use the train, validation and test splits as defined in Lee and Dernoncourt (2016).

Table 2 shows the statistics for both datasets. They are highly imbalanced in terms of class distribution, with the DA classes `Statement-non-opinion` and `Acknowledge/Backchannel` in SwDA and `Statement` in MRDA making up over 50% of the labels in each set.

5 Results

5.1 Dialogue Act Classification

We compare the classification accuracy of our model against several other recent methods (Table 3).[1] Four approaches (Chen et al., 2018; Tran et al., 2017; Ortega and Vu, 2017; Shen and Lee, 2016) use attention in some form to model the conversations, but none of them have explored self-attention for the task. The last three use CRFs in the final layer of sequence labeling. Only one other method (Chen et al., 2018) uses character-level word embeddings. All models and their variants were trained ten times and we report the average test performance. Our model outperforms state-of-the-art methods by 1.6% on SwDA, the primary dataset for this task, and comes within 0.6% on MRDA. It also beats a TF-IDF GloVe baseline (described in Section 5.2) by 16.4% and 12.2%, respectively.

The improvements that the model is able to make over the other methods are significant, however, the gains on MRDA still fall short of the state-of-the-art by 0.6%. This can mostly be attributed to the conversation/context lengths and label noise at the conversation level. Conversations in MRDA (1493 utterances on average) are significantly longer than in SwDA (271 utterances on average). In spite of having nearly 12% the number of labels (5 vs 43) compared to SwDA, MRDA has 6 times the normalized label entropy in its data. Consequently, due to the noise in label dependencies, and hence, in the inherent conversational structure, the model is not able to yield as big of a gain on the MRDA as it does on the SwDA. Consequently, learning long-range dependencies is a challenge because of noisier and longer path lengths in the network. This is illustrated in Figures 2 and 3, which show for every class, the variation between the entropy of the previous label in a conversation, and the accuracy of that class. MRDA was found to have a high negative correlation[2] (-0.68) between previous label entropy and accuracy, indicating the impact of label noise, which was compounded by longer conversations. On the other hand, SwDA was found to have a low positive correlation (+0.22), which could be compensated by significantly shorter conversations.

5.2 Utterance Representation Learning

One of the primary motivations for this work was to investigate whether one can improve performance by learning better representations for utterances. To address this, we retrained our model by replacing the utterance representation learning (utterance-level RNN + context-aware self-attention) component with various sentence representation learning methods (either pre-training them or learning jointly), and feeding them into the conversation-level recurrent layers in the hierarchical model, so that the performance is indicative of the quality of utterance representations.

There are three main categories of utterance representation learning approaches: (i) the baseline which uses a TF-IDF weighted sum of GloVe word embeddings; (ii) pre-trained on cor-

---

[1] Contemporaneous to this submission, (Li et al., 2018; Wan et al., 2018; Ravi and Kozareva, 2018) proposed different approaches for the task. We do not focus on them here per NAACL 2019 guidelines, however note that our system outperforms the first two. (Ravi and Kozareva, 2018) bypasses the need for complex networks with huge parameters but its overall accuracy is 4.2% behind our system, despite being 0.2% higher on SwDA.

Table 4: Performance of utterance representation methods when integrated with the hierarchical model

pus, where we first learn utterance representations on the corpus using Skip-Thought Vectors (Kiros et al., 2015) and Paragraph Vectors (Le and Mikolov, 2014), and then use them with the rest of the model; (iii) jointly learned with the DA classification task. Table 4 describes the performance of different utterance representation learning methods when combined with the overall architecture on both datasets.

Introducing the word-level attention mechanism (Yang et al., 2016) enables the model to learn better representations by attending to more informative words in an utterance, resulting in better performance (Bi-RNN + Attention). The self-attention mechanism (Bi-RNN + Self-attention) leads to even greater overall improvements. Adding context information (previous recurrent state of the conversation) boosts performance significantly.

A notable aspect of our model is how contextual information is leveraged at different levels of the sequence modeling task. The combination of conversation-level contextual states for utterance-representation learning (+ Context) and a CRF at the conversation level to further inform conversation sequence modeling, leads to a collective performance improvement. This is particularly pronounced on the SwDA dataset: the two variants of the context-aware attention models (Bi-RNN + Attention + Context and Bi-RNN + Self-attention + Context) have significant performance gains.

6 Conclusion

We developed a model for DA classification with context-aware self-attention, which significantly outperforms earlier models on the commonly-used SwDA dataset and is very close to state-of-the-art on MRDA. We experimented with different utterance representation learning methods and showed that utterance representations learned at the lower levels can impact the classification performance at the higher level. Employing self-attention, which has not previously been applied to this task, enables the model to learn richer, more effective utterance representations for the task.

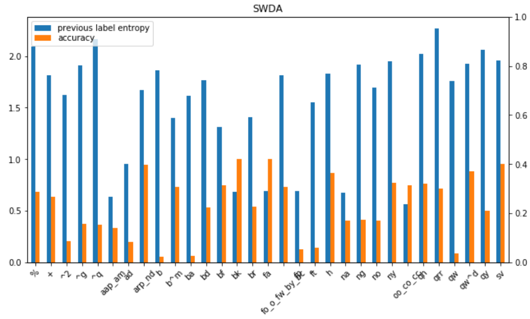

Figure 2: Previous Label Entropy vs. Accuracy on the SwDA Dataset

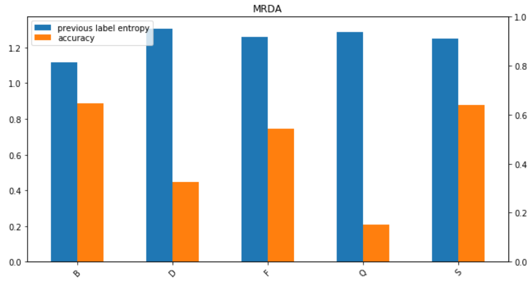

Figure 3: Previous Label Entropy vs. Accuracy on the MRDA Dataset

As future work, we would like to experiment with other attention mechanisms such as multi-head attention (Vaswani et al., 2017), directional self-attention (Shen et al., 2018a), block self-attention (Shen et al., 2018b), or hierarchical attention (Yang et al., 2016), since they have been shown to address the limitations of vanilla attention and self-attention by either incorporating information from different representation subspaces at different positions to capture both local and long-range context dependencies, encoding temporal order information, or by attending to context dependencies at different levels of granularity.

A Supplementary Material

A.1 Training & Hyperparameters

All hyperparameters were selected by tuning one hyperparameter at a time while keeping the others fixed. Validation splits were used for the tuning process. The final set of hyperparameters were then used to train two different models, one each on SwDA and MRDA training splits. Table 5 lists the range of values for each parameter that we experimented with, and the final value that was chosen. Dropout was applied to the utterance embeddings. Early stopping was used on the validation set with a patience of 15 epochs.

Abstract

The majority of current systems for end-to-end dialog generation focus on response quality without an explicit control over the affective content of the responses. In this paper, we present an affect-driven dialog system, which generates emotional responses in a controlled manner using a continuous representation of emotions. The system achieves this by modeling emotions at a word and sequence level using: (1) a vector representation of the desired emotion, (2) an affect regularizer, which penalizes neutral words, and (3) an affect sampling method, which forces the neural network to generate diverse words that are emotionally relevant. During inference, we use a reranking procedure that aims to extract the most emotionally relevant responses using a human-in-the-loop optimization process. We study the performance of our system in terms of both quantitative (BLEU score and response diversity), and qualitative (emotional appropriateness) measures.

1 Introduction

Recent breakthroughs in deep learning techniques have had an impact on end-to-end conversational systems (Chen et al., 2017). Current research is mainly focused on functional aspects of conversational systems: keyword extraction, natural language understanding, and pertinence of generated responses (Ilievski et al., 2018). Although these aspects are indeed key features for building a commercial system, most existing solutions lack social intelligence. Conversational systems could benefit from incorporating social intelligence by: (1) avoiding interaction problems that may arise when the system does not understand the user's request (e.g., inappropriate responses that cause user anger) (Maslowski et al., 2017), and (2) building rapport with the user (Strohkorb et al., 2016). Our method makes such conversational systems more social by outputting responses expressing emotion in a controlled manner, without sacrificing grammatical correctness, coherence, or relevance.

Existing sequence-to-sequence (seq2seq) architectures, either recurrent- (Sordoni et al., 2015; Serban et al., 2015), attention- (Vaswani et al., 2017) or convolutional neural network (CNN)-based (Fan et al., 2018), do not provide a straightforward way to generate emotionally relevant output in a controlled manner. We introduce EMOTIonal CONversational System (EMOTICONS), which generates emotion-specific responses. It is based on novel contributions presented in this paper which fall in two main categories: explicit models which allow a controlled emotion-based response generation (e.g., methods based on emotion embeddings, affective sampling, and affective re-ranking), and implicit models with no direct control over the desired emotion (i.e., affective regularizer). We show that EMOTICONS outperforms both the system proposed by Zhou et al. (2018) (current state of the art for our task) and the vanilla seq2seq in terms of BLEU score (Papineni et al., 2002) (improvement up to 7.7%) and response diversity (improvement up to 52%). Additionally, we qualitatively evaluate the emotional content of the generated text (see example responses in Table 1). The user study (22 people) demonstrates that EMOTICONS is able to generate grammatically correct, coherent, emotionally-rich text in a controlled manner.

2 Related Work

Sequence-to-sequence (seq2seq) models have attracted a lot of attention in the past few years, especially in the fields of Neural Machine Translation (Sutskever et al., 2014; Bahdanau et al., 2014) and Neural Dialogue Generation (Sordoni et al., 2015; Vinyals and Le, 2015; Serban et al.,

	Input	Good to see you again.	Be careful, I have a knife.	You're the only one who can help us.
	Baseline	It's good to see you.	Don't worry about it.	There's a lot of people here.
EMOTICONS	Fear	What are you doing here?	I'm just trying to get out of here.	What are you going to do with me?
	Anger	I'm not here.	I'm going to kill you.	You're not the only one who can help me.
	Joy	Good to see you.	I'm going to marry you.	I can protect you.
	Surprise	You want to talk to me?	I'm just going to the party.	You've got to be kidding me.

Table 1: Example responses from the baseline (seq2seq) model and the four EMOTICONS models with different emotions.

2015). Prior work has focused on designing architectures that lead to the best performance in terms of BLEU (Papineni et al., 2002) and Perplexity scores. Most seq2seq models are based on gated recurrent neural networks, either Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Unit (GRU) (Serban et al., 2015), but in general it is difficult to conclude which gating mechanism performs better (Chung et al., 2014). In our model, we use GRU because it has fewer parameters to optimize, and it is faster to train.

In order to overcome the problem of generating trivial or mundane responses, there have been developments in inference techniques for encoder-decoder systems. Use of beam search has been shown to improve the general quality of generated answers, while Maximum Mutual Information (MMI) (Li et al., 2016) has improved the diversity of generated answers, leading to more meaningful output. We build on these techniques during affective inference.

Emotion-based (affective) dialog generation systems have received increasing attention in the past few years. Huang et al. (2018) use emotion tokens (special "words" in a dictionary representing specific emotions) at either the encoder or decoder side, forcing the decoder to output a sentence with one specific emotion. Zhou et al. (2018) build their system using external and internal memory, where the former forces the network to generate emotional words, and the latter measures how emotional a generated sequence is compared to a target sequence. Lubis et al. (2018) modeled emotions in Valence-Arousal (VA) space for response generation. We extend this idea by using a Valence-Arousal-Dominance (VAD) Lexicon (Mohammad, 2018), as it has been shown by Broekens (2012) that the third dimension (Dominance) is useful for modeling affect. Asghar et al. (2017) used the VAD Lexicon, but they let the neural network choose the emotion to generate (by maximizing or minimizing the affective dissonance) and their system cannot generate different emotional outputs for the same input, nor generate a specified emotion.

3 System Architecture

Our system (see overview in Figure 1) is divided into three main components: (1) Emotion Labeling – automatic labeling of sentences according to the emotional content they express, using an emotion classifier (§3.2.1); labeling of words with VAD Lexicon values (§4.2), (2) Affective Training – training of two seq2seq networks, which use an encoder-decoder setting. The first network is trained with prompt-response pairs (S-T), whereas the second (used during Affective Inference) is trained with reversed pairs (T-S), (3) Affective Inference – generation of many plausible responses, which are re-ranked based on emotional content.

3.1 Preliminaries

Let $V = \{w_1, w_2, \ldots, w_{|V|}\}$ be a vocabulary, and $\mathcal{X} = (x_1, x_2, \ldots, x_{|\mathcal{X}|})$ a sequence of words (e.g. a sentence). We denote $E_{\mathcal{X}} \in \mathbb{R}^6$ as an emotion vector representing a probability distribution over six emotions associated with the sequence $\mathcal{X}$:

$$E_{\mathcal{X}} = \begin{bmatrix} p_{\text{anger}} \\ p_{\text{surprise}} \\ p_{\text{joy}} \\ p_{\text{sadness}} \\ p_{\text{fear}} \\ p_{\text{disgust}} \end{bmatrix}$$

Note that in this work we focus on six basic emotions proposed by Paul Ekman (Ekman et al., 1983) but the techniques we develop are general and can be extended to a more fine grained list of emotions. $\mathcal{X}$ can be an input sequence, candidate response, final response, or target response (denoted respectively as $\mathcal{S}$, $\mathcal{R}_C$, $\mathcal{R}_{\text{final}}$, $\mathcal{R}_0$). We introduce E_0, which during training, is the representation of the emotion of the target response ($\mathcal{R}_0$). During testing, E_0 indicates a desired emotion for the final response ($\mathcal{R}_{\text{final}}$), and can be set manually. For

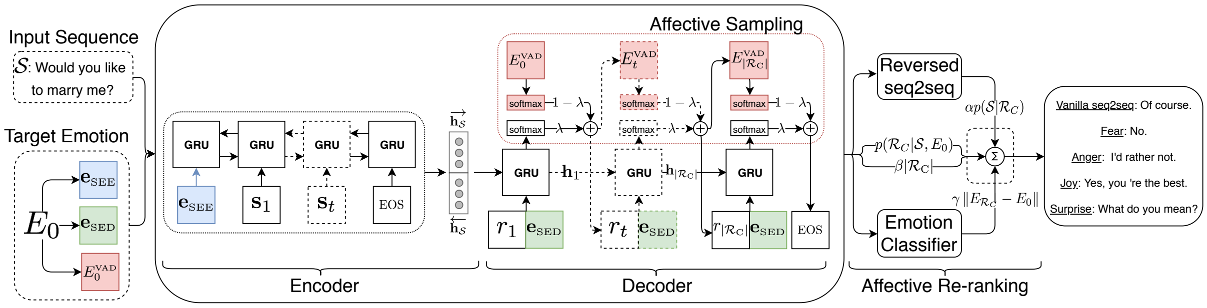

Figure 1: System overview: The input sequence and the target emotion (automatically extracted from the target response using the emotion classifier during training, and set by the user during inference) are fed into the seq2seq. The generated candidate responses are re-ranked based on the output of the reversed seq2seq, the length, and the emotional content.

example, in the case of ‘anger’, E_0 would be a one-hot vector with 1 at the first position, and 0 elsewhere.

In our work, we extend the standard seq2seq model (Sutskever et al., 2014), that predicts the final response $\mathcal{R}_{\text{final}} = \text{argmax}_{\mathcal{R}_C}\, p(\mathcal{R}_C|S)$. The proposed affective system aims to extend the inference mechanism by incorporating emotions encoded in E_0:

$$\mathcal{R}_{\text{final}} = \underset{\mathcal{R}_C}{\text{argmax}}\, p(\mathcal{R}_C|S, E_0) \tag{1}$$

3.2 Affect Modeling

We extend the standard seq2seq architecture by including emotion-specific information during the training and the inference. A critical challenge in both generating and evaluating responses is a reliable assessment of emotional state. We use two representations of emotion: (1) a categorical representation with six emotions (anger, surprise, joy, sadness, fear, disgust), and (2) a continuous representation in a VAD space. The latter uses a VAD Lexicon introduced by Mohammad (2018), where each of 20k words is mapped to a 3D vector of VAD values, ranging from 0 (lowest) to 1 (highest) ($\mathbf{v} \in [0,1]^3$). Valence measures the positivity/negativity, Arousal the excitement/calmness, and Dominance the powerfulness/weakness of the emotion expressed by a word. This expands the work of Lubis et al. (2018), who modeled emotions only in VA space. In the following sections we describe different versions of the proposed model.

3.2.1 Emotion Classifier

Affective training requires E_0, the emotion representation of the target sequence. In order to label all sentences of the corpus with E_0, we use an Emotion Classifier by Witon et al. (2018). The classifier predicts a probability distribution over class of six emotions. The classifier predictions for Cornell Movie-Dialogs Corpus (Cornell) have been shown to be highly correlated with human predictions (Witon et al., 2018).

3.2.2 Sequence-Level Explicit Encoder Model (SEE)

To explicitly generate responses with emotion, this version of the model includes an emotion embedding at the encoder side. We feed the encoder with $\mathcal{S}' = (\mathbf{e}_{\text{SEE}}, s_1, s_2, \ldots, s_{|S|})$, where $\mathbf{e}_{\text{SEE}} = \mathbf{A}_{SEE}E_0$ is an Emotion Embedding ($\mathbf{e}_{\text{SEE}} \in \mathbb{R}^3$), and $\mathbf{A}_{SEE} \in \mathbb{R}^{3\times 6}$ is a mapping (learned during training) from E_0 into an emotion embedding space.

3.2.3 Sequence-Level Explicit Decoder Model (SED)

Another way of forcing an emotional output is to explicitly indicate the target emotion at every step in decoding along with other inputs. Formally, the GRU hidden state at time t is calculated as $\mathbf{h}_t = f(\mathbf{h}_{t-1}, r'_t)$ with $r'_t = [r_{t-1}; \mathbf{e}_{\text{SED}}]$, where $\mathbf{e}_{\text{SED}}$ is defined similarly as $\mathbf{e}_{\text{SEE}}$. It is worth noting that $\mathbf{A}_{SEE}$ and $\mathbf{A}_{SED}$ are different, which implies that the emotion embedding spaces they map to are also different. Compared to a similar approach introduced by Huang et al. (2018), our solution enables the desired emotional content, E_0, to be provided in a continuous space.

3.2.4 Word-Level Implicit Model (WI)

To model the word-level emotion carried by each sequence, we introduce an Affective Regularizer (AR), which expresses the affective distance between $\mathcal{R}_{\text{final}}$ and $\mathcal{R}_0$, in the VAD space. It forces the neural network to prefer words in the vocabulary that carry emotions in terms of VAD. Mathematically, we extend the regular Negative Log Likelihood (NLL) loss with an affective regularizer, $\mathcal{L}_{\text{AR}}$:

$$\begin{aligned}\mathcal{L} &= \mathcal{L}_{\text{NLL}} + \mathcal{L}_{\text{AR}} \\ &= -\log p(\mathcal{R}_{\text{final}}|\mathcal{S}) + \mu \mathcal{L}_{\text{VAD}}(\mathcal{R}_{\text{final}}, \mathcal{R}_0)\end{aligned}$$

$$\mathcal{L}_{\text{VAD}}(\mathcal{R}_{\text{final}}, \mathcal{R}_0) = \left\| \sum_{t=1}^{|\mathcal{R}_{\text{final}}|} \frac{\mathbf{E}^{\text{VAD}}\mathbf{s}_t}{|\mathcal{R}_{\text{final}}|} - \sum_{t=1}^{|\mathcal{R}_0|} \frac{\mathbf{e}^{\text{VAD}}_{r_{0_t}}}{|\mathcal{R}_0|} \right\|,$$

where $\mathbf{s}_t = \text{softmax}(\mathbf{h}_t)$ ($\mathbf{s}_t \in \mathbb{R}^{|V|}$) is a confidence of the system of generating words $w_1, \ldots, w_{|V|}$ at time t and $\mu \in \mathbb{R}$. $\mathbf{e}^{\text{VAD}}_x \in \mathbb{R}^3$ is a 3D vector representing emotion associated with a word x in VAD space (note that $\mathbf{e}^{\text{VAD}}_x$ is constant with respect to t), and $\mathbf{E}^{\text{VAD}} \in \mathbb{R}^{3\times|V|}$ is a matrix containing $\mathbf{e}^{\text{VAD}}_{w_v}$ for all $|V|$ words in the vocabulary:

$$\mathbf{E}^{\text{VAD}} = \left[\, \mathbf{e}^{\text{VAD}}_{w_1} ; \; \ldots \; ; \mathbf{e}^{\text{VAD}}_{w_{|V|}} \right]$$

Intuitively, the regularizer penalizes the deviation of the emotional content of the generated response, $\mathcal{R}_{\text{final}}$, from the desired response, $\mathcal{R}_0$. The emotional information carried by $\mathcal{R}_{\text{final}}$ is the weighted sum of emotion representations $\mathbf{e}^{\text{VAD}}_{w_i}$ for all words w_i in the vocabulary, where the weights are determined by the confidence $\mathbf{s}_t$.

3.2.5 Word-Level Explicit Model (WE)

Sequential word generation allows sampling of the next word, based on the emotional content of the current incomplete sequence. If some words in a sequence do not express the target emotion E_0, other words can compensate for this by changing the final affective content, e.g., in a sentence "I think that the cat really loves me!", the first 6 words are neutral, whereas the end of the sentence make it clearly express joy. We incorporate this observation by explicitly generating the next word using an Adaptive Affective Sampling Method:

$$\log p(\mathcal{R}_C|\mathcal{S}, E_0) = \sum_{t=1}^{|\mathcal{R}_C|} \log p(r_t|r_{<t}, \mathbf{e}_{r_{<t}}, \mathbf{h}_{\mathcal{S}}, E_0),$$

$$\begin{aligned}p(r_t|r_{<t}, \mathbf{e}_{r_{<t}}, \mathbf{h}_{\mathcal{S}}, E_0) = {}& \lambda \,\text{softmax}\, g(\mathbf{h}_t) + \\ & (1-\lambda)\,\text{softmax}\, v(E^{\text{VAD}}_t),\end{aligned}$$

where $g(\mathbf{h}_t)$ is a linear mapping from GRU hidden state $\mathbf{h}_t$ to an output vector of size $|V|$, and $0 \leq \lambda \leq 1$ is learned during training. The first term in Equation 3.2.5 is responsible for generating words according to a language model preserving grammatical correctness of the sequence, whereas the second term forces generation of words carrying emotionally relevant content. $E^{\text{VAD}}_t \in \mathbb{R}^3$ is a vector representing the remaining emotional content needed to match a goal (E^{VAD}_0) after generating all words up to time t. It is updated every time a new word r_t with an associated emotion vector $\mathbf{e}^{\text{VAD}}_{r_t}$ is generated:

$$E^{\text{VAD}}_t = E^{\text{VAD}}_{t-1} - \mathbf{e}^{\text{VAD}}_{r_{t-1}}$$

$$E^{\text{VAD}}_0 = \begin{cases} \sum_{t=1}^{|\mathcal{R}_0|} \mathbf{e}^{\text{VAD}}_{r_{0t}}, & \text{training} \\ \mathbf{M}_{\text{VAD}} E_0 \cdot \text{max}_{\text{length}}, & \text{inference} \end{cases}$$

where $\mathbf{e}^{\text{VAD}}_{r_{0t}}$ is an emotion vector associated with words r_{0_t} in the target sequence, $\text{max}_{\text{length}}$ is a maximum length set for the seq2seq model, and $\mathbf{M}_{\text{VAD}} \in \mathbb{R}^{3\times6}$ is a mapping from six-dimensional emotion space into VAD space (every emotion has a VAD vector as introduced by Hoffmann et al. (2012), scaled to a range [0, 1]):

$$\mathbf{M}_{\text{VAD}} = \begin{array}{cccccc|c} \text{anger} & \text{surprise} & \text{joy} & \text{sadness} & \text{fear} & \text{disgust} & \\ 0 & 1 & 1 & 0 & 0 & 0 & V \\ 1 & 1 & 1 & 0 & 1 & 0.5 & A \\ 1 & 0 & 1 & 0 & 0 & 0.5 & D \end{array}$$

$v(E^{\text{VAD}}_t)$ is a vector, whose i-th component measures the potential remaining emotional content of the sequence in the case of choosing the i-th word w_i:

$$v(E^{\text{VAD}}_t) = -\begin{bmatrix} \left\|E^{\text{VAD}}_t - \mathbf{e}_{w_0}\right\| \\ \cdots \\ \left\|E^{\text{VAD}}_t - \mathbf{e}_{w_{|V|}}\right\| \end{bmatrix}$$

In the following, we set a constant $\lambda = 1$ after generating the first $\text{max}_{\text{length}}/2$ words, as this setting ensures that the first generated words carry the right emotional content, while not sacrificing the grammatical correctness of the whole response. This leads to an improvement in performance.

3.3 Affective Inference

The methods described in the previous sections aim to improve the seq2seq training/sampling procedure. We hypothesize that a good inference strategy is crucial for generating diverse and emotion-specific responses. As Li et al. (2016) suggest, traditional objective functions, i.e., likelihood of a response given an input, can be improved by using an N-best list and MMI during inference. We build upon this idea; our hypothesis is that by generating B diverse sequences and re-ranking the responses, we are more likely to infer one best emotion-specific response. The B-best list is found using Beam Search of size B with length normalization.

In the MMI-bidi setting, Li et al. (2016) rank all responses found during beam search based on a score calculated as:

$$\mathcal{R}_{\text{final}} = \underset{\mathcal{R}_C}{\operatorname{argmax}}\, p(\mathcal{R}_C|\mathcal{S}) + \alpha p(\mathcal{S}|\mathcal{R}_C) + \beta|\mathcal{R}_C|, \tag{2}$$

where $p(\mathcal{S}|\mathcal{R}_C)$ is a model with the same architecture as $p(\mathcal{R}_C|\mathcal{S})$ trained on reversed prompt-response pairs (T-S), and $|R_C|$ is the length of the candidate response, R_C. We modify this objective in the following form:

$$\begin{aligned}\mathcal{R}_{\text{final}} = \underset{\mathcal{R}_C}{\operatorname{argmax}}\, & p(\mathcal{R}_C|\mathcal{S}, E_0) + \alpha p(\mathcal{S}|\mathcal{R}_C) \\ & + \beta|\mathcal{R}_C| - \gamma \left\| E_{\mathcal{R}_C} - E_0 \right\|, \end{aligned} \tag{3}$$

where the last term penalizes the deviation of the emotional content, $E_{\mathcal{R}_C}$, of the candidate response, $\mathcal{R}_C$, from the desired emotional content, E_0. The task is to find optimal values of parameters α, β and γ, which give the best responses in terms of grammatical correctness, diversity (α, β) and emotional content (γ) (see §5 and §6).

4 Model Training

In this section, we describe corpora used for training, the baseline models and the training procedure for the models presented in §3.

4.1 Corpora

Cornell contains around 10K movie characters and around 220K dialogues (Danescu-Niculescu-Mizil and Lee, 2011).

OpenSubtitles2018 is a collection of translated movie subtitles with 3.35G sentence fragments (Tiedemann, 2009). It has been filtered to get pairs of consecutive sequences (containing between 5 and 30 words), with respective timestamps within an interval of 5 seconds, that are part of a conversation of at least 4 turns. The filtered dataset contains 2.5M utterances.

Preprocessing Each dataset is tokenized using the spaCy[1] tokenizer, converted to lowercase, and non-ASCII symbols are removed. To restrain the vocabulary size and correct the typos, we use a default vocabulary of fixed size 42K words from spaCy. Each word in the dataset is then compared with the vocabulary using the difflib library[2] in Python (algorithm based on the Levenshtein distance), and mapped to the most similar word in the vocabulary. If no word with more than 90% of similarity is found, the word is considered a rare word or a typo, and is mapped to the out-of-vocabulary (OOV) word. For Cornell, less than 1% of the unigrams are OOV.

4.2 Affective Dictionary

The VAD lexicon may not have all the words in the vocabulary. Based on the word similarity (using difflib library), each word of the vocabulary is assigned a VAD value of the most similar word in the VAD lexicon. If no word with more than 90% of similarity is found, a "neutral" VAD value ($\mathbf{v} = [0.5, 0.5, 0.5]$) is assigned.

4.3 Baselines

We compare our work to two different baselines: a vanilla seq2seq and the ECM introduced by Zhou et al. (2018). For the external memory we use our affective dictionary and train the model using the default parameters provided by authors.

4.4 Training Details

All the hyper-parameters have been optimized on the validation set using BLEU score (Papineni et al., 2002). For the encoder, we use two-layer bidirectional GRUs (hidden size of 256). The final hidden states from both directions are concatenated and fed as an input to the decoder of one-layer unidirectional GRUs (hidden size of 512). The embedding layer is initialized with pre-trained word vectors of size 300 (Mikolov et al., 2018), trained with subword information (on Wikipedia 2017, UMBC web-base corpus and statmt.org news dataset), and updated during training. We use ADAM optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 for learning $p(\mathcal{R}_C|\mathcal{S}, E_0)$ (resp. 0.01 for $p(\mathcal{S}|\mathcal{R}_C)$), which is updated by using a scheduler with a patience of 20 epochs and a decreasing rate of 0.5. The gradient norm is clipped to 5.0, weight decay is set to $1e^{-5}$, and dropout (Srivastava et al., 2014) is set to 0.2. The maximum sequence length is set to 20 for Cornell and to 30 for OpenSubtitles. The models have been trained on 94%, validated on 1%, and tested on 5% of the data.

Table 2: Quantitative results: Results for all proposed models trained on Cornell (C) and OpenSubtitles (OS). distinct-1 and distinct-2 count the number of distinct unigrams and bigrams, respectively, normalized by the total number of generated tokens in 200 candidate responses. The performance boost is computed with respect to the vanilla seq2seq model.

5 Quantitative Evaluation for Model Selection

To evaluate language models, we use BLEU score (computed using 1- to 4-grams), as it has been shown to correlate well with human judgment (Agarwal and Lavie, 2008). Perplexity does not provide a fair comparison across the models: during the training of the baseline seq2seq model, we minimize the cross entropy loss (logarithm of perplexity), whereas in other models (e.g., WI) we aim to minimize a different loss not directly related to perplexity (cross entropy extended with the affective regularizer). Having more diverse responses makes the affective re-ranking more efficient, to evaluate diversity we count the number of distinct unigrams (distinct-1) and bigrams (distinct-2), normalized by the total number of generated tokens.

The performance of different models introduced in §3 are presented in Table 2. MMI$_{\text{bas.}}$ refers to a system that re-ranks responses based on Equation 2, where both $p(\mathcal{R}_C|\mathcal{S})$ and $p(\mathcal{S}|\mathcal{R}_C)$ are baseline seq2seq models. EMOTICONS is a system based on Equation 3, where $p(\mathcal{R}_C|\mathcal{S}, E_0)$ is computed using a composition of Word-Level Implicit Model (WI) and Word-Level Explicit Model (WE), and $p(\mathcal{S}|\mathcal{R}_C)$ is computed using WI (as we are not interested in explicitly using the input emotion). We optimize α and β on the validation set using BLEU score, since Li et al. (2016) have shown that adding MMI during inference improves the BLEU score. We set $\gamma = 0$ and find optimal values $\alpha_{opt} = 50.0$ and $\beta_{opt} = 0.001$ using grid search.

Improving BLEU score and diversity was not the goal of our work, but the observed improvement (after adding emotions) shows that the different systems are able to extract and use emotional patterns to improve the general language model.

5.1 Response Diversity

From Table 2, we observe that for both Cornell and OpenSubtitles datasets, SED, WI, and WE models outperform the vanilla seq2seq and the ECM for at least one of the two distinct measures. SEE has the worst performance overall and does not compete with either the baseline, nor with SED. This is expected according to the results reported by Huang et al. (2018). It seems that the model is not able to capture the information carried by the additional emotion embedding token – it is treated as just one additional word among 20 others. SED makes better use of the emotion information, as it is used at each time step during decoding. In addition, it is more natural to use these features during the decoding, since the emotion embedding represents the desired emotion of the response. The combination of WI and WE performs best in terms of distinct-1 and distinct-2 measures among all models without re-ranking, yielding an improvement of up to 13.1%. It suggests that the word level emotion models suit the seq2seq architecture better. During training, both models are encouraged not only to match the target words, but also to promote less frequent words that are close to the target words in terms of VAD values (affective regularizer and affective sampling), fostering the model to generate more diverse responses.

As expected, by adding MMI, we observe an improvement in diversity, but the relative improvement for OpenSubtitles ($\text{MMI}_{\text{bas.}}$) is smaller than the one reported by Li et al. (2016). This could originate from the different data filtering and beam search strategy, and the fact the hyper-parameter optimization has been performed on Cornell. EMOTICONS is a combination of WI + WE (best performing model) for $p(\mathcal{R}_C|\mathcal{S}, E_0)$ and WI for $p(\mathcal{S}|\mathcal{R}_C)$, it is better than $\text{MMI}_{\text{bas.}}$ (up to 52.5% gain in distinct-1).

It is worth noting that we observe higher scores in terms of diversity for the reversed model $p(\mathcal{S}|\mathcal{R}_C)$ compared to the normal model $p(\mathcal{R}_C|\mathcal{S}, E_0)$, while training on Cornell. We can explain this using the data distribution: distinct-2 is higher for the questions than for the answers (0.167 and 0.154 for Cornell, respectively).

5.2 Response Quality

Table 2 shows that, in general, introducing emotional features into the process of generating responses does not reduce the BLEU score. To reduce the potential negative impact of choosing inappropriate first words in the sequence, we compute the BLEU score on the result of beam search of size 200. For example, if the first word is "I", the seq2seq models tend to generate a response "I don't know" with high probability, due to the high number of appearances of such terms in the training set. In certain cases, like WI and SED, we observe an improvement. Such an improvement is expected, since our model takes into account additional (affective) information from the target sequence during response generation.

6 Human-in-the-Loop Hyper-Parameter Estimation

The quantitative evaluation shows that EMOTICONS outperforms the baseline while adding the emotional features during response generation. The re-ranking phase did not take into account the affective term ($\gamma = 0$ in Equation 3). Setting a different value would not necessarily improve any of the available metrics (e.g., BLEU score, diversity), as they do not explicitly take into account affective content in their definition. In this section, we describe an optimization procedure, relying on human judgment, for finding the optimal value of γ.

6.1 Experiment Description

We asked annotators to evaluate (using an AffectButton) the generated responses. We use AffectButton (Broekens and Brinkman, 2013), a reliable affective tool for assigning emotions, which, to our knowledge, has never been used for estimating the emotional content of the generated responses. In our experiment, the AffectButton lets users choose a facial expression from a continuous space (see Figure 3), that best matches the emotional state associated with the sequence, which is then mapped into the VAD space. In order to conduct the experiment, we chose a pool of 12 annotators, who annotated a total of 400 sequences. The prompts were randomly chosen from the test set of Cornell, among the 200 sequences that create the most diverse responses in terms of distinct-2. The more diverse the responses are, the more likely we are to select a response carrying a desired emotion. The responses for the prompts were generated using EMOTICONS where the target emotion was either fear, anger, joy, or surprise; the four corners of the AffectButton. γ was randomly chosen among 20 uniformly sampled values in $[0, 10]$.

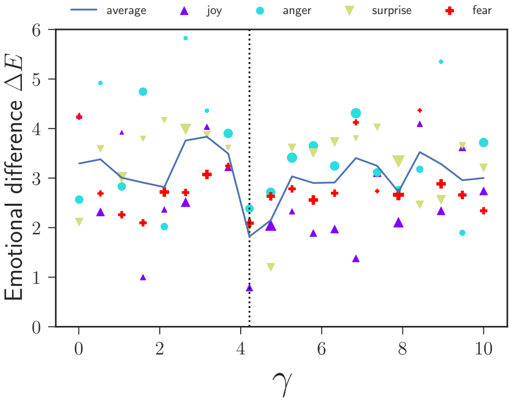

Figure 2: Hyper-parameter optimization: For different values of γ, users assign a face to the generated response. Each point represents an average ΔE of annotations for each emotion. ΔE is the difference between the VAD representation of the face assigned by the user and the desired emotion for the response. The size is proportional to the number of collected annotations. ΔE is at a minimum for $\gamma_{\text{opt}} = 4.2$.

6.2 Experiment Results

In Figure 2, we present the difference between the VAD value according to the face assigned by the user, and the desired emotion for the response. The average curve presents a global minimum at $\gamma_{opt} = 4.2$. The system does not perform equally well at generating different emotions according to the human judgment. On average, we observe lower values for joy compared to anger in Figure 2. This phenomenon is expected, as in the re-ranking

	Model	Grammatical Correctness	User Preference Total	User Preference Majority Vote
	$\text{MMI}_{\text{bas.}}$	83 %	39	8
EMOTICONS	Fear	82 %	96	37
	Anger	80 %		
	Joy	84 %		
	Surprise	79 %		

Table 3: User study results: *Grammatical Correctness* shows the ratio of grammatically correct sentences among all generated responses, whereas *User Preference* shows the number of times each model was preferred by the users.

process $E_{\mathcal{R}_C}$ is estimated using the emotion classifier (Witon et al., 2018) which detects joy more accurately than anger (77% versus 57%), surprise (62%) and fear (69%).

7 Qualitative Evaluation

In this section, we qualitatively evaluate the emotional content and correctness of the responses generated by $\text{EMOTICONS}_{\gamma=\gamma_{opt}}$ compared to the ones from $\text{MMI}_{\text{bas.}}$ through a user study. It consists of three different experiments which measure grammatical correctness, user preference, and emotional appropriateness. For all experiments, we chose prompts from the test set of Cornell, for which the most diverse responses were created by $\text{MMI}_{\text{bas.}}$ in terms of distinct-2. We test EMOTICONS by generating responses according to four emotions: fear, anger, joy, and surprise (beam size of 200).

7.1 Grammatical Correctness

In this experiment, we used 40 prompts. For each prompt, we generated 5 sentences (4 for EMOTICONS, and 1 for $\text{MMI}_{\text{bas.}}$) that were presented in a random order to 3 native English speakers. They assigned either 0 (sentence grammatically incorrect), or 1 (sentence grammatically correct) for all sentences. To measure the agreement across annotators, we calculate Fleiss' $\kappa = 0.4128$, which corresponds to "moderate agreement". Our model does not substantially sacrifice the grammatical correctness of the responses (see Table 3).

7.2 User Preference

In this setting, we quantify how likely the user is going to prefer the response generated by EMOTICONS compared to the one generated by $\text{MMI}_{\text{bas.}}$. We asked 18 annotators to choose their favorite response to the input query among eight proposed answers (top four responses coming from the MMI_{bas} and 4 coming from EMOTICONS with the four different target emotions). Each of 45 sentences were annotated by three different annotators. Results of the experiment (Table 3) indicate that users strongly prefer EMOTICONS over $\text{MMI}_{\text{bas.}}$.

(a) Bas. (b) Fear (c) Anger (d) Joy (e) Surprise

Figure 3: Emotional faces: AffectButton presents faces according to average VAD vectors (in parentheses) obtained for the (a) $\text{MMI}_{\text{bas.}}$ ($[0.47, 0.98, 0.36]$), and for the four EMOTICONS models with different target emotions: (b) Fear ($[0.2, 0.95, 0.38]$), (c) Anger ($[0.54, 0.92, 0.65]$), (d) Joy ($[0.68, 0.97, 0.66]$), and (e) Surprise ($[0.37, 0.97, 0.52]$).

7.3 Emotional Appropriateness

In this experiment, we show that our model is able to generate emotions in a controlled manner. For each of the 5 models, 22 users assign a face via the AffectButton. We generate responses for 120 different prompts. We keep the responses that were annotated with a VAD vector with the norm greater than 2, corresponding to those expressing strong emotions. We compute the average VAD vectors for the annotated sequences for each model, with corresponding AffectButton faces (Figure 3). The majority of user-assigned faces have a high arousal value, which can be explained by the fact that users tend to click in one of the four corners of the AffectButton. The majority of the faces represent an accurate portrayal of the desired emotion. The poor performance of EMOTICONS at expressing surprise comes from the fact that (1) users often mismatch surprise with joy, leading to a neutral dominance value, and (2) surprise is one of the most difficult emotions to judge (see §6).

8 Conclusion

We have presented EMOTICONS, a system that can generate responses with controlled emotions. The flexibility of the presented solution allows it to be used in any kind of neural architecture as long it fits the encoder-decoder framework. Currently, EMOTICONS does not generate different emotions equally well. Future work could include incorporating contextual information that would help EMOTICONS to better capture emotional content.

Abstract

Recent end-to-end task oriented dialog systems use memory architectures to incorporate external knowledge in their dialogs. Current work makes simplifying assumptions about the structure of the knowledge base (such as the use of triples to represent knowledge) and combines dialog utterances (context), as well as, knowledge base (KB) results, as part of the same memory. This causes an explosion in the memory size, and makes reasoning over memory, harder. In addition, such a memory design forces hierarchical properties of the data to be fit into a triple structure of memory. This requires the memory reader to learn how to infer relationships across otherwise connected attributes.

In this paper we relax the strong assumptions made by existing architectures and use separate memories for modeling dialog context and KB results. Instead of using triples to store KB results, we introduce a novel multi-level memory architecture consisting of cells for each query and their corresponding results. The multi-level memory first addresses queries, followed by results and finally each key-value pair within a result. We conduct detailed experiments on three publicly available task oriented dialog data sets and we find that our method conclusively outperforms current state-of-the-art models. We report a 15-25% increase in both entity F1 and BLEU scores.

1 Introduction

Task oriented dialog systems are designed to complete a user specified goal, or service an information request using natural language exchanges. Unlike open domain end-to-end neural dialog models, task oriented systems rely on external knowledge sources, outside of the current conversation context, to return a response (Henderson et al., 2014a; Su et al., 2016; Bordes and Weston, 2017a; Eric and Manning, 2017; El Asri et al., 2017). For instance, in the example shown in Table 1, a dialog agent giving tour package recommendations needs to be able to first query an external knowledge source to determine packages that meet a user's requirement, and then respond accordingly.

Origin	**Dest.**	**Hotel**	**Price**	**Cat.**	**Rating**	**...**
Dallas	Mannheim	Regal Resort	$2800	5.0	8.98	...
Toronto	Calgary	Amusement	$1864.4	4.0	6.91	...
Dallas	Mannheim	Vertex Inn	$3592.8	3.0	7.15	...
Dallas	Santos	Globetrotter	$2000	3.0	8.37	..
Dallas	Mannheim	Starlight	$4018.1	4.0	8.56	
...	...	...	...	...	...	...

Role	**Turn**	**Utterance**
Agent	1	how can i help
User	2	i've got a few days off from aug 26-aug 31. I'm not flexible on this, but i want to somehow treat myself with an 8 day trip. I'm leaving Dallas and I want to check out Munich
Agent	2	sorry we dont have any package for Munich
User	3	how about Mannheiem?
Agent	3	would a 5 day trip suffice
User	4	sure dude
Agent	4	A 5 star hotel called the Regal resort, it has free wifi and a spa
User	5	dates?
Agent	5	starts on august 27th until the 30th
User	6	ok that could work. I would like to see my options in Santos.
Agent	6	there is Hotel Globetrotter in Santos. it has 3 stars and comes with breakfast and wifi, it leaves on august 25th and returns on 30th, all for $2000
User	7	ahh i can't leave until august 26th though. I guess i'll just have to go to Mannheim then.
Agent	7	the Regal resort package costs $2800 with economy class.
User	8	yeah i will book it

Table 1: A goal oriented dialog based on the Frames dataset (El Asri et al., 2017) along with an external knowledge source with each row containing a tour package.

In order to enable end-to-end goal oriented dialog tasks, current state of the art methods use neural memory architectures to incorporate external knowledge (Su et al., 2016; Eric and Manning, 2017; Madotto et al., 2018). As can be seen in Table 1, agent responses may also include entity values present only in the dialog context (eg: "Munich" in the Agent response in Turn 2). In order to support such utterances, models also include tokens from the input dialog context in the same memory (Madotto et al., 2018).

Proceedings of NAACL-HLT 2019, pages 3744–3754
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

Existing memory based architectures for task oriented dialog suffer from multiple limitations. First, the creation of a shared memory for copying values from dialog context, as well as the knowledge base (KB) results, forces the use of a common memory reader for two different types of data. This makes the task of reasoning over memory, harder – not only does the memory reader need to determine the right entries from a large memory (since each word from context also occupies a memory cell), it also needs to learn to distinguish between the two forms of data (context words and KB results) stored in the same memory.

Subject	Relation	Object	Subject	Relation	Object
Vertex Inn	Price	\$3592.8	Vertex Inn	Category	3.0
Regal Resort	Price	\$2800	Regal Resort	Rating	8.98
Regal Resort	Category	5.0	Starlight	Price	\$4018.1
Starlight	Rating	8.56	Starlight	Category	4.0
...	...	...	...	...	...

Table 2: Results from Dallas to Mannheim stored in the form of triples.

Second, all current neural memory architectures store results, returned by a knowledge source, in the form of triples (eg. $subject - relation - object$). This modeling choice makes it hard for the memory reader to infer relationships across otherwise connected attributes. For instance, consider the example triple store in Table 2 showing results for a query executed for packages between "Dallas" and "Mannheim". If the user asks the dialog agent to check the price of stay at a 5 star hotel, the memory reader needs to infer that the correct answer is $2800 by learning that the price, category and hotel need to be linked inorder to return an answer (shown in blue).

Lastly, current models treat conversations as a sequential process, involving the use of KB results from only the most recent information request/query. In contrast, in real world dialogs such as the one shown in Table 1, the agent may have to refer to results (*to Mannheim*) from a previously executed query (see Turn 7). Thus, at each turn, the system has to memorize all the information exchanged during the dialog, and infer the package being referred to, by the user. In order to support such dialogs, the memory needs to store results of all queries executed during the course of the dialog. The problem of inferring over such results (which may be from multiple queries) is exacerbated when memory is represented in the form of triples.

In this paper, we present our novel multi-level memory architecture that overcomes the limitations of existing methods: (i) We separate the memory used to store tokens from the input context and the results from the knowledge base. Thus, we learn different memory readers for context words as well for knowledge base entities (ii) Instead of using a $subj - rel - obj$ store, we develop a novel multi-level memory architecture which encodes the natural hierarchy exhibited in knowledge base results by storing queries and their corresponding results and values at each level. We first attend on the queries, followed by the results in each query to identify the result being referred to, by the user. We then attend on the individual entries in the result to determine which value to copy in the response. Figure 1c shows our multi-level memory storing the results from queries executed as part of the dialog in Table 1.

Our paper makes the following contributions:

1. We propose the use of separate memories for copying values from context and KB results. Thus, the model learns separate memory readers for each type of data.

2. Our novel multi-level memory for KB results, models the queries, results and their values in their natural hierarchy. As our experiments show, the separation of memory as well as our multi-level memory architecture, both, contribute to significant performance improvements.

3. We present detailed experiments demonstrating the benefit of our memory architecture along with model ablation studies. Our experiments on three publicly available datasets (**CamRest676** (Su et al., 2016), **InCar assistant** (Eric and Manning, 2017), **Maluuba Frames** (El Asri et al., 2017)) show a substantial improvement of 15-25 % in both entity F1 scores, and BLEU scores as compared to existing state of the art architectures. To the best of our knowledge, we are the first to attempt end-to-end modeling of task oriented dialogs with non-sequential references as well as multiple queries, as seen in the Maluuba Frames dataset. A human evaluation on model outputs also shows our model is preferred by users over existing systems such as KVRet (Eric and Manning, 2017) and Mem2Seq (Madotto et al., 2018).

2 Related work

Recent methods, such as (Vinyals and Le, 2015; Serban et al., 2016, 2017), proposed for end-to-end learning of dialogs were aimed at modeling open-domain dialogs. While they can be used for learning task oriented dialogs, they are not well suited to interface with a structured KB. To better adapt them to handle task oriented dialogs: 1) (Bordes and Weston, 2017b) proposed a memory network based architecture to better encode KB tuples and perform inferencing over them and 2) (Madotto et al., 2018) incorporated copy mechanism to enable copying of words from the past utterances and words from KB while generating responses. All successful end-to-end task oriented dialog networks (Eric and Manning, 2017; Bordes and Weston, 2017b; Madotto et al., 2018) make assumptions while designing the architecture: 1) KB results are assumed to be a triple store, 2) KB triples and past utterances are forced to be represented in a shared memory to enable copying over them. Both these assumptions make the task of inferencing much harder. Any two fields linked directly in the KB tuple are now linked indirectly by the subject of the triples. Further, placing the KB results and the past utterances in same memory forces the architecture to encode them using a single strategy. In contrast, our work uses two different memories for past utterances and KB results. The decoder is equipped with the ability to copy from both memories, while generating the response. The KB results are represented using a multi-level memory which better reflects the natural hierarchy encoded by sets of queries and their corresponding result sets.

Memory architectures have also been found to be helpful in other tasks such as question answering. Work such as (Xu et al., 2016) defines a hierarchical memory architecture consisting of sentence level memory followed by word memory for a QA task while (Chandar et al., 2016) defines a memory structure that speeds up loading and inferencing over large knowledge bases. Recent work by (Chen et al., 2018) uses a variational memory block along with a hierarchical encoder to improve diversity of open domain dialog responses.

3 Multi-Level Memory Network

In this section, we describe our end-to-end model for task oriented dialogues. Our model[1] (Figure 1a) consists of: (i) a hierarchical encoder which encodes the current input context consisting of the user and agent utterances (ii) a multi-level memory that maintains the queries and knowledge base results seen so far in the course of the dialogue, and (iii) copy augmented sequence decoder that uses separate context and multi-level memory. The queries and their corresponding results are maintained in a multi-level memory. The decoder uses a gating mechanism for memory selection while generating a response.

3.1 Encoder

Our model uses a standard hierarchical encoder as proposed by (Sordoni et al., 2015). The encoder takes a sequence of utterances as input. For the t^{th} turn, the dialogue context can be represented as $(c_1, c_2, ...c_{2t-1})$, which consists of t user utterances and $t-1$ system utterances. Each utterance c_i is further a sequence of words $(w_{i1}, w_{i2}, ...w_{im})$. We first embed each word w_{ij} using a word embedding function ϕ^{emb} that maps each word to a fixed-dimensional vector. We then generate utterance representations, $\varphi(c_i)$ using a single layer bi-directional GRU. h^e_{ij} denotes the hidden state of word w_{ij} in the bi-directional GRU. The input representation c is generated by passing each utterance representation $\varphi(c_i)$ through another single layer GRU.

3.2 Multi-level Memory

Motivation: Current approaches break down KB results by flattening them into (*subj-rel-obj*) triples. However, converting KB results into triples leads to loss of relationship amongst attributes in the result set. This makes the reasoning over memory difficult as model now has to infer relationships when retrieving values from memory. Instead, we use a multi-level memory which keeps the natural hierarchy of results intact (without breaking them into triples). We store the queries and their corresponding results and individual values at different *levels*. We first attend on the queries and then on the results for each query to identify which result the user is referring to. This also enables us to handle user requests that refer to results from a previously executed query. We propose that a representation of all the values in the result, and not just one of the values (designated as *subj*), should be used while attending over a result in KB. We attend on this compound representation of the result before attending on the individual key-value pairs in each result, to determine which value to copy into the generated response.

---

(c) Expanded view of the multi-level KB memory corresponding to example in Table 1

Figure 1: Model architecture (a) along with schematic representation of context memory (b) and multi-level KB memory (c)

3.2.1 Memory Representation

Let $q_1, q_2, ...q_k$ be the queries fired to the knowledge base till the current state of the dialogue. Every query q_i is a set of key-value pairs $\{k^{q_i}_a : v^{q_i}_a, 1 < a < n_{q_i}\}$, corresponding to the query's slot and argument where n_{q_i} is the number of slots in query q_i. For example, after the user utterance at Turn 3 in Table 1, the query fired by the system on the knowledge base would be $\{$*'origin':'Dallas','destination':'Manheim','Start': 'Aug 26', 'end': 'Aug 31', 'Adults':1*$\}$. The execution of a query on an external knowledge base, returns a set of results. Let r_{ij} be the j^{th} result of query q_i. Each result r_{ij} is also a set of slot-value pairs $\{k^{r_{ij}}_a : v^{r_{ij}}_a, 1 < a < n_{r_{ij}}\}$ where $n_{r_{ij}}$ is the number of attributes in result r_{ij}. A visualization of the memory with queries and their corresponding results can be seen in Figure 1c.

The first level of memory contains the query representations. Each query q_i is represented by q^v_i = Bag of words over the word embeddings of values ($v^{q_i}_a$) in q_i. The second level of memory contains the result representations. Representation of each result r_{ij} is given by r^v_{ij} = Bag of words over the word embeddings of values ($v^{r_{ij}}_a$) in r_{ij}. The third level of memory contains the result cells which have the key-value pairs ($k^{r_{ij}}_a : v^{r_{ij}}_a$) of the results. The values ($v^{r_{ij}}_a$) which are to be copied into the system response are thus present in the final level of memory . We now describe how we apply attention over the context and multi-level memory.

3.3 Decoder

The model generates the agent response word-by-word; a word at time step t is either generated from the decode vocabulary or is a value copied from one of the two memories (knowledge base or context memory). A soft gate g_1 controls whether a value is generated from vocabulary or copied from memory. Another gate g_2 determines which of the two memories is used to copy values.

3.3.1 Generating words:

Let the hidden state of the decoder at time t be h_t.

$$h_t = GRU(\phi^{emb}(y_{t-1}), h_{t-1}) \tag{1}$$

The hidden state h_t is used to apply attention over the input context memory. Attention is applied over the hidden states of the input bi-directional (BiDi) GRU encoder using the "*concat*" scheme as given in (Luong et al., 2015). The attention for the jth word in the ith utterance is given by:

$$a_{ij} = \frac{exp(w_1^T tanh(W_2 tanh(W_3[h_t, h^e_{ij}])))}{\sum_{ij} exp(w_1^T tanh(W_2 tanh(W_3[h_t, h^e_{ij}])))} \tag{2}$$

The attention scores a_{ij} are combined to create an attended context representation d_t,

$$d_t = \sum_{i,j} a_{i,j} h^e_{ij} \tag{3}$$

and similar to (Luong et al., 2015), the decoder word-generation distribution is given by :

$$P_g(y_t) = softmax(W_1[h_t, d_t] + b_1) \tag{4}$$

3.3.2 Copying words from context memory:

The input context memory is represented using the hidden states h^e_{ij} of the input Bi-Di GRU encoder. Similar to (Gulcehre et al., 2016), the attention scores a_{ij}, are used as the probability scores to form the copy distribution $P_{con}(y_t)$ over the input context memory.

$$P_{con}(y_t = w) = \sum_{ij:w_{ij}=w} a_{ij} \tag{5}$$

3.3.3 Copying entries from KB memory:

The context representation d_t, along with the hidden state of decoder h_t, is used to attend over the multi-level memory. The first level attention, $\alpha_.$, is applied over the queries $q_.$.

$$\alpha_i = \frac{exp(w_2^T tanh(W_4[d_t, h_t, q^v_i]))}{\sum_i exp(w_2^T tanh(W_4[d_t, h_t, q^v_i]))} \tag{6}$$

The second level attention, $\beta_{i.}$, is the attention over the results $r_{i.}$ of query q_i.

$$\beta_{ij} = \frac{exp(w_3^T tanh(W_5[d_t, h_t, r^v_{ij}]))}{\sum_j exp(w_3^T tanh(W_5[d_t, h_t, r^v_{ij}]))} \tag{7}$$

The product of first level attention and second level attention is the attention over results of all the queries in the multi-level memory. The weighted sum of the first level attention, second level attention and result representations gives us the attended memory representation, m_t.

$$m_t = \sum_i \sum_j \alpha_i \beta_{ij} r^v_{ij} \tag{8}$$

Each result is further composed of multiple result cells. On the last level of memory, which contains the result cells, we apply key-value attention similar to (Eric and Manning, 2017). The key of the result cell is the word embedding of the slot, $k^{r_{ij}}_a$, in the result. The attention scores, $\gamma_{ij.}$, for the keys represent the attention over the result cells of each result r_{ij}.

$$\gamma_{ijl} = \frac{exp(w_4^T tanh(W_6[d_t, h_t, \phi^{emb}(k^{r_{ij}}_l)]))}{\sum_l exp(w_4^T tanh(W_6[d_t, h_t, \phi^{emb}(k^{r_{ij}}_l)]))} \tag{9}$$

The product of first level attention α_i, second level attention β_{ij} and third level attention γ_{ijl} gives the final attention score of the value $v^{r_{ij}}_l$ in the KB memory. These final attention scores when combined (Eq. 10), form the copy distribution, $P_{kb}(y_t)$, over the values in KB memory.

$$P_{kb}(y_t = w) = \sum_{ijl:v^{r_{ij}}_l = w} \alpha_i \beta_{ij} \gamma_{ijl} \tag{10}$$

3.3.4 Decoding

Similar to (Gulcehre et al., 2016), we combine the generate and copy distributions - we use gate g_2 (Eq. 11) to obtain the copy distribution $P_c(y_t)$ (Eq. 12) by combining $P_{kb}(y_t)$ and $P_{con}(y_t)$.

$$g_2 = sigmoid(W_7[h_t, d_t, m_t] + b_2) \tag{11}$$

$$P_c(y_t) = g_2 P_{kb}(y_t) + (1 - g_2) P_{con}(y_t) \tag{12}$$

Finally, we use gate g_1 to obtain the final output distribution $P(y_t)$, by combining generate distribution $P_g(y_t)$ and copy distribution $P_c(y_t)$ as shown below:

$$g_1 = sigmoid(W_8[h_t, d_t, m_t] + b_3) \tag{13}$$

$$P(y_t) = g_1 P_g(y_t) + (1 - g_1) P_c(y_t) \tag{14}$$

We train our model by minimizing the cross entropy loss $-\sum_{t=1}^{T} log(P(y_t))$.

4 Experiments

4.1 Datasets

We present our experiments using three real world publicly available multi-turn task oriented dialogue datasets: the InCar assistant (Eric and Manning, 2017), CamRest (Su et al., 2016) and the Maluuba Frames dataset (El Asri et al., 2017). All three datasets contain human-human task oriented dialogues which were collected in a Wizard-of-Oz (Wen et al., 2017) setting.

(i) **InCar assistant dataset** consists of 3031 multi-turn dialogues in three distinct domains: calendar scheduling, weather information retrieval, and point-of-interest navigation. Each dialogue has it's own KB information provided and thus, the system does not have to make any queries.

(ii) **CamRest dataset**, consists of 676 human-to-human dialogues set in the restaurant reservation domain. There are three queryable slots (food, price range, area) that users can specify. This dataset has currently been used for evaluating slot-tracking systems. Recent work by (Lei et al., 2018) uses an end-to-end network without a KB and substitutes slot values with placeholders bearing the slot names in agent responses. However, we formatted the data to evaluate end-to-end systems by adding API call generation from the slot values so that restaurant suggestion task can proceed from the KB results.

(iii) **Maluuba Frames dataset**, consists of 1369 dialogues developed to study the role of memory in task oriented dialogue systems. The dataset is set in the domain of booking travel packages which involves flights and hotels. In contrast to the previous two datasets, this dataset contains dialogs that require the agent to remember all information presented previously as well as support results from multiple queries to the knowledge base. A user's preferences may change as the dialogue proceeds, and can also refer to previously presented queries (non-sequential dialog). Thus, to store multiple queries, we require 3 levels in our multi-level memory as compared to 2 levels in the other datasets, since they don't have more than one query. We do not use the dialogue frame annotations and use only the raw text of the dialogues. We map ground-truth queries to API calls that are also required to be generated by the model. Recent work has used this dataset only for frame tracking (Schulz et al., 2017) and dialogue act prediction (Peng et al., 2017; Tang et al., 2018). To the best of our knowledge we are the first to attempt the end-to-end dialog task using this dataset. Table 3 summarizes the statistics of the datasets.

	InCar	CamRest	Maluuba Frames
Train Dialogs	2425	406	1095
Val Dialogs	302	135	137
Test Dialogs	304	135	137
Avg. no. of turns	2.6	5.1	9.4
Avg length. of sys. resp.	8.6	11.7	14.8
Avg no. of sys. entities	1.6	1.7	2.9
Avg no. of queries	0	1	2.4
Avg no. of KB entries	66.1	13.5	141.2

Table 3: Statistics for 3 different datasets.

4.2 KB API Call Generation

In this section, we briefly describe how the knowledge base queries are generated as API calls as part of the model response. The InCar assistant dataset has a fixed KB for each dialogue whereas the CamRest and Maluuba datasets require queries to be fired on a global KB. Queries in CamRest dataset can have 3 slots namely cuisine, area and pricerange, whereas those in Maluuba can have 8 slots, which are destination, origin, start date, end date, budget, duration, number of adults and children. Any query that is to be fired on the KB is expected to be generated by the model as an API call, by considering a fixed ordering of slots in the generated response. For eg., in CamRest dataset, ApiCall(area=south, pricerange=cheap) would be generated by the model as *api_call dontcare south cheap*, with *dontcare* meaning that the user does not have any preference for cuisine and, *south*, *cheap* being the user constraints for area and pricerange respectively. Therefore, the task of API call generation typically involves copying relevant entities that are present in dialog context.

4.3 Training

Our model is trained end-to-end using Adam optimizer (Kingma and Ba, 2014) with a learning rate of $2.5e^{-4}$. The batch-size is sampled from [8,16]. We use pre-trained Glove vectors (Pennington et al., 2014) with an embedding size of 200. The GRU hidden sizes are sampled from [128, 256]. We tuned the hyper-parameters with grid search over the validation set and selected the model which gives best entity F1.

4.4 Evaluation Metrics

4.4.1 BLEU

We use the commonly used BLEU metric (Papineni et al., 2002) to study the performance of our systems as it has been found to have strong correlation (Sharma et al., 2017) with human judgments in task-oriented dialogs.

4.4.2 Entity F1

To explicitly study the behaviour of different memory architectures, we use the entity $F1$ to measure how effectively values from the knowledge base are used in the dialog. To compute the entity F1, we micro-average the precision and recall over the entire set of system responses to compute the micro F1[2]. For the InCar Assistant dataset, we compute a per-domain entity F1 as well as the aggregated entity F1. Since our model does not have slot-tracking by design, we evaluate

---

[2] We observe that (Madotto et al., 2018) reports the micro average of recall as the micro F1.

	InCar					CamRest		Maluuba Frames	
Model	BLEU	F1	Calendar F1	Weather F1	Navigate F1	BLEU	F1	BLEU	F1
Attn seq2seq (Luong et al., 2015)	11.3	28.2	36.9	35.7	10.1	7.7	25.3	3.7	16.2
Ptr-UNK (Gulcehre et al., 2016)	5.4	20.4	22.1	24.6	14.6	5.1	40.3	5.6	25.8

Mem2Seq (Madotto et al., 2018)	11.8	40.9	61.6	39.6	21.7	14.0	52.4	7.5	28.5
Multi-level Memory Model (MM)	**17.1**	**55.1**	**68.3**	**53.3**	**44.5**	**15.9**	**61.4**	**12.4**	**39.7**

Table 4: Comparison of our model with baselines

on entity F1 instead of the slot-tracking accuracy as in (Henderson et al., 2014b; Wen et al., 2017)

4.5 Baselines

We experiment with the following baseline models for comparing the performance of our Multi-Level Memory architecture:

Attn seq2seq[3] (Luong et al., 2015): A model with simple attention over the input context at each time step during decoding.

Ptr-UNK[3] (Gulcehre et al., 2016): The model augments a sequence-to-sequence architecture with attention-based copy mechanism over the encoder context.

KVRet (Eric and Manning, 2017): The model uses key value knowledge base in which the KB is represented as triples in the form of $subject - relation - object$. This model does not support copying words from context. The sum of word embeddings of $subject$, $relation$ is used as the key of the corresponding $object$.

Mem2Seq[3] (Madotto et al., 2018): The model uses a memory networks based approach for attending over dialog history and KB triples. During decoding, at each time step, the hidden state of the decoder is used to perform multiple hops over a single memory which contains both dialog history and the KB triples to get the pointer distribution used for generating the response.

4.6 Results

Table 4 shows the performance of our model against our baselines. We find that our multi- level memory architecture comprehensively beats all existing models, thereby establishing new state-of-the- art benchmarks on all three datasets. Our model outperforms each baseline on both BLEU and entity F1 metrics.

InCar: On this dataset, we show entity F1 scores for each of the scheduling, weather and navigation domains. Our model has the highest F1 scores across all the domains. It can be seen that our model strongly outperforms Mem2Seq on each domain. A detailed study reveals that the use of triples cannot handle cases when a user queries with *non-subject* entries or in cases when the response requires inferencing over multiple entries. In contrast, our model is able to handle such cases since we use a compound representation of entire result (bag of words over values) while attending on that result.

CamRest: Our model achieves the highest BLEU and entity F1 scores on this dataset. From Table 4, we see that simpler baselines like Ptr-UNK show competitive performance on this dataset because, as shown in Table 3, CamRest dataset has relatively fewer KB entries. Thus, a simple mechanism for copying from context results in good entity F1 scores.

	InCar		**CamRest**		**Maluuba**	
	Ctxt.	KB	Ctxt.	KB	Ctxt.	KB
Mem2Seq	66.2	25.3	63.7	36.5	17.7	8.9
Multi-level Mem.	81.6	37.5	70.1	53.4	27.2	14.6

Table 5: Percentage (%) of category-wise (context vs KB) ground truth entities correctly captured in generated response. Abbreviation Ctxt denotes context.

Maluuba Frames: The Maluuba Frames dataset was introduced for the frame tracking task. Here, a dialog frame is a structured representation of the current dialog state. Instead of explicitly modeling the dialog frames, we use the context representation d_t to directly attend on the Multi-level memory. As Table 3 shows, this dataset contains significantly longer contexts as well as larger number of entities, as compared to the other two datasets. In addition, unlike other datasets, it also contains non-linear dialog flows where a user may refer to previously executed queries and results. The complexity of this dataset is reflected in the relatively lower BLEU and F1 scores as compared to other datasets.

4.7 Analysis

4.7.1 Entity source-wise performance

To further understand the effect of separating context memory from KB memory and using a multi-

---

[3] We use the implementation provided by (Madotto et al., 2018) at https://github.com/HLTCHKUST/Mem2Seq

	InCar					CamRest		Maluuba Frames	
Model	BLEU	F1	Calendar F1	Weather F1	Navigate F1	BLEU	F1	BLEU	F1
Unified Context and KB memory (Mem2Seq)	11.8	40.9	61.6	39.6	21.7	14.0	52.4	7.5	28.5
Separate Context and KB Memory	14.3	44.2	56.9	54.1	24.0	14.3	55.0	12.1	36.5
+Replace KB Triples with Multi-level memory	17.1	55.1	68.3	53.3	44.5	15.9	61.4	12.4	39.7

Table 6: Model ablation study : Effect of (i) separate memory and (ii) multi-level memory design.

level memory for KB, Table 5 shows the percentage of ground-truth entities, according to their category, which were also present in the generated response. For example, on the InCar dataset, out of the 930 entities in ground-truth response that were to be copied from the KB, our model was able to copy 37.5% of them into the generated response. From Table 5, it can be seen that our model is able to correctly copy a significantly larger number of entities from both, KB and context, as compared to the recent Mem2Seq model in all datasets.

4.7.2 Model ablation study

We report results from ablation studies on all three datasets. Table 6 shows the incremental benefit obtained from individual components used in our model. We investigate the gains made by (i) Using separate memory for context and KB triples (ii) Replacing KB triples with a Multi-level memory. We use the recent Mem2Seq model for comparison with a unified context and KB memory model.

As can be seen from Table 6, the separation of context memory and KB memory leads to a significant improvement in BLEU and F1 scores on all datasets. This validates our hypothesis that storing context words and KB results in a single memory confuses the memory reader. The use of a multi-level memory instead of triples leads to further gains. This suggests, better organization of KB result memory by keeping the natural hierarchy intact is beneficial.

4.7.3 Error Analysis

We analyzed the errors made by our dialog model on 100 dialog samples in test set of Maluuba Frames. We observed that the errors can be divided into five major classes: (i) Model outputs wrong KB result entry due to incorrect attention (27%), (ii) Model returns package details instead of asking for more information from the user (16%), (iii) Model incorrectly captures user intent (13%), (iv) Model makes an error due to non-sequential nature of dialog (22%). In such errors, our model either generates an API call for a result already present in memory, or our model asks for a query-slot value that was already provided by the user, (v) Data specific characteristics such as insufficient samples for certain classes of utterances (eg: more than one package returned) or returning different, but meaningful package attributes as compared to ground-truth data, contribute to 22% of the errors.

	CamRest			**Maluuba**		
	Info.	Lang.	MRR	Info.	Lang.	MRR
KVRet	2.49	4.38	0.57	2.42	3.31	0.64
Mem2Seq	2.48	3.72	0.51	1.78	2.55	0.50
Our Model	**3.62**	**4.48**	**0.76**	**2.45**	**3.93**	**0.69**

Table 7: Informational accuracy and language quality scores using a human study.

4.8 Human Evaluation

We also conducted a blind user study that compared outputs from our model, Mem2Seq and KVRet systems. We used 96 randomly selected examples from each test split of Maluuba and CamRest datasets resulting in a total of 192 examples. Our study was split across 8 users who were provided with results fetched from the KB, current dialog context, gold response and the outputs of each of the models. Model outputs were shuffled in each example and users were asked to score each output between 1 (lowest) to 5 (highest) in terms of its accuracy of information in response and the quality of language. The results of this study are presented in Table 7. We also report the MRR (mean-reciprocal rank) for model preference along with other scores.

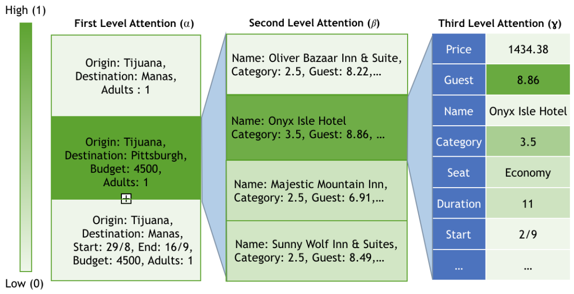
It can be seen that our model consistently ranks high for both information accuracy and language quality as well as reports a higher MRR. To further understand the quality of model performance, we asked the human evaluators whether their best ranked model output was a useful response. We saw that the evaluators agreed in 76.04% and 58.33% of the cases for CamRest and Maluuba datasets respectively. We observe that the results from human evaluation go hand-in-hand with automatic evaluation and reinforce our claim that separating context, KB memory and using a multi-level representation for the KB memory are useful for improving dialog modeling.

Role	Turn	Utterance
Agent	1	hello ! how can i help you today ?
User	2	*i just need to dream a bit. i have 4500 dollars but no vacation days. i'm wondering what a hypothetical trip to Manas would be like*
Agent	2	i can help with that, where are you departing from
User	3	*i'm in Tijuana, not departing any time soon unfortunately though*
...	...	...
Agent	5	`[API_CALL manas tijuana 29/8 16/9 4500 ...]`
...	...	...
User	7	*that's fine, what about pittsburgh*
Agent	7	`[API_CALL pittsburgh tijuana ...  4500 ...]`
...	...	...
Agent	8	that i do have! would you be satisfied with a 3.5 star hotel ?
User	9	*as of now i'm satisfied with a tent and a backpack .* *what are the hotel details?*
Agent	9	the hotel is situated near a park, comes with free parking, wifi and breakfast ! does this sound good
User	10	*sounds quite nice, what about the guest rating ?*
Gold		the guest rating is impressive : **8.86**
Mem2Seq		this is the only available with the same
KVRet		it's a 2.5 star hotel near a park, museum and airport.it has a guest rating of 8.22
Our Model		the onyx isle hotel has a **8.86** guest rating and offers free parking, breakfast and wifi.

Table 8: Comparing the responses generated by various models on an example in test set of Maluuba Frames.

4.9 Attention Visualization

Analyzing the attention weights is a useful way to understand how the model is inferencing over the memory to copy entities from it. Table 8 shows an example of a dialog from the Maluuba Frames dataset and the outputs generated by different models. Here, the user first wants to know about packages to 'Manas' and then requests for trips to 'Pittsburgh'. Later, the user becomes interested in the 3.5 star hotel in Pittsburgh which was suggested by the agent and wants to know its guest rating. It can be seen from Table 8 that our model outputs the correct guest rating (8.86) of the hotel. Mem2Seq fails to understand the context and generates an irrelevant response. KVRet generates a readable response but points to the guest rating of a different hotel.



(a) Attention over the multi-level KB memory

Word	rating	guest	3.5	1	park	...
Score	0.9132	0.0721	0.0108	0.0030	0.0005	...

(b) Decreasing order of attention scores over words in dialogue context

Figure 2: Visualization of attention over memory while generating the word '8.86' for the example in Table 8.

The attention over the memory while generating the word '8.86' for this example is shown in Fig 2. Fig 2a shows that the query with destination as 'Pittsburgh' gets the highest attention and among the results of this query, the package with the 3.5 star rated hotel gets highest attention. Within this result, the model gives highest score to the result cell with guest rating as the key. To further understand why the correct result hotel gets higher attention, Fig 2b shows the attention scores over the words in context memory. The context representation d_t captures the important words (3.5, guest, rating) in context which are in-turn used to apply attention over the multi-level memory.

Lastly, studying the values of the gates g_1 (prob. of generating from vocabulary) and g_2 (prob. of copying from KB), we found that gate g_1 had a probability value of *0.08* thereby driving the model to copy from memory instead of generating from output vocabulary and gate g_2, with a probability value of *0.99*, was responsible for selecting KB memory over context memory.

5 Conclusion

In this paper, we presented an end-to-end trainable novel architecture with multi-level memory for task oriented dialogues. Our model separates the context and KB memory and combines the attention on them using a gating mechanism. The multi-level KB memory reflects the natural hierarchy present in KB results. This also allows our model to support non-sequential dialogs where a user may refer to a previously suggested result. We find that our model beats existing approaches by 15-25% on both entity F1 and BLEU scores, establishing state-of-the-art results on three publicly available real-world task oriented dialogue datasets. In a user study comparing outputs from our system against recent models, we found that our model consistently scored higher for both language quality as well as correctness of information in the response. We also present the benefits of each of our design choices by performing an ablation study. In future work, we would like to incorporate better modeling of latent dialog frames so as to improve the attention signal on our multi-level memory. As our error analysis suggests, nearly 22% of the errors could possibly be reduced by improved modeling of the dialog context. We believe that model performance can also be improved by capturing user intent better in case of non-sequential dialog flow.

Abstract

Success of deep learning techniques have renewed the interest in development of dialogue systems. However, current systems struggle to have consistent long term conversations with the users and fail to build rapport. Topic spotting, the task of automatically inferring the topic of a conversation, has been shown to be helpful in making a dialog system more engaging and efficient. We propose a hierarchical model with self attention for topic spotting. Experiments on the Switchboard corpus show the superior performance of our model over previously proposed techniques for topic spotting and deep models for text classification. Additionally, in contrast to offline processing of dialog, we also analyze the performance of our model in a more realistic setting i.e. in an online setting where the topic is identified in real time as the dialog progresses. Results show that our model is able to generalize even with limited information in the online setting.

1 Introduction

Recently, a number of commercial conversation systems have been introduced e.g. Alexa, Google Assistant, Siri, Cortana, etc. Most of the available systems perform well on goal-oriented conversations which spans over few utterances in a dialogue. However, with longer conversations (in open domains), existing systems struggle to remain consistent and tend to deviate from the current topic during the conversation. This hinders the establishment of long term social relationship with the users (Dehn and Van Mulken, 2000). In order to have coherent and engaging conversations with humans, besides other relevant natural language understanding (NLU) techniques (Jokinen and McTear, 2009), a system, while responding, should take into account the topic of the current conversation i.e. Topic Spotting.

Topic spotting has been shown to be important in commercial dialog systems (Bost et al., 2013; Jokinen et al., 2002) directly dealing with the customers. Topical information is useful for speech recognition systems (Iyer and Ostendorf, 1999) as well as in audio document retrieval systems (Hazen et al., 2007; Hazen, 2011). Importance of topic spotting can be gauged from the work of Alexa team (Guo et al., 2018), who have proposed topic based metrics for evaluating the quality of conversational bots. The authors empirically show that topic based metrics correlate with human judgments.

Given the importance of topical information in a dialog system, this paper proposes self attention based hierarchical model for predicting topics in a dialog. We evaluate our model on Switchboard (SWBD) corpus (Godfrey et al., 1992) and show that our model supersedes previously applied techniques for topic spotting. We address the evaluative limitations of the current SWBD corpus by creating a new version of the corpus referred as SWBD2. We hope that SWBD2 corpus would provide a new standard for evaluating topic spotting models. We also experiment with an online setting where we examine the performance of our topic classifier as the length of the dialog is varied and show that our model can be used in a real time dialog system as well.

2 Related Work

Topic spotting is the task of detecting the topic of a dialog (Hazen et al., 2007). Topic spotting has been an active area of research over the past few decades both in the NLP community as well as in the speech community. In this section we briefly outline some of the main works in this area. For a detailed survey of prior research in this area, the reader is referred to Hazen (2011).

Most of the methods proposed for topic spotting use features extracted from transcribed text as in-

Proceedings of NAACL-HLT 2019, pages 3755–3761
Minneapolis, Minnesota, June 2 - June 7, 2019.

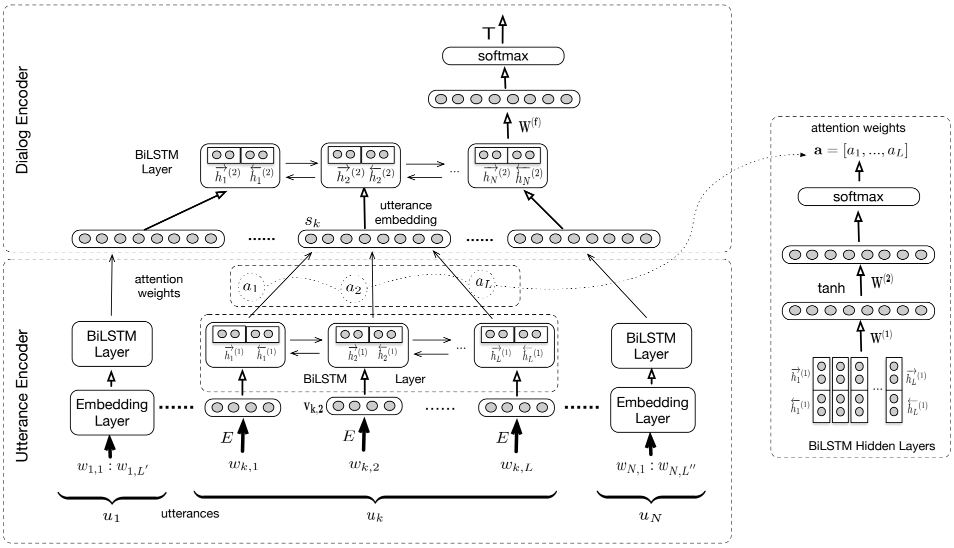

Figure 1: Model Architecture

put to a classifier (typically Naïve Bayes or SVM). Extracted features include: Bag of Words (BoW), TF-IDF (Sparck Jones, 1972; Schütze et al., 2008), n-grams, and word co-occurrences (Hazen, 2011; Myers et al., 2000). Some approaches (in addition to word co-occurrences features) incorporate background world knowledge using Wikipedia (Gupta and Ratinov, 2007). In our work, we do not explicitly extract the features but learn these during training. Moreover, unlike previous approaches, we explicitly model the dependencies between utterances via self attention mechanism and hierarchical structure.

Topic spotting has been explored in depth in the speech processing community (see for example, Wright et al. (1996); Kuhn et al. (1997); Nöth et al. (1997); Theunissen (2002)). Researchers in this community have attempted to predict the topic directly from the audio signals using phoneme based features. However, the performance of word based models supersedes those of audio models (Hazen et al., 2007).

Recently, there has been lot of work in deep learning community for text classification (Kalchbrenner et al., 2014; Zhang et al., 2015; Lai et al., 2015; Lin et al., 2015; Tang et al., 2015). These deep learning models use either RNN-LSTM based neural networks (Hochreiter and Schmidhuber, 1997) or CNN based neural networks (Kim, 2014) for learning representation of words/sentences. We follow similar approach for topic spotting. Our model is related to the Hierarchical Attention Network (HN-ATT) model proposed by Yang et al. (2016) for document classification. HN-ATT models the document hierarchically by composing words (with weights determined by first level of attention mechanism) to get sentence representations and then combines the sentence representations with help of second level attention to get document representation which is then used for classification.

The aim of this paper is not to improve text classification but to improve topic spotting. Topic spotting and text classification differ in various aspects. We are among the first to show the use of hierarchical self attention (HN-SA) model for topic spotting. It is natural to consider applying text classification techniques for topic spotting. However, as we empirically show in this paper, text classification techniques do not perform well in this setting. Moreover, for the dialog corpus simple BoW approaches perform better than more recently proposed HN-ATT model (Yang et al., 2016).

3 Hierarchical Model with Self Attention

We propose a hierarchical model with self attention (HN-SA) for topic spotting. We are given a topic label for each dialog and we want to learn a model mapping from space of dialogues to the space of topic labels. We learn a prediction model by minimizing Negative Log Likelihood ($\mathcal{NLL}$) of the data.

3.1 Model Architecture

We propose a hierarchical architecture as shown in Figure 1. An *utterance encoder* takes each utterance in the dialog and outputs the corresponding utterance representation. A *dialog encoder* processes the utterance representations to give a compact vector representation for the dialog which is used to predict the topic of the dialog.

Utterance Encoder: Each utterance in the dialog is processed sequentially using single layer Bidirectional Long Short Term Memory (BiLSTM) (Dyer et al., 2015) network and self-attention mechanism (Vaswani et al., 2017) to get the utterance representation. In particular, given an utterance with one-hot encoding for the tokens, $u_k = \{\mathbf{w_{k,1}}, \mathbf{w_{k,2}}, ..., \mathbf{w_{k,L}}\}$, each token is mapped to a vector $\mathbf{v_{k,i}} = \mathbf{E}\mathbf{w_{k,i}} \;\; ; i = 1, 2, ...L$ using pretrained embeddings (matrix $\mathbf{E}$).

Utterance representation ($\mathbf{s_k} = \mathbf{a}^T\mathbf{H^{(1)}}$) is the weighted sum of the forward and backward direction concatenated hidden states at each step of the BiLSTM ($\mathbf{H}^{(1)} = [\mathbf{h_1^{(1)}}, ..., \mathbf{h_L^{(1)}}]^T$ where $\mathbf{h_i^{(1)}} = [\overrightarrow{\mathbf{h_i}}^{(1)} : \overleftarrow{\mathbf{h_i}}^{(1)}] = \mathbf{BiLSTM}(\mathbf{v_{k,i}})$). The weights of the combination ($\mathbf{a} = \text{softmax}(\mathbf{h_a^{(2)}})$) are determined using self-attention mechanism proposed by Vaswani et al. (2017) by measuring the similarity between the concatenated hidden states ($\mathbf{h_a^{(2)}} = \mathbf{W_a^{(2)}}\mathbf{h_a^{(1)}} + \mathbf{b_a^{(2)}}$ and $\mathbf{h_a^{(1)}} = \tanh(\mathbf{W_a^{(1)}}\mathbf{H}^{(1)} + \mathbf{b_a^{(1)}})$) at each step in the utterance sequence. Self-attention computes the similarity of a token in the context of an utterance and thus, boosts the contribution of some keywords to the classifier. It also mitigates the need for a second layer of attention at a dialog level reducing the number of parameters, reducing the confusion of the classifier by not trying to reweigh individual utterances and reducing the dependence on having all utterances (full future context) for an accurate prediction. A simple LSTM based model (HN) and HN-ATT perform worse than the model using self attention (§5), indicating the crucial role played by self-attention mechanism.

Dialog Encoder: Utterance embeddings (representations) are sequentially encoded by a second single layer BiLSTM to get the dialog representation ($\mathbf{h_k^{(2)}} = [\overrightarrow{\mathbf{h_k}}^{(2)} : \overleftarrow{\mathbf{h_k}}^{(2)}] = \mathbf{BiLSTM}(\mathbf{s_k}) \;\; ; k = 1, 2, ...N$). Bidirectional concatenated hidden state corresponding to the last utterance (i.e. last step of BiLSTM) is used for making a prediction via a linear layer followed by softmax activation ($p(\mathsf{T}|\mathsf{D}) = \text{softmax}(\mathbf{h_D})$ where $\mathbf{h_D} = \mathbf{W_f}\mathbf{h_N^{(2)}}$).

4 Experimental Setup

As in previous work (§2), we use Switchboard (SWBD) (Godfrey et al., 1992) corpus for training our model. SWBD is a corpus of human-human conversations, created by recording (and later transcribing) telephonic conversations between two participants who were primed with a topic. Table 1 gives the corpus statistics. Topics in SWBD range over a variety of domains, for example, politics, health, sports, entertainment, hobbies, etc., making the task of topic spotting challenging.

Dialogues in the test set of the original SWBD cover a limited number of topics (12 vs 66). The test set is not ideal for evaluating topic spotting system. We address this shortcoming by creating a new split and we refer to this version of the corpus as *SWBD2*. The new split provides opportunity for more rigorous evaluation of a topic spotting system. SWBD2 was created by removing infrequent topics ($<$ 10 dialogues) from the corpus and then randomly moving dialogues between the train/development set and the test set, in order to have instances of each topic in the test set. The majority class baseline in SWBD2 is around 5%.

In transcribed SWBD corpus some punctuation symbols such as #, ?, have special meanings and non-verbal sounds have been mapped to special symbols e.g. <Laughter>. To preserve the meanings of special symbols we performed minimal preprocessing. Dialog Corpora is different from text classification corpora (e.g. product reviews). If we roughly equate a dialog to a document and an utterance to a sentence, dialogs are very long documents with short sentences. Moreover, the vocabulary distribution in a dialog corpus is fundamentally different, e.g. presence of back-channel words like 'uhm' and 'ah'.

Model Hyper-parameters: We use GloVe embeddings (Pennington et al., 2014) with dimensionality of 300. The embeddings are updated during training. Each of the LSTM cell in the utterance and dialog encoder uses hidden state of dimension 256. The weight matrices in the attention network have dimension of 128. The hyper-parameters were found by experimenting with the

development set. We trained the model by minimizing the cross-entropy loss using Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001. The learning rate was reduced by half when development set accuracy did not change over successive epochs. Model took around 30 epochs to train.

5 Experiments and Results

We compare the performance of our model (Table 2) with traditional Bag of Words (BoW), TF-IDF, and n-grams features based classifiers. We also compare against averaged Skip-Gram (Mikolov et al., 2013), Doc2Vec (Le and Mikolov, 2014), CNN (Kim, 2014), Hierarchical Attention (HN-ATT) (Yang et al., 2016) and hierarchical network (HN) models. HN it is similar to our model HN-SA but without any self attention.

Analysis: As is evident from the experiments on both the versions of SWBD, our model (HN-SA) outperforms traditional feature based topic spotting models and deep learning based document classification models. It is interesting to see that simple BoW and n-gram baselines are quite competitive and outperform some of the deep learning based document classification model. Similar observation has also been reported by Mesnil et al. (2014) for the task of sentiment analysis. The task of topic spotting is arguably more challenging than document classification. In the topic spotting task, the number of output classes (66/42 classes) is much more than those in document classification (5/6 classes), which is done mainly on the texts from customer reviews. Dialogues in SWBD have on an average 200 utterances and are much longer texts than customer reviews. Additionally, the number of dialogues available for training the model is significantly lesser than customer reviews. We further investigated the performance on SWBD2 by examining the confusion matrix of the model. Figure 2 shows the heatmap of the normalized confusion matrix of the model on SWBD2. For most of the classes the classifier is able to predict accurately. However, the model gets confused between the classes which are semantically close (w.r.t. terms used) to each other, for example, the model gets confused between pragmatically similar topics e.g. HOBBIES vs GARDENING, MOVIES vs TV PROGRAMS, RIGHT TO PRIVACY vs DRUG TESTING.

Online Setting: In an online conversational system, a topic spotting model is required to predict the topic accurately and as soon as possible during the dialog. We investigated the relationship between dialog length (in terms of number of utterances) and accuracy. This would give us an idea about how many utterances are required to reach a desirable level of accuracy. For this experiment, we varied the length of the dialogues from the test set that was available to the model for making prediction. We created sub-dialogues of length starting with $1/32$ of the dialog length and increasing it in multiples of 2, up to the full dialog. Figure 3 shows both the absolute accuracy and the accuracy relative to that on the full dialog. With just a few (3.125%) initial utterances available, the model is already 72% confident about the topic. This may be partly due to the fact that in a discussion, the first few utterances explicitly talk about the topic. However, as we have seen, since SWBD covers many different topics which are semantically close to each other but are assigned distinct classes, it is equally challenging to predict the topic with the same model. By the time the system has processed half the dialog in SWBD2 it is already within 99% accuracy of the full system. The experiment shows the possibility of using the model in an online setting where the model predicts the topic with high confidence as the conversation progresses.

6 Conclusion and Future Work

In this paper we presented a hierarchical model with self attention for topic spotting. The model outperforms the conventional topic spotting techniques as well as deep learning techniques for text classification. We empirically show that the proposed model can also be used in an online setting. We also introduced a new version of SWBD corpus: SWBD2. We hope that it will serve as the new standard for evaluating topic spotting models.

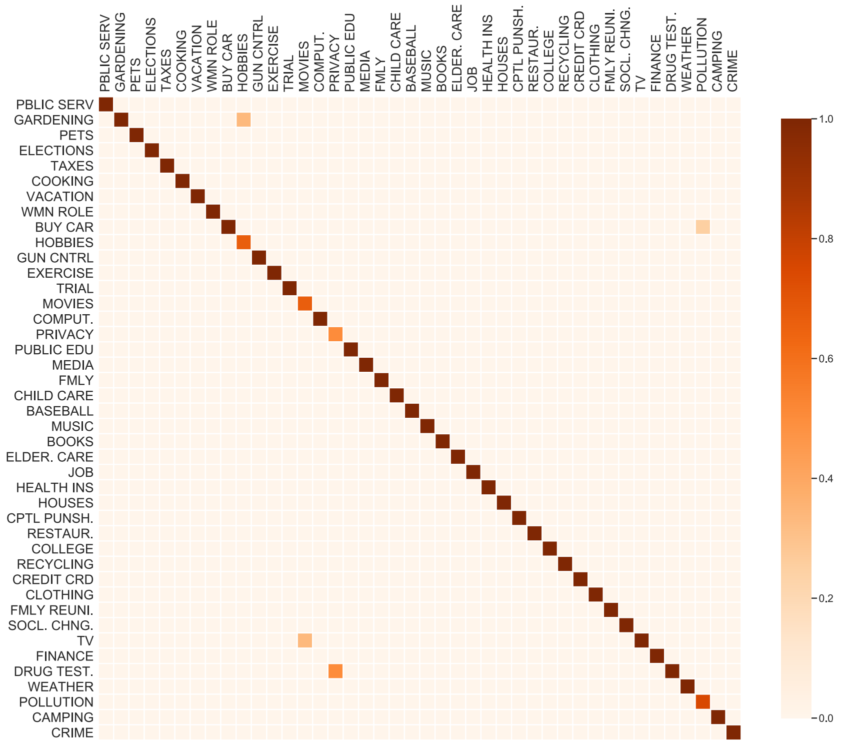

Figure 2: Normalized Confusion Matrix in form of heatmap for model predictions on SWBD2. Vertical axis is the target class.

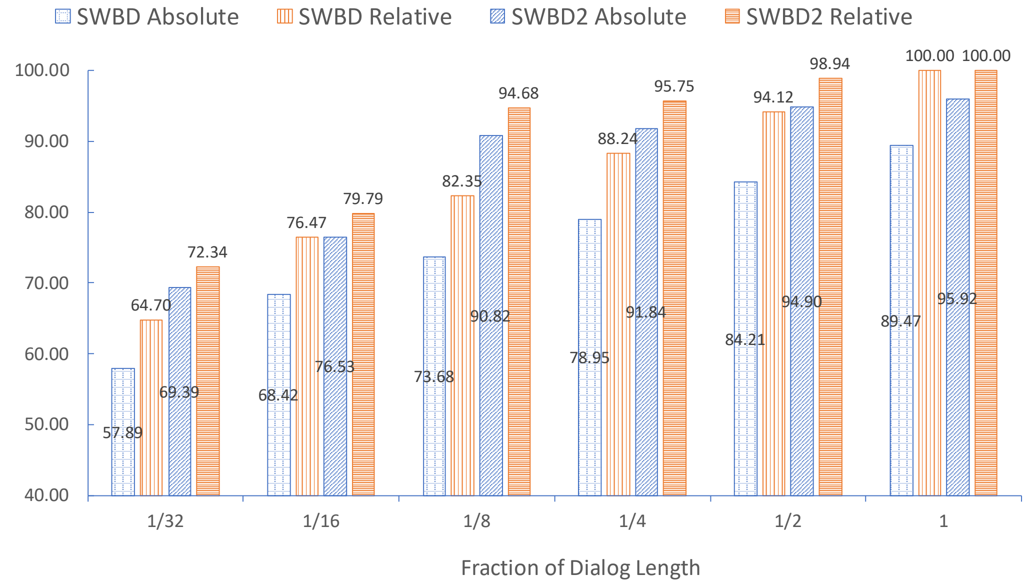

Figure 3: Effect of Dialog Length on Accuracy. Plot shows both the absolute accuracy and relative accuracy (w.r.t. full model) for different fractions of the data.

Moving forward, we would like to explore a more realistic multi-modal topic spotting system. Such a system should fuse two modalities: audio and transcribed text to make topic predictions.

Abstract

We consider neural language generation under a novel problem setting: generating the words of a sentence according to the order of their first appearance in its lexicalized PCFG parse tree, in a depth-first, left-to-right manner. Unlike previous tree-based language generation methods, our approach is both (i) top-down and (ii) explicitly generating syntactic structure at the same time. In addition, our method combines neural model with symbolic approach: word choice at each step is constrained by its predicted syntactic function. We applied our model to the task of dialog response generation, and found it significantly improves over sequence-to-sequence baseline, in terms of diversity and relevance. We also investigated the effect of lexicalization on language generation, and found that lexicalization schemes that give priority to content words have certain advantages over those focusing on dependency relations.

1 Introduction

Neural encoder-decoder architectures have shown promise and become very popular for natural language generation. Over the past few years, there has seen a surging interest in sequence-to-sequence learning for dialog response generation using neural encoder-decoder models (Vinyals and Le, 2015; Serban et al., 2017). Typically, an encoder encodes conversational context (source side) information into vector representations, and a decoder auto-regressively generates word tokens conditioned on the source vectors and previously generated words.

Two problems arise with the standard left-to-right decoding mechanism. First, no future information is available at any step of the decoding process, while the study of linguistic dependency structure shows that certain words depend on the others that come right to them. Second, preceding words define the context for following words in left-to-right, auto-regressive language models, while linguistic theories may prefer other hierarchies (e.g., adjectives modifying nouns, adverbs modifying verbs). Psycho-linguistics studies also suggest that human may first generate the abstract representation of the things to say, and then linearize them into sentences (Dell et al., 1999).

Therefore, it is appealing to consider language generation in alternative orders. This poses a greater challenge because a mechanism in extra to word generation is needed for deciding the position of each word. Some recent works adopt a syntax-free approach to address this problem. (Mehri and Sigal, 2018) proposed a middle-out decoder that starts from the middle of sentences and finishes the rest in forward and backward directions. (Mou et al., 2016) and (Li and Sun, 2018) start with one or two predicted keywords and generate the rest of sentences in a similar fashion. Others incorporate tree structures without syntactic relations and categories. (Zhou et al., 2018) canonicalizes the dependency structures of sentences into ternary trees, and generate only the words top-down. Yet another line of work aim to model the full syntactic trees. (Gū et al., 2018) generates phrase structures and part-of-speech tags along with words for machine translation. (Dyer et al., 2016) generates shift-reduce action sequences of context-free grammars in addition to words for language model and parsing. But words are still generated in left-to-right order in their approaches.

In the domain of dialog, we believe language generation can benefit from alternative orders, for the same reasons argued earlier. On the other hand, in human conversations, the structure of utterances usually correspond with dialog states (e.g., wh-noun or wh-adverb phrases are more

Proceedings of NAACL-HLT 2019, pages 3762–3771
Minneapolis, Minnesota, June 2 - June 7, 2019.

likely to be used in a request state), so modelling phrase structures can potentially help capturing discourse level information. In order to be able to generate complete syntactic trees, while be flexible about word generation order at the same time, the use of lexicalized grammar becomes a natural choice.

2 Related Work

Recent years has seen works in language model and generation through alternative orders. (Zhang et al., 2016) developed a top-down neural architecture for language model that alternates between four LSTM decoders according to given dependency relations. (Ford et al., 2018) proposed a two-stage language model, of which the first stage is a language model that generates templates, and the second stage is a translation model that fills in the blanks. Word generation order varies with the choice of words that are generated at different stages.

Language generation with tree structures has been explored more thoroughly for neural machine translation. (Eriguchi et al., 2017) and (Aharoni and Goldberg, 2017) generate CFG trees in bracketed form. (Wu et al., 2017) generates the sequence of transitions to form dependency trees. More recent works have focused on explicitly generating tree structures (Wang et al., 2018; Gū et al., 2018).

Regarding neural architectures for tree generation in the field of natural language processing, (Dong and Lapata, 2016) and (Yin and Neubig, 2017) use a single decoder with parent-feeding mechanism to generate logical forms and programming codes. (Gū et al., 2018) applied the doubly-recurrent neural networks of (Alvarez-Melis and Jaakkola, 2016) with attention mechanism to machine translation. Their model uses two decoders, of which one memorizes the ancestors, and the other remembers the siblings. (Wang et al., 2018) also uses two decoders, but one for generating words and the other for generating syntax trees.

In the domain of dialog response generation, the use of syntactic structures is under-studied. (Mou et al., 2016) and (Li and Sun, 2018) considered starting with keywords, and finish the sentences in forward and backward directions. Their models in principle are not tree-structured. The closest thing to our knowledge is by (Zhou et al., 2018). They proposed to convert dependency trees to ternary trees, but ignore the type of dependency relations. In other words, they modelled on trees of which the nodes and edges have no labels. The key difference between their approach and ours is that we generate syntax trees with labels, and word choices are also constrained by the labels.

3 Design Choices

We first consider the following three requirements when generating an L-PCFG syntax tree:

Deciding the structure of children. Several mechanisms have been proposed for deciding the structure of children of each node in the context of tree generation. One of them decide tree topology by using a sequence model to generate children one by one and predict stopping tokens (Alvarez-Melis and Jaakkola, 2016). Then there is a simpler approach that treats each combination of the labels of the children as one token, and predict such tokens when generating the parent node (Yin and Neubig, 2017). For language generation, we adopt the second approach and predict the combination of the labels of children, i.e. the rules, for two reasons: (i) the space of grammar rules is generally sparse even when its dimensionality is exponential of the number of labels, and (ii) with sequential generation of labels, as in the first approach, it is hard to enforce the labels of the children to form a valid grammar rule.

Deciding the heir of a node. Recall the definition of lexicalized PCFG: let W, N, R be the sets of lexicons, labels, and rules, where each rule is one of the following forms:

- $X(h) \to h$
- $X(h) \to Y_1(h_1) \dots Y_k(h_k)$ such that there exists i, $h_i = h$.

where $X, Y_1, \dots, Y_k \in N$, $h, h_1, \dots, h_k \in W$. We do not restrict ourselves to Chomsky Normal Form, and rules can have any number of children. The i^{th} children in the second case is called the *heir*. The key difficulty to top-down generation of lexicalized PCFG parse tree is deciding which child would be the heir. One way is to make explicit decision to select the child by adding a switch variable, at the cost of increasing the complexity of the problem. Instead, we make a change to the second case above, and simplify the problem by restricting the rules to be of the following form:

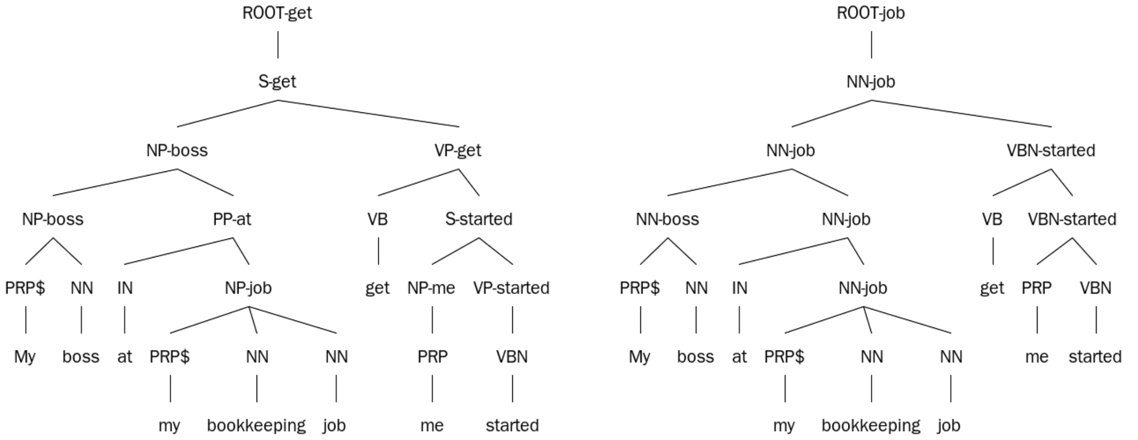

Figure 1: The first tree is the result of Stanford parser. The second one is obtained by performing content-based lexicalization on the first tree. All labels are replaced by part-of-speech tags of heirs. Unary rules NP-me → PRP and VP-started → VBN are removed.

- $X(h) \rightarrow Y_1(h_1)\dots Y_k(h_k)$ such that there exists i, $h_i = h$ and $Y_i = X$.

In other words, the heir would inherit both the lexicalization and the label of the parent (with the possible exception that the root node may produce children that are not labeled with “root”). When generating a parent node and its children, we restrict the choice of rules to those containing the label of the parent, so the heir can be inferred from the chosen rules by looking for the child that has the same label as its parent (in case there are multiple children that have the same label, we choose the rightmost one; other heuristics are possible). Note that under such restriction we end up with parse trees in which all labels are part-of-speech tags.

Sequentialization of a tree. Previous works adopt various construction orders of trees. (Zhang et al., 2016), (Zhou et al., 2018), (Alvarez-Melis and Jaakkola, 2016), and (Gū et al., 2018) generate trees through level-order traversal (breadth-first, left-to-right), whereas (Yin and Neubig, 2017) and (Wang et al., 2018) generate trees through pre-order traversal (depth-first, left-to-right). (Kuncoro et al., 2018) also experimented with bottom-up and left-corner construction orders for language model. While finding the optimal order of generating trees is beyond the scope of this work, we follow (Yin and Neubig, 2017) and (Wang et al., 2018), and generate lexicalized PCFG syntax trees through pre-order traversal.

4 Methods

4.1 Definitions

In this paper, we give the following graph-theoretic definition of L-PCFG syntax trees. Let W and N be the sets of lexicons and labels. Let $R = \bigcup_{k=1}^{\infty} N^k$ be the set of production rules. Then an L-PCFG syntax tree T is an *ordered tree* defined by the triple of vertices $v \in V \subset W \times N \times R \times \mathbb{N}$, edges $e \in E \subset V \times V$, and bijection $f : V \times \mathbb{N}^+ \rightarrow V$ such that $(v, f(v, j)) \in E$, where j range from 1 to the number of children of v. The fourth coordinate of v is the index of its heir, that is,

$$(w, n, r, i) = f((w_0, n_0, r_0, i_0), i_0) \\ \Longrightarrow w = w_0, n_0 = n$$

We say a node $v = (w, n, r, i)$ is a *leaf* if r is unary:

$$\text{v is a leaf} \iff r \in N$$

The parent of v_k is denoted by $v_{p(k)} = (w_{p(k)}, m_{p(k)}, n_{p(k)}, i_{p(k)})$.

4.2 Generation Procedure

Following previous work, we sequentialize L-PCFG parse trees and generate its content in an auto-regressive manner. When generating k^{th} node, we predict the lexicalization w_k and the rule r_k. The pre-order history available when generating k^{th} node is $n_1 \cdots n_{k-1}, w_1 \cdots w_{k-1}, r_1 \cdots r_{k-1}$, denoted by

H_k. The label "ROOT" is given at the start of generation. The label of the k^{th} node is inferred from the production rule of its parent and the order of k^{th} node among its siblings, and is used as input together with H_k. When a leaf node is reached, the program backtraces until it finds an ancestor that has unfinished child, and proceeds to the first such child.

We factor the joint probability of w_k and r_k into two component: a word model and a syntax model, as follow:

$$P(w_k, r_k \,|n_k, H_k) = \\ P(w_k \mid n_k, H_k) \cdot P(r_k \mid n_k, H_k)$$

The details of both models are given in the following sections.

4.3 Lexicalization Schemes

We parse the responses in training corpus using the lexicalized parser by (Klein and Manning, 2003) (which we call Stanford parser for the rest of this paper). We then replace the label of each node with that of their heir in a bottom-up manner. Unary rules at non-leaf nodes are removed as they become redundant given our definition of lexiclaized PCFG.

Stanford parser lexicalizes PCFG phrase structures by looking for the most likely combination of phrase structure and dependency structure. While their approach is optimized for parsing, the syntax trees lexicalized this way has a drawback for the purpose of generation. Empirically, their parser tends to lexicalize the first few nodes with auxiliary verbs or common verbs (e.g. be, must), and in some cases prefer function words over content words (e.g. in preposition phrases). We hypothesize that choosing content words over functions, or infrequent words over frequent words as lexicalization heads will help making the generation more specific and meaningful. Hence, we consider two alternative lexicalization schemes:

Content-based lexicalization. We rank words according to their part-of-speech in the sentence by the following order: nouns $>$ verbs $=$ adjectives $>$ adverbs $>$ everything else. If two words have the same rank, we give priority to the rightmost one. See Figure 1 for an example.

Frequency-based lexicalization. We ignore part-of-speech information and rank all words by their frequencies. We regard less frequent words as more important.

4.4 Encoding Tree Histories

To represent the state of a tree node by encoding its pre-order history H_k, we use 3 LSTMs to memorize the lexical and grammatical contents in H_k.

Encoding lexicalization history. We use 2 LSTMs to encode the lexicalization history, i.e. $w_1 \cdots w_{k-1}$: a *surface* decoder, L_s, which takes the lexicalization of the leaves in the history as inputs; and an *ancestor* decoder, L_a, which is given the lexicalization of the ancestors of the current node. This is another form of doubly-recurrent neural networks. Different from (Alvarez-Melis and Jaakkola, 2016), we chose to encode leaves instead of siblings. Denote the lexicalizaiton of leaves and ancestors in H_k by $\{w_{l(k)_i}\}$ and $\{w_{a(k)_i}\}$. We show that for an L-PCFG syntax tree, $\{w_{l(k)_i}\}$ and $\{w_{a(k)_i}\}$ sufficiently cover the lexical content of H_k:

Proposition. For any index set $I_k \subset \{1, 2, \dots, k-1\}$, if $w_n \in \{w_j\}_{j \in I_k}$ for all $n < k$, then $\{l(k)_i\} \bigcup \{a(k)_i\} \subset I_k$, i.e. $\{l(k)_i\}$ and $\{a(k)_i\}$ together is the minimal index set to cover $w_1 \cdots w_{k-1}$.

Encoding syntactic history. We encode the previous labels and rules using the full history with a single LSTM, L_g. At step k, the input to L_g is the concatenation of the embeddings of n_k, the rule of parent node $r_{p(k)}$, and depth of the node d. The depths of nodes deeper than 10 are rounded down to 10.

4.5 Encoding Source and Attention Mechanism

We adopt attention mechanism into our architecture for response generation. We use a one-layered LSTM to encode the dialog history, which is the concatenation of the last few utterances. The initial hidden states of L_s, L_a, and L_g is computed from the last hidden state of source encoder using 2 fully-connected layers with rectified linear activation. At time step t, the concatenation of the hidden states of L_s and L_a at step $t-1$ is used as the key for querying the source. The attention weights are the inner products of the key and the hidden states at source side, normalized by softmax function. The weighted sum of source hidden states results in the attention context, $c(k)$

4.6 Decoding

Denote the hidden states of L_s, L_a, L_g at node k as $h_s(k), h_a(k), h_g(k)$. Denote the softmax func-

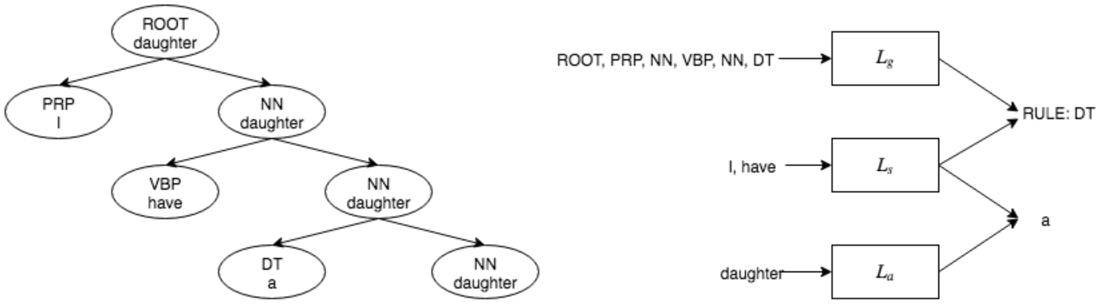

Figure 2: Demonstration of inputs and outputs at node DT. The sequence of inputs to each encoder are shown in the graph. The inputs to L_g is a sequence of labels, rules of parents, and tree depths (only labels are shown). L_s and L_a are used for predicting the word for DT. L_s and L_g are used for predicting the rule for DT. "RULE: DT" indicates DT will be a leaf node since the number of symbols is 1. In this tree, words are generated in the order: daughter - I - have - a.

tion by σ. $E_w \in \mathbb{R}^{|W| \times d_w}$ and $E_r \in \mathbb{R}^{|P| \times d_r}$ are embedding matrices for words, labels, and rules. $A_w \in \mathbb{R}^{n_w \times d_w}$ and $A_r \in \mathbb{R}^{n_p \times d_r}$ are weight matrices (n_w, n_p are the dimensions of input neurons). We use weight tying (Press and Wolf, 2017) to limit the search space for parameters.

Word prediction. To decode for w_k, we use the the hidden states of surface decoder L_s and ancestor decoder L_a. If v_k is a heir, then

$$P(w_k \mid n_k, H_k) = \begin{cases} 1 & w_k = w_{p(k)} \\ 0 & w_k \neq w_{p(k)} \end{cases}$$

Otherwise, the probability of w_k is given by:

$$P(w_k \, | n_k, H_k) = \sigma(tanh([h_s(k); h_a(k); c(k)] \, A_w) E_w^T)$$

At decoding time, we impose an additional constraint that w_k be a valid word for label n_k, to enforce grammaticality. This is estimated from the co-occurrence of w_k and n_k in the tagged training corpus. We only use those words whose frequency of co-occurrence with the given label is above a certain threshold.

Rule prediction. The probability of r_k is given by

$$P(r_k \, | n_k, H_k) = \sigma(tanh([h_s(k); h_g(k); c(k)] \, A_r) E_r^T)$$

Given the definition of L-PCFG syntax tree, we only consider rules that contain n_k at decoding time. There is one exception: at "ROOT" node, only unary rules are considered, and they do not have to contain the label "ROOT".

Hence, we train our architecture by minimizing the negative log-likelihood of words and rules:

$$\begin{aligned} & -\log P(T) = \\ & \quad -\frac{1}{|W(T)|} \sum_{\substack{k \\ v_k \neq f(v_{p(k)}, i_{p(k)})}} \log P(w_k \mid n_k, H_k) \\ & \quad -\frac{1}{|T|} \sum_k \log P(r_k \mid n_k, H_k) \end{aligned}$$

where $|W(T)|$ is the number of non-heir nodes (or the number of words in the original sentence), and $|T|$ is the number of nodes in T. Note that the log probability of each word in the sentence appears exactly once in the above equation. At test time, we conduct beam search and use the same equation to score each generation for selecting words and rules.

In our experiments, we use unlexicalized PCFG as an additional baseline. We still replace the labels of each node with their heirs' in the parse tree returned from Stanford parser, but words are generated only at leaf nodes. This baseline has syntactic structure while generating words from left to right. We use it as a test against top-down generation of words with syntax.

4.7 Training Details

All models are implemented using PyTorch. The hidden size of all LSTM encoders and decoders are 512. The size of embeddings of words, labels, rules, and tree depth are 300. We trained our models using stochastic gradient descent (SGD) with momentum and exponential learning rate decay. Dropout is applied to the input and output layer of LSTMs.

	Stand.	Depend.	Content

	Stand.	Depend.	Freq.
1	.0262	.0095	.0002
2	.0149	.0274	.0238
3	.0147	.0116	.0156
4	.0133	.0145	.0147
5	.0134	.0131	.0146

Table 2: Average frequency of first five words in different generation orders.

5 Experiments and Analysis

5.1 Data

We evaluate our model for dialog response generation on Persona dataset ((Zhang et al., 2018)). Each person is give a list of persona descriptions in simple sentences, and they are required to converse according to the given persona. We use last 3 utterances for each response as source. We prepend persona descriptions to source. We use global attention over persona descriptions to compute context vectors. During pre-processing, we truncate all trailing punctuations.

5.2 Positional Statistics

We measure how early do each type of words appear in different generation orders – standard left-to-right order, dependency-based lexicalization (as in Stanford parser), and content-based lexicalization. The earlier a word appear, the less context there is for predicting it. As shown in Table 1, content-based lexicalization can make nouns and verbs appear much earlier, while delaying function words.

To verify frequency-based lexicalization is making infrequent words appear earlier, we show the average frequencies of the first five words. The first few words are more important since they decide the context for generating the following words. In Table 2, the first two words of each parse tree under frequency-based lexicalization are much less frequent.

	Seq2seq	Ours
Standard	3.682	N/A
Dependency	4.015	3.964
Content	4.115	3.865
Frequency	4.088	3.827

Table 3: Perplexities.

5.3 Perplexity

We compare per word likelihood given different generation orders and architectures. For left-to-right sequence decoder, the non-standard generation orders are obtained by linearizing L-PCFG parse trees in pre-order traversal, and words of heirs are not repeated in the linearization. Note that our word model generates word without using rules and labels as inputs to its networks. As can be seen from Table 3, alternative word generation orders all make it harder for standard left-to-right sequence decoder to learn to predict the next word. On the other hand, using a doubly-recurrent architecture, specifically the surface decoder and the ancestor decoder, can improve perplexity scores for top-down word generation over the left-to-right decoder. While our word model with top-down word generation orders has higher perplexity scores than simple model with standard generation order, we emphasize that perplexity is not an appropriate measure for generation tasks.

5.4 Evaluation Metrics

Word Overlap Based Metrics. We use BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) scores as automatic evaluation metrics. While the reliability of such metrics has been criticized (Liu et al., 2016), there is also evidence that for task-oriented domains, these metrics correlate with human judgment to a certain extent (Sharma et al., 2017).

Word Embedding Based Metrics. We evaluate the semantic similarity between generated responses and human responses/persona by the cosine distance of their sentence embeddings. We use the word averaging approach by (Arora et al., 2016) to embed the responses, which has been demonstrated to be very good at capturing lexical level semantic similarity. The normalizing singular vector is obtained from the responses in training set.

	Human	Baseline	PCFG	L-PCFG (Dependency)	L-PCFG (Content)	L-PCFG (Frequency)
Length	10.35	7.21	9.39	8.96	**11.04**	**9.74**

i am great . i just got back from the club	this is my favorite time of the year season wise	that is cool what do you do for a living	awesome ! i am getting ready to go to the club
sure i like tv , what do you watch ?	really anything , what about you ?	i watch a lot of tv	i watch lot of tv movies . i like to watch tv
oh . tell me something about yourself .	well i do not like heights very much and i love animals . what about you ?	i am an accountant . what do you do	i am trying to learn how to work with animals
i live in texas . i love riding my bike here .	are you a christian ? i am jewish	i have never been to the west coast . do you have any hobbies	i do too ! i wish i was there so i can do that for school

Table 5: Examples of generated responses.

Novelty and diversity. We measure word overlapping between generated responses and the responses in training set using BLEU and ROUGE as a proxy for novelty. The responses in training set with most common words with generated responses are used as references. For diversity, we count the number of distinct n-grams. In addition, we perform a k-means clustering on the sentence embeddings of responses into 10 clusters, and measure average squared Euclidean distance between members of each cluster (Inertia). The larger the number, the harder it is to separate embeddings into 10 clusters, thus the greater the diversity.

5.5 Main Results

5.5.1 Quantitative Analysis

Evaluation results are shown in Table 4. For metrics that are not measured using ground truth response as reference, we consider the closer to the number for human responses the better. We first look at measures for overall generation quality. We can see modelling syntactic structures is capable of generating longer responses. BLEU scores are positively correlated with lengths. While syntactic models do better on BLEU, and slightly better on METEOR than sequence-to-sequence baseline, they are generally not on par with the baseline in terms of ROUGE-L, except for frequency-based lexicalization. Among grammar models, lexicalized grammars out-performed unlexicalized grammar.

Relevance is measured using cosine similarities with the previous utterance and persona. Syntactic models with lexicalized grammar beat the baseline in terms of relevance. Furthermore, content-based lexicalization is much more on topic with the last source utterance than dependency-based

	$L_g + L_s$	$L_g + L_s + L_a$	L_g
Lengths	11.04	7.95	8.46
Distinct uni-gram	813	383	376
Distinct bi-gram	5427	1763	1775
Distinct tri-gram	10787	3061	3522
Inertia	3756	2049	2346
BLEU on training	0.5402	0.8056	0.6612
ROUGE on training	0.6226	0.8543	0.7417

Table 6: Ablation studies.

and frequence-based lexicalization. Dependency-based lexicalization is best at being adherent to personas than the other two lexicalization schemes.

All syntactic models generate more novel responses than sequence-to-sequence baseline, as reflected in the last two rows in 4. This is consistent with the observation that sequence-to-sequence model exhibits retrieval-like behaviour, selecting what is most common in the training corpus. Syntactic models also have larger vocabularies. As for cluster analysis, unlexicalized grammar model and dependency-based lexicalized grammar model have better diversity than sequence-to-sequence model; content-based and frequency-based lexicalization have slightly smaller inertia than the baseline.

5.5.2 Qualitative Analysis

We present a few examples generated by sequence-to-sequence baseline and L-PCFG model. There is a clear difference of how left-to-right decoder and L-PCFG tree decoder do conjunctions. Most of the time, standard LSTM decoder combine sentences with periods, while tree decoders learn to use conjunction words, or even clauses.

We also performed an error analysis on the generated responses by L-PCFG, and in Table 7 we selected the most peculiar and representative. These examples are all syntactically fine, but they do not follow the convention of the language or common sense. The first example contains the most common errors in the responses generated by L-PCFG: misuse of prepositions and determiners. It can be fixed by replacing “as a” with “for”. The error of other two examples have even less to do with syntax. The second one misuses the verb “be”, which is probably caused by the high frequency of the word in the corpus. The error of the third example is beyond surface level. Note that phrases such as “cooking as a dinner” and “be a dog” never appear in the corpus. It is clear that L-PCFG models are learning to make compositions of words and phrases, unlike standard LSTM decoder, which seems to only memorize word combinations.

i am doing well . just finished cooking as a dinner
i am sure it is nice . i am going to be a dog
i like to ride my horses on my bike

Table 7: Some peculiar examples generated by L-PCFG models.

5.6 Ablation Studies

We perform ablation studies on our architecture, with content-based lexicalization. Specifically, we consider two alternative ways of making rule prediciton. The first one takes only the hidden state of L_g for predicting rules, hence making the prediction of rules entirely independent from words. The second one takes both the hidden states of L_s and L_a, together with L_g, for predicting rules, in which way future lexical information is used for the construction of syntax trees.

For rule prediction using the hidden states of both surface decoder and ancestor decoder, we noticed a significant drop in diversity in generated responses. The model over-predicts “what do you do for a living” for than 50% of the time, and the lengths of responses tend to be shorter.

For the other choice in which rule prediction is independent from words, the results are closer to the original model, but there are still some decreases in lengths and lexical diversity. Upon manual inspection, we found that this model behaved more like sequence-to-sequence model. There are less compound sentences, and more conjunctions of simple sentences by end punctuation marks.

The proportion of simple sentences are also larger.

6 Conclusion

We consider the problem of generating natural language in alternative orders and with syntactic tree structures, with the use of lexicalized grammar. By incorporating syntactic structures, our models are capable of generating longer sentences. By changing lexicalizaion schemes and making content words appear earlier in generation process, our models are able to make word choices that are more relevant to source. Furthermore, incorporating syntax facilitates response generation with richer vocabularies and more complex structures. On the other hand, as shown in our error analysis, there is still room for improvement on discourse and pragmatics level.

A Appendices

A.1 Proof sketch for *Proposition* in Section 4.4

We prove by contradiction. Suppose there is a node n_k, whose lexicalization is not in the leaves before node k, nor in the ancestors of node n_k. There must be a leaf l inheriting the lexicalization of node n_k. Since n_k is not an ancestor of node k, l must be a leaf before k, so we have a contradiction.

What do Entity-Centric Models Learn? Insights from Entity Linking in Multi-Party Dialogue

Abstract

Humans use language to refer to entities in the external world. Motivated by this, in recent years several models that incorporate a bias towards learning entity representations have been proposed. Such entity-centric models have shown empirical success, but we still know little about why.

In this paper we analyze the behavior of two recently proposed entity-centric models in a referential task, Entity Linking in Multi-party Dialogue (SemEval 2018 Task 4). We show that these models outperform the state of the art on this task, and that they do better on lower frequency entities than a counterpart model that is not entity-centric, with the same model size. We argue that making models entity-centric naturally fosters good architectural decisions. However, we also show that these models do not really build entity representations and that they make poor use of linguistic context. These negative results underscore the need for model analysis, to test whether the motivations for particular architectures are borne out in how models behave when deployed.

1 Introduction

Modeling reference to entities is arguably crucial for language understanding, as humans use language to talk about things in the world. A hypothesis in recent work on referential tasks such as co-reference resolution and entity linking (Haghighi and Klein, 2010; Clark and Manning, 2016; Henaff et al., 2017; Aina et al., 2018; Clark et al., 2018) is that encouraging models to learn and use entity representations will help them better carry out referential tasks. To illustrate, creating an entity representation with the relevant information upon reading *a woman* should make it easier to resolve a pronoun mention like *she*.[1] In the mentioned work, several models have been proposed that incorporate an explicit bias towards entity representations. Such **entity-centric** models have shown empirical success, but we still know little about what it is that they effectively learn to model. In this analysis paper, we adapt two previous entity-centric models (Henaff et al., 2017; Aina et al., 2018) for a recently proposed referential task and show that, despite their strengths, they are still very far from modeling entities.[2]

JOEY TRIBBIANI (183):
"*. . . see Ross, because I think you love her .*"
335 183 335 306

Figure 1: Character identification: example.

The task is character identification on multi-party dialogue as posed in SemEval 2018 Task 4 (Choi and Chen, 2018).[3] Models are given dialogues from the TV show *Friends* and asked to link entity mentions (nominal expressions like *I*, *she* or *the woman*) to the characters to which they refer in each case. Figure 1 shows an example, where the mentions *Ross* and *you* are linked to entity 335, mention *I* to entity 183, etc. Since the TV series revolves around a set of entities that recur over many scenes and episodes, it is a good benchmark to analyze whether entity-centric models learn and use entity representations for referential tasks.

Our contributions are three-fold: First, we adapt two previous entity-centric models and show that they do better on lower frequency entities

(a significant challenge for current data-hungry models) than a counterpart model that is not entity-centric, with the same model size. Second, through analysis we provide insights into how they achieve these improvements, and argue that making models entity-centric fosters architectural decisions that result in good inductive biases. Third, we create a dataset and task to evaluate the models' ability to encode entity information such as gender, and show that models fail at it. More generally, our paper underscores the need for the analysis of model behavior, not only through ablation studies, but also through the targeted probing of model representations (Linzen et al., 2016; Conneau et al., 2018).

2 Related Work

Modeling. Various memory architectures have been proposed that are not specifically for entity-centric models, but could in principle be employed in them (Graves et al., 2014; Sukhbaatar et al., 2015; Joulin and Mikolov, 2015; Bansal et al., 2017). The two models we base our results on (Henaff et al., 2017; Aina et al., 2018) were explicitly motivated as entity-centric. We show that our adaptations yield good results and provide a closer analysis of their behavior.

Tasks. The task of entity linking has been formalized as resolving entity mentions to referential entity entries in a knowledge repository, mostly Wikipedia (Bunescu and Paşca, 2006; Mihalcea and Csomai, 2007 and much subsequent work; for recent approaches see Francis-Landau et al., 2016; Chen et al., 2018). In the present entity linking task, only a list of entities is given, without associated encyclopedic entries, and information about the entities needs to be acquired from scratch through the task; note the analogy to how a human audience might get familiar with the TV show characters by watching it. Moreover, it addresses multi-party dialogue (as opposed to, typically, narrative text), where speaker information is crucial. A task closely related to entity linking is *coreference resolution*, i.e., predicting which portions of a text refer to the same entity (e.g., *Marie Curie* and *the scientist*). This typically requires clustering mentions that refer to the same entity (Pradhan et al., 2011). Mention clusters essentially correspond to entities, and recent work on coreference and language modeling has started exploiting an explicit notion of entity (Haghighi and Klein, 2010; Clark and Manning, 2016; Yang et al., 2017). Previous work both on entity linking and on coreference resolution (cited above, as well as Wiseman et al., 2016) often presents more complex models that incorporate e.g. hand-engineered features. In contrast, we keep our underlying model basic since we want to systematically analyze how certain architectural decisions affect performance. For the same reason we deviate from previous work to entity linking that uses a specialized coreference resolution module (e.g., Chen et al., 2017).

Analysis of Neural Network Models. Our work joins a recent strand in NLP that systematically analyzes what different neural network models learn about language (Linzen et al., 2016; Kádár et al., 2017; Conneau et al., 2018; Gulordava et al., 2018b; Nematzadeh et al., 2018, a.o.). This work, like ours, has yielded both positive and negative results: There is evidence that they learn complex linguistic phenomena of morphological and syntactic nature, like long distance agreement (Gulordava et al., 2018b; Giulianelli et al., 2018), but less evidence that they learn how language relates to situations; for instance, Nematzadeh et al. (2018) show that memory-augmented neural models fail on tasks that require keeping track of inconsistent states of the world.

3 Models

We approach character identification as a classification task, and compare a baseline LSTM (Hochreiter and Schmidhuber, 1997) with two models that enrich the LSTM with a memory module designed to learn and use entity representations. LSTMs are the workhorse for text processing, and thus a good baseline to assess the contribution of this module. The LSTM processes text of dialogue scenes one token at a time, and the output is a probability distribution over the entities (the set of entity IDs are given).

3.1 Baseline: BILSTM

The BILSTM model is depicted in Figure 2. It is a standard bidirectional LSTM (Graves et al., 2005), with the difference with most uses of LSTMs in NLP that we incorporate speaker information in addition to the linguistic content of utterances.

The model is given chunks of dialogue (see Appendix for hyperparameter settings such as the chunk size). At each time step i, one-hot vectors for token $\mathbf{t}_i$ and speaker entities $\mathbf{s}_i$ are embedded

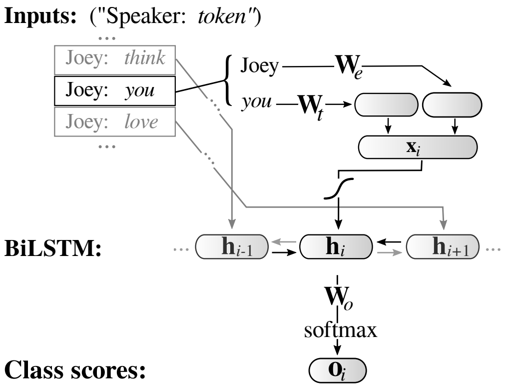

Figure 2: BILSTM applied to "...think you love..." as spoken by Joey (from Figure 1), outputting class scores for mention "you" (bias b_o not depicted).

via two distinct matrices $\mathbf{W}_t$ and $\mathbf{W}_e$ and concatenated to form a vector $\mathbf{x}_i$ (Eq. 1, where $\|$ denotes concatenation; note that in case of multiple simultaneous speakers S_i their embeddings are summed).

$$\mathbf{x}_i = \mathbf{W}_t\, \mathbf{t}_i \,\|\, \sum_{\mathbf{s} \in S_i} \mathbf{W}_e\, \mathbf{s} \tag{1}$$

The vector $\mathbf{x}_i$ is fed through the nonlinear activation function tanh and input to a bidirectional LSTM. The hidden state $\overrightarrow{\mathbf{h}_i}$ of a *uni*directional LSTM for the i^{th} input is recursively defined as a combination of that input with the LSTM's previous hidden state $\overrightarrow{\mathbf{h}}_{i-1}$. For a *bi*directional LSTM, the hidden state $\mathbf{h}_i$ is the concatenation of the hidden states $\overrightarrow{\mathbf{h}_i}$ and $\overleftarrow{\mathbf{h}_i}$ of two unidirectional LSTMs which process the data in opposite directions (Eqs. 2-4).

$$\overrightarrow{\mathbf{h}_i} = \mathrm{LSTM}(\tanh(\mathbf{x}_i), \overrightarrow{\mathbf{h}}_{i-1}) \tag{2}$$

$$\overleftarrow{\mathbf{h}_i} = \mathrm{LSTM}(\tanh(\mathbf{x}_i), \overleftarrow{\mathbf{h}}_{i+1}) \tag{3}$$

$$\mathbf{h}_i = \overrightarrow{\mathbf{h}_i} \,\|\, \overleftarrow{\mathbf{h}_i} \tag{4}$$

For every entity mention $\mathbf{t}_i$ (i.e., every token[4] that is tagged as referring to an entity), we obtain a distribution over all entities, $\mathbf{o}_i \in [0,1]^{1 \times N}$, by applying a linear transformation to its hidden state $\mathbf{h}_i$ (Eq. 5), and feeding the resulting $\mathbf{g}_i$ to a softmax classifier (Eq. 6).

$$\mathbf{g}_i = \mathbf{W}_o\, \mathbf{h}_i + \mathbf{b}_o \tag{5}$$

$$\mathbf{o}_i = \mathrm{softmax}(\mathbf{g}_i) \tag{6}$$

Eq. 5 is where the other models will diverge.

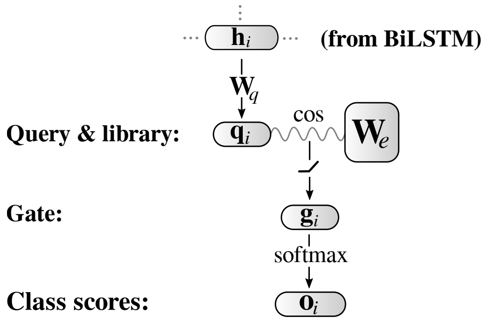

Figure 3: ENTLIB; everything before $\mathrm{h_i}$, omitted here, is the same as in Figure 2.

3.2 ENTLIB (Static Memory)

The ENTLIB model (Figure 3) is an adaptation of our previous work in Aina et al. (2018), which was the winner of the SemEval 2018 Task 4 competition. This model adds a simple memory module that is expected to represent entities because its vectors are tied to the output classes (accordingly, Aina et al., 2018, call this module *entity library*). We call this memory 'static', since it is updated only during training, after which it remains fixed.

Where BILSTM maps the hidden state $\mathbf{h}_i$ to class scores $\mathbf{o}_i$ with a single transformation (plus softmax), ENTLIB instead takes two steps: It first transforms $\mathbf{h}_i$ into a 'query' vector $\mathbf{q}_i$ (Eq. 7) that it will then use to query the entity library. As we will see, this mechanism helps dividing the labor between representing the context (hidden layer) and doing the prediction task (query layer).

$$\mathbf{q}_i = \mathbf{W}_q\, \mathbf{h}_i + \mathbf{b_q} \tag{7}$$

A weight matrix $\mathbf{W}_e$ is used as the entity library, which is the same as the speaker embedding in Eq. 1: the query vector $\mathbf{q}_i \in \mathbb{R}^{1 \times k}$ is compared to each vector in $\mathbf{W}_e$ (cosine), and a *gate* vector $\mathbf{g}_i$ is obtained by applying the ReLU function to the cosine similarity scores (Eq. 8).[5] Thus, the query extracted from the LSTM's hidden state is used as a soft pointer over the model's representation of the entities.

$$\mathbf{g}_i = \mathrm{ReLU}(\cos(\mathbf{W}_e, \mathbf{q}_i)) \tag{8}$$

As before, a softmax over $\mathbf{g}_i$ then yields the distribution over entities (Eq. 6). So, in the ENTLIB

---

[4] For multi-word mentions this is done only for the last token in the mention.

[5] In Aina et al. (2018), the gate did not include the ReLU nonlinear activation function. Adding it improved results.

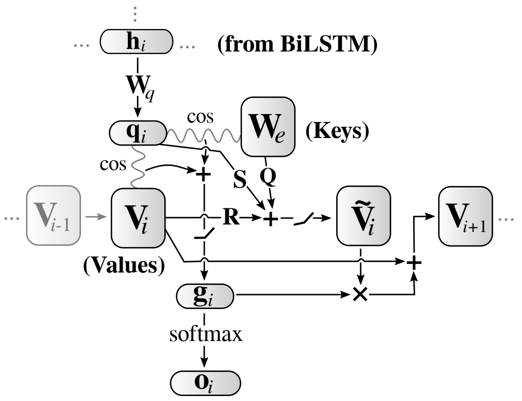

Figure 4: ENTNET; everything before $\mathrm{h_i}$, omitted here, is the same as in Figure 2.

model Eqs. 7 and 8 together take the place of Eq. 5 in the BILSTM model.

Our implementation differs from Aina et al. (2018) in one important point that we will show to be relevant to model less frequent entities (training also differs, see Section 4): The original model did not do parameter sharing between speakers and referents, but used two distinct weight matrices.

Note that the contents of the entity library in ENTLIB do not change during forward propagation of activations, but only during backpropagation of errors, i.e., during training, when the weights of $\mathbf{W}_e$ are updated. If anything, they will encode permanent properties of entities, not properties that change within a scene or between scenes or episodes, which should be useful for reference. The next model attempts to overcome this limitation.

3.3 ENTNET (Dynamic Memory)

ENTNET is an adaptation of *Recurrent Entity Networks* (Henaff et al., 2017, Figure 4) to the task. Instead of representing each entity by a single vector, as in ENTLIB, here each entity is represented jointly by a context-invariant or 'static' *key* and a context-dependent or 'dynamic' *value*. For the keys the entity embedding $\mathbf{W}_e$ is used, just like the entity library of ENTLIB. But the values $\mathbf{V}_i$ can be dynamically updated throughout a scene.

As before, an entity query $\mathbf{q}_i$ is first obtained from the BILSTM (Eq. 7). Then, ENTNET computes gate values $\mathbf{g}_i$ by estimating the query's similarity to both keys and values, as in Eq. 9 (replacing Eq. 8 of ENTLIB).[6] Output scores $\mathbf{o}_i$ are computed as in the previous models (Eq. 6).

$$\mathbf{g}_i = \mathrm{ReLU}(\cos(\mathbf{W}_e, \mathbf{q}_i) + \cos(\mathbf{V}_i, \mathbf{q}_i)) \quad (9)$$

The values $\mathbf{V}_i$ are initialized at the start of every scene ($i = 0$) as being identical to the keys ($\mathbf{V}_0 = \mathbf{W}_e$). After processing the i^{th} token, new information can be added to the values. Eq. 10 computes this new information $\tilde{\mathbf{V}}_{i,j}$, for the j^{th} entity, where $\mathbf{Q}$, $\mathbf{R}$ and $\mathbf{S}$ are learned linear transformations and PReLU denotes the parameterized rectified linear unit (He et al., 2015):

$$\tilde{\mathbf{V}}_{i,j} = \mathrm{PReLU}(\mathbf{Q}\mathbf{W}_{ej} + \mathbf{R}\mathbf{V}_{i,j} + \mathbf{S}\mathbf{q}_i) \quad (10)$$

This information $\tilde{\mathbf{V}}_{i,j}$, multiplied by the respective gate $\mathbf{g}_{i,j}$, is added to the values to be used when processing the next ($i + 1^{\text{th}}$) token (Eq. 11), and the result is normalized (Eq. 12):

$$\mathbf{V}_{i+1,j} = \mathbf{V}_j + \mathbf{g}_{i,j} * \tilde{\mathbf{V}}_{i,j} \quad (11)$$

$$\mathbf{V}_{i+1,j} = \frac{\mathbf{V}_{i+1,j}}{\|\mathbf{V}_{i+1,j}\|} \quad (12)$$

Our adaptation of the Recurrent Entity Network involves two changes. First, we use a biLSTM to process the linguistic utterance, while Henaff et al. (2017) used a simple multiplicative mask (we have natural dialogue, while their main evaluation was on bAbI, a synthetic dataset). Second, in the original model the gates were used to retrieve and output information about the query, whereas we use them directly as output scores because our task is referential. This also allows us to tie the keys to the characters of the Friends series as in the previous model, and thus have them represent entities (in the original model, the keys represented entity types, not instances).

4 Character Identification

The training and test data for the task span the first two seasons of *Friends*, divided into scenes and episodes, which were in turn divided into utterances (and tokens) annotated with speaker identity.[7] The set of all possible entities to refer to is given, as well as the set of mentions to resolve. Only the dialogues and speaker information are available (e.g., no video or descriptive text). Indeed,

---

[6] Two small changes with respect to the original model (motivated by empirical results in the hyperparameter search) are that we compute the gate using cosine similarity instead of dot product, and the obtained similarities are fed through a ReLU nonlinearity instead of sigmoid.

[7] The dataset also includes automatic linguistic annotations, e.g., PoS tags, which our models do not use.

models	#par	all (78) F$_1$	all (78) Acc	main (7) F$_1$	main (7) Acc

Table 1: Model parameters and results on the character identification task. First block: top systems at SemEval 2018. Results in the second block marked with * are statistically significantly better than biLSTM at $p < 0.001$ (approximate randomization tests, Noreen, 1989).

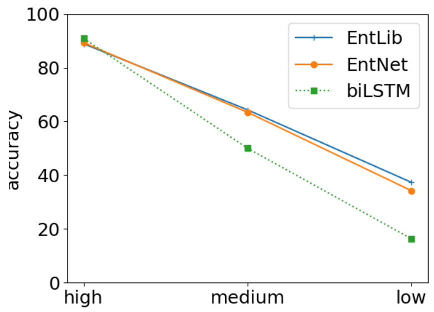

Figure 5: Accuracy on entities with high (>1000), medium (20–1000), and low (<20) frequency.

one of the most interesting aspects of the SemEval data is the fact that it is dialogue (even if scripted), which allows us to explore the role of speaker information, one of the aspects of the extralinguistic context of utterance that is crucial for reference. We additionally used the publicly available 300-dimensional word vectors that were pre-trained on a Google News corpus with the word2vec Skip-gram model (Mikolov et al., 2013a) to represent the input tokens. Entity (speaker/referent) embeddings were randomly initialized.

We train the models with backpropagation, using the standard negative log-likelihood loss function. For each of the three model architectures we performed a random search (> 1500 models) over the hyperparameters using cross-validation (see Appendix for details), and report the results of the best settings after retraining without cross-validation. The findings we report are representative of the model populations.

Results. We follow the evaluation defined in the SemEval task. Metrics are macro-average F$_1$-score (which computes the F$_1$-score for each entity separately and then averages these over all entities) and accuracy, in two conditions: *All entities*, with 78 classes (77 for entities that are mentioned in both training and test set of the SemEval Task, and one grouping all others), and *main entities*, with 7 classes (6 for the main characters and one for all the others). Macro-average F$_1$-score on all entities, the most stringent, was the criterion to define the leaderboard.

Table 1 gives our results in the two evaluations, comparing the models described in Section 3 to the best performing models in the SemEval 2018 Task 4 competition (Aina et al., 2018; Park et al., 2018). Recall that our goal in this paper is not to optimize performance, but to understand model behavior; however, results show that these models are worth analyzing, as that they outperform the state of the art. All models perform on a par on main entities, but entity-centric models outperform biLSTM by a substantial margin when all characters are to be predicted (the difference between EntLib and EntNet is not significant).

The architectures of EntLib and EntNet help with lower frequency characters, while not hurting performance on main characters. Indeed, Figure 5 shows that the accuracy of biLSTM rapidly deteriorates for less frequent entities, whereas EntLib and EntNet degrade more gracefully. Deep learning approaches are data-hungry, and entity mentions follow the Zipfian distribution typical of language, with very few high frequency and many lower-frequency items, such that this is a welcome result. Moreover, these improvements do not come at the cost of model complexity in terms of number of parameters, since all models have roughly the same number of parameters ($3.3 - 3.4$ million).[8]

Given these results and the motivations for the model architectures, it would be tempting to conclude that encouraging models to learn and use entity representations helps in this referential task. However, a closer look at the models' behavior reveals a much more nuanced picture.

Figure 6 suggests that: (1) models are quite good at using speaker information, as the best performance is for first person pronouns and determiners (*I*, *my*, etc.); (2) instead, models do not seem to be very good at handling other contextual information or entity-specific properties, as the worst

---

[8] See Appendix for a computation of the models' parameters.

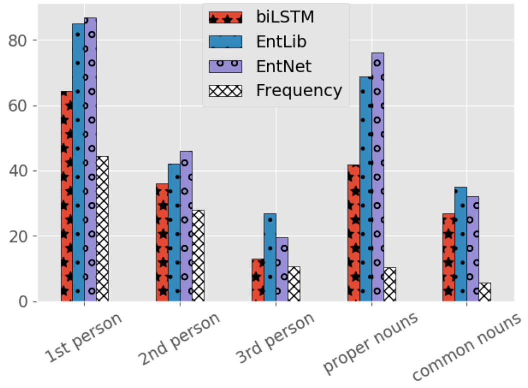

Figure 6: F_1-score (*all entities* condition) of the three models, per mention type, and token frequency of each mention type.

performance is for third person mentions and common nouns, which require both;[9] (3) EntLib and EntNet behave quite similarly, with performance boosts in (1) and smaller but consistent improvements in (2). Our analyses in the next two sections confirm this picture and relate it to the models' architectures.

5 Analysis: Architecture

We examine how the entity-centric architectures improve over the biLSTM baseline on the reference task, then move to entity representations (Section 6).

Shared speaker/referent representation. We found that an important advantage of the entity-centric models, in particular for handling low-frequency entities, lies in the integrated representations they enable of entities both in their role of speakers and in their role of referents. This explains the boost in first person pronoun and proper noun mentions, as follows.

Recall that the integrated representation is achieved by parameter sharing, using the same weight matrix $\mathbf{W}_e$ as speaker embedding and as entity library/keys. This enables entity-centric models to learn the linguistic rule "a first person pronoun (*I, me*, etc.) refers to the speaker" regardless of whether they have a meaningful representation of this particular entity: It is enough that speaker representations are distinct, and they are because they have been randomly initialized. In contrast, the simple biLSTM baseline needs to independently learn the mapping between speaker embedding and output entities, and so it can only learn to resolve even first-person pronouns for entities for which it has enough data.

model type	main	all
biLSTM	0.39	0.02
EntLib	0.82	0.13
EntNet	0.92	0.16
#pairs	21	22155

Table 2: RSA correlation between speaker/referent embeddings W_e and token embeddings W_t of the entities' names, for main entities vs. all entities (right)

For proper nouns (character names), entity-centric models learn to align the token embeddings with the entity representations (identical to the speaker embeddings). We show this by using Representation Similarity Analysis (RSA) (Kriegeskorte et al., 2008), which measures how topologically similar two different spaces are as the Spearman correlation between the pair-wise similarities of points in each space (this is necessary because entities and tokens are in different spaces). For instance, if the two spaces are topologically similar, the relationship of entities 183 and 335 in the entity library will be analogous to the relationship between the names *Joey* and *Ross* in the token space. Table 2 shows the topological similarities between the two spaces, for the different model types.[10] This reveals that in entity-centric models the space of speaker/referent embeddings is topologically very similar to the space of token embeddings restricted to the entities' names, and more so than in the biLSTM baseline. We hypothesize that entity-centric models can do the alignment better because referent (and hence speaker) embeddings are closer to the error signal, and thus backpropagation is more effective (this again helps with lower-frequency entities).

Further analysis revealed that in entity-centric models the beneficial effect of weight sharing between the speaker embedding and the entity representations (both $\mathbf{W}_e$) is actually restricted to first-person pronouns. For other expressions, having

---

[9] 1st person: *I*, *me*, *my*, *myself*, *mine*; 2nd person: *you*, *your*, *yourself*, *yours*; 3rd person: *she*, *her*, *herself*, *hers*, *he*, *him*, *himself*, *his*, *it*, *itself*, *its*.

[10] As an entity's name we here take the proper noun that is most frequently used to refer to the entity in the training data. Note that for the *all entities* condition the absolute values are lower, but the space is much larger (over 22K pairs). Also note that this is an instance of slow learning; models are not encoding the fact that a proper noun like *Rachel* can refer to different people.

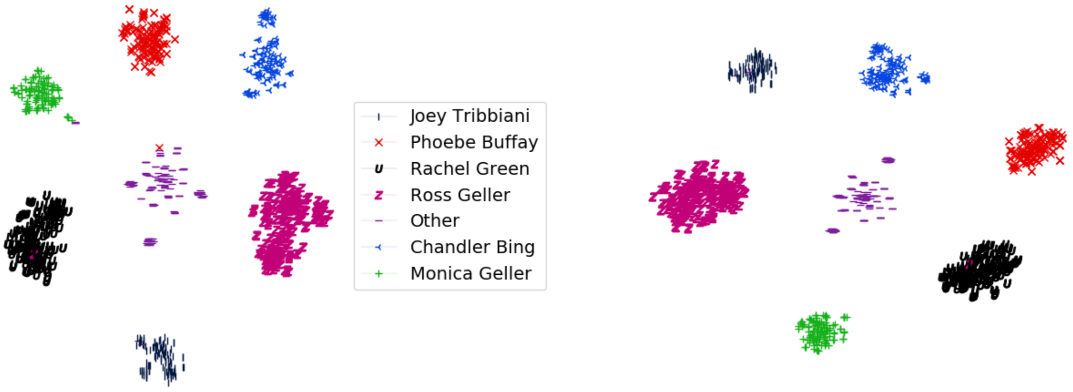

Figure 7: ENTLIB, 2D TSNE projections of the activations for first-person mentions in the test set, colored by the entity referred to. The mentions cluster into entities already in the hidden layer h_i (left graph; query layer q_i shown in the right graph). Best viewed in color.

Figure 8: ENTLIB, 2D TSNE projections of the activations for mentions in the test set (excluding first person mentions), colored by the entity referred to. While there is already some structure in the hidden layer h_i (left graph), the mentions cluster into entities much more clearly in the query q_i (right graph). Best viewed in color.

two distinct matrices yielded almost the same performance as having one (but still higher than the BILSTM, thanks to the other architectural advantage that we discuss below).

In the case of first-person pronouns, the speaker embedding given as input corresponds to the target entity. This information is already accessible in the hidden state of the LSTM. Therefore, mentions cluster into entities already at the hidden layer h_i, with no real difference with the query layer q_i (see Figure 7).

Advantage of query layer. The entity querying mechanism described above entails having an extra transformation after the hidden layer, with the query layer $\mathbf{q}$. Part of the improved performance of entity-centric models, compared to the BILSTM baseline, is due not to their bias towards 'entity representations' per se, but due to the presence of this extra layer. Recall that the BILSTM baseline maps the LSTM's hidden state $\mathbf{h}_i$ to output scores $\mathbf{o}_i$ with a single transformation. Gulordava et al. (2018a) observe in the context of Language Modeling that this creates a tension between two conflicting requirements for the LSTM: keeping track of contextual information across time steps, and encoding information useful for prediction in the current timestep. The intermediate query layer $\mathbf{q}$ in entity-centric models alleviates this tension. This explains the improvements in context-dependent mentions like common nouns or second and third pronouns.

We show this effect in two ways. First, we compare the average mean similarity s of mention pairs $T_e = \{(t_k, t_{k'}) | \; t_k \rightarrow e \wedge k \neq k'\}$ referring to the same entity e in the hidden layer (Eq. 13) and the

biLSTM	EntLib		EntNet	
$\mathbf{h}_i$	$\mathbf{h}_i$	$\mathbf{q}_i$	$\mathbf{h}_i$	$\mathbf{q}_i$
0.34	0.24	0.48	0.27	0.60

Table 3: Average cosine similarity of mentions with the same referent.

query layer.[11]

$$s = \frac{1}{|E|}\sum_{e\in E}\frac{1}{|T_e|}\sum_{(t_k,t_{k'})\in T_e}\cos(h_{t_k},h_{t_{k'}}) \quad (13)$$

Table 3 shows that, in entity-centric models, this similarity is lower in the hidden layer $\mathbf{h}_i$ than in the case of the biLSTM baseline, but in the query layer $\mathbf{q}_i$ it is instead much higher. The hidden layer thus is representing other information than referent-specific knowledge, and the query layer can be seen as extracting referent-specific information from the hidden layer. Figure 8 visually illustrates the division of labor between the hidden and query layers. Second, we compared the models to variants where the cosine-similarity comparison is replaced by an ordinary dot-product transformation, which converts the querying mechanism into a simple further layer. These variants performed almost as well on the reference task, albeit with a slight but consistent edge for the models using cosine similarity.

No dynamic updates in EntNet. A surprising negative finding is that EntNet is not using its dynamic potential on the referential task. We confirmed this in two ways. First, we tracked the values $\mathbf{V}_i$ of the entity representations and found that the pointwise difference in $\mathbf{V}_i$ at any two adjacent time steps i tended to zero. Second, we simply switched off the update mechanism during testing and did not observe any score decrease on the reference task. EntNet is thus only using the part of the entity memory that it shares with EntLib, i.e., the keys $\mathbf{W_e}$, which explains their similar performance.

This finding is markedly different from Henaff et al. (2017), where for instance the BaBI tasks could be solved only by dynamically updating the entity representations. This may reflect our different language modules: since our LSTM module already has a form of dynamic memory, unlike the simpler sentence processing module in Henaff et al. (2017), it may be that the LSTM takes this burden off of the entity module. An alternative is that it is due to differences in the datasets. We leave an empirical comparison of these potential explanations for future work, and focus in Section 6 on the static entity representations $\mathbf{W}_e$ that EntNet essentially shares with EntLib.

This person is {a/an/the} <PROPERTY> [and {a/an/the} <PROPERTY>]{0,2}.
This person is the brother of Monica Geller.
This person is a paleontologist and a man.

Figure 9: Patterns and examples (in italics) of the dataset for information extraction as entity linking.

6 Analysis: Entity Representations

The foregoing demonstrates that entity-centric architectures help in a reference task, but not that the induced representations in fact contain meaningful entity information. In this section we deploy these representations on a new dataset, showing that they do not—not even for basic information about entities such as gender.

Method. We evaluate entity representations with an information extraction task including attributes and relations, using information from an independent, unstructured knowledge base—the Friends Central Wikia.[12] To be able to use the models as is, we set up the task in terms of entity linking, asking models to solve the reference of natural language descriptions that uniquely identify an entity. For instance, given *This person is the brother of Monica Geller.*, the task is to determine that *person* refers to *Ross Geller*, based on the information in the sentence.[13] The information in the descriptions was in turn extracted from the Wikia. We do not retrain the models for this task in any way—we simply deploy them.

We linked the entities from the Friends dataset used above to the Wikia through a semi-automatic procedure that yielded 93 entities, and parsed the Wikia to extract their attributes (*gender* and *job*) and relations (e.g., *sister*, *mother-in-law*; see Appendix for details). We automatically generate the natural language descriptions with a simple pattern (Figure 9) from combinations of properties that uniquely identify a given entity within the set of Friends characters.[14] We

---

[11] For the query layer, Eq. 13 is equivalent, with $\cos(q_{t_k}, q_{t_{k'}})$.

[12] `http://friends.wikia.com`.

[13] The referring expression is the whole DP, *This person*, but we follow the method in Aina et al. 2018 of asking for reference resolution at the head noun.

[14] Models require inputting a speaker; we use speaker UN-

model	description	gender	job
Random	1.5	50	20
biLSTM	0.4	-	-
EntLib	2.2	55	27
EntNet	1.3	61	24

Table 4: Results on the attribute and relation prediction task: percentage accuracy for natural language descriptions, mean reciprocal rank of characters for single attributes (lower is worse).

consider unique descriptions comprising at most 3 properties. Each property is expressed by a noun phrase, whereas the article is adapted (definite or indefinite) depending on whether that property applies to one or several entities in our data. This yields 231 unique natural language descriptions of 66 characters, created on the basis of overall 61 relation types and 56 attribute values.

Results. The results of this experiment are negative: The first column of Table 4 shows that models get accuracies near 0.

A possibility is that models do encode information in the entity representations, but it doesn't get used in this task because of how the utterance is encoded in the hidden layer, or that results are due to some quirk in the specific setup of the task. However, we replicated the results in a setup that does not encode whole utterances but works with single attributes and relations. While the methodological details are in the Appendix, the 'gender' and 'job' columns of Table 4 show that results are a bit better in this case but models still perform quite poorly: Even in the case of an attribute like gender, which is crucial for the resolution of third person pronouns (*he/she*), the models' results are quite close to that of a random baseline.

Thus, we take it to be a robust result that entity-centric models trained on the SemEval data do not learn or use entity information—at least as recoverable from language cues. This, together with the remainder of the results in the paper, suggests that models rely crucially on speaker information, but hardly on information from the linguistic context.[15] Future work should explore alternatives such as pre-training with a language modeling task, which could improve the use of context.

7 Conclusions

Recall that the motivation for entity-centric models is the hypothesis that incorporating entity representations into the model will help it better model the language we use to talk about them. We still think that this hypothesis is plausible. However, the architectures tested do not yet provide convincing support for it, at least for the data analyzed in this paper.

On the positive side, we have shown that framing models from an entity-centric perspective makes it very natural to adopt architectural decisions that are good inductive biases. In particular, by exploiting the fact that both speakers and referents are entities, these models can do more with the same model size, improving results on less frequent entities and emulating rule-based behavior such as "a first person expression refers to the speaker". On the negative side, we have also shown that they do not yield operational entity representations, and that they are not making good use of contextual information for the referential task.

More generally, our paper underscores the need for model analysis to test whether the motivations for particular architectures are borne out in how the model actually behaves when it is deployed.

Acknowledgments

We gratefully acknowledge Kristina Gulordava and Marco Baroni for the feedback, advice and support. We are also grateful to the anonymous reviewers for their valuable comments. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 715154), and from the Spanish Ramón y Cajal programme (grant RYC-2015-18907). We are grateful to the NVIDIA Corporation for the donation of GPUs used for this research. We are also very grateful to the Pytorch developers. This paper reflects the authors' view only, and the EU is not responsible for any use that may be made of the information it contains.

KNOWN.

[15] Note that 44% of the mentions in the dataset are first person, for which linguistic context is irrelevant and the models only need to recover the relevant speaker embedding to succeed. However, downsampling first person mentions did not improve results on the other mention types.

A Appendices

A.1 Hyperparameter search

Besides the LSTM parameters, we optimize the token embeddings $\mathbf{W}_t$, the entity/speaker embeddings $\mathbf{W}_e$, as well as $\mathbf{W}_o$, $\mathbf{W}_q$, and their corresponding biases, where applicable (see Section 3). We used five-fold cross-validation with early stopping based on the validation score. We found that most hyperparameters could be safely fixed the same way for all three types. Specifically, our final models were all trained in batch mode using the Adam optimizer (Kingma and Ba, 2014), with each batch covering 25 scenes given to the model in chunks of 750 tokens. The token embeddings ($\mathbf{W}_t$) are initialized with the 300-dimensional word2vec vectors, $\mathbf{h}_i$ is set to 500 units, and entity (or speaker) embeddings ($\mathbf{W}_e$) to k = 150 units.With this hyperparameter setting, ENTLIB has fewer parameters than BILSTM: the linear map $\mathbf{W}_o$ of the latter (500 × 401) is replaced by the query extractor $\mathbf{W}_q$ (500 × 150) followed by (non-parameterized) similarity computations. This holds even if we take into account that the entity embedding $\mathbf{W}_e$ used in both models contains 274 entities that are never speakers and that are, hence, used by ENTLIB but not by BILSTM.

Our search also considered different types of activation functions in different places, with the architecture presented above, i.e., tanh before the LSTM and ReLU in the gate, robustly yielding the best results. Other settings tested—randomly initialized token embeddings, self-attention on the input layer, and a uni-directional LSTM—did not improve performance.

We then performed another random search ($>$ 200 models) over the remaining hyperparameters: learning rate (sampled from the logarithmic interval 0.001–0.05), dropout before and after LSTM (sampled from 0.0–0.3 and 0.0–0.1, respectively), weight decay (sampled from 10^{-6}–10^{-2}) and penalization, i.e., whether to decrease the relative impact of frequent entities by dividing the loss for an entity by the square root of its frequency. This paper reports the best model of each type, i.e., BILSTM, ENTLIB, and ENTNET, after training on all the training data without cross-validation for 20, 80 and 80 epochs respectively (numbers selected based on tendencies in training histories). These models had the following parameters:

	BILSTM	ENTLIB	ENTNET
learning rate:	0.0080	0.0011	0.0014
dropout pre	0.2	0.2	0.0
dropout post:	0.0	0.02	0.08
weight decay:	1.8e-6	4.3e-6	1.0e-5
penalization:	no	yes	yes

B Attribute and relation extraction

B.1 Details of the dataset

We performed a two-step procedure to extract all the available data for the SemEval characters. First, using simple word overlap, we automatically mapped the 401 SemEval names to the characters in the database. In a second, manual step, we corrected these mappings and added links that were not found automatically due to name alternatives, ambiguities or misspellings (e.g., SemEval *Dana* was mapped to *Dana Keystone*, and *Janitor* to *The Zoo Employee*). In total, we found 93 SemEval entities in Friends Central, and we extracted their attributes (gender and job) and their mutual relationships (relatives).

Model	**Gender** (93;2)		**Occupation**	**Relatives**
	(wo)man	(s)he	(24;17)	(56;24)
RANDOM	.50	.50	.20	.16
ENTLIB	.55	.58	.27	.22
ENTNET	**.61**	.56	.24	**.26**

Table 5: Results on the attribute prediction task (mean reciprocal rank; from 0 (worst) to 1 (best)). The number of considered test items and candidate values, respectively, are given in the parentheses. For gender, we used *(wo)man* and *(s)he* as word cues for the values (fe)male.

B.2 Alternative setup

We use the same models, i.e. ENTLIB and ENTNET trained on Experiment 1, and (without further training) extract representations for the entities from them. The former are directly obtained from the entity embedding $\mathbf{W}_e$ of each model.

In the **attribute prediction** task, we are given an attribute (e.g., *gender*), and all its possible values $\mathcal{V}$ (e.g., $\mathcal{V} = \{$*woman, man* $\}$). We formulate the task as, given a character (e.g., *Rachel*), producing a ranking of the possible values in descending order of their similarity to the character, where similarity is computed by measuring the cosine of the angle between their respective vector representations in the entity space. We obtain representations of attributes values, in the same space as the entities, by inputting each attribute value as a separate utterance to the models, and extracting the corresponding entity query ($\mathbf{q}_i$). Since the models also expect a speaker for each utterance, we set it to either *all entities*, *main entities*, a *random* entity, or *no* entity (i.e., speaker embedding with zero in all units), and report the best results.

We evaluate the rankings produced for both tasks in terms of mean reciprocal rank (Craswell, 2009), scoring from 0 to 1 (from worst to best) the position of the target labels in the ranking. The two first columns Table 5 presents the results. Our models generally perform poorly on the tasks, though outperforming a random baseline. Even in the case of an attribute like gender, which is crucial for the resolution of third person pronouns, the models' results are still very close to that of the random baseline.

Instead, the task of **relation prediction** is to, given a pair of characters (e.g., *Ross* and *Monica*), predict the relation R which links them (e.g., *sister, brother-in-law, nephew*; we found 24 relations that applied to at least two pairs). We approach this following the vector offset method introduced by Mikolov et al. (2013b) for semantic relations between words. This leverages on regularities in the embedding space, taking the embeddings of pairs that are connected by the same relation to have analogous spatial relations. For two pairs of characters (a, b) and (c, d) which bear the same relation R, we assume $\mathbf{a} - \mathbf{b} \approx \mathbf{c} - \mathbf{d}$ to hold for their vector representations. For a target pair (a, b) and a relation R, we then compute the following measure:

$$\mathrm{s}_{rel}((a,b),R) = \frac{\sum_{(x,y)\in R} \cos(\mathbf{a}-\mathbf{b}, \mathbf{x}-\mathbf{y})}{|R|} \tag{14}$$

Equation (14) computes the average relational similarity between the target character pair and the exemplars of that relation (excluding the target itself), where the relational similarity is estimated as the cosine between the vector differences of the two pairs of entity representations respectively. Due to this setup, we restrict to predicting relation types that apply to at least two pairs of entities. For each target pair (a, b), we produce a rank of candidate relations in descending order of their scores s_{rel}. Table 5 contains the results, again above baseline but clearly very poor.

Continuous Learning for Large-scale Personalized Domain Classification

Abstract

Domain classification is the task of mapping spoken language utterances to one of the natural language understanding domains in intelligent personal digital assistants (IPDAs). This is a major component in mainstream IPDAs in industry. Apart from official domains, thousands of third-party domains are also created by external developers to enhance the capability of IPDAs. As more domains are developed rapidly, the question of how to continuously accommodate the new domains still remains challenging. Moreover, existing continual learning approaches do not address the problem of incorporating personalized information dynamically for better domain classification. In this paper, we propose CoNDA, a neural network based approach for domain classification that supports incremental learning of new classes. Empirical evaluation shows that CoNDA achieves high accuracy and outperforms baselines by a large margin on both incrementally added new domains and existing domains.

1 Introduction

Domain classification is the task of mapping spoken language utterances to one of the natural language understanding (NLU) domains in intelligent personal digital assistants (IPDAs), such as Amazon Alexa, Google Assistant, and Microsoft Cortana, etc. (Sarikaya, 2017). Here a domain is defined in terms of a specific application or functionality such as weather, calendar or music, which narrows down the scope of NLU. For example, given an utterance "*Ask Uber to get me a ride*" from a user, the appropriate domain would be one that invokes the "Uber" app.

Traditionally IPDAs have only supported dozens of well-separated domains, where each is defined in terms of a specific application or functionality such as calendar and weather (Sarikaya et al., 2016; Tur and De Mori, 2011; El-Kahky et al., 2014). In order to increase the domain coverage and extend the capabilities of the IPDAs, mainstream IPDAs released tools to allow third-party developers to build new domains. Amazons Alexa Skills Kit, Googles Actions and Microsofts Cortana Skills Kit are examples of such tools. To handle the influx of new domains, large-scale domain classification methods like SHORTLISTER (Kim et al., 2018b) have been proposed and have achieved good performance.

As more new domains are developed rapidly, one of the major challenges in large-scale domain classification is how to quickly accommodate the new domains without losing the learned prediction power on the known ones. A straightforward solution is to simply retraining the whole model whenever new domains are available. However, this is not desirable since retraining is often time consuming. Another approach is to utilize continual learning where we dynamically evolve the model whenever a new domain is available. There is extensive work on the topic of continual learning, however there is very little on incrementally adding new domains to a domain classification system.

To mitigate this gap, in this paper we propose the CoNDA solution for continuous domain adaptation. Given a new domain, we keep all learned parameters, but only add and update new parameters for the new domain. This enables much faster model updates and faster deployment of new features to customers. To preserve the learned knowledge on existing domains to avoid the notorious catastrophic forgetting problem (Kemker et al., 2018), we propose cosine normalization for output prediction and domain embedding regularization for regularizing the new domain embedding. Also, we summarize the data for existing domains by sampling exemplars, which will be used together

Proceedings of NAACL-HLT 2019, pages 3784–3794
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

with the new domain data for continuous domain adaptation. This is shown to further alleviate the overfitting on the new domain data. Empirical evaluation on real data with 900 domains for initial training and 100 for continuous adaptation shows that CoNDA out performs the baselines by a large margin, achieving 95.6% prediction accuracy on average for the 100 new domains and 88.2% accuracy for all seen domains after 100 new domains have been accommodated (only 3.6% lower than the upperbound by retraining the model using all domain data). To summarize, we make the following contributions in this paper:

- We introduce the problem of continuous domain adaptation for large-scale personalized domain classification.
- We describe CoNDA, a new solution for continuous domain adaptation with Cosine normalization, domain embedding regularization and negative exemplar sampling techniques. Our solution advances the research in continuous domain adaptation.
- We conduct extensive experiments showing that CoNDA achieves good accuracy on both new and existing domains, and outperforms the baselines by a large margin.

2 Background and Problem Definition

2.1 Domain Classification

Domain classification is the task of mapping spoken language utterances to one of the NLU domains in IPDAs. A straightforward solution to tackle this problem is to ask users to explicitly mention the domain name with a specific invocation pattern. For example, for the utterance "*Ask Uber to get me a ride*", the invocation pattern is "*Ask* $\{$*domain*$\}$ *to* $\{$*perform action*$\}$". While it makes things much simpler for the domain classifier, this significantly limits natural interaction with IPDAs as users need to remember the domain names as well as the invocation pattern. To address this limitation, *name-free domain classification* methods were developed for more user friendly interactions, and have been getting more attention recently. We specifically focus on the name-free scenario in this paper.

2.2 The Shortlister System

To our knowledge, the state-of-the-art for name-free domain classification is SHORTLISTER (Kim et al., 2018b), which leverages personalized user provided information for better classification performance. Specifically, it contains three main modules.

The first module is the LSTM-based encoder to map an utterance to a dimension-fixed vector representation. Given an utterance, each word is first represented as dense vectors using word embeddings, then a bidirectional LSTM (Graves and Schmidhuber, 2005) is be used to encode the full utterance.

The second module is the personalized domain summarization module. For each utterance from an IPDA user, a list of domains have been enabled by the user. These enabled domains can be viewed as user-specific personalized information. It has been shown that the domain classification accuracy can be significantly improved by leveraging information about enabled domains (Kim et al., 2018b). To represent the domain enablement information, first each enabled domain is mapped to a fixed-dimensional embedding, then a summarization vector is generated by taking an attention weighted sum (Luong et al., 2015) over the enabled domain embeddings.

Once the utterance representation and the enabled domain summarization are calculated, we concatenate the two vectors as the final representation. Then the third module, a feed-forward network, is used to predict the confidence score with a sigmoid function for each domain.

2.3 Continuous Domain Adaptation

As more new domains are developed, a major challenges in large-scale domain classification is quickly accommodating the new domains into the live production domain classification model without having to perform a full retrain. We refer to this problem as *Continuous Domain Adaptation* (CDA). In this paper, we specifically focus on the case of purely online learning where new domains where added one by one, since in practice we want to quickly integrate a new domain into the system as soon as it becomes available. We formally define the problem below.

Definition 1 *(Online continuous domain adaptation) Given a collection of* k *domains* $S_k = \{s_1, s_2, \ldots, s_k\}$, *suppose we have a dataset* $\mathcal{D}_k$ *defined on* S_k *where each item is a triple* (u, s, E) *with the utterance* $u \in U$ *(the set for all possible utterances), the ground-truth domain* $s \in S_k$, *and* *the enabled domains $E \subseteq S_k$. Denote $\mathcal{P}(S_k)$ as the powerset of S_k, a model $M_k : U \times \mathcal{P}(S_k) \rightarrow S_k$ has been trained on $\mathcal{D}_k$ for domain classification with the accuracy $M_k(\mathcal{D}_k)$. At some point, a new domain s_{k+1} is available with the corresponding dataset $D_{k+1} = \{(u, s_{k+1}, E) \mid E \subseteq S_{k+1}\}$ with $S_{k+1} = S_k \cup \{s_{k+1}\}$. Taking advantage of D_{k+1}, the continuous adaptation for s_{k+1} is to update M_k to $M_{k+1} : U \times \mathcal{P}(S_{k+1}) \rightarrow S_{k+1}$ so that the model can make predictions for s_{k+1}, with the goal of maximizing $M_{k+1}(D_{k+1})$ and minimizing $M_k(\mathcal{D}_k) - M_{k+1}(\mathcal{D}_k)$.*

3 The CoNDA Solution

We introduce CoNDA (**Co**ntinuous **N**eural **D**omain **A**daptation), a variation of SHORTLISTER that is capable of handling online CDA decribed in Definition 1. Similar to SHORTLISTER, it has three main modules.

The first module is the LSTM-based utterance encoder which shares the same architecture as the one used in SHORTLISTER, that maps an input utterance into a dense vector. After the training on the initial k-domain data $\mathcal{D}_k$, we freeze all parameters (i.e., the word embedding lookup and the bi-LSTM parameters) of this module from changing for the subsequent online domain adaptation tasks. Usually the value of k is large enough (hundreds or even thousands in real-world, at least 100 in our experiments), thus it is safe to assume that the parameters have been tuned sufficiently well to encode utterances from all existing and future domains. In this work we treat new words in the new domains as unknown and leave the problem of vocabulary expansion as future work.

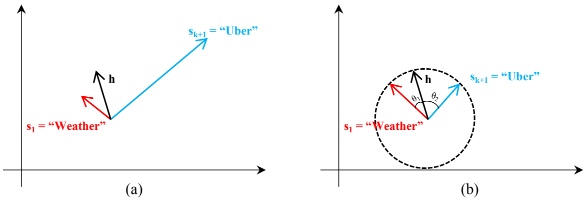
The second module is the personalized domain summarization module which will map the enabled domains of an input utterance to a dense vector representation. It is also similar to the one in SHORTLISTER, except we will evolve the module as we are adding new domains. Specifically, given dataset $\mathcal{D}_k$ on k domains for initial training, a domain embedding table $T_k \in R^{k \times d_s}$ will be learned where d_s is the size of the domain embeddings. When a new domain s_{k+1} is available, we expand T_k to $T_{k+1} \in R^{(k+1) \times d_s}$ by: (1) freezing the learned embeddings for all known domains; (2) adding a new row $t_{k+1} \in R^{d_s}$ to T_k as the domain embedding for s_{k+1} and updating the new parameters t_{k+1} using all available training data at hand (i.e., the dataset D_{k+1} and the negative samples which will be discussed later in this section). We repeat this procedure whenever a new domain is available. To avoid over-fitting on t_{k+1}, we introduce a new regularization term into the loss function. We describe the details in Section 3.2.

The third module is a two-layer feed-forward network as the classifier. The first layer $f^{(1)} : R^{d_u+d_s} \rightarrow R^{d_h}$ maps the concatenation of the utterance embedding (in size d_u) and domain summarization (in size d_s) into fix-sized hidden representation (in size d_h) using a fully connected layer followed by SELU activation (Klambauer et al., 2017), which is identical to the one in SHORTLISTER. Then the prediction layer $f^{(2)} : R^{d_h} \rightarrow R^k$ maps the hidden representation to the final domain prediction scores. Unlike SHORTLISTER where the final prediction score is the dot product of the weight vector and the hidden representation, we choose to use the cosine score of the two, referred to as *cosine normalization*. To support online CDA when a new domain is available, we apply a similar approach to the domain embedding expansion described above to expand the prediction layer. Specifically, denote $W_k^{(2)} \in R^{k \times d_h}$ be the weights for the prediction layer that has been trained on the initial k domains. To adapt the new domain d_{k+1}, we expand $W_k^{(2)}$ to $W_{k+1}^{(2)} \in R^{(k+1) \times d_h}$ by first freezing all learned parameters and adding a new row of learnable parameters $w_{k+1} \in R^{d_h}$ to $W_k^{(2)}$.

As each time we only add one new domain, all training utterances during the update will have the same label. Thus, it's easy to overfit the new data such that catastrophic forgetting occurs. Inspired by (Rebuffi et al., 2017), we also propose a negative sampling procedure to leverage (limited) information on the known domains to alleviate the catastrophic forgetting problem. For the rest of the section, we will first talk about cosine normalization, and then domain embedding regularization, and finally negative sampling.

3.1 Cosine Normalization

As mentioned above, we use the cosine similarity of the weights and the hidden representation vector instead of the linear dot product in the prediction layer. Formally, let $f_k^{(2)} : R^{d_h} \rightarrow [-1, 1]^k$ be the prediction layer for k domains with parameters $W_k^{(2)} \in R^{k \times d_h}$. Given an input hidden representation $h \in R^{d_h}$ from $f^{(1)}$, the score for the i-th



(a) (b)

Figure 1: Cosine Example.

domain under cosine normalization is:

$$f_{k,i}^{(2)}(h) = \cos\left(h, W_{k,i}^{(2)}\right) = \frac{h \cdot W_{k,i}^{(2)}}{\|h\| \left\|W_{k,i}^{(2)}\right\|} \tag{1}$$

To understand why cosine is better in the case of online CDA, let's first see the problem with the dot-product method. Suppose we are accommodating s_{k+1} with dataset D_{k+1}, because we train the new parameters w_{k+1} only on D_{k+1} where all utterances have the same domain s_{k+1}, the model can easily get good training performance on $M_{k+1}(D_{k+1})$ by simply maximizing the values in w_{k+1} such that the dot product of the hidden representation with w_{k+1} is larger than the dot product with any other $w_i, 1 \leq i \leq k$. Effectively this leads to the model predicting domain s_{k+1} for any given utterance. Using cosine normalization instead as described in Eq. 1 removes the incentive to maximize the vector length of w_{k+1}.

Example 1 *Suppose M_k has been initially trained on $\mathcal{D}_k$, and domain s_1="Weather". Given an utterance u = "What's the weather today?", M_k correctly classifies u into s_1. Now a new domain s_{k+1}="Uber" is coming and we evolve M_k to M_{k+1}. As the norm of the weights w_{k+1} could be much larger than w_1 in the prediction layer, even if the hidden representation h of u is closer to s_1 in direction, M_{k+1} will classifier u into s_{k+1} as it has a higher score, shown in Figure 1.a. However if we measure the cosine similarity, M_{k+1} will classify u correctly because we now care more about the directions of the vectors, and the angle θ_1 between h and s_1 is smaller (representing higher similarity) than the angle θ_2 between h and s_{k+1}, as shown in Figure 1.b.*

As we use the cosine normalization, all prediction scores are mapped into the range [-1, 1]. Therefore it's not proper to use log-Sigmoid loss function as in SHORTLISTER. So accompanying with the cosine normalization, the following hinge loss function has been used instead:

$$\begin{aligned}\mathcal{L}_{hinge} = &\sum_{i=1}^{n} y_i \max\{\Delta_{pos} - o_i, 0\} \\ &+ \sum_{i=1}^{n} (1 - y_i) \max\{o_i - \Delta_{neg}, 0\}\end{aligned} \tag{2}$$

where n is the number of all domains, o_i is the predicted score for each domain, y is a n-dimensional one-hot vector with 1 in the ground-truth label and 0 otherwise. Δ_{pos} and Δ_{neg} are the hinge thresholds for the true and false label predictions respectively. The reason we use hinge loss here is that it can be viewed as another way to alleviate the overfitting on new data, as the restrictions are less by only requiring the prediction for the ground-truth to be above Δ_{pos} and false domain predictions below Δ_{neg}. Our experiments show that this helps the model get better performance on the seen domains.

3.2 Domain Embedding Regularization

In this section, we introduce the regularizations on the domain embeddings used in the personalized domain summarization module. Recall that given an utterance u with h^u as the hidden representation from the encoder and its enabled domains E, personalized domain summarization module first compares u with each $s_i \in E$ (by calculating the dot product of h^u and the domain embedding t_i of s_i) to get a score a_i, then gets the weight $c_i = \exp(a_i)/\sum_{a_j} \exp(a_j)$ for domain s_i, and finally computes the personalized domain summary as $\sum_{e_i \in E} c_i \cdot t_i$. We observed that after training on the initial dataset D_k, the domain embedding vectors tend to roughly cluster around a certain (random) direction in the vector space. Thus, when we add a new domain embedding s_{k+1} to this personalization module, the model tends to learn to move this vector to a different part of the vector space such that its easier to distinguish the new domain from all other domains. Moreover, it also increases the ℓ_2 norm of the new domain embedding t_{k+1} to win over all other domains.

Example 2 *Suppose a similar scenario to Example 1 where we have s_1 = "Weather" in S_k and a new domain s_{k+1} = "Uber". As most utterances in D_{k+1} have s_{k+1} as an enabled domain, it's easy for the model to learn to enlarge the norm of the new domain embedding t_{k+1} as well as make it close to the context of ride sharing, so that t_{k+1}*

can dominate the domain summarization. Then coordinating with the new weights w_{k+1} in the prediction layer $f^{(2)}_{k+1}$, the network can easily predict high scores s_{k+1} and fit the dataset D_{k+1}. However, when we have utterances belonging to s_1 with s_{k+1} as an enabled domain, s_{k+1} may still dominate the summarization which makes the prediction layer tends to cast those utterances to s_{k+1}. We don't observe this on the initial training on $\mathcal{D}_k$ because s_{k+1} was not visible at that time, thus cannot be used as an enabled domain. And it's even worse if s_1 is similar to s_{k+1} in concept. For example if s_1 = "Lyft", in this case the utterances of the two domains are also similar, making the dot product of t_{k+1} and the hidden representations of the s_1's utterances even larger.

To alleviate this problem, we add a new domain embedding regularization term in the loss function to constrain the new domain embedding vector length and force it to direct to a similar area where the known domains are heading towards, so that the new domain will not dominate the domain summarization. Specifically,

$$\mathcal{L}_{der} = \sum_{i=1}^{k} \lambda_i \max\{\Delta_{der} - \cos(t_{k+1}, t_i), 0\} + \frac{\lambda_{norm}}{2} \|t_{k+1}\|^2 \quad (3)$$

We call the first part of Eq. 3 on the right hand side as the *domain similarity loss* where we ask the new domain embedding t_{k+1} to be similar to known domain t_i's controlled by a Cosine-based hinge loss. As we may not need t_{k+1} to be similar to all seen domains, a coefficient λ_i is used to weight the importance each similarity loss term. In this paper we encourage t_{k+1} to be more similar to the ones sharing similar concepts (e.g. "Uber" and "Lyft"). We assume all training data are available to us, and measure the similarity of two domains by comparing their average of utterance hidden representations.

Specifically, denote $\varphi : U \rightarrow R^{d_u}$ as the LSTM-encoder that will map an utterance to its hidden representation with dimension d_u. For each domain $s_i \in S_{k+1}$, we first calculate the average utterance representation on D_i

$$\widetilde{h}_i = \sum_{(u,s_i,e)\in D_i} \frac{\varphi(u)}{|D_i|} \quad (4)$$

Then we set $\lambda_i = \lambda_{dsl} \max\{\cos(\widetilde{h}_i, \widetilde{h}_{k+1}), 0\}$ with λ_{dsl} as a scaling factor.

Combining Eq. 2 and 3, the final loss function for optimization is: $\mathcal{L}_{total} = \mathcal{L}_{hinge} + \mathcal{L}_{der}$

3.3 Sampling Negative Exemplars

So far we developed our method by training only on the new data D_{k+1}, and use regularizations to prevent overfitting. However, in many real applications all of the training data, not only D_{k+1}, is actually available, but it's not affordable to retrain the full model using all data. Inspired by (Rebuffi et al., 2017), we can select a set of exemplars from the previously trained data to further improve continual adaptation.

Suppose we are handling the new domain s_{k+1} with D_{k+1}, and all data trained previously is $\mathcal{D}_k$ on k domains S_k. For each known $s_i \in S_k$, we pick N utterances from D_i as the exemplars for s_i. Denote P_i be the exemplar set for s_i and $P = \bigcup_{i=1}^{k} P_i$ be the total exemplar set. To generate each P_i, we pick the top-N utterances that are closest to the average of the utterance hidden representation. Specifically, following Eq. 4, we first get the average representation $\widetilde{h}_i$, then P_i is defined as follow:

$$P_i =_{P_i \subseteq D_i, |P_i|=N} \sum_{(u,s_i,e)\in P_i} \cos\left(\varphi(u), \widetilde{h}_i\right) \quad (5)$$

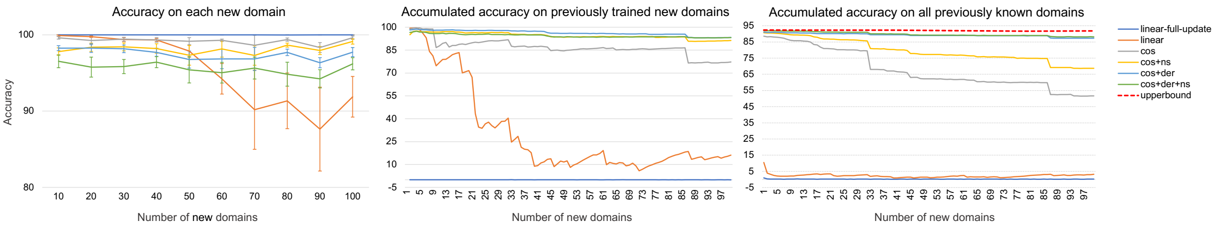
If multiple candidates satisfying Eq. 5 for P_i, we randomly pick one as P_i to break the tie. Once the domain adaptation for s_{k+1} is done, we similarly generate P_{k+1} and merge it to P. We repeat this procedure for negative sampling whenever a new domain is coming later.

As we add more new domains, the exemplar set P also grows. For some new domain D_{k+1}, we may have $|P| \gg |D_{k+1}|$. In this case, the prediction accuracy on the new domain data could be very low as the model will tend to not making mistakes on P rather than fitting D_{k+1}. To alleviate this problem, when $|P| > |D_{k+1}|$, we select a subset $P' \subseteq P$ with $|P'| = |D_{k+1}|$, and P' will be used as the final exemplar set to train together with D_{k+1}. To generate P', we just randomly sample a subset from P, since it was observed to be effective in our experiments.

4 Empirical Evaluation

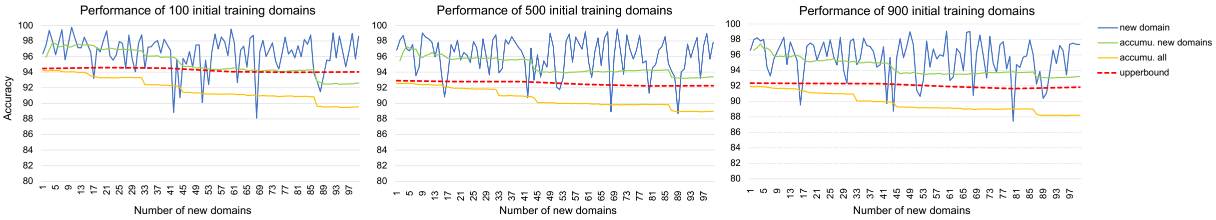
4.1 Experiment Setup

Dataset: We use a dataset defined on 1000 domains for our experiments which has 2.53M utterances, and we split them into two parts. The first



(a) (b) (c)

Figure 2: Overall evaluation. (a) shows the accuracy for new domains. (b) shows the accumulated accuracy for previous new domains that have been adapted to the model so far. (c) shows the accumulated accuracy for all known domains including the ones used for initial training and all previously adapted new domains.



(a) (b) (c)

Figure 3: The model performance on different number of initial training domains. The red dashed line shows the upperbound of the accumulated accuracy, which is generated by retraining the model on all domains seen so far.

part contains 900 domains where we use it for the initial training of the model. It has 2.06M utterances, and we split into training, development and test sets with ratio of 8:1:1. We refer to this dataset as "InitTrain". The second part consists of 100 domains and is used for the online domain adaptation. It has 478K utterances and we split into training, development and test sets with the same 8:1:1 ratio. We refer to this dataset as "IncTrain".

Training Setup: We implement the model in PyTorch (Paszke et al., 2017). All of the experiments are conducted on an Amazon AWS p3.16xlarge[1] cluster with 8 Tesla V100 GPUs. For initial training, we train the model for 20 epochs with learning rate 0.001, batch size 512. For the continuous domain adaptation, we add the new domains in a random order. Each domain data will be trained independently one-by-one for 10 epochs, with learning rate 0.01 and batch size 128. For both training procedures, we use Adam as the optimizer. The development data is used to pick the best model in different epoch runs. We evaluate the classification accuracy on the test set.

4.2 Overall Performance

We first talk about the overall performance. In our experiments we select two baselines. The first one `linear-full-update` which simply extends SHORTLISTER by adding new parameters for new domains and conducting full model updating. The second `linear` is similar to the first baseline except that we freeze all trained parameters and only allow new parameter updating. Both the two baselines update the model with D_{k+1} dataset only. To show the effectiveness of each component of CONDA, we choose four variations. The first one is `cos` where we apply the Cosine Normalization (CosNorm). The second one `cos+der` applies CosNorm with the domain embedding regularization. The third one `cos+ns` uses both CosNorm and negative exemplars. And the last one `cos+der+ns` is the combination of all three techniques, which is our CONDA model. For hyperparameters, we pick $\Delta_{pos} = 0.5, \Delta_{neg} = 0.3, \Delta_{der} = 0.1, \lambda_{dsl} = 5$, and $\lambda_{norm} = 0.4$.

Figure 2 shows the accuracy for new domain adaptations. From the figure, here are the main observations. First, without any constraints, `linear-full-update` can easily overfits the new data to achieve 100% accuracy as shown in Figure 2(a), but it causes catastrophic forgetting such that the accuracy on seen domains is (almost) 0 as shown in Figure 2(b) and (c). By freezing the all trained parameters, the catastrophic forgetting problem is a bit alleviated for `linear`, but the accuracy on the seen domains is still very low as we add more new domains. Second, `cos` produces much better accuracy on seen domains with a bit

---

[1] https://aws.amazon.com/ec2/instance-types/p3/

lower accuracy on each new domain, showing the effectiveness of the Cosine normalization. Third, as we add more regularizations to the model, we get better accuracy on the seen domains (Figure 2 (b) and (c)), at the cost of sacrificing a bit on the new domain accuracy (Figure 2 (a)). Also, `cos+der+ns` (the CoNDA model) achieves the best performance, with an average of 95.6% accuracy for each new domain and 88.2% accuracy for all previously seen domains after we add 100 new ones, which is only 3.6% lower than the upperbound (by retraining the model on the whole dataset). These demonstrate the superiority of our method.

4.3 Micro-benchmarks

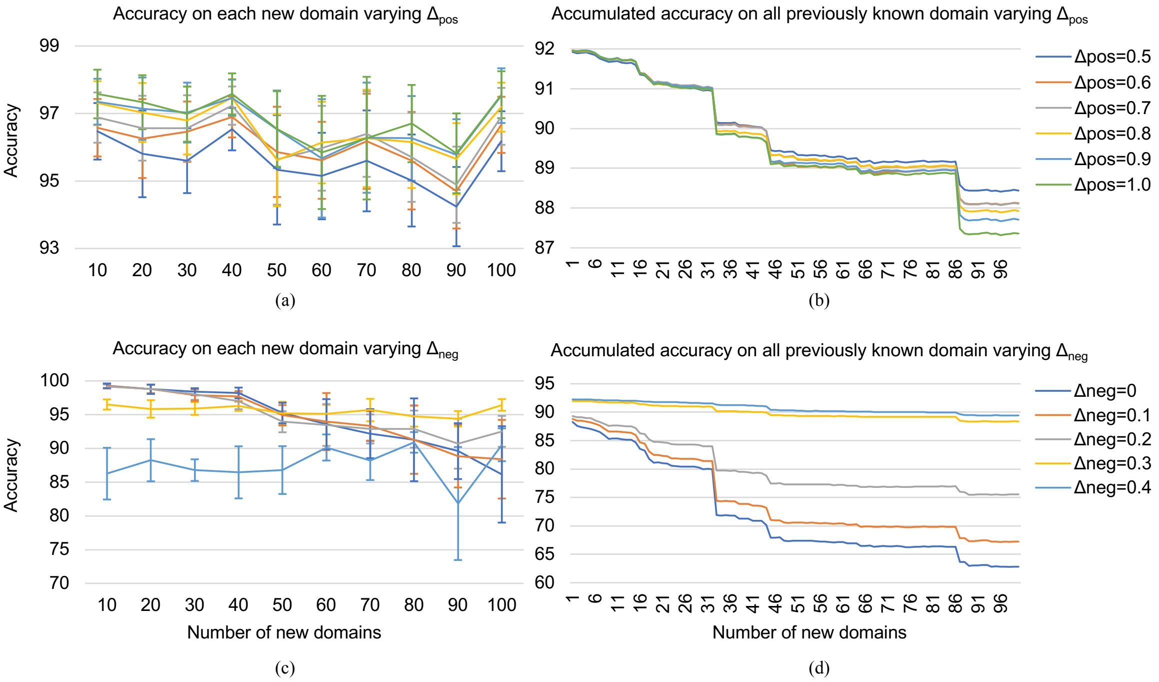
Using Different Number of Initial Domains: We vary the number of domains for initial training to see if it will have a big impact on the model performance. Specifically, we pick 100 and 500 domains from InitTrain, and use the same IncTrain data for domain adaptation. Figure 3 compares the model performance on these three different number (i.e., 100, 500, 900) of initial training domains. From the figure we can see that the curves share a similar pattern regardless of the number of initial domains, showing that our model is stable to the number of domains used for initial training.

Varying the hinge loss thresholds: We vary the classification hinge loss thresholds Δ_{pos} and Δ_{neg} to see how it will affect the performance. Specifically, we fix $\Delta_{neg} = 0.3$ and vary Δ_{pos} from 0.5 to 1.0, and fix $\Delta_{pos} = 0.5$ and vary Δ_{neg} from 0 to 0.4, respectively. For both of the them we use 0.1 as the step size. Figure 4 shows the model performance. From the figures, we summarize the following observations. First, as we increase Δ_{pos}, on average the accuracy on each new domain gets better (Figure 4(a)), but we loss performance on all seen domains (Figure 4(b)). This is in accord with our intuition that a larger Δ_{pos} puts more constraint on the new domain predictions such that it tends to overfit the new data and exacerbates catastrophic forgetting on existing domains. Second, as we increase Δ_{neg}, on average the accuracy on each new domain gets worse (Figure 4(c)), but we get better performance on existing domains. This is because a larger Δ_{neg} narrows down the prediction "margin" between positive and negative domains (similar to decreasing Δ_{pos}), so that less constraint has been put onto predictions to alleviate overfitting on the new domain data.

Varying the domain similarity loss threshold: We vary the threshold Δ_{der} to see how it will affect the model performance. Specifically, we vary Δ_{der} from 0 to 0.5 with step size 0.1, and Figure 5 shows the model performance. As we increase Δ_{der}, the performance on the new domains gets worse, and the drop is significant when Δ_{der} is large. On the other hand, the accumulated accuracy on seen domains increases when we start to increase Δ_{der}, and drops when Δ_{der} is too large. This means we when we start to make the new domain embeddings to be similar to the existing ones, we alleviate the problem that the new domain dominates the domain summarization. Thus the accuracy on existing domains improves at the cost of sacrificing some accuracy on the new domains. However, if we continue to increase Δ_{der} to make it very similar to some of existing domains, the new domain will compete with some existing ones so that we loss accuracy on both new and existing domains.

Varying the weights for domain similarity loss: To see how the weighted domain similarity loss will affect the performance, we compare it against the plain version without the utterance similarity weights. Specifically, we set each $\lambda_i = \lambda_{dsl}$ having the same value. And our experiments show that the plain version gets the average accuracy 94.1% on the new domains, which is 1.5% lower than the weighted version, and 88.7% accumulated accuracy on all domains after adding 100 new domains, which is 0.5% higher than the weighted version. This means we can get a bit higher accumulated accuracy at the cost of sacrificing more new domain accuracy. In real applications, the decision to whether use weighted domain similarity loss should be made by trading off the importance of the new and existing domains.

Varying the number of used negative exemplars: As we mentioned before, we down-sample the negative exemplar set P to reduce the impact on new domain performance. To see if it's necessary, we compare it against the one without down-sampling. Our experiments show that without down-sampling, the model achieves 87.5% new domain accuracy on average which is 8.1% lower than the down-sampling version, and 87.2% accumulated accuracy on all domains which is 1.0% lower than the down-sampling one.



(a) (b) (c) (d)

Figure 4: Model performance by varying the hinge loss thresholds. (a) and (b) shows accuracy on new domain and accumulated accuracy for all seen domains respectively by varying Δ_{pos}. Similarly, (c) and (d) shows the accuracy performance by varying Δ_{neg}.

Prediction Method	**100 initial domains**	**500 initial domains**	**900 initial domains**
Linear	95.2	93.9	93.4
Cosine	94.5	92.9	92.4

Table 1: Linear dot product versus Cosine normalization on initial training for different number of domains.

This means down-sampling effectively improve the model performance.

Effect of Cosine normalization in initial training: We have shown Cosine normalization with hinge loss works better than linear dot product with sigmoid loss (used in SHORTLISTER) for CDA. Here we compare the two on the regular training setting where we train the model from scratch on a large dataset. Specifically, we compare the initial training performance on 100, 500, and 900 domains which are the same as we used earlier. Table 1 shows the accuracy numbers. From the table we see that Linear works better than Cosine by 0.7-1.0% across different number of domains. Though the difference is not large, this means Linear could be a better option than Cosine when we train the model from scratch.

Varying the order of the new domains: To see if the incoming order of the new domains will affect the performance, we generate two different orders apart from the one used in overall evaluation. The first one sorts the new domains on the number of utterances in the decreasing order, and the second in the increasing order. Denote these three orders as "random", "decreasing", and "increasing", and we conduct domain adaptation on these orders. Our experiments show that they achieve 95.6%, 95.5%, and 95.6% average accuracy on new domains respectively, and 88.2%, 88.2%, and 88.1% accumulated accuracy on all domains after accommodating all 100 new domains. This indicates that there is no obvious difference on model performance, and our model is insensitive to the order of the new domains.

Using more new domains: We also experimented with adding a large number of new domains to see the limit of CONDA. Figure 6 shows the results by continuously adapting 900 new domains one-by-one. From the figure we can see that at the early stage of the new domain adaptation (e.g., first 200 new domains), we get high new domain accuracy with little performance decrease on the existing domains. After that, the new domain performance becomes more unstable with violent oscillation, and the existing domain accuracy decreases more quickly. This suggests that we cannot run the new domain adaptation forever, and

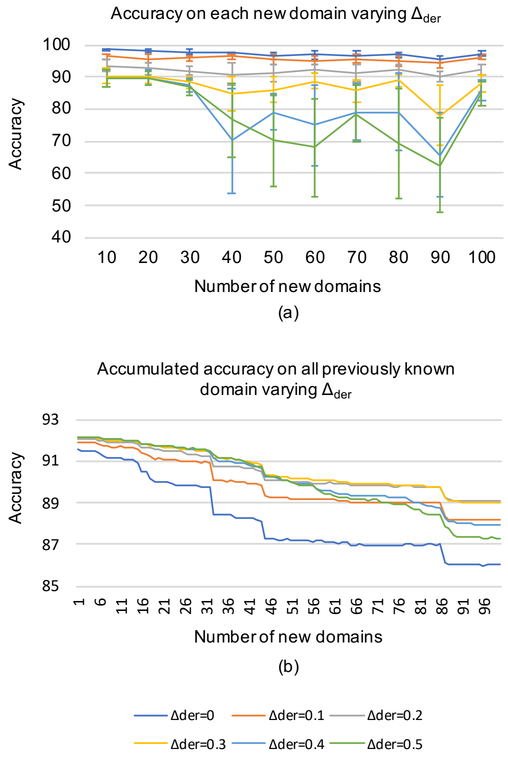


Figure 5: Model performance by varying Δ_{der}. (a) shows the accuracy on new domains, and (b) shows the accumulated accuracy for all seen domains.

after adapting a certain number of new domains (e.g., 200 new domains), it's more preferable to train the whole model from scratch.

5 Related Work

Domain Classification: Traditional domain classifiers were built on simple linear models such as Multinomial logistic regression or Support Vector Machines (Tur and De Mori, 2011). They were typically limited to a small number of domains which were designed by specialists to be well-separated. To support large-scale domain classification, (Kim et al., 2018b) proposed SHORTLISTER, a neural-based model. (Kim et al., 2018a) extended SHORTLISTER by using additional contextual information to rerank the predictions of SHORTLISTER. However, none of them can continuously accommodate new domains without full model retrains.

Continuous Domain Adaptation: To our knowledge, there is little work on the topic of continuous domain adaptation for NLU and IPDAs. (Kim et al., 2017) proposed an attention-based method for continuous domain adaptation, but it introduced a separate model for each domain and therefore is difficult to scale.

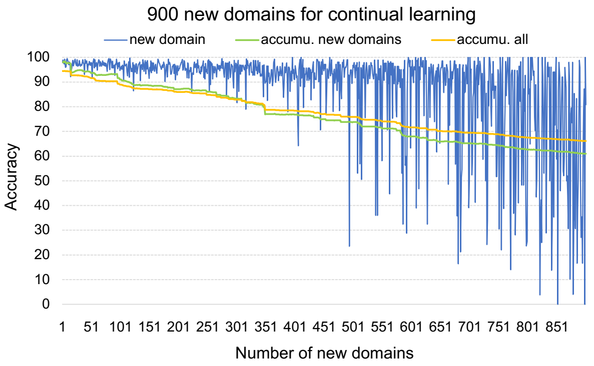

Figure 6: Using 900 new domains for continual learning.

Continual Learning: Several techniques have been proposed to mitigate the catastrophic forgetting (Kemker et al., 2018). Regularization methods add constraints to the network to prevent important parameters from changing too much (Kirkpatrick et al., 2017; Zenke et al., 2017). Ensemble methods alleviate catastrophic forgetting by explicitly or implicitly learning multiple classifiers and using them to make the final predictions (Dai et al., 2009; Ren et al., 2017; Fernando et al., 2017). Rehearsal methods use data from existing domains together with the new domain data being accommodated to mitigate the catastrophic forgetting (Robins, 1995; Draelos et al., 2017; Rebuffi et al., 2017). Dual-memory methods introduce new memory for handling the new domain data (Gepperth and Karaoguz, 2016). Among the existing techniques, our model is most related to the regularization methods. However, unlike existing work where the main goal is to regularize the learned parameters, we focus on regularizations on the newly added parameters. Our model also shares similar ideas to (Rebuffi et al., 2017) on the topic of negative exemplar sampling.

6 Conclusion and Future Work

In this paper, we propose CONDA for continuous domain adaptation. By using various normalization and regularizations, our model achieves high accuracy on both the accommodated new domains and the existing known domains, and outperforms the baselines by a large margin. For future work, we consider extending the model to handle unknown words. Also, we want to find a more principled way to down sample the negative exemplars.

Abstract

One of the first steps in the utterance interpretation pipeline of many task-oriented conversational AI systems is to identify user intents and the corresponding slots. Since data collection for machine learning models for this task is time-consuming, it is desirable to make use of existing data in a high-resource language to train models in low-resource languages. However, development of such models has largely been hindered by the lack of multilingual training data. In this paper, we present a new data set of 57k annotated utterances in English (43k), Spanish (8.6k) and Thai (5k) across the domains weather, alarm, and reminder. We use this data set to evaluate three different cross-lingual transfer methods: (1) translating the training data, (2) using cross-lingual pre-trained embeddings, and (3) a novel method of using a multilingual machine translation encoder as contextual word representations. We find that given several hundred training examples in the the target language, the latter two methods outperform translating the training data. Further, in very low-resource settings, multilingual contextual word representations give better results than using cross-lingual static embeddings. We also compare the cross-lingual methods to using monolingual resources in the form of contextual ELMo representations and find that given just small amounts of target language data, this method outperforms all cross-lingual methods, which highlights the need for more sophisticated cross-lingual methods.

1 Introduction

One of the first steps in many conversational AI systems that are used to parse utterances in personal assistants is the identification of what the user intends to do (the *intent*) as well as the arguments of the intent (the *slots*) (Mesnil et al., 2013; Liu and Lane, 2016). For example, for a request such as *Set an alarm for tomorrow at 7am*, a first step in fulfilling such a request is to identify that the user's intent is to set an alarm and that the required time argument of the request is expressed by the phrase *tomorrow at 7am*.

Given these properties of the task, the problem can be stated as a joint sentence classification (for intent classification) and sequence labeling (for slot detection) task and therefore naturally lends itself to using a biLSTM-CRF sequence labeling model (Lample et al., 2016; Vu, 2016) where the biLSTM layer is also used as the input for a projection layer for intent detection.

These models are very powerful and given enough training data, they achieve very high accuracy on the intent classification as well as the slot detection task. However, given the requirement of large amounts of labeled training data, developing a conversational AI system for many new languages is a very resource-intensive task and clearly not feasible to be done for the more than 6,500 languages that are currently spoken around the world.

For this reason, one would like to make use of methods that enable transfer learning from a high-resource language to a low-resource language. However, the development of sophisticated cross-lingual transfer methods for intent detection and slot filling has so far been hindered by the lack of multilingual data sets that have been annotated according to the same guidelines.[1] In this work, we therefore present a novel data set containing a large number of English utterances (the high-resource data) as well as a smaller set of utterances in Spanish and in Thai (the low-resource data), which were annotated according to the same annotation scheme. This data allows the systematic in-

Proceedings of NAACL-HLT 2019, pages 3795–3805
Minneapolis, Minnesota, June 2 - June 7, 2019.

Domain	Number of utterances English	 Spanish	 Thai	Intent types	Slot types
Alarm	9,282/1,309/2,621	1,184/691/1,011	777/439/597	6	2
Reminder	6,900/943/1,960	1,207/647/1,005	578/336/442	3	6
Weather	14,339/1,929/4,040	1,226/645/1,027	801/460/653	3	5
Total	30,521/4,181/8,621	3,617/1,983/3,043	2,156/1,235/1,692	12	11

Table 1: Summary statistics of the data set. The three values for the number of utterances correspond to the number of utterances in the training, development, and test splits. Note that the slot type *datetime* is shared across all three domains and therefore the total number of slot types is only 11.

vestigation of cross-lingual transfer learning methods from high-resource languages to low-resource languages.

We use this data set to explore different strategies to make use of training data from a high-resource language to improve intent and slot detection models for other languages. We investigate two previously proposed strategies for cross-lingual transfer, namely using cross-lingual pre-trained embeddings (XLU embeddings; see Ruder et al., 2017 for a review) as well as automatically translating the English training data to the target language. Further, we present a novel technique that uses a bidirectional neural machine translation encoder as cross-lingual contextual word representations. We compare the cross-lingual transfer methods to models that are only trained on the target language data.

Across the two languages and the various transfer methods, we find that joint training on the high-resource and the low-resource target language improves results on the target language. We further find that the optimal choice of transfer method depends on the size of the available training data in the target language: In the zero-shot case where no target language data is available, translating the training data gives the best results. However, if a small amount of training data is available, we find that jointly training on the high-resource and low-resource data works better than training on translated data.

We release the data at `https://fb.me/multilingual_task_oriented_data`.

2 Data

We originally collected a data set of around 43,000 English utterances across the domains ALARM, REMINDER, and WEATHER. Data collection proceeded in three steps. First, native English speakers were asked to produce utterances for each intent, e.g., provide examples of how they would ask for the weather. In a second step, two annotators would label the intent and the spans corresponding to slots for each utterance. As a third step, if annotators disagreed on the annotation of an utterance, a third annotator who corresponded with the authors of the guidelines adjudicated between the two annotations.

For the Spanish and Thai data, native speakers of the target language translated a sample of the English utterances. These translated utterances were then also annotated by two annotators. For Spanish, if annotators disagreed, a third annotator who was bilingual in Spanish and English adjudicated these disagreements in communication with the guideline authors. Unfortunately, for Thai, we did not have a bilingual speaker available and hence we decided to discard all utterances for which the annotators disagreed. We hope to rectify this for future data collection efforts.

We believe this data presents a great opportunity to investigate cross-lingual semantic models and to the best of our knowledge, this is the first parallel data set for a word tagging task that has been annotated according to the same guidelines across multiple languages.

Table 1 contains several summary statistics of the data set. Note that the percentage of training examples as compared to development and test examples is much higher for the English data than for the Thai and Spanish data. We decided for a more even split for the latter two languages so that we had a sufficiently large data set for model selection and evaluation.

3 NLU models

The intent detection and slot-filling model consists of two parts: It first uses a sentence classification model to identify the domain of the user utterance (in our case, ALARM, REMINDER, or WEATHER), and then uses a domain-specific model to jointly predict the intent and slots. Figure 1 shows the ba-

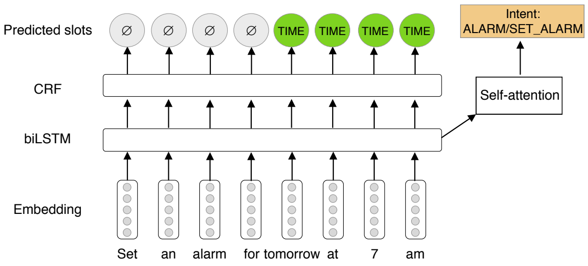

Figure 1: Slot and intent model architecture. Word embeddings are passed through a biLSTM layer which is shared across the slot detection and intent prediction tasks.

sic architecture of the joint intent-slot prediction model. It first embeds the utterance using an embedding matrix and then passes the word vectors to a biLSTM layer. For intent classification, we use a self-attention layer (Lin et al., 2017) over the hidden states of the biLSTM as input to a softmax projection layer; for slot detection, we pass for each word the concatenation of the forward and backward hidden states through a softmax layer, and then pass the resulting label probability vectors through a CRF layer for final predictions.

In our experiments, we vary how the tokens are embedded:

- **Zero embeddings**: We train the parameters of a 0-initialized embedding matrix that contains each word that appears in the training data.

- **XLU embeddings**: We embed the tokens through lookup in a pre-trained cross-lingual embedding matrix and concatenate these embeddings with tuned zero embeddings. Here, we follow Dozat et al. (2017) in having a fixed pre-trained embedding matrix combined with tuneable zero-embeddings.

- **Encoder embeddings**: We embed tokens by passing the entire utterance through a pre-trained biLSTM sentence encoder and using the hidden states of the top layer as input. We keep the parameters of the pre-trained encoder fixed and concatenate them with tuneable zero-embeddings. (See Section 4 for a detailed description of the different encoders.)

4 Encoder models

As mentioned in the previous section, some of our models use a pre-trained biLSTM encoder to generate contextual word embeddings. In all our experiments, we use a bidirectional LSTM encoder with two layers. Overall, we compare three strategies for training these encoders. The motivation for choosing these strategies is to investigate whether there is a benefit of using multilingual embeddings.

- **CoVe**: Following McCann et al. (2017), we train a neural machine translation model to translate from the low-resource language (Spanish or Thai) to English.

- **Multilingual CoVe**: We train a neural machine translation model to translate from the low-resource language to English and from English to the low-resource language. We encode the translation direction using target language-specific start tokens in the decoder (Yu et al., 2018a). In this model, the encoder does not have access to the target language and therefore we expect it to learn to encode phrases with similar meanings into similar vector spaces across languages.

- **Multilingual CoVe w/ autoencoder:** We train a bidirectional neural machine translation model and combine it with an autoencoder objective. For the language pair Spanish-English, that means given a Spanish input sentence we train the model to generate either an English translation or to reproduce the Spanish sentence depending on the start token in the decoder. Likewise, given an English sentence, we train the model to output either a Spanish translation or to reproduce the English sentence depending on the start token in the decoder. The motivation for this approach is that using the joint translation and autoencoder objective might lead to more general representations since the decoder has to be capable to output sentences in either language independent of what the source language was, and unlike in the previous model the source language does not determine the target language. We train an analogous model for the Thai-English language pair.

Spanish	Epoch	es→en	en→es	es→es	en→en
CoVe (unidirectional)	81	8.50	-	-	-
Mult. CoVe	98	8.27	6.90	-	-
Mult. CoVe + autoencoder	282	9.15	7.29	1.15	1.14
Thai	Epoch	th→en	en→th	th→th	en→en
CoVe (unidirectional)	12	13.06	-	-	-
Mult. CoVe	35	12.73	17.00	-	-
Mult. CoVe + autoencoder	92	11.76	16.31	1.12	1.13

Table 2: Perplexities on validation set for different encoder models for the Spanish-English and Thai-English language pairs. A hyphen means that an encoder was not trained for the corresponding language pair.

For Spanish, for which pre-trained ELMo (Peters et al., 2018) embeddings are available, we also evaluate the use of the ELMo embeddings by Che et al. (2018); Fares et al. (2017). Note that the ELMo encoder and the CoVe encoder are trained to encode only the low-resource language and therefore neither of them are multilingual encoders.

Implementation details We train all models using a wrapper around the fairseq (Gehring et al., 2016, 2017) sequence-to-sequence models. We use 300d randomly initialized word vectors as input to the first embedding layer. Each direction in each hidden layer has 512 dimensions which results in a total encoder output dimension of 1024. For the machine translation models, we further use dot-product attention (Luong et al., 2015) and to improve efficiency, we limit the output space of the softmax to 30 translation candidates as determined by word alignments as well as the 2,000 most frequent words (L'Hostis et al., 2016).

Data For the Spanish models, we use two copies[2] of Europarl v7 (Koehn, 2005), every eighth sentences of the Paracrawl data,[3] and the newstest2008-2011 data. For model selection, we use the newstest2012-2013 data. For the Thai models, we use 10 copies of the IWSTL training data (Cettolo et al., 2012) as well as the OpenSubtitles data (Lison et al., 2018) for training, and the IWSTL development and test data for model selection. We use the 20,000 most common words in the training data as the vocabulary. For the multilingual models, we take the union of the vocabulary from both languages. We tokenize the data using an in-house rule-based (for English and Spanish) and dictionary-based (for Thai) tokenizer. We further lowercase all data and remove all duplicates within a data set. We discard all sentences whose length exceeds 100 tokens.

Training details We train the models using stochastic gradient descent with an initial learning rate of 0.5. We decrease the learning rate by 1% after an epoch whenever perplexity on the validation data is higher than for the epoch with the lowest perplexity. We train all models for up to 100 epochs, except for the Spanish bidirectional MT model with an autoencoder which we trained for 300 epochs since it took considerably longer to converge. For multilingual models, we choose the model that has the lowest average perplexity on both translation tasks.

Table 2 shows the perplexities for the different models. In general, the translation perplexities are very similar independent of whether we train a unidirectional MT system or a bidirectional MT system, except for the Spanish bidirectional MT model with an autoencoder which even after 300 epochs still yields higher perplexities on the validation data than the other translation models.[4]

5 Cross-lingual learning

In our first set of experiments, we explore the following baselines and strategies for training models in Spanish and Thai given a large amount of English training data and a small amount of Spanish and Thai training data.

- **Target only**: Using only the low-resource target language data.

---

[2] We upsample the Europarl (for Spanish) and IWSLT (for Thai) data since these data sets are presumably of higher quality than the largerly automatically mined Paracrawl and OpenSubtitles data.

[3] https://paracrawl.eu, the version that was used in the WMT 2018 task

[4] We hypothesize that the slow convergence as well as the lower performance might be caused by the fact that the sentences in the Spanish-English parallel data are much longer than in the Thai-English data which might make it harder to learn good universal sentence representations.

English	Embedding type	Exact match	Domain acc.	Intent acc.	Slot F1
Target only	-	90.91	-	99.11	94.81
Spanish	Embedding type	Exact match	Domain acc.	Intent acc.	Slot F1

Table 3: Results using the full training data averaged over 5 training runs. The *translate train* models are trained on the union of translated English and target language data; the *cross-lingual* models are trained on English and target language data.

- **Target only with encoder embeddings**: Using only the low-resource language training data and using pre-trained encoder embeddings.
- **Translate train**: Combining the target training data with the English data that has been automatically translated to the target language. The slot annotations are projected via the attention weights (Yarowsky et al., 2001). We translate the data using the Facebook neural machine translation system.
- **Cross-lingual with XLU embeddings**: Joint training on the English and target language data with pre-trained MUSE (Conneau et al., 2017) cross-lingual embeddings. Since MUSE embeddings are not available for Thai, we only evaluate this method for Spanish.
- **Cross-lingual with encoder embeddings**: Joint training on the English and target language data using pre-trained encoder embeddings.

Implementation details We implement all classification and sequence labeling models within the PyText framework (Aly et al., 2018). We train models for 20 epochs and select the model that performs best on the development set. We use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.01. We use dropout of 0.3 in the BiLSTM and we set the size of the self-attention layer to 128 dimensions.

Evaluation We evaluate our models according to four metrics: Domain accuracy, which measures the accuracy of the domain classification task; intent accuracy, which measures the accuracy of identifying the correct intent; slot F1, which is the geometric mean of the slot precision and slot recall; and the exact match metric, which indicates the number of utterances for which the domain, intent, and all slots were correctly identified. Exact match is thus the strictest metric of all. We micro-average all metrics across domains.

Results and discussion Table 3 shows the results for all evaluated models. While we get

Spanish	Embedding type	Exact match	Domain acc.	Intent acc.	Slot F1
Translate train	-	**54.95**	**88.70**	**85.39**	**72.87**
Cross-lingual	-	0.63	37.74	36.17	5.50
Cross-lingual	XLU embeddings	4.01	38.24	36.94	17.50
Cross-lingual	CoVe	1.37	39.42	37.13	5.35
Cross-lingual	mult. CoVe	10.56	59.29	53.34	22.50
Cross-lingual	mult. CoVe + auto	9.28	59.25	53.89	19.25
Cross-lingual	ELMo	0.18	35.98	35.36	2.53

Thai	Embedding type	Exact match	Domain acc.	Intent acc.	Slot F1

Cross-lingual	-	0.20	39.36	39.11	3.44
Cross-lingual	CoVe	5.82	66.75	54.24	8.84
Cross-lingual	mult. CoVe	15.37	73.84	66.35	32.52
Cross-lingual	mult. CoVe + auto	20.84	81.95	70.70	35.62

Table 4: Zero-shot results averaged over 5 training runs. All models were trained only on the English data. In the case of the *translate train* models, the English data was automatically translated into the target language.

slightly different results for the two languages, there are several consistent patterns. For Spanish, we observe that adding contextual word representations to the *target only* model, consistently improves results. Not surprisingly since the ELMo embeddings were trained on a large monolingual corpus, the model that uses these embeddings outperforms all other *target only* models.

If we turn to the cross-lingual models for Spanish, the results indicate that the translation method works well for domain and intent classification but less so for slot detection, presumably due to noisy projection of the slot annotations. For slot detection, we get the best results using the ELMo embeddings which outperform the XLU embeddings as well as the bidirectional MT encoder in terms of exact match and slot F_1. Similarly as in the *target only* setting, the model with multilingual CoVe embeddings combined with the autoencoder performs worse than the other CoVe encoders. Overall, however, the choice of embeddings seems to have only a relatively small impact on the performance of the cross-lingual models. Importantly, however, we see improvements across all metrics as compared to training only on the target language data.

We observe similar results for Thai. The translation approach again yields the worst results for slot detection and we again see a consistent improvement from cross-lingual training as compared to training only on Thai data. And we again only observe small differences depending on the type of embeddings in the cross-lingual training scenario, but in this case, the models with the multilingual CoVe encoders outperform the model with the monolingual encoder.

Table 3 also shows the results for English. Not surprisingly, since we have an order of magnitude more data for English, the model trained and tested on English data still performs better than any of the evaluated methods for the other two languages. However, the gap between the numbers for English and the numbers for the other two languages does get considerably smaller for the cross-lingual models. Prima facie, the results also indicate that the models perform better for Thai than for Spanish. However, this is potentially an artifact of the data. As we mentioned above, we had to discard some of the Thai utterances for which the annotations disagreed with the annotations of their English translations and it is possible that we discarded a disproportionate number of more complex utterances which in return made parsing the Thai utterances easier.

In summary, the results from both languages suggest that pre-trained word representations as well as cross-lingual training improve results over training only on target language data without any pre-trained embeddings. The choice of embeddings, however, seems to matter less, and the overall performance seems to depend only very little on whether we use dynamic or static word representations or whether we use monolingual or bilingual word representations.

However, interestingly, for Spanish for which we compared more types of word representations than for Thai, the cross-lingual model with monolingual ELMo embeddings provided the best results. This potentially indicates that the benefit of cross-lingual training comes from sharing the biLSTM layer or the CRF layer and that embedding the tokens of the high-resource and the low-resource language in a similar space is not as important. At the same time, considering that we are getting relatively good results for both languages if we only train on the target language data, the potential of cross-lingual training might be limited in this case. To investigate whether the embedding type matters in more extreme low-resource scenarios, we also performed a series of zero-shot and low-resource experiments, which we describe in the next section.

6 Zero-shot learning and learning curves

As mentioned in the previous section, from the results on the full data, it is not entirely clear whether there is an advantage of using cross-lingual embeddings. We therefore conducted additional experiments with even smaller training sets in the target language: the case where we no annotated data in the target language exists (zero-shot) and the case where a very limited amount of training data in the target language exists. If there is no advantage of using cross-lingual embeddings over using monolingual embeddings, we expect to see similar results for all models independent of the training data size. On the other hand, if the multilingual CoVe encoder actually embeds phrases with similar meanings in the two languages in a similar vector space, we would expect the model with multilingual CoVe embeddings to perform much better in the zero-shot and very low-resource scenarios than any of the models with monolingual embeddings. Further, we can also investigate whether there is an advantage of translating the training data over other methods in extremely low-resource scenarios.

Experiments We used the same models with the same parameters as in the previous section. In the zero-shot case, we only use English data for training and model selection. For the learning curve experiments, we sample 10, 50, 100, or 200 utterances from each domain for the target language for training and model selection and upsample the target language data so that it roughly matches the size of the English data. For the zero-shot results, we present the average numbers across 5 runs. For the learning curve experiments, since we introduced another random factor by randomly sampling the training and model selection data, we repeat this process 10 times and report the average as well as the minimum and maximum values of the exact match metric for these experiments.

Results and discussion Table 4 shows the zero-shot results. These results indicate that using the multilingual CoVe embeddings works better than not using any encoder embeddings or using monolingual CoVe embeddings. This is true for the sentence-level domain and intent classification tasks as well as for slot detection. The Spanish results also suggest that in the zero-shot case, the multilingual encoder embeddings lead to better results than the XLU embeddings. However, also the models that use cross-lingual embeddings perform very poorly and contrary to the case where we have some training data in the target language, in the zero-shot scenario, the translation method works considerably better than any other of the transfer methods.

The results for different training set sizes are shown in Figure 2. These results generally confirm the patterns that we observed in the experiments with all available training data: cross-lingual training improves the results over training only on the target language (to a much bigger extent when there is much less target language training data available) and using pre-trained word representations leads to further improvements. We further observe that cross-lingual learning seems to lead to much more stable training which can be seen in the much smaller ranges of results as compared to the models trained only on the target language. Also in the extremely low-resource scenarios, the choice of embeddings seems to have very little effect. Lastly, as these plots show, the translation approach works better when there is very little training data available but the performance quickly plateaus and once there are are several hundred target language training examples available, joint training on multiple languages leads to better results.

Considering all results together, we find a consistent advantage of using cross-lingual training across all languages, training set sizes and embedding types. We further observe that the choice of embedding type has little effect as long as some form of pre-trained embeddings is being used. These facts together suggest that the main advantage of cross-lingual training comes from sharing the biLSTM and CRF layer across languages.

Figure 2: Results for different training set sizes. The top and the bottom of the error bars correspond to the highest and lowest value of the exact match metric among the 10 runs.

This is in line with the results by de Lhoneux et al. (2018) who found for cross-lingual training of dependency parsers, sharing the MLP layer for parser decisions improved results for all language pairs that they considered, whereas sharing of lower-level parameters only led to improvements for a limited set of language pairs.

7 Related work

Cross-lingual sequence labeling The task of cross-lingual and multilingual sequence labeling has gained a lot of attention recently. Yang et al. (2017) used shared character embeddings for cross-lingual transfer, and Lin et al. (2018) used shared character and sentence embeddings that were trained in a multitask setting for part-of-speech tagging and named entity recognition. Upadhyay et al. (2018) used cross-lingual embeddings for training multilingual slot-filling systems. Xie et al. (2018) used a similar model for NER but they first “translated” the high-resource training data by replacing each token with the token in the target language that was closest in vector space, and they further used character embeddings and a self-attention mechanism. Yu et al. (2018b) investigated using character-based language models for NER in several languages but did not do any cross-lingual learning. Plank and Agić (2018) used cross-lingual embeddings, projected annotations, and dictionaries for zero-shot cross-lingual part-of-speech tagging.

Cross-lingual sentence representations Recently, there was also a lot of work of using cross-lingual sequence encoders for sentence classifications using either multilingual MT encoders similar to ours (e.g., Eriguchi et al., 2018; Yu et al., 2018a; Singla et al., 2018) or training encoders and then aligning their vector spaces after pretraining (Conneau et al., 2018; Schuster et al., 2019). Even more recently, Lample and Conneau (2019) and Mulcaire et al. (2019) showed that it is also possible to directly train contextual word representations jointly on multiple languages.

Cross-lingual transfer for other tasks Apart from tasks such as slot filling and NER, cross-lingual transfer learning has also been investigated a lot for syntactic tasks, and in particular for part-of-speech tagging and dependency parsing. Early work trained part-of-speech taggers for individual languages and then trained delexicalized dependency parsers (e.g., Zeman and Resnik, 2008; McDonald et al., 2011). Further, a lot of syntactic and semantic parsing models recently successfully incorporated parameter sharing for training parsers in closely related langauges (Duong et al., 2015; Ammar et al., 2016; Susanto and Lu, 2017; Smith et al., 2018; de Lhoneux et al., 2018). In the domain of dialog managers, Mrkšić et al. (2017) and Chen et al. (2018) presented methods for cross-lingual transfer for dialog state tracking.

8 Conclusion and future work

In this paper, we presented a new multilingual intent and slot filling data set for task oriented dialog of around 57,000 utterances and evaluated the performance of different methods for cross-lingual transfer learning, including a novel method using cross-lingual contextual word representations. For both investigated languages, we consistently found that cross-lingual learning improves results as compared to only training on limited amounts of target language data, and our results suggest that the choice of multilingual or monolingual embeddings has only a small impact on the overall performance.

Despite the range of models that we considered in this paper, we only scratched at the surface of possible cross-lingual (embedding) models, and hence there are many future directions of this work. First, except for the Spanish ELMo embeddings, we did not use any character embeddings in any of our experiments or models. This presumably makes sense for the English-Thai transfer learning case since these two languages use different writing systems but given the results by Lin et al. (2018) and Yang et al. (2017), we would expect additional improvements by sharing character embeddings for languages with similar writing systems.

Second, one could try to include a specific learning objective to embed translations into a similar vector space as used by Yu et al. (2018a) and Conneau et al. (2018) for multilingual sentence representations.

As yet another extension, one could combine the approaches of multilingual CoVe embeddings and monolingual ELMo (or BERT, Devlin et al., 2018) embeddings and jointly train an encoder with a language model and an MT objective, which would potentially combine the benefit of training a model on large monolingual corpora while at the same time aligning the vector spaces of the two languages. A similar approach worked well for cross-lingual NLI inference on the XNLI data set (Conneau et al., 2018) as well as for unsupervised machine translation (Lample and Conneau, 2019).

We hope that our data set will facilitate research in these directions and ultimately lead to improved natural language understanding models for low-resource languages.

Acknowledgements

We thank the three anonymous reviewers for their thoughtful comments. We also thank Luke Zettlemoyer and Christopher Manning for valuable feedback throughout this project, and Maria Sumner and Neghesti Tinsew for their help with collecting the annotations and improving their consistency.

Abstract

Evaluating open-domain dialogue systems is difficult due to the diversity of possible correct answers. Automatic metrics such as BLEU correlate weakly with human annotations, resulting in a significant bias across different models and datasets. Some researchers resort to human judgment experimentation for assessing response quality, which is expensive, time consuming, and not scalable. Moreover, judges tend to evaluate a small number of dialogues, meaning that minor differences in evaluation configuration may lead to dissimilar results. In this paper, we present interpretable metrics for evaluating topic coherence by making use of distributed sentence representations. Furthermore, we introduce calculable approximations of human judgment based on conversational coherence by adopting state-of-the-art entailment techniques. Results show that our metrics can be used as a surrogate for human judgment, making it easy to evaluate dialogue systems on large-scale datasets and allowing an unbiased estimate for the quality of the responses.

1 Introduction

Recently, we have witnessed a big success in the capability of computers to seemingly understand natural language text and to generate plausible responses to conversations (Serban et al., 2016; Xing et al., 2017; Sordoni et al., 2015; Li et al., 2016; Serban et al., 2017; Devlin et al., 2018; Radford et al., 2018). A challenging task of building dialogue systems lies in evaluating the quality of their responses. Typically, evaluating goal-oriented dialogue systems is done via human-generated judgment like a task completion test or user satisfaction score (Walker et al., 1997; Möller et al., 2006). However, the task of evaluating open-ended dialogue systems is not well defined as there is no clear explicit goal for conversations. Indeed, dialog systems are ultimately created to satisfy the user's need which can be associated with how entertaining and engaging the conversation was. It is unclear how to define a metric that can account comprehensibly for the semantic meaning of the responses. Moreover, grasping the underlying meaning of text has always been fraught with difficulties, which are essentially attributed to the complexities and ambiguities in natural language. Generally, a good dialogue can be described as an exchange of information that sustain coherence through a train of thoughts and a flow of topics. Therefore, a plausible way to evaluate open-ended dialogue systems is to measure the consistency of the responses. For example, a neural dialogue system can respond to the utterance "*Do you like animals?*" by "*Yes, I have three cats*", thereafter replies to "*How many cats do you have*" by "*I don't have cats.*". Here, we can notice that the dialogue system failed to provide a coherent answer and instead generated an inconsistent response.

In this work, we characterize the consistency of dialogue systems as a natural language inference (NLI) (Dagan et al., 2006) problem. In particular, NLI is focused on recognizing whether a hypothesis is inferred from a premise. In dialogue systems, we cast a generated response as the hypothesis and the conversation history as the premise, projecting thus the automatic evaluation into an NLI task. In other words, we propose directly calculable approximations of human evaluation grounded on conversational coherence and affordance by using state-of-the-art entailment techniques. For this purpose, we build a synthesized inference data from conversational corpora. The intuition behind this choice is motivated by the fact that utterances in a human conversation tend to follow a consistent and coherent flow where each utterance can be inferred from the previous interactions. We train the state-of-the-art infer-

ence models on our conversational inference data and then the learned models are used to evaluate the coherence in a given conversation. Finally, we fare our proposed evaluation method against existing automated metrics. The results highlight the capability of inference models to automatically evaluate dialogue coherence. The source code and the dataset are available at `https://github.com/nouhadziri/DialogEntailment`

2 Related Work

Evaluating open-ended dialogue systems has drawn the attention of several researchers in recent years. Unfortunately, word-overlapping metrics such as BLEU have been shown to correlate weakly with human evaluation, which in turn, introduces bias against certain models (Liu et al., 2016). Many studies have been proposed to improve the quality of automated metrics. In particular, Lowe et al. (Lowe et al., 2017) introduced an automatic evaluation system called ADEM which learns to score responses from an annotated dataset of human responses scores. However, such system is heavily biased towards the training data and struggles with generalization capabilities on unseen datasets. Further, collecting an annotated gold standard of human judgment is very expensive and thus, ADEM is less flexible and extensible. Venkatesh et al. (Venkatesh et al., 2018) introduced a framework for evaluating the quality of the conversations based on topical diversity, coherence, engagement and conversational depth and showed that these metrics conform with human evaluation. However, a big part of their metrics relies on human labels, which makes the evaluation system not scalable. Recently, Welleck et al. (Welleck et al., 2018) investigated the use of NLI models (e.g., ESIM (Chen et al., 2016) and InferSent (Conneau et al., 2017)) to measure consistency in dialogue systems. They built a Dialogue NLI dataset which consists of sentence pairs labeled as entailment, neutral, or contradiction. The utterances are derived from a two-agent persona-based dialogue dataset. To annotate the dataset, they used human annotation from Amazon Mechanical Turk. In this work, we propose a method that employs NLI approaches to detect coherence in dialogue systems. The proposed evaluation procedure does not require human labels, making progress towards scalable and autonomous evaluation systems.

3 Natural Language Inference

Reasoning about the semantic relationship between two utterances is a fundamental part of text understanding. In this setting, we consider inference about entailment as a useful testing bed for the evaluation of coherence in dialogue systems. The success of NLI models[1] allows us to frame automated dialogue evaluation as an entailment problem. More specifically, given a conversation history H and a generated response r, the goal is to understand whether the premise-hypothesis pair (H, r) is entailing, contradictory, or neutral.

3.1 Coherence in Dialogue Systems

The essence of neural response generation models is designed by maximizing the likelihood of the target response given source utterances. Therefore, a dialogue generation task can be formulated as a next utterance prediction problem. In particular, the model predicts a response u_{i+1} given a conversation history $(u_1, ..., u_i)$. One key factor for a successful conversation is having coherence across multiple turns. A machine's response can be considered as incoherent when it contradicts directly its previous utterances or follows an illogical reasoning throughout the whole conversation. Inconsistency can be clearly identified when it corresponds to logical discrepancy between two facts. For example, when you indicate clearly during the conversation that you have cats but when you get asked "*How many cats do you have*", you answer by "*I don't have cats.*". Nevertheless, in general, inconsistency can be less explicitly recognizable as it may describe an error between what the person has said and what she/he truly believes given her/his personality and background information.

To detect dialogue incoherence, we consider two prominent models that have shown promising results in commonsense reasoning: the Enhanced Sequential Inference Model (ESIM) (Chen et al., 2016) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018):

ESIM (Chen et al., 2016): employs a Bi-LSTM model (Graves and Schmidhuber, 2005) to encode the premise and the hypothesis. Also, it explores the effectiveness of syntax for NLI by encoding syntactic parse trees of premise and hypothesis through Tree-LSTM (Zhu et al., 2015). Then, the

---

[1] Recent models have achieved high accuracy in Stanford NLI corpus (Bowman et al., 2015) (90.1%) and GLUE Benchmark (Wang et al., 2018) (86.7%)

input encoding part is followed by a matrix attention layer, a local inference layer, another BiLSTM inference composition layer, and finally a pooling operation before the output layer. We further boost ESIM with by incorporating contextualized word embeddings, namely ELMo (Peters et al., 2018), into the inference model.

BERT (Devlin et al., 2018): exploits a multi-layer Bidirectional Transformers model (Vaswani et al., 2017) to learn pre-trained universal representations of text using only a plain text corpus from Wikipedia. BERT has achieved state-of-the art results on various natural language understanding tasks and has been shown to handle strongly long-range dependencies in text. BERT can be fine-tuned to achieve several tasks by solely adding a small layer to the core model. In this work, we adopted BERT to the task of NLI.

Overall, the goal of the above models is to learn a function G_{NLI} that predicts one of three categories (i.e., entailment, contradiction or neutral) given premise-hypothesis pairs.

4 Inference Corpus for Dialogues

To train the inference models, we build a synthesized dataset geared toward evaluating consistency in dialogue systems. To this end, the Persona-Chat conversational data (Zhang et al., 2018) is used to form the basis of our conversational inference data. The continuity of utterances in human conversation facilitates the use of entailment in the dialogue domain. Typically, when we interact with one another, we tend to reference information from previous utterances to engage with the interlocutor. This is why we build our synthetic inference dataset upon a dialogue corpus. The Persona-Chat corpus is a crowd-sourced dataset where two people converse with each other based on a set of randomly assigned persona. To build an inference corpus, we need to find three different labels (i.e., *entailment*, *contradiction*, and *neutral*). For this purpose, we map an appropriate and on topic response to the *entailment* label. Consequently, the *entailment* instances are derived from the utterances in the conversations. For *contradiction*, grammatically-impaired sentences are constructed by randomly choosing words from the conversation. We also added randomly drawn contradictory instances from the MultiNLI corpus (Williams et al., 2018) to account for meaningful inconsistencies. Finally, random utterances from other conversations or generic responses such as "*I don't know*" comprise the *neutral* instances. Following this approach, we build a corpus of 1.1M premise-hypothesis pairs, namely **InferConvAI**. Table 1 summarizes the statistics of InferConvAI.

	Train	**Dev**	**Test**
#entailment	218.2K	12.2K	1.4K
#neutral	579.5K	28.0K	3.1K
#contradiction	261.9K	9.8K	1.1K
Total	1.1M	50.2K	5.6K

Table 1: Distribution of labels in the InferConvAI corpus.

5 Experiments

In this section, we focus on the task of evaluating the next utterance given the conversation history. We used the following models to generate responses. These models were trained on the conversational datasets, using optimization, until convergence:

- Seq2Seq with attention mechanism (Bahdanau et al., 2015): predicts the next response given the previous utterance using an encoder-decoder model.
- HRED (Serban et al., 2016): extends the Seq2Seq model by adding a context-RNN layer that accounts for contextual information.
- TA-Seq2Seq (Xing et al., 2017): extends the Seq2Seq model by biasing the overall distribution towards leveraging topic words in the response.
- THRED (Dziri et al., 2018): builds upon TA-Seq2Seq model by levering topic words in the response in a multi-turn dialogue system.

The training was conducted on two datasets: OpenSubtitles (Tiedemann, 2012) and Reddit (Dziri et al., 2018). Due to lack of resources, we randomly sampled 6M dialogues as training data from each dataset, 700K dialogues as development data, and 40K dialogues as test data. Each dialogue corresponds to three turn exchanges. To evaluate accurately the quality of the generated responses, we recruited five native English speakers. The judges annotated 150 dialogues from Reddit

E$_{\text{word2vec}}$	-0.065	0.118

Table 3: The Pearson Correlation between different metrics and human judgments with p-value < 0.001. The semantic similarity (SS) metric is measured with respect to the most recent utterance H_{-1} and the most recent two utterances H_{-2} in the conversation history. We adopt different embedding algorithms to compute the word vectors: ELMo (Peters et al., 2018), BERT (Devlin et al., 2018), word2vec (Mikolov et al., 2013) and Universal Sentence Encoder (USE) (Cer et al., 2018).

and 150 dialogues from OpenSubtitles. All subjects have informed consent as required from the Ethics Review Board at the University of Alberta. Due to lack of space, we will omit an exhaustive description of the human evaluation process and refer readers to (Dziri et al., 2018) as we conducted the same evaluation procedure.

5.1 NLI in Dialogues

In this section, we evaluate the performance of the state-of-the-art entailment models on predicting a score for the generated utterances. In particular, the conversation history H is treated as a hypothesis, whereas the generated response r acts as a premise. We pick two state-of-the-art NLI models (i.e., ESIM (Chen et al., 2016) and BERT (Devlin et al., 2018)). These models were trained on the InferConvAI dataset. During evaluation, we use our test dialogue corpus from Reddit and OpenSubtitles, in which the majority vote of the 4-scale human rating constitutes the labels. The results are illustrated in Table 2. Both models reach reasonable performance in this setting, while BERT outperforms ESIM. Note that this experiment examines the generalization capabilities of these inference models as the test datasets are drawn from an entirely different distribution than the training corpus. Figure 1 illustrates the performance of BERT for each class with respect to the human scores. The test utterances that are predicted as *entailment* tend to be rated higher than other utterances, exhibiting that the entailment models correlate quite well with what humans perceive as a coherent response. Another observation is that the inference models often classify acontextual and off-topic responses as *neutral* and the annotators typically dislike these types of responses. This contributes to the lower scores of *neutral*-detected responses compared to responses predicted as *contradiction*.

5.2 Automated Metrics

5.2.1 Word-level Metrics

We consider as evaluation metrics baselines three textual similarity metrics (Liu et al., 2016) based on word embeddings: Average (A), Greedy (G), and Extrema (E). These word-level embedding metrics have been proven to correlate with human judgment marginally better than other world-overlap metrics (e.g., BLEU, ROUGE and METEOR) (Liu et al., 2016). One critical flaw of these embedding metrics is that they assume that

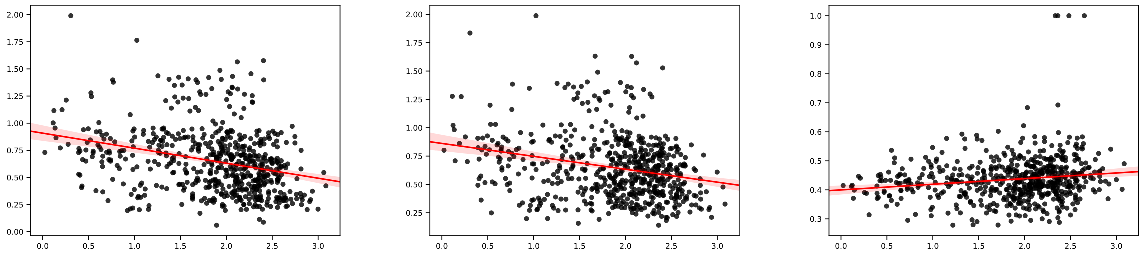

Figure 2: Scatter plots illustrating correlation between human judgment and the automated metrics on the Reddit test dataset. In order to better visualize the density of the points, we added stochastic noise generated by Gaussian distribution $\mathcal{N}(0, 0.1)$ to the human ratings (i.e., horizontal axis) at the cost of lowering correlation, as done in (Lowe et al., 2017). From left to right: SS_{USE} w.r.t. the second most recent utterance (H_{-2}), SS_{USE} w.r.t. the most recent utterance (H_{-1}), and $\text{Extrema}_{\text{BERT}}$

each word is independent of the other words in the sentence. Further, the sentence is treated as a bag-of-words, disregarding words order and dependencies that are known to be substantial for understanding the semantic of a sentence. The correlation of these metrics with human judgment is showcased in Table 3. We can notice that the three metrics A, G and E correlate weakly with human judgment in both datasets, demonstrating the need for a well-designed automated metric that provides an accurate evaluation of dialogues.

5.2.2 Semantic Similarity

The Semantic Similarity (SS) metric was suggested by (Dziri et al., 2018). It measures the distance between the generated response and the utterances in the conversation history. The intuition of this metric revolves around capturing good and consistent responses by showing whether the machine-generated responses maintain the topic of the conversation. In this project, we measured SS with respect to two different utterances, the conversation history H and the most recent utterance H_{-1}. The conversation history is formed by concatenating the two most recent utterances. We report the Pearson coefficient of this metric with human judgment in Table 3. The SS metric is expected to have a negative correlation as the higher human ratings correspond to the lower semantic distance. The results demonstrate that SS metrics correlate better than word-level metrics as they make use of word interactions to represent utterances. Moreover, the Universal Sentence Encoder (USE) (Cer et al., 2018) model performs better on Reddit, whereas the ELMo embeddings achieve higher correlation on OpenSubtitles. This arguably underlines that deep contextualized word representations can manage better complex characteristics of natural language (e.g., syntax and semantics). The SS metric, which requires no pretraining, reaches a Pearson correlation of -0.404 with respect to the most recent utterance on OpenSubtitles. Such correlation can be compared with a correlation of 0.436 achieved by ADEM (Lowe et al., 2017) which required large amounts of training data and computation. Moreover, in order to investigate whether the results in Table 3 are in line with human evaluation, we visualized the correlation between the human ratings and SS metric as scatter plots in Figure 2.

6 Conclusion

Evaluating dialogue systems has been heavily investigated, but researchers are still on the quest for a strong and reliable metric that highly conforms with human judgment. Existing automated metrics show poor correlation with human annotations. In this paper, we present a novel paradigm for evaluating the coherence of dialogue systems by using state-of-the-art entailment techniques. We aim at building a system that does not require human annotation, which in turn, can lead to a scalable evaluation approach. While our results illustrate that the proposed approach correlates reasonably with human judgment and provide an unbiased estimate for the response quality, we believe that there is still room for improvement. For instance, measuring the engagingness of the conversation would be helpful in improving evaluating different dialogue strategies.

Abstract

Recent advances in Question Answering have lead to the development of very complex models which compute rich representations for query and documents by capturing all pairwise interactions between query and document words. This makes these models expensive in space and time, and in practice one has to restrict the length of the documents that can be fed to these models. Such models have also been recently employed for the task of predicting dialog responses from available background documents (e.g., Holl-E dataset). However, here the documents are longer, thereby rendering these complex models infeasible except in select restricted settings. In order to overcome this, we use standard simple models which do not capture all pairwise interactions, but learn to emulate certain characteristics of a complex teacher network. Specifically, we first investigate the conicity of representations learned by a complex model and observe that it is significantly lower than that of simpler models. Based on this insight, we modify the simple architecture to mimic this characteristic. We go further by using knowledge distillation approaches, where the simple model acts as a student and learns to match the output from the complex teacher network. We experiment with the Holl-E dialog data set and show that by mimicking characteristics and matching outputs from a teacher, even a simple network can give improved performance.

1 Introduction

The advent of large scale datasets for QA has lead to the development of increasing complex neural models with specialized components for (i) encoding the query (ii) encoding the document(s) (iii) capturing interactions between document and query words and (iv) generating/extracting the correct answer span from the given document (Seo et al., 2016; Hu et al., 2017; Yu et al., 2018). While these models give state-of-the-art performance on a variety of datasets, they have very high space and time complexity. This is a concern, and in practice, it is often the case that one has to resort to restricting the maximum length of the input document such that the model can run with reasonable resources (say, a single 12GB Tesla K80 GPU).

Such complex span prediction models are also being adapted for other NLP tasks such as dialog response prediction (Moghe et al., 2018), which is the focus of this work. In particular, we refer to the *Holl-E* dataset where the task is to extract the next response from a document which is relevant to the conversation (see Figure 1). This setup is very similar to QA wherein the input is {context, document} as opposed to {query, document} and the correct response span needs to be extracted from the given document. Given this similarity, it is natural to adopt existing QA models (Seo et al., 2016; Yu et al., 2018) for this task. However, the documents in *Holl-E* dataset are longer, and the authors specifically report that they were unable to run these models when the entire document was given as input. Hence, they report results only in constrained oracle settings where the document is trimmed such that the response still lies in the shortened document. The above situation suggests that there is clearly a trade-off needed. On one hand, we want to harness the power of these complex models to achieve better performance and on the other hand we want to be able to run them with reasonable compute resources without arbitrarily trimming the input document.

This trade-off situation naturally leads to the following question: *Is it possible to build a simple model, with low memory and compute requirements, that copy desirable characteristics from complex models?* To answer this, we start with a relatively simple model with very basic components for encoding query, document and capturing interactions. Once these interactions are cap-

Minneapolis, Minnesota, June 2 - June 7, 2019.

Source Doc: ...comes in. As soon as the door is open, the Bride's fist crashes into Vernita's face. A savage fight follows, first with fists, then with knives.... The fight pauses ... At this point Vernita is introduced as a member of the Deadly Vipers, codename Copperhead. ...

Sample Conversation:
Prober (S1): Which is your favourite character in this?
Responder (S2): My favorite character was Copperhead because she was kicking butt.
Prober (S3): Oh my goodness I agree, because the fight with Vernita was the best in the whole movie.
Responder (S4): It's starts off action packed because as soon as the door is open, the Bride's fist crashes into Vernita's face. A savage fight follows, first with fists, then with knives.
Prober (S5): And it gets better when we find out they are both assassins.
Responder (S6): And a group of them, Vernita is introduced as a member of the Deadly Vipers, codename Copperhead.

Figure 1: Sample Conversation from the Holl-E Dataset. Note that the underlined responses directly correspond to spans in the background document.

tured, the model computes a final representation which is then fed to a decoder to predict the correct span in the document. This recipe is very similar to BiDAF (Seo et al., 2016), QANeT (Yu et al., 2018) but the main difference is that these models use much more complex encoder and interaction components to arrive at the final representation. As expected, the performance of this model is poor when compared to BiDAF, QANeT. The aim now is to improve the performance of this model by carefully analysing or learning from complex models. Given that the complex model differs in the manner in which the final representation is computed, one hypothesis is that it learns richer final representations than the simple model. Indeed, on investigation, we found that the final representations learned by complex models are diverse for different inputs (context, document pairs) as compared to the simple model. Based on this insight, we propose a modification to the simple model which increases the diversity of the embeddings, thereby improving the performance.

While this insight obtained by manual investigation is useful, there is clearly scope for learning by exploring other characteristics of the model. One principled way of doing this is to use knowledge distillation (Hinton et al., 2015) where the simple model acts as a student and learns to mimic the probability distributions predicted by a teacher. In other words, instead of simply maximizing the log likelihood of the training data, the simple model now gets additional signals from the teacher which act as hints while training.

Our experiments, using the *Holl-E* dataset show that by (i) improving the conicity (Chandrahas et al., 2018) of the representations learned by the simple model and (ii) mimicking the outputs of the complex teacher model the simple model can give improved performance with fewer compute and memory requirements. In particular, when compared to a standalone simple model the student model shows an improvement of 3.4% (compare SAM-mul-train (LD) and SAM-add-topk (LD) entries in Table 2 and Table 3 respectively).

2 Related Work

Over the past few years neural sequence prediction models which take a question as input and predict the corresponding answer span in a given document have evolved rapidly. Such models have also been adapted for dialog response prediction in the context of the *Holl-E* dataset (Moghe et al., 2018). These models typically differ in the components used for capturing interactions between query and document, capturing interactions between sentences in a document and refining the query/document representation over multiple passes (Shen et al., 2017; Dhingra et al., 2017; Sordoni et al., 2016).

In particular, a co-attention network which computes the importance of every query word w.r.t. every document word and the importance of every document word w.r.t. every query word is an important component in most state of the art models (Hermann et al., 2015; Kadlec et al., 2016; Cao et al., 2016; Xiong et al., 2016; Seo et al., 2016; Gong and Bowman, 2017; Dhingra et al., 2017; Wang et al., 2017; Shen et al., 2017; Trischler et al., 2016; Group and Asia, 2017; Tan et al., 2017; Sordoni et al., 2016). Similarly, some models (Group and Asia, 2017; Seo et al., 2016; Hu et al., 2017) contain a self-attention network which computes the importance of every document word w.r.t. every other document word. In general, the most successful models (for example, BiDAF (Seo et al., 2016), QANeT (Yu et al., 2018)) use a combination of these components which capture all pairwise interactions and are thus computationally very expensive. As a result, in practice, these models are not suitable for longer documents.

We now quickly review existing works which use the idea of knowledge distillation to build compact models (Cheng et al., 2017). For example, Ba and Caruana (2014); Hinton et al. (2015); Lopez-Paz et al. (2016); Chen et al. (2017) train a shallow student network using soft targets (or class probabilities) generated by an expensive teacher instead of the hard targets present in the training data. Romero et al. (2015) extend this idea to train a student model using the intermediate representations learned by the teacher model which act as additional *hints*. This idea of *Knowledge Distillation* has also been tried in the context of pruning networks for multiple object detection (Chen et al., 2017), speech recognition (Wong and Gales, 2016). In the context of reading comprehension or span prediction, Hu et al. (2018) have very recently shown that we can distill knowledge from an ensemble of models into a single model. However, unlike our work, the single model itself is a complex model (Hu et al., 2017) containing an expensive self attention network and a RL agent. To the best of our knowledge, ours is the first work which tries to build a simple span prediction model by distilling knowledge from a complex model.

3 Models For Response Prediction

We view a conversation as sequence of utterances by a *prober* and a *responder*. The response prediction (RP) model aims to predict the utterance by the responder based on a source document, when given the query (prober's most recent utterance) and the history (past utterance by the prober and responder). See Figure 1 for an example.

We denote the lengths of source document, query, prober history and responder history as T, I, J, K. The LSTMs/GRUs used all have the same number of cells, denoted by d. In particular, the document length T is of the order of a few thousands and the query/history lengths I, J, K are of the order of a few hundreds. Contrast this with QA tasks, where T is only of the order of a few hundreds, and the query length $(I+J+K)$ is of the order of a few tens.

3.1 BiDAF for RP

BiDAF (Seo et al., 2016) is an extremely popular model used for span prediction in reading comprehension based question answering problems. We can frame the problem of response prediction as one of question answering by concatenating the query, prober history, and responder history into a single "question". BiDAF has proven to be hugely successful in QA tasks, but has a large number of parameters (about 2.5 million) and consumes a large amount of computational space and time during training and prediction.

We use the BiDAF model as a guiding post while constructing our model, and in particular focus on the so called *query to context attention*, which is a vector (denoted by $\widetilde{\mathbf{h}}$) that indicates the weighted sum of the most important words in the source document, with respect to the query and histories.

3.2 QANeT for RP

QANeT (Yu et al., 2018) is another recent model used for span prediction in QA tasks and specifically targets better space and time efficiency than BiDAF. Despite this, it still has a large number of parameters (about 1.3 million) and still consumes a large amount of computational space and time during training and prediction. The QANeT model can also be modified for response prediction in a similar manner to BiDAF.

3.3 Simple Attention Model for RP

We now describe the simple attention model that we aim to learn. In a fashion similar to that of BiDAF and QANeT architectures, the simple model also operates in 3 distinct layers. See Figure 2 for an overview into the model.

3.3.1 Word Embedding Layer

The words from the source document, the utterances by the prober and the responder are all encoded using standard GloVe embeddings (Pennington et al., 2014).

3.3.2 Contextual Embedding Layer

In the next layer we encode the query (prober's most recent utterance) using a BiGRU/BiLSTM, and encode the previous utterances of the prober and responder in a query sensitive manner.

Query Encoder: Embedded query words are passed through BiGRU where final state $q_I \in \mathbb{R}^{2d}$ acts as query representation.

Query Sensitive History Summariser: The history of the prober and responder are passed through a BiGRU to get context sensitive vectors $\mathbf{h}_j^{\mathrm{P}} \in \mathbb{R}^{2d}$ and $\mathbf{h}_k^{\mathrm{R}} \in \mathbb{R}^{2d}$ for $j \in [J]$ and $k \in [K]$.

These vectors are combined to get vectors $\mathbf{h}^{\mathrm{P}}$ and $\mathbf{h}^{\mathrm{R}}$. This process of combining uses the query representation $\mathbf{q}_I$, and hence $\mathbf{h}^{\mathrm{P}}$ and $\mathbf{h}^{\mathrm{R}}$ can

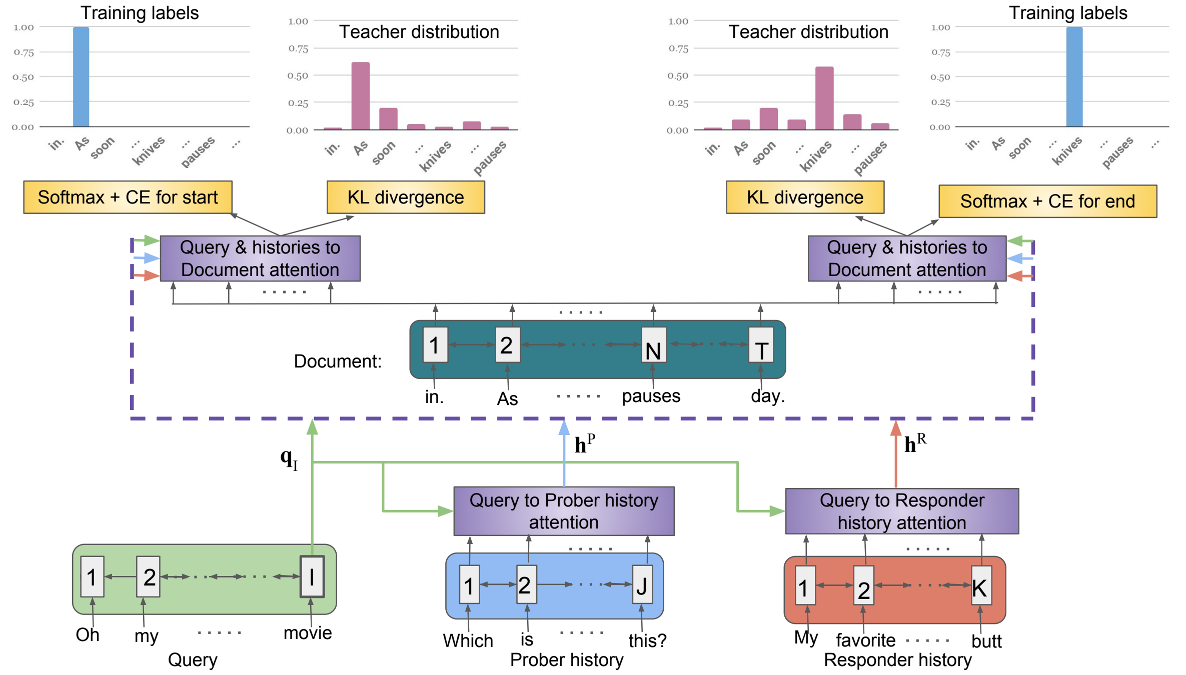

Figure 2: A Simple Attention Model with (1) Query Encoder, Prober History Encoder, Responder History Encoder, and Document Encoder (2) Query to Prober History Attention, Query to Responder History Attention, and Query & histories to Document Attention (3) Training Labels and Teacher Distribution.

be viewed as query-aware representations of the prober and responder history. The equations for $\mathbf{h}^{\text{P}}$ are given below. The vector $\mathbf{h}^{\text{R}}$ is also calculated in a similar manner.

$$e_j = \text{mul}^{W^{\text{P}}}(\mathbf{h}^{\text{P}}_j, \mathbf{q}_I)$$
$$\boldsymbol{\alpha} = \text{softmax}(\mathbf{e})$$
$$\mathbf{h}^{\text{P}} = \sum_j \alpha_j \mathbf{h}^{\text{P}}_j$$

where $\text{mul}^W(\mathbf{v}_0, \mathbf{v}_1) = \mathbf{v}_0^\top W \mathbf{v}_1$ is a parameterized multiplicative way of capturing the interaction between two vectors.

3.3.3 Span Prediction Layer

The source document is finally used in this layer to predict the start and end indices of the response. The GloVe embedded words of the source document are passed through a BiGRU to get context sensitive vectors $\mathbf{u}_t \in \mathbb{R}^{2d}$, for all $t \in [T]$. Each index t gets a score s_t based on the interaction between $\mathbf{u}_t$ and the query/history vectors $\mathbf{q}_I, \mathbf{h}^{\text{P}}, \mathbf{h}^{\text{R}}$. The scores s_t are normalized by a softmax and is taken to be the prediction of the starting word index.

$$s_t = \text{mul}^{W^{\text{strt}}}(\mathbf{u}_t, \mathbf{q}_I, \mathbf{h}^{\text{P}}, \mathbf{h}^{\text{R}})$$
$$\boldsymbol{\alpha} = \text{softmax}(\mathbf{s})$$

where $\text{mul}^W(\mathbf{u}_0, \ldots, \mathbf{u}_a) = \mathbf{u}_0^\top \left(\sum_{i=1}^a W^i \mathbf{u}_i\right)$

A similar method is used for the prediction of the ending word index as well.

4 Bridging The Gap Between Simple and Complex Models

We performed several experiments on the Holl-E dataset and observed that the complex models (QANeT and BiDAF) perform better than the simple attention model described in Section 3.3. However, they take significantly more time and memory for training and inference. In fact, for the examples with longer source documents, both BiDAF and QANeT run into memory issues when training. During prediction, the memory issues in QANeT and BiDAF can be sidestepped by breaking the source document into multiple chunks and taking the highest scoring span.

In the rest of this section we study several approaches to nudge the simple attention model to take parameters that make it have similar behaviour as the complex models, and check if the so nudged model demonstrates better performance on the Holl-E dataset.

4.1 Diversity of Embeddings

We observed that for the simple attention model, the response predictions at different points in the

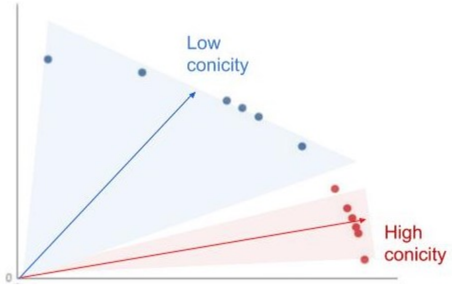

Figure 3: Conicity (*i.e.*, average cosine similarity of vectors with the mean of all the vectors) of two sets of vectors with standard deviation 0.1 (red) and 1.3 (blue)

same conversation are often the same, even though the "right response" is different in those points. For example, consider the conversation in Figure 1. We expect the trained model to be such that

$$\text{Pred\_span}(SD, S_1, S_2, S_3) = \text{span}_{SD}(S_4)$$

where SD is the source document, and S_i are the the utterances in the conversation. Similarly, we expect the trained model to be such that

$$\text{Pred\_span}(SD, S_3, S_4, S_5) = \text{span}_{SD}(S_6)$$

However we often find that our simple model predicts the same span for both the cases above, which is wrong (unless S_4 and S_6 are the same.)

We hypothesize this as being due to the context sensitive embeddings of the history not depending strongly on the query, and hence the span prediction model picks up most information from the source document. To support this point of view we measured the diversity of the context-to-query vectors $\widetilde{\mathbf{h}}$ of the BiDAF model for several examples grouped by conversation. In more detail we computed the *conicity* (Chandrahas et al., 2018) of vectors $\widetilde{\mathbf{h}}(SD, S_1, S_2, S_3), \widetilde{\mathbf{h}}(SD, S_3, S_4, S_5), \ldots$ for every conversation in the test set and averaged it over all conversations. (See Figure 3 for an overview on conicity). This average conicity was observed to be about 0.6 (see Table 6), which, according to Chandrahas et al. (2018), is low (low conicity implies high diversity).

We observe similar behaviour for QANeT as well. The average conicity of the row sums of the *similarity matrix* grouped by conversation was also observed to be about 0.6 (see Table 6).

On the other hand, for our simple attention model, the average conicity of the vectors $\mathbf{h}^{\mathrm{R}}$ and $\mathbf{h}^{\mathrm{P}}$, when computed in a similar fashion as mentioned above were generally high (about 0.8) (see Table 6).

Based on these observations we hypothesize that decreasing the conicity of the vectors $\mathbf{h}^{\mathrm{R}}$ and $\mathbf{h}^{\mathrm{P}}$ would improve the performance of the simple attention model. In particular, we propose to change the multiplicative method of combining vectors into an additive method instead.

In particular we propose to replace the function mul in our simple model with the function add defined as follows:

$$\mathrm{add}^{W}(\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_a) = \mathbf{w}^{\top} \tanh\left(\sum_{i=0}^{a} W^i \mathbf{v}_i\right)$$

where the vector $\mathbf{w}$ and the matrices W^i parameterize the mode of combining the input vectors. This is motivated by Chandrahas et al. (2018) who show that using additive model in embedding of entities in knowledge graphs gives consistently better diversity than using multiplicative models.

4.2 Standard Knowledge Distillation from Complex Models

While borrowing high level ideas from complex models, like increasing diversity of the learned representation can help to some extent, one can push this further to distill the learned complex model (Hinton et al., 2015) into the simple attention model. To achieve this, we train a teacher model (BiDAF or QANeT) on the training set and use it to make predictions on the same training set. The simple attention model would minimise the sum of two loss functions: 1) Cross entropy loss of the predicted start and end indices with the train labels of the start and end indices, 2) KL-divergence of the predicted start and end indices from the teacher prediction of the same. The loss on a single training sample is given below

$$\mathrm{D}(\mathbf{p}_{\mathrm{b}}^{\mathrm{T}}||\mathbf{p}_{\mathrm{b}}^{\mathrm{S}}) + \mathrm{D}(\mathbf{y}_b||\mathbf{p}_{\mathrm{b}}^{\mathrm{S}}) + \mathrm{D}(\mathbf{p}_{\mathrm{e}}^{\mathrm{T}}||\mathbf{p}_{\mathrm{e}}^{\mathrm{S}}) + \mathrm{D}(\mathbf{y}_e||\mathbf{p}_{\mathrm{e}}^{\mathrm{S}}) \tag{1}$$

where D denotes the KL divergence, $\mathbf{p}_{\mathrm{b}}^{\mathrm{T}}, \mathbf{p}_{\mathrm{e}}^{\mathrm{T}}$ denote the predicted begin index and end index distribution of the teacher model, and $\mathbf{p}_{\mathrm{b}}^{\mathrm{S}}, \mathbf{p}_{\mathrm{e}}^{\mathrm{S}}$ denote the predicted begin and end index distribution of the student model and $\mathbf{y}_{\mathrm{b}}, \mathbf{y}_{\mathrm{S}}$ denote the true begin and end index in one-hot vector form.

4.3 Top-k Based Knowledge Distillation

Another variant of knowledge distillation is as follows. We do not view the teacher predicted distribution for all indices with importance and just take the top few predicted indices. In particular the loss on a single training sample is given below

$$\mathrm{D}(\widetilde{\mathbf{p}}_{\mathrm{b}}^{\mathrm{T}}||\widetilde{\mathbf{p}}_{\mathrm{b}}^{\mathrm{S}}) + \mathrm{D}(\mathbf{y}_b||\mathbf{p}_{\mathrm{b}}^{\mathrm{S}}) + \mathrm{D}(\widetilde{\mathbf{p}}_{\mathrm{e}}^{\mathrm{T}}||\widetilde{\mathbf{p}}_{\mathrm{e}}^{\mathrm{S}}) + \mathrm{D}(\mathbf{y}_e||\mathbf{p}_{\mathrm{e}}^{\mathrm{S}}) \tag{2}$$

where $\widetilde{\mathbf{p}}_{\mathrm{b}}^{\mathrm{T}}, \widetilde{\mathbf{p}}_{\mathrm{e}}^{\mathrm{T}}$ gives just the (normalised) probability of the top-k predictions of teacher model on the begin and end indices. Similarly $\widetilde{\mathbf{p}}_{\mathrm{b}}^{\mathrm{S}}, \widetilde{\mathbf{p}}_{\mathrm{e}}^{\mathrm{S}}$ gives the student predictions for the begin and end indices restricted to the top-k entries given by the teacher model.

4.4 Other Knowledge Distillation Approaches

As the teacher model is already trained, and the main objective in knowledge distillation is to have the student model mimic the teacher model, there is no need to restrict the objective terms 1 and 3 in equation 1 to only the training data. Hence by hallucinating conversations and documents we can get more terms in the objective and has an effect similar to data augmentation.

Another possible way to take advantage of teacher models is to extract more information than simply the predicted spans for each training example from the teacher models. In particular one easy way to extract piece of information is the gradient of the model output with respect to the input for the teacher model. The so called Sobolev training (Czarnecki et al., 2017) exploits this information and adds two more extra terms to the objective in (1).

$$||\nabla\mathbf{p}_{\mathrm{b}}^{\mathrm{T}} - \nabla\mathbf{p}_{\mathrm{b}}^{\mathrm{S}}||^2 + ||\nabla\mathbf{p}_{\mathrm{e}}^{\mathrm{T}} - \nabla\mathbf{p}_{\mathrm{e}}^{\mathrm{S}}||^2$$

The gradients are all taken with respect to the model input, which would be the source document, the query and the histories.

5 Experiments

In this section, we describe the setup used for our experiments and discuss the results.

5.1 Experiment Setup

We perform experiments using the Holl-E conversation dataset (Moghe et al., 2018) which contains crowdsourced conversations from the movie domain. Every conversation in this dataset is associated with background knowledge comprising of plot details (from Wikipedia), reviews and comments (from Reddit). Every alternate utterance in the conversation is generated by copying and/or modifying sentences from this unstructured background knowledge. We refer the reader again to Figure 1 for a sample from this dataset.

We use the same train, test and validation splits as provided by the authors of the original paper (Moghe et al., 2018). For each chat in the training data, the authors construct training triplets of the form {document, context, response} where the number of train, test and validations triplets are 34486, 4388 and 4318 respectively. The context contains (i) the query (the prober's most recent utterance) and (ii) the history (past 2 utterances by the prober and the responder) as described earlier. The task then is to train a model which can predict the response given the document and the context. At test time, the model is shown document, context and predicts the response.

As mentioned earlier, the authors of Holl-E found that BiDAF and QANeT run into memory issues when evaluated on their dataset. Hence, they propose two setups (i) long document (LD) setup and (ii) short document (SD) setup. In the long document setup, the authors do not trim the document from which the response needs to be predicted. In the short document setup, the authors trim the document to 256 words such that the span containing the response is contained in the trimmed document. This enables them to evaluate BiDAF and QANeT on the trimmed document. We also report experiments using both the LD and SD setup.

As mentioned above complex models (BiDAF and QANeT) face memory issues on training set with long documents. So for all situations where we need predictions from complex models for long documents, we use a BiDAF/QANeT model trained on short document examples, and the prediction on the long document is made by splitting the long documents into chunks and feeding it to the trained BiDAF/QANeT model. The final predicted span is the largest scoring span across all chunks.

For all models, we considered the following hyperparameters and tuned them using the validation set. We tried batch sizes of 32 and 64 and the following GRU sizes: 64, 100, 128. We experimented with 1, 2 and 3 layers of GRU. We used pre-trained publicly available Glove word embeddings [1] of 100 dimensions. The best performance

was with the batch size of 32, 2 layers of GRU with hidden size 64. We used Adam (Kingma and Ba, 2014) optimizer with initial learning rate set to 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.999$. We performed L2 weight decay with decay rate set to 0.001.

5.2 Model Variant Details

The models that we experiment with are listed below:

1. **SAM-add-Train** : The simple attention model with additive interactions and no teacher terms in the objective (Only terms 2 and 4 in Eqn. (1)).
2. **SAM-add-Teach** : The simple attention model with additive interactions and only knowledge distillation terms in the objective (Only terms 1 and 3 in Eqn. (1)).
3. **SAM-add** : The simple attention model with additive interactions and both knowledge distillation terms and training data terms in the objective (all terms in 1).
4. **SAM-add-topk** : The simple attention model with additive interactions and knowledge distillation applied to the top-k indices and training data terms in the objective (all terms in 2).
5. **SAM-add-aug** : The SAM-add model, where the teacher terms are evaluated on hallucinated data in addition to training data. The hallucinated data are derived from the original training set by reordering the words in the source document, query and histories.
6. **SAM-add-grad** : The SAM-add model, with extra terms in the loss penalising the deviation of the gradient of the simple model from the gradient of the teacher model.
7. **SAM-add-both** : Same as the SAM-add model, but has 6 terms instead of the 4 terms in Equation 1. The extra two terms arise from using **both** QANeT and BiDAF instead of just one.
8. **SAM-add-ensemble** : Same as the SAM-add model, but the teacher predictions $\mathbf{p}^{\mathrm{T}}$ are set as the average of the QANeT and BiDAF predictions.

All the "add" models above also have a "mul" variant where the additive interaction add is replaced by a multiplicative interaction mul.

5.3 Results and Discussion

The F1-scores of the various models we train are given in Table 2, Table 3 and Table 4. A summary of the space and time complexity of prediction with the simple model and the complex models is given in Table 1. The training times and parameter counts of the models are given in Table 5 We draw several conclusions and inferences from these results and make some comments below.

Efficient Training with Simple Model: From Table 5, we observe that simple attention model has 5 to 10 times less parameters than QANeT and BiDAF. The training time of the simple model is also significantly lesser than that of the complex models.

Efficient Prediction with Simple Model: From Table 1, we observe that the simple model takes significantly less memory and time during prediction as well. The complex models run out of memory on the large document test set, but a prediction can still be made with a trained BiDAF or QANeT

Model Details	BiDAF	QANeT
SAM-add-teach	20.23	-
SAM-mul	40.81	40.76
SAM-add	42.05	41.89
SAM-add-topk	41.71	42.01

Complex Models	0.6
SAM-mul	0.8
SAM-add	0.7

Table 6: Comparison of conicity between variants of simple-attention model and complex models.

model by splitting the source document into manageable chunks.

Conicity of Multiplicative models vs Additive Models: As noted before we use two distinct methods to capture the interaction between a group of vectors : an additive mechanism add, and a multiplicative mechanism mul. As mentioned earlier, an additive model for capturing interactions has been hypothesized to increase diversity. This is true in our case as well: the conicity of the $\mathbf{h}^{\mathrm{P}}$ and $\mathbf{h}^{\mathrm{R}}$ vectors goes down from about 0.8 to 0.7 (compare SAM-mul and SAM-add entries in Table 6) when using the additive model instead of the multiplicative model.

F1 scores of Multiplicative models vs Additive Models: In addition to improving diversity, using the additive model add instead of the multiplicative model mul increases F1-scores all across the board. We have not reported scores for certain multiplicative variants because their performance is significantly worse.

F1 scores of Simple Model with Knowledge Distillation: We observe that using a teacher model for knowledge distillation using the objective in (1) almost always improves the performance of the simple model.

Importance of training labels: The objective in knowledge distillation (Equation (1)) involves both the training labels and the teacher predicted distribution. Even though the teacher predicted distribution also incorporates the training data, removing the training data term from the objective of knowledge distillation worsens performance significantly.

Top-k Distillation: The knowledge distillation approach based on top-k predicted indices results in the best simple model for long document examples (see Table 3). The value of k was chosen to be 50 for the short document case and it is 20 for the long document case.

Add-Both Knowledge Distillation: Learning from multiple teachers could lead to better performance hence we trained the student model with two teachers (BiDAF+QANeT). Here the objective function of student is to minimize KL Divergence between predictions for both teachers. We achieved best results with this technique on short document (SD) test set.

Data Augmentation and Gradient Distillation: While the data augmentation and gradient distillation methods hold a lot of promise, in the experiments that we conducted, we did not see a significant improvement.

QANeT Teachers vs BiDAF Teachers: Using either QANeT or BiDAF as a teacher doesn't seem to make any difference in the performance of the student models (compare the two columns in Table 3 and 4).

6 Conclusion

In this work, we address the trade-off between simple models on one hand which have low memory and compute requirements and complex models on the other hand which give better performance but are computationally expensive. We propose a middle ground by training a simple model to mimic the characteristics of a complex model. In particular, we make observations from a complex model which learns very diverse representations for different inputs and suitably modify the simple model to learn similar diverse representations. We go further, by using knowledge distillation techniques to improve the simple model by training it to match the outputs from the complex model. We experimented with the Holl-E conversation dataset and showed that by mimicking characteristics of the teacher a simple model can give improved performance.

Cross-lingual Multi-Level Adversarial Transfer to Enhance Low-Resource Name Tagging

Abstract

We focus on improving name tagging for low-resource languages using annotations from related languages. Previous studies either directly project annotations from a source language to a target language using cross-lingual representations or use a shared encoder in a multitask network to transfer knowledge. These approaches inevitably introduce noise to the target language annotation due to mismatched source-target sentence structures. To effectively transfer the resources, we develop a new neural architecture that leverages multi-level adversarial transfer: (1) word-level adversarial training, which projects source language words into the same semantic space as those of the target language without using any parallel corpora or bilingual gazetteers, and (2) sentence-level adversarial training, which yields language-agnostic sequential features. Our neural architecture outperforms previous approaches on CoNLL data sets. Moreover, on 10 low-resource languages, our approach achieves up to 16% absolute F-score gain over all high-performing baselines on cross-lingual transfer without using any target-language resources.[1]

1 Introduction

Low-resource language name tagging is an important but challenging task. An effective solution is to perform cross-lingual transfer, by leveraging the annotations from high-resource languages. Most of these efforts achieve cross-lingual annotation projection based on bilingual parallel corpora combining with automatic word alignment (Yarowsky et al., 2001; Wang et al., 2013; Fang and Cohn, 2016; Ehrmann et al., 2011; Ni et al., 2017), bilingual gazetteers (Feng et al., 2017; Zirikly and Hagiwara, 2015), cross-lingual word embedding (Fang and Cohn, 2017; Wang et al., 2017; Huang et al., 2018), or cross-lingual Wikification (Kim et al., 2012; Nothman et al., 2013; Tsai et al., 2016; Pan et al., 2017), but these resources are still only available for dozens of languages. Recent efforts on multi-task learning model each language as one single task while all the tasks share the same encoding layer (Yang et al., 2016, 2017; Lin et al., 2018). These methods can transfer knowledge via the shared encoder without using bilingual resources. However, different languages usually have different underlying sequence structures, as shown in Figure 1. Without an explicit constraint, the encoder is not guaranteed to extract language-independent sequential features. Moreover, when the size of annotated resources is not balanced, the encoder is likely to be biased toward the resource-dominant language.

Figure 1: Example of parallel sentences between English (ENG), Spanish (ESP) and Dutch (NED) from Europarl Parallel Corpus (Koehn, 2005). The information units with the same color and superscript are aligned.

Considering these challenges, we develop a new neural architecture which can effectively transfer resources from source languages to improve target language name tagging. Our neural architecture is built upon a state-of-the-art sequence tagger: bi-directional long short-term memory as input to conditional random fields (Bi-LSTM-CRF) (Lample et al., 2016; Huang et al., 2015; Ma and

Minneapolis, Minnesota, June 2 - June 7, 2019.

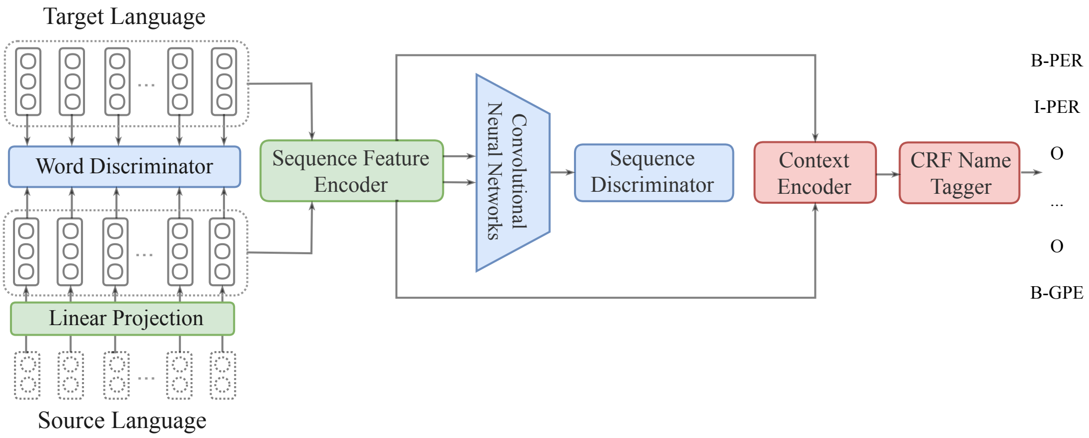

Figure 2: Architecture overview.

Hovy, 2016), integrated with multi-level adversarial transfer: (1) word level adversarial transfer, similar to Conneau et al. (2017), applying a projection function on the source language and a discriminator to distinguish each word of the target language from that of the source language, resulting in a bilingual shared semantic space; (2) sentence-level adversarial transfer, where a discriminator is trained to distinguish each sentence of the target language from that of the source language,[2] and a sequence encoder is applied to each sentence of both languages to prevent the discriminator from correctly predicting the source of each sentence, yielding language-agnostic sequential features. These features can better facilitate the resource transfer from the source language to the target language.

Our contributions are twofold: (1) without requiring any parallel corpora or bilingual gazetteers, the multi-level adversarial approach can efficiently transfer annotated resources from the source language to the target language and improve target language name tagging; (2) In addition to outperforming previous high-performing baselines on CoNLL data sets, we also evaluate cross-lingual name tagging on 10 low-resource languages and achieve up to 16% absolute F-score gain over all baselines when there is no annotated resource for the target language.

2 Approach

2.1 Approach Overview

Figure 2 shows the overview of our neural architecture. It consists of three components:

Cross-lingual word embedding learning with adversarial training: Given pre-trained monolingual word embeddings for a target language t and a source language s, we first apply a mapping function to each word representation from s, then feed both the projected source word representations and the target word representations to a word discriminator to predict the language of each word. If the discriminator cannot distinguish the language of t from the projection of s, then we consider t and the projection of s to be in a shared space.

Language-agnostic sequential feature extraction: For each sentence of t and s, we apply a sequence encoder to extract sequential features, and a Convolutional Neural Network (CNN) (Krizhevsky et al., 2012) based sequence discriminator to predict the language source of each sentence. The sequence encoder is trained to prevent the sequence discriminator from correctly predicting the language of each sentence, such that it finally extracts language-agnostic sequential features.

Language-independent name tagger The language-agnostic sequential features from both t and s are further fed into a context encoder to better capture and refine contextual information and a conditional random field (CRF) (Lafferty et al., 2001) based name tagger.

Next we show the details of each component in our architecture.

2.2 Word-level Adversarial Transfer

To better leverage the resources from the source language, our first step is to construct a shared se-

---

[2] For the name tagging task, 'sequence' always means 'sentence.'

mantic space where the words from the source and target languages are semantically aligned. Without requiring any bilingual gazetteers, recent efforts (Zhang et al., 2017b; Conneau et al., 2017; Chen and Cardie, 2018) explore unsupervised approaches to learn cross-lingual word embeddings and achieve comparable performance to supervised methods. Following these studies, we perform word-level adversarial training to automatically align word representations from s and t.

Formally, assume we are given pre-trained monolingual word embeddings $\mathbf{V}_t = \{\mathbf{v}_1^t, \mathbf{v}_2^t, ..., \mathbf{v}_N^t\} \in \mathbb{R}^{N \times d_t}$ for t, and $\mathbf{V}_s = \{\mathbf{v}_1^s, \mathbf{v}_2^s, ..., \mathbf{v}_M^s\} \in \mathbb{R}^{M \times d_s}$ for s, where $\mathbf{v}_i^t$ and $\mathbf{v}_j^s$ are the vector representations of words w_i^t and w_i^s from t and s, N and M denote the vocabulary sizes, d_t and d_s denote the embedding dimensionality of t and s respectively. We then apply a mapping function f to project s into the same semantic space as t:

$$\widetilde{\mathbf{V}}_s = f(\mathbf{V}_s) = \mathbf{V}_s\mathbf{U} \tag{1}$$

where $\mathbf{U} \in \mathbb{R}^{d_s \times d_t}$ is the transformation matrix. $\widetilde{\mathbf{V}}_s \in \mathbb{R}^{M \times d_t}$ are the projected word embeddings for s, and $\Theta_f = \{\theta_f\}$ denotes the set of parameters to be optimized for f.

Similar to Xing et al. (2015), Conneau et al. (2017), and Chen and Cardie (2018), we constrain the transformation matrix $\mathbf{U}$ to be orthogonal with singular value decomposition (SVD) to reduce the parameter search space:

$$\mathbf{U} = \mathbf{A}\mathbf{B}^\top \text{, with } \mathbf{A}\Sigma\mathbf{B}^\top = \text{SVD}(\widetilde{\mathbf{V}}_s\mathbf{V}_s^\top) \tag{2}$$

To automatically optimize the mapping function f without using extra bilingual signals, we introduce a multi-layer perceptron D as a word discriminator, which takes word embeddings of t and projected word embeddings of s as input features and outputs a single scalar. $D(w_i^*)$ represents the probability of w_i^* coming from t. The word discriminator is trained by minimizing the binary cross-entropy loss:

$$\begin{aligned} L_{dis}^w = &- \frac{1}{I_{t;s}} \cdot \sum_{i=0}^{I_{t;s}} \Big(y_i \cdot \log(D(w_i^*)) \\ &+ (1 - y_i) \cdot \log(1 - D(w_i^*)) \Big) , \\ y_i =& \delta_i(1 - 2\epsilon) + \epsilon , \end{aligned}$$

where $\delta_i = 1$ when w_i^* is from t and $\delta_i = 0$ otherwise. $I_{t;s}$ represents the number of words sampled from the vocabulary of t and s together. ϵ is a smoothed value added to the positive and negative labels. $\Theta_{dis} = \{\theta_D\}$ is the parameter set.

The mapping function f and word discriminator D are two adversarial players, thus we flip the word labels and optimize f by minimizing the following loss:

$$\begin{aligned} L_f^w = &- \frac{1}{I_{t;s}} \cdot \sum_{i=0}^{I_{t;s}} \Big((1 - y_i) \cdot \log(D(w_i^*)) \\ &+ y_i \cdot \log(1 - D(w_i^*)) \Big) , \\ y_i =& \delta_i(1 - 2\epsilon) + \epsilon \end{aligned}$$

Following the standard training procedures of deep adversarial networks (Goodfellow et al., 2014), we train the word discriminator and the mapping function successively with stochastic gradient descent (SGD) (Bottou, 2010) to minimize L_{dis}^w and L_f^w. Similar to Conneau et al. (2017), after word-level adversarial training, we also adopt a refinement step to construct a bilingual dictionary for the top-k most frequent words in the source language[3] based on $\widetilde{\mathbf{V}}_s$ and $\mathbf{V}_t$, and further optimize $\mathbf{U}$ with Equation 2 in a supervised way.

2.3 Sentence-level Adversarial Transfer

Once s is projected into the same semantic space as t, we can regard both sentences as coming from one unified language and directly project annotations from s to t. However, name tagging not only relies on word level features, but also on sequential contextual features for entity type classification. Without constraints, the sequence encoder can only extract sequential features for both t and s based on their final training signals while these features are not necessarily beneficial to the target language. Thus, we further design sentence level adversarial transfer to encourage the encoder to extract language-agnostic sequential features.

Given a sentence $x^t = \{w_1^t, w_2^t, ...\}$ from t and a sentence $x^s = \{w_1^s, w_2^s, ...\}$ from s, we first use $\mathbf{V}_t$ and $\widetilde{\mathbf{V}}_s$ to initialize a vector representation for each w_i^t and w_i^s. We also apply a character-based CNN (denoted as CharCNN) (Kim et al., 2016) for each language to compose a word representation from its characters. For each word, we

---

[3] We set k=15,000 in our experiment.

concatenate its word representation and character based representation. Then we feed the sequence of vector representations into a weight sharing Bi-LSTM encoder E to obtain sequential features $\mathbf{H}_t = \{\mathbf{h}_1^t, \mathbf{h}_2^t, ...\}$ and $\mathbf{H}_s = \{\mathbf{h}_1^s, \mathbf{h}_2^s, ...\}$ for x^t and x^s respectively. The parameter set of optimizing both language-dependent CharCNN and the sequence encoder can be denoted as $\Theta_e = \{\theta_{\text{CharCNN}_t}, \theta_{\text{CharCNN}_s}, \theta_E\}$.

Based on these sequential features, we use a sequence discriminator to predict the language source of each sentence. Given a sentence x^* and its sequential features $\mathbf{H} = \{\mathbf{h}_1^*, \mathbf{h}_2^*, ...\}$ from E, we first apply a language-independent CNN with max-pooling to get an overall vector representation for x^*, then feed it into another multi-layer perceptron, $\tilde{D}$, to predict the probability that x^* comes from language t. The sequence discriminator is trained by minimizing the following binary cross-entropy loss:

$$
\begin{aligned}
L_{dis}^x = &- \frac{1}{\tilde{I}_{t;s}} \cdot \sum_{i=0}^{\tilde{I}_{t;s}} \Big(\tilde{y}_i \cdot \log(\tilde{D}(x_i^*)) \\
&+ (1 - \tilde{y}_i) \cdot \log(1 - \tilde{D}(x_i^*)) \Big) , \\
\tilde{y}_i = &\tilde{\delta}_i(1 - 2\eta) + \eta ,
\end{aligned}
$$

where $\tilde{\delta}_i = 1$ if the sentence x_i^* is from t and $\tilde{\delta}_i = 0$ otherwise. $\tilde{I}_{t;s}$ represents the number of sentences sampled from the whole data set of t and s. η is another smoothed value for sequence labels. $\Theta_{\widetilde{dis}} = \{\theta_{\text{CNN}}, \theta_{\tilde{D}}\}$ denotes the parameter set for optimizing the sequence discriminator.

The sequence encoder E and the sequence discriminator $\tilde{D}$ are two adversarial players and E is optimized by trying to fool $\tilde{D}$ to correctly predict the language source of each sentence. Thus we flip the sequence labels and optimize E by minimizing the following loss:

$$
\begin{aligned}
L_e^x = &- \frac{1}{\tilde{I}_{t;s}} \cdot \sum_{i=0}^{\tilde{I}_{t;s}} \Big((1 - \tilde{y}_i) \cdot \log(\tilde{D}(x_i^*)) \\
&+ \tilde{y}_i \cdot \log(1 - \tilde{D}(x_i^*)) \Big) , \\
\tilde{y}_i = &\tilde{\delta}_i(1 - 2\eta) + \eta
\end{aligned}
$$

        update $\Theta_e, \Theta_c$ to minimize $loss^{'}$
```

2.4 Name Tagger Training

With the language-agnostic sequential features from E, we can directly combine all annotated training data from both t and s to train the name tagger for t. To do so, we feed the sequential features from E to another Bi-LSTM encoder E_c to refine the context information for each token, and use a CRF output layer to render predictions for each token, which can effectively capture dependencies among name tags (e.g., an “inside-organization” token cannot follow a “beginning-person” token).

Specifically, given an input sentence $x = \{w_1, w_2, ...w_n\}$, we extract language-agnostic sequential features with E, and further obtain a new sequence of contextual features $\widetilde{\mathbf{H}} = \{\tilde{\mathbf{h}}_1, \tilde{\mathbf{h}}_2, ..., \tilde{\mathbf{h}}_n\}$ with E_c. Then we a apply a linear layer ℓ to further convert each $\tilde{\mathbf{h}}_i$ to a score vector $\mathbf{y}_i$, in which each dimension denotes the predicted score for a tag (the starting, inside or outside of a name mention with a pre-defined entity type). Then we feed the sequence of score vectors $\mathbf{Y} = \{\mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_n\}$ into the CRF layer. The score of a sequence of tags $\mathbf{Z} = \{z_1, z_2, ..., z_n\}$ is defined as:

$$
Score(x, \mathbf{Y}, \mathbf{Z}) = \sum_{i=1}^{n} (R_{z_{i-1}, z_i} + Y_{i, z_i})
$$

where R is a transition matrix and $R_{p,q}$ denotes the binary score of transitioning from tag p to tag q.

$Y_{i,z}$ represents the unary score of assigning tag z to the i-th word.

Given the annotated sequence of tags $\mathbf{Z}$, the CRF loss is:

$$L_{crf} = \log \sum_{\mathbf{Z}' \in \tilde{\mathbf{Z}}} e^{Score(x,\mathbf{Y},\mathbf{Z}')} - Score(x, \mathbf{Y}, \mathbf{Z})$$

where $\tilde{\mathbf{Z}}$ is the set of all possible tagging paths. The parameter set for optimizing the name tagger can be denoted as $\Theta_c = \{\theta_{E_c}, \theta_\ell, \theta_{\text{CRF}}\}$.

We jointly optimize the sequence encoder E, the context encoder E_c and the CRF together by minimizing the loss $L' = L_e^x + L_{crf}$, and successively minimize L_{dis}^x and L' with SGD. The end-to-end training for our neural architecture is described in Algorithm 1.

3 Experiment

3.1 Data and Experimental Setup

We evaluate our methods from multiple settings. We first evaluate our architecture on 10 low-resource languages from the DARPA LORELEI project. The annotations are released by the Linguistic Data Consortium (LDC).[4] Each dataset has four predefined name types: person (PER), organization (ORG), location (LOC) and geo-political entity (GPE). For each target low-resource language, we choose a source language if they are from the same language family or use the same script. To show the impact of resource transfer between distinct languages, we also use English as a source language for each target low-resource language. We create the English annotated resource by combining the TAC-KBP 2015 English Entity Discovery and Linking (Ji et al., 2015) data set and the Automatic Content Extraction (ACE2005) data set.[5] To avoid the impact of parameter initialization, we perform 5-fold cross validation. For each experiment, we run twice and get the averaged F-score. Table 1 shows the statistics of each data set.

Language	# of Sents	# of Tokens	# of Names

English (en)	17,936	388,120	23,938

Table 1: Data set statistics for each low-resource language.

We also evaluate our approach on high-resource languages. We use Dutch (nl) and Spanish (es) data sets from the CoNLL 2002 (Tjong Kim Sang, 2002) shared task as target languages, and use English (en) data from the CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003) shared task as the source language. All the data sets have four pre-defined name types: PER, ORG, LOC and miscellaneous (MISC). Table 2 shows the statistics of these data sets.

For fair comparison, we use the same pre-trained word embeddings of English, Dutch and Spanish as Lin et al. (2018), while for each low-resource language we train their word embeddings using the documents from their LDC packages with FastText.[6] Table 3 lists the key hyper-parameters we used in our experiments.

3.2 Baselines

We compare our methods with three categories of baseline methods:[7]

- **Monolingual Name Tagging** Using monolingual annotations only, the current state-of-the-art name tagging model is the Bi-LSTM-CRF network (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016).[8]

- **Multi-task Learning** Lin et al. (2018) apply multi-task learning to boost name tagging performance by introducing additional annotations from source languages using a weight sharing context encoder across multiple languages.

- **Language Universal Representations** We apply word adversarial transfer only to project the source language into the same semantic space as the target language, then train the name tagger on the annotations of source and target languages. Word-Adv^1 refers to the approach which is directly trained on the combination of the anno-

---

tations, while Word-Adv^2 refers to the baseline that is first trained on the target language annotations and then further tuned on the related language annotations.

3.3 Cross-lingual Transfer with Zero Target Language Annotated Resource

We first evaluate our approach on a cross-lingual transfer setting without using any annotated training data from the target language. We conduct experiments on 8 low-resource languages. Among those, some pairs, such as Amharic (am) and Tigrinya (ti), Oromo (om) and Somali (so), or Yoruba (yo) and Swahili (sw), are from the same language family and are closely related, while some are not, such as Arabic (ar) and Farsi (fa). Since our approach requires some unlabeled sentences from the target language to train the sentence-level discriminator, we entirely remove the annotations from the annotated data set of the target language. Table 4 presents the results.

Our approach significantly outperforms the previous methods on all languages. Specifically, compared with the Word-Adv^1 baseline, which only performs word-level adversarial transfer, our approach achieves 10% absolute F-score gain on average, which demonstrates the effectiveness of the sentence-level adversarial transfer. In addition, compared with Lin et al. (2018), who only apply a shared context-encoder to transfer the knowledge, our approach not only includes a language-sharing encoder, but also performs multi-level adversarial training to encourage the semantic alignment of words from both languages and a sequence encoder to extract language-agnostic sequential features.

Here we use some Arabic (Farsi) examples to further show the effectiveness of each level of adversarial training in our architecture. Without using any annotated training data from Arabic, both our approach and the Word-Adv^1 baseline successfully identify الفرنسية (*French*) as a *GPE* from the Arabic (ar) sentence in Figure 3, since with word-level adversarial training, the semantics of الفرنسية is well aligned with the *GPE* names in Farsi annotated data, such as فرانسه (*France*), روسیه (*Russia*) and آلمان (*Germany*). However, both the Word-Adv^1 and Lin et al. (2018) baselines fail to identify الجزائرية (*Algerian*) as a *GPE* since its top ranked similar words in Farsi include مذاکرات (*negotiations*), دوحه (*Doha*) and توافقنامه (*agreement*). With sentence-level adversarial training, our approach successfully captures language-agnostic sequential features, such as "او (*or*) *usually connects two names with the same type*", thus our approach successfully identifies الجزائرية (*Algerian*) as a *GPE* name.

3.4 Cross-lingual Transfer for Low-Resource Languages

We also investigate the impact of cross-lingual transfer when the target languages have some annotated resources. For each target low-resource language, we explore the use of a related low-resource language vs. using the high-resource En-

target (related)	Monolingual Bi-LSTM-CRF	Cross-lingual Embedding Word-Adv^1	Word-Adv^2	Multitask Learning	Our Approach Multi-Adversarial

يحملون الجنسية الفرنسية^3 او^2 الجزائرية^1 في غالبيتهم ، كافية .

EN: The deputy prosecutor has ruled that the evidence against those with French^3 or^2 Algerian^1 nationality is mostly sufficient.

Figure 3: Example of an Arabic (ar) name tagging output with Farsi (fa) annotated training data only.

glish as our source language. Table 5 shows the performance on 10 low-resource languages.

Comparing cross-lingual embedding based baselines to the monolingual baseline, we observe that for most low-resource languages, directly adding the annotations from the source language to the target language slightly hurts the model. This suggests that when the training data for the target language is not enough, the model will be very sensitive to noise. The multitask learning based baseline (Lin et al., 2018) performs better than the monolingual baseline only when the target and source languages are very close, such as Amharic (am) and Tigrinya (ti), or Swahili (sw) and Yoruba (yo).

By introducing annotated training data from English, the performance of all the baselines becomes worse than the monolingual baseline. Since the script and sequence structure of English is very different from these low-resource languages, the addition of English to the limited target language training data yields a considerably noisy corpus. However, by forcing the sequence encoder to extract language-agnostic features, our approach still achieves better performance than the monolingual baseline for most languages. All of these experiments demonstrate that our approach is more effective in leveraging annotations from other languages to improve target language name tagging.

3.5 Cross-lingual Transfer for High Resource Languages

Language	Model	F-score
Dutch	Lampie et al. (2016)	81.74
	Yang et al. (2017)	85.19
	Lin et al. (2018)	85.71
	Gillick et al. (2016)	82.84
	Word-Adv^1	85.87
	Word-Adv^2	86.43
	Our Model (Bi-LSTM)	**86.87**
Spanish	Lample et al. (2016)	85.75
	Yang et al. (2017)	85.77
	Lin et al. (2018)	85.02
	Gillick et al. (2016)	82.95
	Word-Adv^1	85.92
	Word-Adv^2	85.84
	Our Model (Bi-LSTM)	**86.41**

Table 6: Comparison on cross-lingual transfer for Dutch and Spanish with various baselines: monolingual baseline (Lample et al. (2016)), multitask baselines (Yang et al. (2017) and Lin et al. (2018)), language universal representation baselines (Gillick et al. (2016), Word-Adv^1, Word-Adv^2).

We finally investigate the results when both the source and target languages are all high-resource languages. Table 6 presents the performance on Dutch and Spanish while using English as the source language. Our approach significantly outperforms all the other approaches even when the size of the annotated training data for the target language is huge. We notice that our approach achieves larger improvement on Dutch than Spanish. The reason may be that, compared with Spanish, Dutch is much closer to English (Cutler and Pasveer, 2006). Both English and Dutch are from the same *West Germanic* branch of the *Indo-European* language family while Spanish is from the *Italic* branch.

3.6 Impact of Annotation Size from Source and Target Languages

We use Amharic as the target language and Tigrinya as the source language to show the impact of the size of their annotations. Specifically, to explore the impact of the size of target language annotations, we use 0, 10%, 50%, or 100% annotated training data from Amharic. Similarly, to show the effect of the size of source language annotations, for each experiment, we also gradually add 0, 20%, 50%, or 100% annotated training data from Tigrinya. For all experiments, we use the same dev and test set of Amharic. As Figure 4 shows, as we gradually add annotations from the source or target language, the performance can always be improved. When the size of target language annotations is small, such as 400 sentences, we can achieve 5%-30% F-score gain by adding about 4,000 sentences from the source language. When the size of target language annotations is over 2,000 sentences, the improvement is about 2% if we add in about 4,000 sentences from source language annotations.

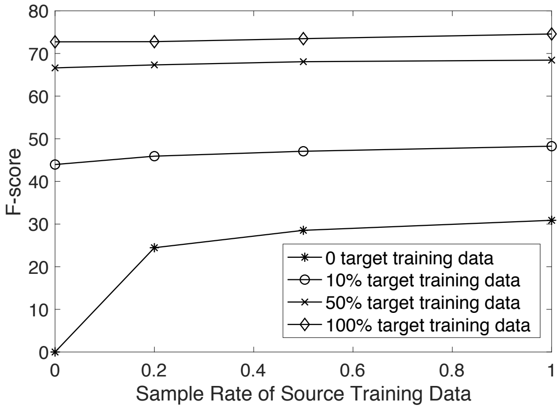

Figure 4: The impact of the size of annotations from source and target languages on Amharic name tagging.

4 Related Work

Name tagging methods based on sequence labeling have been widely studied in recent years. Huang et al. (2015) and Lample et al. (2016) propose an effective Bi-LSTM-CRF architecture; the Bi-LSTM encodes previous and following contexts, and the CRF is used for tag prediction. Other studies incorporate a character-level CNN (Ma and Hovy, 2016), global contexts (Zhang et al., 2018), or language models (Liu et al., 2018; Peters et al., 2017, 2018; Devlin et al., 2018) to improve name tagging. In addition, several approaches (Zhang et al., 2016a, 2017a; Al-Badrashiny et al., 2017) attempt to incorporate hand-crafted linguistic features into a Bi-LSTM-CRF to improve low-resource name tagging performance.

Recent attempts on cross-lingual transfer for name tagging can be divided into two categories: the first projects annotations from a source language to a target language via parallel corpora (Yarowsky et al., 2001; Wang and Manning, 2013; Wang et al., 2013; Zhang et al., 2016b; Fang and Cohn, 2016; Ehrmann et al., 2011; Enghoff et al., 2018; Ni et al., 2017), a bilingual gazetteer (Feng et al., 2017; Zirikly and Hagiwara, 2015), Wikipedia anchor links (Kim et al., 2012; Nothman et al., 2013; Tsai et al., 2016; Pan et al., 2017), and language universal representations, including Unicode bytes (Gillick et al., 2016) and cross-lingual word embeddings (Fang and Cohn, 2017; Wang et al., 2017; Huang et al., 2018; Xie et al., 2018). The second is based on multitask learning via a weight sharing encoder (Yang et al., 2016, 2017; Lin et al., 2018). Compared to these studies, our approach not only automatically learns cross-lingual word embeddings without requiring any parallel resources, but also carefully extracts language-agnostic sequential features, yielding better performance.

Adversarial training has also been extensively studied and applied for cross-lingual and cross-domain transfer. Several studies (Barone, 2016; Zhang et al., 2017c,b; Conneau et al., 2017; Chen and Cardie, 2018) explore adversarial training to automatically induce bilingual and multilingual word representations without using any parallel corpora or bilingual gazetteers. Adversarial training is also applied to extract language-agnostic (Chen et al., 2016; Zou et al., 2018; Wang and Pan, 2018; Kim et al., 2017a; Muis et al., 2018; Cao et al., 2018) and domain-agnostic features (Kim et al., 2017b; Ganin et al., 2016; Tzeng et al., 2017; Chen et al., 2017; Li et al., 2017; Fu et al., 2017; Bousmalis et al., 2016; Shi et al., 2018) for cross-lingual and cross-domain adaptation. Compared with these methods, our approach combines both word-level and sentence-level adversarial training.

5 Conclusions and Future Work

We design a new neural architecture which integrates multi-level adversarial transfer into a Bi-LSTM-CRF to improve low-resource name tagging. With word-level adversarial training, it can automatically project the source language into a shared semantic space with the target language without requiring any comparable data or bilingual gazetteers. Moreover, considering the different underlying sequential structures among various languages, we further design a sentence-level adversarial transfer to encourage the sequence encoder to extract language-agnostic features. The experiments show that our approach achieves the state-of-the-art on both CoNLL data sets and 10 low-resource languages. In the future, we will further explore selecting the feature-consistent annotations from the source language and add to the target language, and explore unsupervised pretrained cross-lingual language models (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018; Lample and Conneau, 2019) for cross-lingual low resource name tagging.

Unsupervised Extraction of Partial Translations for Neural Machine Translation

Abstract

In neural machine translation (NMT), monolingual data are usually exploited through a so-called back-translation: sentences in the target language are translated into the source language to synthesize new parallel data. While this method provides more training data to better model the target language, on the source side, it only exploits translations that the NMT system is already able to generate using a model trained on existing parallel data. In this work, we assume that new translation knowledge can be extracted from monolingual data, without relying at all on existing parallel data. We propose a new algorithm for extracting from monolingual data what we call partial translations: pairs of source and target sentences that contain sequences of tokens that are translations of each other. Our algorithm is fully unsupervised and takes only source and target monolingual data as input. Our empirical evaluation points out that our partial translations can be used in combination with back-translation to further improve NMT models. Furthermore, while partial translations are particularly useful for low-resource language pairs, they can also be successfully exploited in resource-rich scenarios to improve translation quality.

1 Introduction

Neural machine translation (NMT) systems usually require a large quantity of high-quality bilingual parallel data for training. However, for most language pairs, we do not have such resources, or only in very small quantities, mainly because they are costly to produce.

On the other hand, monolingual corpora are readily available in large quantity for many languages. Previous work has proposed various strategies to integrate monolingual data into NMT systems and has confirmed their usefulness to improve NMT systems. The so-called *back-translation* of monolingual data (Sennrich et al., 2016) is undoubtedly the most prevalent one. This approach simply uses a target-to-source MT system to translate monolingual data in the target language into the source language. The produced new synthetic parallel corpus can be used together with the original parallel data to increase the size of the training data, and eventually to improve NMT systems significantly and consistently. However, on the source side, the synthetic data only contain data that can be generated by the back-translation system trained on some existing parallel data.

Previous work has also studied the extraction of translation pairs of source and target sentences from monolingual data in their respective languages. They have been shown to be useful to train better statistical machine translation (SMT) systems, especially in low-resource conditions. Existing methods on sentence pair extraction mainly rely on the availability of comparable corpora as the source of accurate sentence pairs (Abdul Rauf and Schwenk, 2011), or on the robustness of SMT against noise (Goutte et al., 2012) because sentence pairs extracted from unrelated monolingual corpora tend to be noisy (Tillmann and Xu, 2009; Marie and Fujita, 2017). Most of them also require pre-trained accurate translation models, those of SMT systems for instance, that we may not have in low-resource conditions. Moreover, unlike SMT, NMT has been shown to deal very poorly with noisy training data and still largely underperforms SMT for low-resource language pairs (Koehn and Knowles, 2017) for which comparable corpora are usually not available. Even without an accurate translation model, we still have the possibility of extracting sentence pairs from unrelated source and target monolingual data. However, this is very challenging since we have no guarantee that there are sentence pairs actually retrievable from a given

pair of source and target monolingual corpora.

In this work, we assume (i) that a given pair of monolingual corpora contain sentence pairs that are at least *partial translations*, i.e., pairs of source and target sentences containing phrases (sequences of tokens) that are translations of each other and (ii) that such pairs can help train better NMT systems. On these assumptions, we propose a new algorithm that extracts partial translations from trillions of candidate sentence pairs without any supervision. Relying on an unsupervised phrase table, our algorithm identifies phrases in a source sentence that have likely translations in a target sentence. The extracted partial translations often contain unrelated parts besides aligned phrases. Therefore, we also apply a simple but very effective post-processing to make such noisy sentence pairs exploitable for a target-to-source NMT model, as exemplified in Figure 1.

We report on significant improvements in translation quality for two language pairs and under different experimental conditions when using our extracted partial translations to train NMT systems. While our method is especially designed to provide new training data for low-resource language pairs, we also observed significant improvements over a strong NMT system trained on large quantity of parallel data. Furthermore, we demonstrate the complementarity of our approach with back-translation.

2 Extraction of Partial Translations

The whole framework for extracting partial translations is presented in Figure 2. To extract partial translations, we first induce a phrase table that contains phrases in the source language paired with their most probable translations in the target language (Section 2.1). These phrase pairs are collected from the same monolingual data from which we extract partial translations. Given the induced phrase table, we search for sentence pairs that are the most likely partial translations in the monolingual data (Section 2.2). Finally, the extracted sentence pairs are post-processed (Section 2.3).

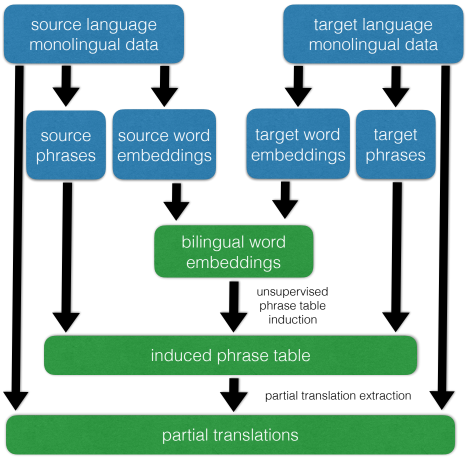

Figure 2: The framework for extracting partial translations from monolingual data.

2.1 Unsupervised Phrase Table Induction

Recent methods addressed the task of finding word translations from monolingual data without any supervision (Lample et al., 2018a; Artetxe et al., 2018a). On the other hand, Marie and Fujita (2018) presented a method for inducing phrase tables from monolingual data using a weakly-supervised framework. To make our approach useful in as many translation tasks as possible, including very low-resource scenarios, we propose a fully unsupervised version of the method in Marie and Fujita (2018). Using phrases instead of only single tokens promotes the extraction of partial translations containing longer sequences of tokens, rather than those with potentially more but discontinuously translated tokens.

Regarding all n-grams of tokens in the monolingual data as phrases and searching the translations for each phrase can be extremely costly. Therefore, we extract meaningful source and target phrases from their respective monolingual data, following the work by Marie and Fujita (2018).[1] Beside extracting phrases, we also train word embeddings on the same source and target monolingual data, independently. Both source and target embedding spaces are aligned in the same space to make word embeddings bilingual, without any supervision (Artetxe et al., 2018a). Using these

---

[1] See Section 3.1 of Marie and Fujita (2018) for the details.

bilingual word embeddings, we compute bilingual phrase embeddings for each of the extracted phrases through the element-wise addition of the embeddings of constituent words of the phrases.

Given the source and target phrase sets, we take their Cartesian product to generate all possible pairs of source and target phrases and compute cosine similarity of each pair using their phrase embeddings. Each pair is also associated with a translation probability (Lample et al., 2018b):

$$p(t_j|s_i) = \frac{\exp\left(\beta \cos(emb(t_j), emb(s_i))\right)}{\sum_k \exp\left(\beta \cos(emb(t_k), emb(s_i))\right)}, \tag{1}$$

where t_j is the j-th phrase in the target phrase list and s_i the i-th phrase in the source phrase list, β a parameter to tune the peakiness of the distribution[2] (Smith et al., 2017), $\cos(\cdot,\cdot)$ cosine similarity between two phrase embeddings, and $emb(\cdot)$ a function returning the bilingual embedding of a given phrase. In practice, to keep the set of phrase pairs to score manageable, we first filter the 300k most frequent phrases in each of the source and target phrase sets.[3]

Retrieved phrase pairs may have a very low translation probability, especially when dealing with distant languages and/or noisy monolingual data. Therefore, we keep only the n-best target phrases for each source phrase, according to Eq. (1). While maintaining the coverage by our phrase table of the source monolingual data the same, we ensure that the phrase translations for each source phrase are the most accurate among all the collected target phrases.

2.2 Partial Translation Extraction

NMT architectures expect parallel sentence pairs as training data, even if we have accurate phrase pairs, they cannot be used directly for training.

Algorithm 1: Partial Translation Extraction

```
Input      : $pt$: a phrase table,
             $M_s$: source monolingual data, and
             $M_t$: target monolingual data
Output     : $P_{\text{translations}}$: a set of the $m_{\text{top}}$-best partial
             translations
Parameters: $m$: the number of target sentence to
             retrieve for each source sentence for the
             PBFD algorithm, and
             $m_{\text{top}}$: the size of $P_{\text{translations}}$
1  $P_{\text{translations}} \leftarrow \{\}$ ;
2  foreach sentence $S$ in $M_s$ do
3      $P_s \leftarrow$ Intersection($pt$, $S$) ;
4      $B_t \leftarrow$ Bow($P_s$, $pt$) ;
5      $T_{\text{candidates}} \leftarrow \{\}$ ;
6      foreach sentence $T$ in $M_t$ do
7          if $\exists w \in T$: $w \in B_t$ then
8              $T_{\text{candidates}} \leftarrow T_{\text{candidates}} \cup T$ ;
9          end
10     end
11     $T_m \leftarrow$ Prune($m$, $T_{candidates}$) ;
12     $T_{\text{best}} \leftarrow$ PBFD($pt$, $S$, $T_m$) ;
13     $P_{\text{translations}} \leftarrow P_{\text{translations}} \cup (T_{\text{best}}, S)$ ;
14 end
15 $P_{\text{translations}} \leftarrow$ GetBest($m_{top}$, $P_{translations}$) ;
16 return $P_{\text{translations}}$
```

Therefore, we propose an algorithm for extracting sentence pairs from the monolingual data that matches the best possible combinations of phrase pairs from the induced phrase table. The pseudocode of this algorithm is presented in Algorithm 1. For each source sentence S (l.2), the algorithm first selects from the phrase table pt all the phrase pairs P_s whose source side appears in S (l.3). It then creates a bag of target words B_t via collecting all the words from the target phrases of P_s (l.4). Subsequently, we keep the m-best target sentences T_m (ll.5–11) according to the following score:

$$F_t(S,T) = \frac{2c_s c_t}{c_s + c_t}, \tag{2}$$

where $c_s = k_t/len(S)$, $c_t = k_t/len(T)$, with S and T respectively a source and a target sentence, k_t the number of tokens in T that are covered by B_t, and $len(\cdot)$ a function that returns the number of tokens in a sentence. With the harmonic mean F_t between c_s and c_t, the algorithm searches for target sentences containing as many words translating source tokens as possible while penalizing the retrieval of very long target sentences that may also contain many tokens having no counterparts in the source sentence.

Then, the algorithm re-ranks the target sentences in T_m with the phrase-based forced decoding (PBFD) algorithm (Zhang et al., 2017) (l.12). PBFD searches for the best combination of phrase pairs covering S and each target sentence in T_m, using the phrase translation probability computed by Eq. (1). However, the original PBFD algorithm penalizes sentence pair with words that are not covered by any phrase pair. It tends to favor very short sentences that are potentially less exploitable for NMT systems, or not even be sentences as it may happen when dealing with noisy

---

[2] We set $\beta = 30$ since it gives consistently good results in our preliminary experiments.

[3] This means that we still have to compute the cosine similarity for 90 billion phrase pairs (300k×300k). This can be done very efficiently on GPU: `https://github.com/facebookresearch/faiss`.

monolingual data.[4] Therefore, we use a slightly modified version which does not penalize uncovered words on the target side in order to favor the extraction of longer target sentences that may contain more translated tokens. Finally, we retain only $P_{\text{translations}}$: the m_{top} sentence pairs with the highest PBFD scores (l.15).

2.3 Post-Processing of Partial Translations

Since the extracted sentence pairs are only partial translations, incorporating them as they are into the training data for NMT may mislead the training of the model due to their noisiness. Since our PBFD algorithm does not penalize target words not covered by any phrase pair, the target side of our partial translations contains longer sentences than the source side, potentially with many words unaligned with any word in the source sentences. Nonetheless, the back-translation approach has proven that NMT can be trained on noisy data at the source side and fluent sentences at the target side. Following this, we use partial translations only to train target-to-source NMT systems, as for back-translated data. It means that the source and target languages of our extraction algorithm becomes respectively the target and source languages of the NMT system.

We want the NMT system to give as much attention as possible to the phrases of the source sentence that have a translation in the target sentence, while ignoring as much as possible the remaining tokens of the source sentence that are likely to be noise, i.e., not translated by the target sentence. Dropping these unaligned tokens is not an appropriate solution since it would produce unlikely sequences of translated tokens. Then, to make the decoder paying its attention to the translated part in the source sentence, we simply replaced all the tokens not covered by the best combination of phrase pairs found by the PBFD algorithm with a made-up token, `UNKPP`.[5]

We expect this post-processing step to particularly well suit the training of a Transformer NMT model (Vaswani et al., 2017), because it can easily learn to pay no attention to `UNKPP` and more attention to correctly translated tokens thanks to the multi-head attention mechanism. Moreover, the Transformer model does not memorize complete sequences and makes time steps independent, unlike recurrent neural networks (RNN). It uses instead positional encodings and has a better ability in linking important features from the entire sequence (Chen et al., 2018), which may make easier the learning from noisy sequences, such as the ones created by introducing `UNKPP`.

We show in Section 4 that using `UNKPP` tokens instead of dropping uncovered tokens leads to a better model. Nonetheless, a better strategy that we leave for future work could be to apply some forced-decoding, with an SMT system for instance, that translates in the source sentence the parts of the target sentence that are not translated, while preserving the partial translations detected by our algorithm in the source sentence.

3 Experiments

We experimented on three language pairs with different degrees of relatedness between the languages of each pair: English→German (en→de), English→Turkish (en→tr), and Bengali→Malay (bn→ms). While our approach is dedicated to improve translation quality for low-resource language pairs, we included the en→de pair for a detailed analysis on the impact of using partial translations in addition to much more training data. bn→ms is expected to be an extremely difficult translation task, because only small quantity of parallel data are available to start with (Section 3.1) and Bengali and Malay are very distant languages which makes very difficult the training of useful unsupervised bilingual word embeddings (Søgaard et al., 2018), which is a key element for inducing the phrase table.

3.1 Data

To train baseline NMT systems, we used for en→de and en→tr 100k parallel sentences randomly extracted from the parallel data provided for the WMT18 News Translation Task,[6] except the ParaCrawl corpus for en→de. For bn→ms, we used the 18k sentence pairs released by the Asian Language Treebank (ALT) project (Riza et al., 2016).[7] As validation and test data for en→de and en→tr, we used Newstest2016 and Newstest2017, respectively, provided by WMT18. For bn→ms,

---

[4] This includes equations, rows of a table, titles, etc.

[5] We made this token different from the usual token reserved for unknown word in the vocabulary, since they are of a different nature.

[6] `http://www.statmt.org/wmt18/translation-task.html`

[7] `http://www2.nict.go.jp/astrec-att/member/mutiyama/ALT/`

we used the official development and test data provided by the ALT project.

We chose this amount of training data for en→de and en→tr, since it suits our need for a low-resource translation task while we can still use the available parallel data for further analysis. Moreover, we needed enough parallel data to train an NMT model that can produce useful back-translated data. In our preliminary experiment, we found out that 100k sentence pairs satisfy the minimum amount to train NMT models for useful back-translation. As such, we did not succeed in training useful models for bn→ms, due to the difficulty of the task, but still decided to report on the results to provide insights and matters for future work.

As for monolingual data, we used the English (239M lines) and German (237M lines) NewsCrawl corpora provided by WMT18, and the NewsCrawl and Common Crawl corpora for Turkish (104M lines). We extracted monolingual data ourselves from the Common Crawl project[8] for Bengali (5.3M lines) and Malay (4.6M lines).

3.2 Methods and Systems

To build an unsupervised phrase table, we first extracted 300k most frequent phrases of up to 6 tokens from the entire monolingual data. We also trained 200-dimensional word embeddings on the same data with `fasttext`.[9] For each source phrase, we retained only the 1-best target phrase in the induced phrase table.

The search for partial translations was performed only for a random sample of 1M lines from the monolingual data for each target language. For each of these lines, we searched for the best partial translation with our algorithm in up to 10M lines randomly extracted from the monolingual data for the source language. Then, to maintain a 1:1 ratio with the parallel data, we retained the 100k best partial translations for en→de and en→tr,[10] and 18k best partial translations for bn→ms.

All our NMT systems, including baselines, were the Transformer model (Vaswani et al., 2017) trained with Marian (Junczys-Dowmunt et al., 2018). Note that we fine-tuned the hyperparameters for training on our validation data for each language pair in order to get best possible baseline systems. We then apply the same hyperparameters in all the experiments for the given language pair. To train systems with partial translations (`partial`), we simply mixed them with the original parallel data during training. We also evaluated the systems using back-translated (`backtr`) and copied[11] (`copy`) (Currey et al., 2017) data, separately mixed with the original parallel data. Note that these data were generated from the same target sentences sampled for extracting partial translations: `partial`, `backtr`, and `copy` had the same target side but different source side.[12] Our NMT systems were evaluated with detokenized BLEU-cased.

Training data	en→de	en→tr	bn→ms
baseline	7.1	9.3	**6.1**
`backtr`	9.1	11.4	5.4
`copy`	9.0	11.2	6.0
`partial`	9.9	10.4	5.5
`backtr+copy`	11.3	11.6	5.5
`backtr+partial`	11.5	11.6	4.5
`backtr+copy+partial`	**11.9**	**12.2**	5.8

Table 1: BLEU scores of NMT systems. All the evaluated systems used the parallel data used to train the baseline system, and other synthetic parallel data generated by back-translation (`backtr`), copy (`copy`), or from extracted partial translation (`partial`).

3.3 Results

The results of our experiments are presented in Table 1. For en→de and en→tr, the baseline systems resulted in a poor translation quality below 10 BLEU points. This highlights how critical it is to get more training data to better train an NMT model for low-resource translation tasks.

Adding 100k synthetic parallel sentences generated by back-translation (`backtr`) improved translation quality by 2.0 and 2.1 BLEU points for en→de and en→tr, respectively. Surprisingly, the simplest `copy` method brought improvements similar to `backtr`. Furthermore, we also observed the complementarity of `backtr` and `copy` (`backtr+copy`), with 4.2 and 2.3 BLEU points of improvements for en→de and en→tr, re-

---

[8] `http://commoncrawl.org/`

[9] `https://fasttext.cc/`

[10] The extraction of 100k partial translations from 10^{13} sentence pairs (1M×10M) required around 26 hours of computation using 100 CPUs.

[11] The `copy` approach simply copies the target sentences to the source side. This method surprisingly offers good results in low-resource conditions, and a good complementarity with back-translation, for languages with some orthographic similarity.

[12] With some source sentences that may be identical.

spectively, over the baseline system. To verify that it is not the consequence of just giving more weight to the target monolingual data that may be in-domain, we also trained `backtr+backtr` but did not observe any improvements over `backtr`.

For en→de, the system using our extracted partial translations (`partial`) outperformed `backtr` and `copy` by 0.8 and 0.9 BLEU points, respectively, and the baseline system by 2.8 BLEU points. For en→tr, `partial` also significantly outperformed the baseline system, by 1.1 BLEU points. However, `backtr` and `copy` brought larger improvements. We can explain the difference between en→de and en→tr by the fact that Turkish is more distant from English than German. It makes unsupervised bilingual word embeddings more difficult to train for en→tr and are consequently significantly less accurate (Søgaard et al., 2018). Extraction of accurate and useful partial translations from monolingual data is a more difficult task for en→tr.

While these three kinds of synthetic parallel data, `backtr`, `copy`, and `partial`, present the same target sentences, we found out that mixing all of them with the original parallel led to the best system (`backtr+copy+partial`). This result shows the complementarity of these three datasets thanks to the diversity of source sides generated by different means. For instance, `partial` provides new original translations that were not generated by back-translation.

As expected, bn→ms is a very difficult task for NMT due to the small size of the training data. We were not able to train an NMT model that can generate useful back-translations. The `copy` method was also unhelpful since Bengali and Malay have different writing systems. Our partial translations did not help either, presumably due to the difficulty in unsupervised learning of bilingual word embeddings. Note also that we used much less monolingual data for this language pair to train the word embeddings. This last result is disappointing, but it confirmed that unsupervised bilingual word embeddings are still far from being useful for truly low-resource and distant language pairs.

4 Analysis

4.1 Impact of the Phrase Table

We induced the phrase table from the 300k most frequent source and target phrases. An obvious and actually simpler alternative is the use of words instead of phrases. Using 300k words instead of 300k phrases, for instance, results in a similar cost for phrase table induction but involves a larger vocabulary introducing a better coverage of the monolingual data. However, involving more, and consequently less frequent, words means that it also introduces words for which the word embedding will be noisier.

Training data	en→de	en→tr
baseline	7.1	9.3
1-best target word	8.6	9.9
1-best target phrase	**9.9**	**10.4**
2-best target phrases	7.6	9.5
5-best target phrases	7.5	9.3

Table 2: BLEU scores of NMT systems based on a phrase table induced from source and target single words, or using the 1-best (as in our default configuration), 2-best, or 5-best target phrase translations for each source phrase.

Another important decision that we made when inducing the phrase table was to take only the 1-best target phrase for each source phrase. Involving noisier translations would have a larger impact on our algorithm by inflating the size of B_t that would contain more and noisier target tokens, resulting in unworthily high F_t scores for target sentences containing these tokens that are nonetheless less likely to be the translations of the corresponding source phrase.

Table 2 presents results obtained when using single words instead of phrases to induce the phrase table, and when used the 1-, 2-, or 5-best target phrases for each source phrase. For en→de, using words instead of phrases still led to useful partial translations, with an improvement of 1.5 BLEU points. However, it was 1.3 BLEU points lower than when using phrases. The use of more than one target phrase for each source phrase in the induced phrase table resulted in the retrieval of noisier partial translations that are much less useful to train better NMT models. We observed the similar tendencies for en→tr.

One of the strongest assumption of this work is that partial translations bring translation knowledge complementary to the manually created parallel data used to the train the NMT system. This new knowledge is unbiased by the existing parallel data since we induce the phrase table without using any given parallel data. On the other hand, we can train a phrase table on the parallel data used

Training data	en→de	bn→ms
baseline	7.1	6.1
induced phrase table	**9.9**	5.5
standard phrase table	9.4	**6.3**

Table 3: BLEU scores of NMT systems based on a phrase table induced from monolingual data or based on a standard phrase table trained on the same parallel data also used to train the baseline system.

Training data	en→de	en→tr
baseline	7.1	9.3
`original`	6.2	7.7
`dropped`	8.8	10.0
`partial`	**9.9**	**10.4**

Table 4: BLEU scores of NMT systems trained on partial translations with (`dropped`, `partial`) and without (`original`) post-processing.

to train the NMT system and use it to extract partial translations. Owing to the supervision, we can expect such a phrase table to be much more accurate than the induced phrase table. However, it would introduce a strong bias that encourages the retrieval of partial translations similar to the parallel data that are already used to train the system. Consequently, the extracted partial translations may be less useful than those extracted with an induced phrase table.

To test the above assumption, we trained a standard phrase table on the given parallel data, extracted partial translations using it, and evaluated their impact on the translation quality. Table 3 shows the results for en→de and bn→ms. The results for en→de supports our hypothesis: using a standard phrase table for extracting partial translations has led to a drop of 0.5 BLEU points compared to the use of an induced phrase table. In contrast, for bn→ms, standard phrase table achieved significantly better results than using the induced phrase table and brought a slight improvement over the baseline system. We speculate that the standard phrase table trained only on 18k sentence pairs is not strong enough to bias the extraction of partial translations.

4.2 Impact of Post-Processing

By replacing unaligned tokens, identified by the PBFD algorithm, with a made-up token `UNKPP`, we aimed to guide the decoder to ignore them during training. This section explores the impact of this post-processing, through comparing the translation quality of NMT systems trained on partial translations without any post-processing (`original`), post-processed by removing unaligned source tokens (`dropped`), and our proposed method that replaces unaligned tokens with `UNKPP` (`partial`).

Table 4 presents our results. Without any post-processing, using partial translations brought a significant drop of translation quality of 0.9 BLEU points for en→de, and 1.6 BLEU points for en→tr, from the baseline system trained only on parallel data. This is expected since the partial translations can be very noisy with many unaligned tokens for which the Transformer model will still try to learn a translation in the target sentence. Removing them helps significantly with, for instance for en→de, a 1.7 BLEU points of improvements over the baseline system. However, their removal hides the existence of unaligned tokens and produces sequences of tokens that are unlikely in the source language, presumably misleading the training of the NMT model. Indeed, replacing them with a made-up token further improved the translation quality by 1.1 BLEU points.

4.3 Impact of Noisier Partial Translations

The baseline systems evaluated in Section 3 were trained on 100k parallel data and augmented with the same amount of back-translated sentences and partial translations. Our algorithm retrieved the best partial translation for each one of the 1M source sentences, and then ranked them according to the PBFD score in order to select the most accurate ones. In fact, partial translations at lower rank contained more unaligned tokens, as shown in Figure 3, and also incorrectly aligned tokens. Using these noisier partial translations may disturb the training of the NMT system. In contrast, we can easily increase the quantity of the back-translated data of a similar quality.

To verify this assumption, we evaluated NMT models for en→de and en→tr trained on different quantities of original parallel data, back-translated data, and partial translations.[13] The results are presented in Table 5. As expected, using more back-translated data was much more helpful than using more partial translations. For en→de, in combination with 100k parallel sentences, using

---

[13] We did not oversample the original parallel data to match the size of original and synthetic parallel data, as commonly performed in multilingual NMT (Johnson et al., 2017).

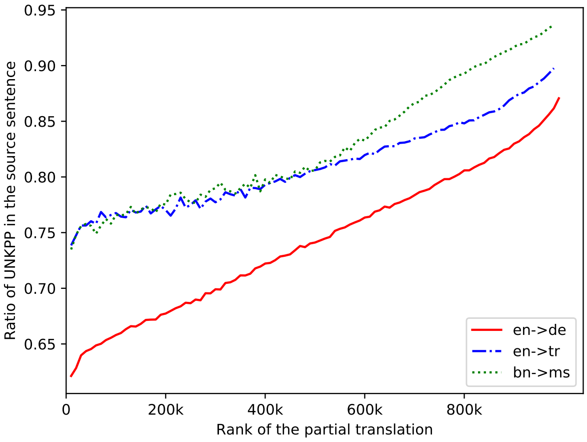

Figure 3: Ratio of `UNKPP` in the source sentence according to the rank of the partial translation. To smooth the curves, we drew the averaged ratio for every batch of 10k consecutively ranked partial translations.

para.	`backtr`	`partial`	en→de	en→tr
100k			7.1	9.3
100k	300k		13.2	13.3
100k		300k	10.8	10.7
100k	300k	300k	**13.6**	**13.7**
100k	1M		16.9	17.9
100k		1M	12.0	11.8
100k	1M	1M	**17.5**	**18.3**
all			26.2	13.6
all	1M		27.7	18.6
all		1M	26.4	14.7
all	1M	1M	**28.2**	**19.0**

Table 5: BLEU scores of NMT systems trained on different combinations of original parallel data (para.), back-translated data (`backtr`), and partial translations (`partial`). "all" denotes the use of all the parallel data provided by the WMT18 News Translation Task: around 5.6M and 207k sentence pairs for en→de and en→tr, respectively.

300k back-translated data achieved better results than using 300k partial translations, with an advantage of 2.4 BLEU points, in contrast to our observation with 100k additional data (Table 1). The gap was even more significant when using 1M additional data: back-translated data achieved 4.9 BLEU points higher than using partial translations. Nonetheless, for en→de, over the configuration using 100k partial translations (9.9 absolute BLEU points), using 300k and 1M partial translations improved by 0.9 and 2.1 BLEU points, respectively. We observed a similar tendency for en→tr. Searching for partial translations in more monolingual data would result in the extraction of a larger number of more accurate partial translations, and presumably help obtain even better NMT models.

Mixing partial translations, back-translated data, and parallel data remains our best configuration. We consistently obtained better results than when using only either partial translations or back-translated data as training data. Even when using the full parallel data of 5.6M sentence pairs and 1M back-translated data[14] for en→de, partial translations still brought an improvement of 0.5 BLEU points. Our best system reached 28.2 BLEU points.[15] This last result confirms that using partial translations as additional training data has also the potential to improve a state-of-the-art NMT system, while it is much more effective in low-resource scenarios.

5 Related Work

There are various methods for extracting sentence pairs from monolingual corpora. However, most of them rely on the availability of document-level information, in comparable corpora for instance, and usually for one specific domain, to efficiently extract accurate sentence pairs (Abdul Rauf and Schwenk, 2011). Other methods extract sentence pairs from completely unrelated monolingual corpora (Tillmann and Xu, 2009; Marie and Fujita, 2017). However, they still rely on an existing accurate translation model trained on large parallel data, introducing a strong bias in the retrieval of sentence pairs. Unlike existing methods, our algorithm for retrieving partial translations is efficient enough to work on large unrelated monolingual data without relying on any document-level information, and also fully unsupervised. Without any bias toward some existing parallel data, it is very suitable for low-resource scenarios.

Previous work has also exploited monolingual data in the target language for improving NMT systems (Sennrich et al., 2016; Currey et al., 2017; Hoang et al., 2018). As demonstrated in this paper, our approach is complementary to previous work, since partial translations can introduce novel information into training. To the best of our knowledge, this is the first work to propose a method for extracting sentence pairs from source and target

---

[14] For this experiment, the NMT system for back-translation was also trained on the full parallel data.

[15] Only 0.1 BLEU points lower than the best reported result at WMT17 for this task. The winning systems used much more back-translated data and an ensemble of several models for decoding.

unrelated monolingual corpora that can be used to train better NMT systems, without requiring any modification of current NMT model architecture.

Wang et al. (2017) proposed a method to train an RNN-based NMT system on partially aligned translations only. However, this method cannot straightforwardly be applied to the state-of-the-art Transformer architecture. In contrast, our proposed method does not assume a particular architecture of NMT, nor requires any modifications of the NMT implementation. In addition, they assume not only that a phrase table is given for their low-resource language pairs, but also that the phrase pairs in the given phrase table are very accurate. We rather focus on augmenting the training data, without assuming phrase pairs of high accuracy. Training NMT only on our extracted partial translations could also be worth investigating.

As confirmed in Section 4.1, the quality of induced phrase table nevertheless affects the usefulness of resulting partial translations. Recent advances in unsupervised MT (Artetxe et al., 2018b; Lample et al., 2018b) have shown that we can obtain phrase tables of better quality through iterating generation of synthetic parallel data and (pseudo-)training of a phrase table on such data. We plan to evaluate whether better phrase tables result in more useful partial translations.

6 Conclusion

We presented a new algorithm for extracting partial translations from unrelated monolingual corpora. Our algorithm is fully unsupervised, i.e., it does not rely on any existing human-made bilingual data, making itself suitable for low-resource language pairs. We demonstrated that very noisy partial translations can be transformed into useful training data for NMT systems with a simple post-processing. While we designed our method specifically for low-resource scenarios, we also showed that partial translations are useful for further improving a state-of-the-art NMT system trained on large parallel data and back-translated synthetic parallel data.

In our future work, we will study the impact of using more partial translations of better quality to train NMT systems. We assume that we can collect better partial translations by searching in more monolingual data. Moreover, we also observed that the top-ranked sentence pairs extracted by our algorithm may be translations of very good quality. We will study the possibility of using such sentence pairs as development data to enable the tuning of unsupervised SMT and NMT systems (Lample et al., 2018b). We will also analyze whether our partial translations are useful because of their noisy nature, since noisy synthetic data have recently been proven useful in some specific configurations (Edunov et al., 2018).

Acknowledgments

We would like to thank the reviewers for their useful comments and suggestions, and Jingyi Zhang for providing the implementation of the phrase-based forced decoding for our experiments. Abstract

We describe a cross-lingual transfer method for dependency parsing that takes into account the problem of word order differences between source and target languages. Our model only relies on the Bible, a considerably smaller parallel data than the commonly used parallel data in transfer methods. We use the concatenation of projected trees from the Bible corpus, and the gold-standard treebanks in multiple source languages along with cross-lingual word representations. We demonstrate that reordering the source treebanks before training on them for a target language improves the accuracy of languages outside the European language family. Our experiments on 68 treebanks (38 languages) in the Universal Dependencies corpus achieve a high accuracy for all languages. Among them, our experiments on 16 treebanks of 12 non-European languages achieve an average UAS absolute improvement of 3.3% over a state-of-the-art method.

1 Introduction

There has recently been a great deal of interest in cross-lingual transfer of dependency parsers, for which a parser is trained for a target language of interest using treebanks in other languages. Cross-lingual transfer can eliminate the need for the expensive and time-consuming task of treebank annotation for low-resource languages. Approaches include annotation projection using parallel data sets (Hwa et al., 2005; Ganchev et al., 2009), direct model transfer through learning of a delexicalized model from other treebanks (Zeman and Resnik, 2008; Täckström et al., 2013), treebank translation (Tiedemann et al., 2014), using synthetic treebanks (Tiedemann and Agić, 2016; Wang and Eisner, 2016), using cross-lingual word representations (Täckström et al., 2012; Guo et al., 2016; Rasooli and Collins, 2017) and using cross-lingual dictionaries (Durrett et al., 2012).

Recent results from Rasooli and Collins (2017) have shown accuracies exceeding 80% on unlabeled attachment accuracy (UAS) for several European languages.[1] However non-European languages remain a significant challenge for cross-lingual transfer. One hypothesis, which we investigate in this paper, is that word-order differences between languages are a significant challenge for cross-lingual transfer methods. The main goal of our work is therefore to reorder gold-standard source treebanks to make those treebanks syntactically more similar to the target language of interest. We use two different approaches for source treebank reordering: 1) reordering based on dominant dependency directions according to the projected dependencies, 2) learning a classifier on the alignment data. We show that an ensemble of these methods with the baseline method leads to higher performance for the majority of datasets in our experiments. We show particularly significant improvements for non-European languages.[2]

The main contributions of this work are as follows:

- We propose two different syntactic reordering methods based on the dependencies projected using translation alignments. The first model is based on the dominant dependency direction in the target language according to the projected dependencies. The second model learns a reordering classifier from the small set of aligned sentences in the Bible parallel data.

---

[1] Specifically, Table 9 of Rasooli and Collins (2017) shows 13 datasets, and 11 languages, with UAS scores of over 80%; all of these datasets are in European languages.

[2] Specifically, performance of our method gives an improvement of at least 2.3% absolute scores in UAS on 11 datasets in 9 languages—Coptic, Basque, Chinese, Vietnamese, Turkish, Persian, Arabic, Indonesian Hebrew—with an average improvement of over 4.5% UAS.

Proceedings of NAACL-HLT 2019, pages 3845–3856
Minneapolis, Minnesota, June 2 - June 7, 2019.

- We run an extensive set of experiments on 68 treebanks for 38 languages. We show that by just using the Bible data, we are able to achieve significant improvements in non-European languages. Our ensemble method is able to maintain a high accuracy in European languages.

- We show that syntactic transfer methods can outperform a supervised model for cases in which the gold-standard treebank is very small. This indicates the strength of these models when the language is truly low-resource.

Unlike most previous work for which a simple delexicalized model with gold part-of-speech tags are used, we use lexical features and automatic part-of-speech tags. Our final model improves over two strong baselines, one with annotation projection and the other one inspired by the non-neural state-of-the-art model of Rasooli and Collins (2017). Our final results improve the performance on non-European languages by an average UAS absolute improvement of 3.3% and LAS absolute improvement of 2.4%.

2 Related Work

There has recently been a great deal of research on dependency parser transfer. Early work on direct model transfer (Zeman and Resnik, 2008; McDonald et al., 2011; Cohen et al., 2011; Rosa and Zabokrtsky, 2015; Wang and Eisner, 2018a) considered learning a delexicalized parser from one or many source treebanks. A number of papers (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Ammar et al., 2016; Wang and Eisner, 2017) have considered making use of topological features to overcome the problem of syntactic differences across languages. Our work instead reorders the source treebanks to make them similar to the target language before training on the source treebanks.

Agić (2017) use part-of-speech sequence similarity between the source and target language for selecting the source sentences in a direct transfer approach. Ponti et al. (2018) preprocess source trees to increase the isomorphy between the source and the target language dependency trees. They apply their method on a simple delexicalized model and their accuracy on the small set of languages that they have tried is significantly worse than ours in all languages. The recent work by Wang and Eisner (2018b) reorders delexicalized treebanks of part-of-speech sequences in order to make it more similar to the target language of interest. The latter work is similar to our work in terms of using reordering. Our work is more sophisticated by using a full-fledged parsing model with automatic part-of-speech tags and every accessible dataset such as projected trees and multiple source treebanks as well as cross-lingual word embeddings for all languages.

Previous work (Täckström et al., 2012; Duong et al., 2015; Guo et al., 2015, 2016; Ammar et al., 2016) has considered using cross-lingual word representations. A number of authors (Durrett et al., 2012; Rasooli and Collins, 2017) have used cross-lingual dictionaries. We also make use of cross-lingual word representations and dictionaries in this paper. We use the automatically extracted dictionaries from the Bible to translate words in the source treebanks to the target language. One other line of research in the delexicalized transfer approach is creating a synthetic treebank (Tiedemann and Agić, 2016; Wang and Eisner, 2016, 2018b).

Annotation projection (Hwa et al., 2005; Ganchev et al., 2009; McDonald et al., 2011; Ma and Xia, 2014; Rasooli and Collins, 2015; Lacroix et al., 2016; Agić et al., 2016) is another approach in parser transfer. In this approach, supervised dependencies are projected through word alignments and then used as training data. Similar to previous work (Rasooli and Collins, 2017), we make use of a combination of projected dependencies from annotation projection in addition to partially translated source treebanks. One other approach is treebank translation (Tiedemann et al., 2014) for which a statistical machine translation system is used to translate source treebanks to the target language. These models need a large amount of parallel data for having an accurate translation system.

Using the Bible data goes back to the work of Diab and Finch (2000) and Yarowsky et al. (2001). Recently there has been more interest in using the Bible data for different tasks, due to its availability for many languages (Christodouloupoulos and Steedman, 2014; Agić et al., 2015, 2016; Rasooli and Collins, 2017). Previous work (Östling and Tiedemann, 2017) has shown that the size of the Bible dataset does not provide a reliable machine translation model. Previous work in the context of machine translation (Bisazza and Federico, 2016; Daiber et al., 2016) presumes the availability of a parallel data that is often much larger than the Bible data.

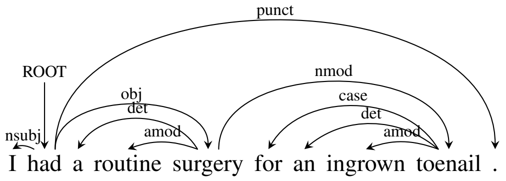
3 Baseline Model

Our model trains on the concatenation of projected dependencies $\mathcal{P}$ and all of the source treebanks $\mathcal{T}_1 \dots \mathcal{T}_k$. The projected data is from the set of projected dependencies for which at least 80% of words have projected dependencies or there is a span of length $l \geq 5$ such that all words in that span achieve a projected dependency. This is the same as the definition of dense structures $\mathcal{P}_{80} \cup \mathcal{P}_{\geq 5}$ by Rasooli and Collins (2015).

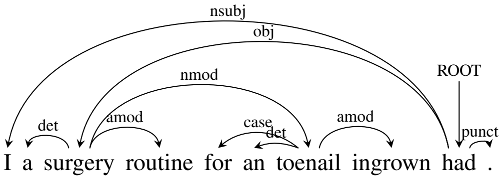
We use our reimplementation of the state-of-the-art neural biaffine graph-based parser of Dozat and Manning (2016)[3]. Because many words in the projected dependencies do not have a head assignment, the parser ignores words without heads during training. Inspired by Rasooli and Collins (2017), we replace every word in the source treebanks with its most frequent aligned translation word from the Bible data in the target language. If that word does not appear in the Bible, we use the original word. That way, we have a code-switched data for which some of the words are being translated. In addition to fine-tuning the word embeddings, we use the fixed pre-trained cross-lingual word embeddings using the training approach of Rasooli and Collins (2017) using the Wikipedia data and the Bible dictionaries.

4 Approach

Before making use of the source treebanks $\mathcal{T}_1 \dots \mathcal{T}_k$ in the training data, we reorder each tree in the source treebanks to be syntactically more similar to the word order of the target language. In general, for a head h that has c modifiers $m_1 \dots m_c$, we decide to put each of the dependents m_i on the left or right of the head h. After placing them in the correct side of the head, the order in the original source sentence is preserved. Figure 1 shows a real example of an English tree that is reordered for the sake of Persian as the target language. Here we see that we have a verb-final sentence, with nominal modifiers following the head noun. If one aims to translate this English sentence word by word, the reordered sentence gives a very good translation without any change in the sentence.



(a) Original tree.



(b) Persian-specific reordered tree.

Figure 1: An example of a gold-standard English tree that is reordered to look similar to the Persian syntactic order.

As mentioned earlier, we use two different approaches for source treebank reordering: 1) reordering based on dominant dependency directions according to the projected dependencies, 2) learning a classifier on the alignment data. We next describe these two methods.

4.1 Model 1: Reordering Based on Dominant Dependency Direction

The main goal of this model is to reorder source dependencies based on dominant dependency directions in the target language. We extract dominant dependency directions according to the projected dependencies $\mathcal{P}$ from the alignment data, and use the information for reordering source treebanks.

Let the tuple $\langle i, m, h, r \rangle$ show the dependency of the m'th word in the i'th projected sentence for which the h'th word is the parent with the dependency label r. $\langle i, m, \texttt{NULL}, \texttt{NULL} \rangle$ shows an unknown dependency for the m'th word: this occurs when some of the words in the target sentence do not achieve a projected dependency. We use the notations $h(i, m)$ and $r(i, m)$ to show the head index and dependency label of the m'th word in the i'th sentence.

Definition 1 *Dependency direction:* $d(i, m)$ *shows the dependency direction of the* m*'th*

---

[3] `https://github.com/rasoolims/universal-parser`

modifier word in the i'th sentence:

$$d(i,m) = \begin{cases} 1 & \texttt{if } h(i,m) > m \\ -1 & \texttt{otherwise} \end{cases}$$

Definition 2 *Dependency direction proportion: Dependency direction proportion of each dependency label l with direction $d \in \{-1, 1\}$ is defined as:*

$$\alpha^{(\mathcal{P})}(l,d) = \frac{\sum_{i=1}^{|\mathcal{P}|} \sum_{m=1}^{|\mathcal{P}^{(i)}|} \mathbb{I}(r(i,m) = l \,\&\, d(i,m) = d)}{\sum_{i=1}^{|\mathcal{P}|} \sum_{m=1}^{|\mathcal{P}^{(i)}|} \mathbb{I}(r(i,m) = l)}$$

Definition 3 *Dominant dependency direction: For each dependency label l, we define the dominant dependency direction $\lambda^{(\mathcal{P})}(l) = d$ if $\alpha^{(\mathcal{P})}(l,d) > 0.75$. In cases where there is no dominant dependency direction, $\lambda^{(\mathcal{P})}(l) = 0$.*

We consider the following dependency labels for extracting dominant dependency direction information: nsubj, obj, iobj, csubj, ccomp, xcomp, obl, vocative, expl, dislocated, advcl, advmod, aux, cop, nmod, appos, nummod, acl, amod. We find the direction of other dependency relations, such as most of the function word dependencies and other non-core dependencies such as conjunction, not following a fixed pattern in the Universal Dependencies corpus.

Reordering condition Given a set of projections $\mathcal{P}$, we calculate the dominant dependency direction information for the projections $\lambda^{(\mathcal{P})}$. Similar to the projected dependencies, we extract *supervised* dominant dependency directions from the gold-standard source treebank $\mathcal{D}$: $\lambda^{(\mathcal{D})}$. When we encounter a gold-standard dependency relation $\langle i, m, h, r \rangle$ in a source treebank $\mathcal{D}$, we change the direction if the following condition holds:

$$\lambda^{(\mathcal{D})}(r) \neq \lambda^{(\mathcal{P})}(r) \ \texttt{and} \ \lambda^{(\mathcal{P})}(r) = -d(i,m)$$

In other words, if the source and target languages do not have the same dominant dependency direction for r and the dominant direction of the target language is the reverse of the current direction, we change the direction of that dependency. Reordering multiple dependencies in a gold standard tree then results in a reordering of the full tree, as for example in the transformation from Figure 1a to Figure 1b.

4.2 Model 2: Reordering Classifier

We now describe our approach for learning a reordering classifier for a target language using the alignment data. Unlike the first model for which we learn concrete rules, this model learns a reordering classifier from automatically aligned data. This model has two steps; the first step prepares the training data from the automatically aligned parallel data, and the second step learns a classifier from the training data.

4.2.1 Preparing Training Data from Alignments

The goal of this step is to create training data for the reordering classifier. This data is extracted from the concatenation of parallel data from all source languages translated to the target language. Given a parallel dataset $(e^{(i)}, f^{(i)})$ for $i = 1 \ldots n$ that contains pairs of source and target sentences $e^{(i)}$ and $f^{(i)}$, the following steps are applied to create training data:

1. **Extracting reordering mappings from alignments:** We first extract intersected word alignments for each source-target sentence pair. This is done by running the Giza++ alignments (Och and Ney, 2003) in both directions. We ignore sentence pairs that more than half of the source words do not get alignment. We create a new mapping $\mu^{(i)} = \mu_1^{(i)} \ldots \mu_{s_i}^{(i)}$ that maps each index $1 \leq j \leq s_i$ in the original source sentence to a unique index $1 \leq \mu_j^{(i)} \leq s_i$ in the reordered sentence.

2. **Parsing source sentences:** We parse each source sentence using the supervised parser of the source language. We use the mapping $\mu^{(i)}$ to come up with a reordered tree for each sentence. In cases for which the number of non-projective arcs in the projected tree increase compared to the original tree, we do not use the sentence in the final training data.

3. **Extracting classifier instances:** We create a training instance for every modifier word $\langle i, m, h, r \rangle$. The decision about the direction of each dependency can be made based on the following condition:

$$d^*(i,m) = \begin{cases} 1 & \texttt{if } \mu_h^{(i)} > \mu_m^{(i)} \\ -1 & \texttt{otherwise} \end{cases}$$

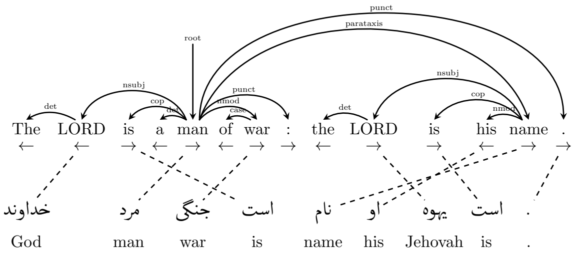


Figure 2: A reordering example from the Bible for English-Persian language pair. The Persian words are written from left to right for the ease of presentation. The arrows below the English words show the new dependency direction with respect to the word alignments to the Persian side. The reordered sentence would be "The LORD a man of war is : his name the LORD is .".

> In other words, we decide about the new order of a dependency according to the mapping $\mu^{(i)}$.

Figure 2 shows an example for the data preparation step. As shown in the figure, the new directions for the English words are decided according to the Persian alignments.

4.2.2 Classifier

The reordering classifier decides about the new direction of each dependency according to the recurrent representation of the head and dependent words. For a source sentence $e^{(i)} = e_1^{(i)} \dots e_{s_i}^{(i)}$ that belongs to a source language $\mathcal{L}$, we first obtain its recurrent representation $\eta^{(i)} = \eta_1^{(i)} \dots \eta_{s_i}^{(i)}$ by running a deep (3 layers) bi-directional LSTM (Hochreiter and Schmidhuber, 1997), where $\eta_j^{(i)} \in \mathbb{R}^{d_h}$. For every dependency tuple $\langle i, m, h, r \rangle$, we use a multi-layer Perceptron (MLP) to decide about the new order $dir \in \{-1, 1\}$ of the m'th word with respect to its head h:

$$p(\mathtt{dir}|i,m,h,r) = \mathtt{softmax}_{\mathtt{dir}}(W\phi(i,m,h,r))$$

where $W \in \mathbb{R}^{2 \times d_\phi}$ and $\phi(i,m,h,r) \in \mathbb{R}^{d_\phi}$ is as follows:

$$\phi(i,m,h,r) = \mathtt{relu}(Hq(i,m,h,r) + B)$$

where `relu` is the rectified linear unit activation (Nair and Hinton, 2010), $H \in \mathbb{R}^{d_\phi \times d_q}$, $B \in \mathbb{R}^{d_\phi}$, and $q(i,m,h,r) \in \mathbb{R}^{d_q}$ is as follows:

$$q(i,m,h,r) = [\eta_m^{(i)}; \eta_h^{(i)}; R[r]; \Lambda[\mathbb{I}(h > m)]; L[\mathcal{L}]]$$

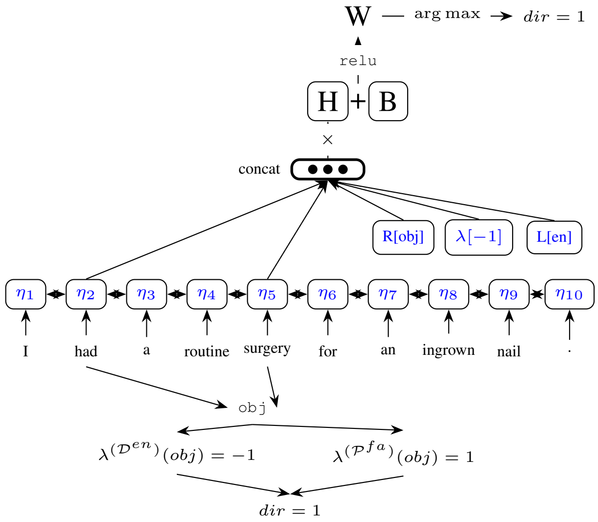

Figure 3: Two different approaches for reordering the dependency order for the example in Figure 1. The reordering classifier is shown on top, for the dependency relation between the words "had" and "surgery" with an "obj" relation. At the bottom, the reordering model based on dominant dependency direction information is shown.

where $\eta_m^{(i)}$ and $\eta_h^{(i)}$ are the recurrent representations for the modifier and head words respectively, R is the dependency relation embedding dictionary that embeds every dependency relation to a $\mathbb{R}^{d_r}$ vector, Λ is the direction embedding for the original position of the head with respect to its head and embeds each direction to a 2-dimensional vector, and L is the language embedding dictionary that embeds the source language id $\mathcal{L}$ to a $\mathbb{R}^{d_L}$ vector.

The input to the recurrent layer is the concatenation of two input vectors. The first vector is the sum of the fixed pre-trained cross-lingual embeddings, and randomly initialized word vector. The second vector is the part-of-speech tag embeddings.

Figure 3 shows a graphical depiction of the two reordering models that we use in this work.

5 Experiments

Datasets and Tools We use 68 datasets from 38 languages in the Universal Dependencies corpus version 2.0 (Nivre et al., 2017). The languages are Arabic (ar), Bulgarian (bg), Coptic (cop), Czech (cs), Danish (da), German (de), Greek (el), English (en), Spanish (es), Estonian (et), Basque (eu), Persian (fa), Finnish (fi), French (fr), Hebrew (he), Hindi (hi), Croatian (hr), Hungarian (hu), Indonesian (id), Italian (it), Japanese (ja), Korean (ko), Latin (la), Lithuanian (lt), Latvian (lv), Dutch (nl), Norwegian (no), Polish (pl), Portuguese (pt), Romanian (ro), Russian (ru), Slovak (sk), Slovene (sl), Swedish (sv), Turkish (tr), Ukrainian (uk), Vietnamese (vi), and Chinese (zh).

We use the Bible data from Christodouloupoulos and Steedman (2014) for the 38 languages. We extract word alignments using Giza++ default model (Och and Ney, 2003). Following Rasooli and Collins (2015), we obtain intersected alignments and apply soft POS consistency to filter potentially incorrect alignments. We use the Wikipedia dump data to extract monolingual data for the languages in order to train monolingual embeddings. We follow the method of Rasooli and Collins (2017) to use the extracted dictionaries from the Bible and monolingual text from Wikipedia to create cross-lingual word embeddings. We use the UDPipe pretrained models (Straka and Straková, 2017) to tokenize Wikipedia, and a reimplementation of the Perceptron tagger of Collins (2002)[4] to achieve automatic POS tags trained on the training data of the Universal Dependencies corpus (Nivre et al., 2017). We use word2vec (Mikolov et al., 2013)[5] to achieve embedding vectors both in monolingual and cross-lingual settings.

Supervised Parsing Models We trained our supervised models on the union of all datasets in a language to obtain a supervised model for each language. It is worth noting that there are two major changes that we make to the neural parser of Dozat and Manning (2016) in our implementation[6] using the Dynet library (Neubig et al., 2017): first, we add a one-layer character BiLSTM to represent the character information for each word. The final character representation is obtained by concatenating the forward representation of the last character and the backward representation of the first character. The concatenated vector is summed with the randomly initialized as well as fixed pre-trained cross-lingual word embedding vectors. Second, inspired by Weiss et al. (2015), we maintain the moving average parameters to obtain more robust parameters at decoding time.

We excluded the following languages from the set of source languages for *annotation projection* due to their low supervised accuracy: Estonian, Hungarian, Korean, Latin, Lithuanian, Latvian, Turkish, Ukrainian, Vietnamese, and Chinese.

Baseline Transfer Models We use two baseline models: 1) Annotation projection: This model only trains on the projected dependencies. 2) Annotation projection + direct transfer: To speed up training, we sample at most thousand sentences from each treebank, comprising a training data of about 37K sentences.

5.1 Reordering Ensemble Model

We noticed that our reordering models perform better in non-European languages, and perform slightly worse in European languages. We use the following ensemble model to make use of all of the three models (annotation projection + direct transfer, and the two reordering models), to make sure that we always obtain an accurate parser.

The ensemble model is as follows: given three output trees for the i'th sentence $\langle i_j, m, h_j, r_j\rangle$ for $j = 1, 2, 3$ in the target language $\mathcal{L}$, where the first tuple ($j = 1$) belongs to the baseline model, the second ($j = 2$) and third ($j = 3$) belong to the two reordering models, we weight each dependency edge with respect to the following conditions:

$$\omega(m,h,r) = z(m,h,r)\cdot\sum_{j=1}^{3} c(j,\mathcal{L})\cdot\mathbb{I}(\langle i_j, m, h, r\rangle)$$

where $c(j,\mathcal{L})$ is a coefficient that puts more weight on the first or the other two outputs depending on the target language family:

$$c(j,\mathcal{L}) = \begin{cases} 2 & \texttt{if } j = 1 \,\&\, \mathcal{L}\texttt{ is European} \\ 2 & \texttt{if } j > 1 \,\&\, \\ & \qquad \mathcal{L}\texttt{ is not European} \\ 1 & \texttt{otherwise} \end{cases}$$

and $z(m,h,r)$ is a simple weighting depending on the dominant order information:

$$z(m,h,r) = \begin{cases} 1 & \text{if } dir(\langle m,h\rangle) = -\lambda^{(\mathcal{P})}(r) \\ 3 & \text{if } dir(\langle m,h\rangle) = \lambda^{(\mathcal{P})}(r) \\ 2 & \text{otherwise } (\lambda^{(\mathcal{P})}(r) = 0) \end{cases}$$

---

Variable	Notation	Size
Word embedding	d_w	100
POS embedding	d_p	100
Bi-LSTM	d_h	400
Dep. relation embedding	d_r	50
Language ID embedding	d_L	50
Hidden layer	d_ϕ	200
Number of BiLSTM layers	–	3
Mini-batch size (tokens)	–	~ 1000

Table 1: Parameter values in the reordering classifier model.

The above coefficients are modestly tuned on the Persian language as our development language. We have not seen any significant change in modifying the numbers: instead, the fact that an arc with a dominant dependency direction is regarded as a more valuable arc, and the baseline should have more effect in the European languages suffices for the ensemble model.

We run the Eisner first-order graph-based algorithm (Eisner, 1996) on top of the edge weights ω to extract the best possible tree.

5.2 Parameters

We run all of the transfer models with 4000 mini-batches, in which each mini-batch contains approximately 5000 tokens. We follow the same parameters as in Dozat and Manning (2016) and use a dimension of 100 for character embeddings. For the reordering classifier, we use the Adam algorithm (Kingma and Ba, 2014) with default parameters to optimize the log-likelihood objective. We filter the alignment data to keep only those sentences for which at least half of the source words have an alignment. We randomly choose 1% of the reordering data as our heldout data for deciding when to stop training the reordering models. Table 1 shows the parameter values that we use in the reordering classifier.

5.3 Results

Table 2 shows the results on the Universal Dependencies corpus (Nivre et al., 2017). As shown in the table, the algorithm based on dominant dependency directions improves the accuracy on most of the non-European languages and performs slightly worse than the baseline model in the European languages. The ensemble model, in spite of its simplicity, improves over the baseline in most of the languages, leading to an average UAS improvement of 0.9 for all languages and 3.3 for non-European languages. This improvement is very significant in many of the non-European languages; for example, from an LAS of 37.6 to 52.7 in Coptic, from a UAS of 44.9 to 53.7 in Basque, from a UAS of 40.6 to 47.0 in Chinese. Our model also outperforms the supervised models in Ukrainian and Latvian. That is an interesting indicator that for cases that the training data is very small for a language (37 sentences for Ukrainian, and 153 sentences for Latvian), our transfer approach outperforms the supervised model.

6 Analysis

In this section, we briefly describe our analysis based on the results in the ensemble model and the baseline. For some languages such as Coptic, the number of dense projected dependencies is too small (two trees) such that the parser gives a worse learned model than a random baseline. For some other languages, such as Norwegian and Spanish, this number is too high (more than twenty thousand trees), such that the baseline model performs very well.

The dominant dependency direction model generally performs better than the classifier. Our manual investigation shows that the classifier kept many of the dependency directions unchanged, while the dominant dependency direction model changed more directions. Therefore, the dominant direction model gives a higher recall with the expense of losing some precision. The training data for the reordering classifier is very noisy due to wrong alignments. We believe that the dominant direction model, besides its simplicity, is a more robust classifier for reordering, though the classifier is helpful in an ensemble setting.

Our detailed analysis show that we are able to improve the head dependency relation for the three most important head POS tags in the dependency grammar. We see that this improvement is more consistent for all non-European languages. Table 3 shows the differences in parsing f-score of dependency relations for adjectives, nouns and verbs as the head. As we see in the Table, we are able to improve the head dependency relation for the three most important head POS tags in the dependency grammar. We see that this improvement is more consistent for all non-European languages. We skip the details of those analysis due to space

Table 2: Dependency parsing results, in terms of unlabeled attachment accuracy (UAS) and labeled attachment accuracy (LAS) after ignoring punctuations, on the Universal Dependencies v2 test sets (Nivre et al., 2017) using supervised part-of-speech tags. The results are sorted by their "difference" between the ensemble model and the baseline. The rows for non-European languages are highlighted with cyan. The rows that are highlighted by pink are the ones that the transfer model outperforms the supervised model. For all of the non-European datasets except "hi", our model outperforms significantly better in terms of UAS with $p < 0.001$ using McNemar's test.

Table 3: Unlabeled attachment f-score of POS tags as heads for the baseline and the reordering ensemble model. As shown in the table, our model improves over the baseline in most cases.

limitations. More thorough analysis can be found in (Rasooli, 2019, Chapter 6).

For a few number of languages such as Vietnamese, the best model, even though improves over a strong baseline, still lacks enough accuracy to be considered as a reliable parser in place of a supervised model. We believe that more research on those language will address the mentioned problem. Our current model relies on supervised part-of-speech tags. Future work should study using transferred part-of-speech tags instead of supervised tags, leading to a much more realistic scenario for low-resource languages.

We have also calculated the POS trigram cosine similarity between the target language gold standard treeebanks, and the three source training datasets (original, and the two reordered datasets). In all of the non-European languages, the cosine similarity of the reordered datasets improved with different values in the range of $(0.002, 0.02)$. For Czech, Portuguese, German, Greek, English, Romanian, Russian, and Slovak, both of the reordered datasets slightly decreased the trigram cosine similarity. For other languages, the cosine similarity was roughly the same.

7 Conclusion

We have described a cross-lingual dependency transfer method that takes into account the problem of word order differences between the source and target languages. We have shown that applying projection-driven reordering improves the accuracy of non-European languages while maintaining the high accuracies in European languages. The focus of this paper is primarily of dependency parsing. Future work should investigate the effect of our proposed reordering methods on truly low-resource machine translation.

Abstract

Adversarial training has shown impressive success in learning bilingual dictionary without any parallel data by mapping monolingual embeddings to a shared space. However, recent work has shown superior performance for non-adversarial methods in more challenging language pairs. In this work, we revisit adversarial autoencoder for unsupervised word translation and propose two novel extensions to it that yield more stable training and improved results. Our method includes regularization terms to enforce cycle consistency and input reconstruction, and puts the target encoders as an adversary against the corresponding discriminator. Extensive experimentations with European, non-European and low-resource languages show that our method is more robust and achieves better performance than recently proposed adversarial and non-adversarial approaches.

1 Introduction

Learning cross-lingual word embeddings has been shown to be an effective way to transfer knowledge from one language to another for many key linguistic tasks including machine translation, named entity recognition, part-of-speech tagging, and parsing (Ruder et al., 2017). While earlier efforts solved the associated word alignment problem using large parallel corpora (Luong et al., 2015), broader applicability demands methods to relax this requirement since acquiring a large corpus of parallel data is not feasible in most scenarios. Recent methods instead use embeddings learned from monolingual data, and learn a linear mapping from one language to another with the underlying assumption that two embedding spaces exhibit similar geometric structures (*i.e.,* approximately *isomorphic*). This allows the model to learn effective cross-lingual representations without expensive supervision (Artetxe et al., 2017).

Given monolingual word embeddings of two languages, Mikolov et al. (2013a) show that a linear mapping can be learned from a seed dictionary of 5000 word pairs by minimizing the sum of squared Euclidean distances between the mapped vectors and the target vectors. Subsequent works (Xing et al., 2015; Artetxe et al., 2016, 2017; Smith et al., 2017) propose to improve the model by normalizing the embeddings, imposing an orthogonality constraint on the mapper, and modifying the objective function. While these methods assume some supervision in the form of a seed dictionary, recently fully unsupervised methods have shown competitive results. Zhang et al. (2017a,b) first reported encouraging results with *adversarial training*. Conneau et al. (2018) improved this approach with post-mapping refinements, showing impressive results for several language pairs. Their learned mapping was then successfully used to train a fully unsupervised neural machine translation system (Lample et al., 2018a,b).

Although successful, adversarial training has been criticized for not being stable and failing to converge, inspiring researchers to propose *non-adversarial* methods more recently (Xu et al., 2018a; Hoshen and Wolf, 2018; Alvarez-Melis and Jaakkola, 2018; Artetxe et al., 2018b). In particular, Artetxe et al. (2018b) show that the adversarial methods of Conneau et al. (2018) and Zhang et al. (2017a,b) fail for many language pairs.

In this paper, we revisit adversarial training and propose a number of key improvements that yield more robust training and improved mappings. Our main idea is to learn the cross-lingual mapping in a projected latent space and add more constraints to guide the unsupervised mapping in this space. We accomplish this by proposing a novel *adversarial autoencoder* framework (Makhzani et al., 2015), where adversarial mapping is done at the (latent) code space as opposed to the original embedding

Proceedings of NAACL-HLT 2019, pages 3857–3867
Minneapolis, Minnesota, June 2 - June 7, 2019.

space (Figure 1). This gives the model the flexibility to automatically induce the required geometric structures in its latent code space that could potentially yield better mappings. Søgaard et al. (2018) recently find that the *isomorphic* assumption made by most existing methods does not hold in general even for two closely related languages like English and German. In their words *"approaches based on this assumption have important limitations"*. By mapping the latent vectors through adversarial training, our approach therefore departs from the isomorphic assumption.

In our adversarial training, not only the mapper but also the target encoder is trained to fool the discriminator. This forces the discriminator to improve its discrimination skills, which in turn pushes the mapper to generate indistinguishable translation. To guide the mapping, we include two additional constraints. Our first constraint enforces *cycle consistency* so that code vectors after being translated from one language to another, and then translated back to their source space remain close to the original vectors. The second constraint ensures reconstruction of the original input word embeddings from the back-translated codes. This grounding step forces the model to retain word semantics during the mapping process.

We conduct a series of experiments with six different language pairs (in both directions) comprising European, non-European, and low-resource languages from two different datasets. Our results show that our model is more robust and yields significant gains over Conneau et al. (2018) for all translation tasks in all evaluation measures. Our method also gives better initial mapping compared to other existing methods (Artetxe et al., 2018b). We also perform an extensive ablation study to understand the contribution of different components of our model. The study reveals that cycle consistency contributes the most, while adversarial training of the target encoder and post-cycle reconstruction also have significant effect. We have released our source code at `https://ntunlpsg.github.io/project/unsup-word-translation/`

The remainder of this paper is organized as follows. After discussing related work in Section 2, we present our unsupervised word translation approach with adversarial autoencoder in Section 3. We describe our experimental setup in Section 4, and present our results with in-depth analysis in Section 5. Finally, we summarize our findings with possible future directions in Section 6.

2 Related Work

In recent years a number of methods have been proposed to learn bilingual dictionary from monolingual word embeddings.[1] Many of these methods use an initial seed dictionary. Mikolov et al. (2013a) show that a linear transformation can be learned from a seed dictionary of 5000 pairs by minimizing the squared Euclidean distance. In their view, the key reason behind the good performance of their model is the similarity of geometric arrangements in vector spaces of the embeddings of different languages. For translating a new source word, they map the corresponding word embedding to the target space using the learned mapping and find the nearest target word. In their approach, they found that simple linear mapping works better than non-linear mappings with multilayer neural networks.

Xing et al. (2015) enforce the word vectors to be of unit length during the learning of the embeddings and modify the objective function for learning the mapping to maximize the cosine similarity instead of using Euclidean distance. To preserve length normalization after mapping, they enforce the *orthogonality* constraint on the mapper. Instead of learning a mapping from the source to the target embedding space, Faruqui and Dyer (2014) use a technique based on Canonical Correlation Analysis (CCA) to project both source and target embeddings to a common low-dimensional space, where the correlation of the word pairs in the seed dictionary is maximized. Artetxe et al. (2016) show that the above methods are variants of the same core optimization objective and propose a closed form solution for the mapper under orthogonality constraint. Smith et al. (2017) find that this solution is closely related to the orthogonal *Procrustes* solution. In their follow-up work, Artetxe et al. (2017) obtain competitive results using a seed dictionary of only 25 word pairs. They propose a *self-learning framework* that performs two steps iteratively until convergence. In the first step, they use the dictionary (starting with the seed) to learn a linear mapping, which is then used in the second step to induce a new dictionary.

A more recent line of research attempts to eliminate the seed dictionary totally and learn the map-

---

[1] see (Ruder et al., 2017) for a nice survey

ping in a purely unsupervised way. This was first proposed by Miceli Barone (2016), who initially used an adversarial network similar to Conneau et al. (2018), and found that the mapper (which is also the encoder) translates everything to a single embedding, known commonly as the *mode collapse* issue (Goodfellow, 2017). To preserve diversity in mapping, he used a decoder to reconstruct the source embedding from the *mapped embedding*, extending the framework to an adversarial autoencoder. His preliminary qualitative analysis shows encouraging results but not competitive with methods using bilingual seeds. He suspected issues with training and with the isomorphic assumption. In our work, we successfully address these issues with an improved model that also relaxes the isomorphic assumption. Our model uses two separate autoencoders, one for each language, which allows us to put more constraints to guide the mapping. We also distinguish the role of an encoder from the role of a mapper. The encoder projects embeddings to latent code vectors, which are then translated by the mapper.

Zhang et al. (2017a) improved adversarial training with orthogonal parameterization and cycle consistency. To aid training, they incorporate additional techniques like noise injection which works as a regularizer. For selecting the best model, they rely on sharp drops of the discriminator accuracy. In their follow-up work (Zhang et al., 2017b), they minimize Earth-Mover's distance between the distribution of the transformed source embeddings and the distribution of the target embeddings. Conneau et al. (2018) show impressive results with adversarial training and refinement with the Procrustes solution. Instead of using the adversarial loss, Xu et al. (2018a) use Sinkhorn distance and adopt cycle consistency inspired by the CycleGAN (Zhu et al., 2017). We also incorporate cycle consistency along with the adversarial loss. However, while all these methods learn the mapping in the original embedding space, our approach learns it in the latent code space considering both the mapper and the target encoder as adversary. In addition, we use a postcycle reconstruction to guide the mapping.

A number of non-adversarial methods have also been proposed recently. Artetxe et al. (2018b) learn an initial dictionary by exploiting the structural similarity of the embeddings and use a robust self-learning algorithm to improve it iteratively. Hoshen and Wolf (2018) align the second moment of word distributions of the two languages using principal component analysis (PCA) and then refine the alignment iteratively using a variation of the Iterative Closest Point (ICP) method used in computer vision. Alvarez-Melis and Jaakkola (2018) cast the problem as an optimal transport problem and exploit the Gromov-Wasserstein distance which measures how similarities between pairs of words relate across languages.

3 Approach

Let $\mathcal{X} = \{x_1, \ldots, x_n\}$ and $\mathcal{Y} = \{y_1, \ldots, y_m\}$ be two sets consisting of n and m word embeddings of d-dimensions for a source and a target language, respectively. We assume that $\mathcal{X}$ and $\mathcal{Y}$ are trained independently from monolingual corpora. Our aim is to learn a mapping $f(x)$ in an unsupervised way (*i.e.,* no bilingual dictionary given) such that for every x_i, $f(x)$ corresponds to its translation in $\mathcal{Y}$. Our overall approach follows the same sequence of steps as Conneau et al. (2018):

(i) Induction of seed dictionary through adversarial training.
(ii) Iterative refinement of the initial mapping through the Procrustes solution.
(iii) Apply CSLS for nearest neighbor search.

We propose a novel adversarial autoencoder model to learn the initial mapping for inducing a seed dictionary in step (i), and we adopt existing refinement methods for steps (ii) and (iii).

3.1 Adversarial Autoencoder for Initial Dictionary Induction

Our proposed model (Figure 1) has two **autoencoders**, one for each language. Each autoencoder comprises an encoder $E_{\mathcal{X}}$ (res. $E_{\mathcal{Y}}$) and a decoder $D_{\mathcal{X}}$ (res. $D_{\mathcal{Y}}$). The encoders transform an input x (res. y) into a latent code z_x (res. z_y) from which the decoders try to reconstruct the original input. We use a linear encoder and l_2 **reconstruction loss**

$$z_{x_i} = \theta_{E_{\mathcal{X}}} x_i; \qquad \hat{x}_i = \theta_{D_{\mathcal{X}}} z_{x_i} \qquad (1)$$

$$\mathcal{L}_{\text{autoenc}_{\mathcal{X}}}(\theta_{E_{\mathcal{X}}}, \theta_{D_{\mathcal{X}}}) = \frac{1}{n} \sum_{i=1}^{n} \|x_i - \hat{x}_i\|^2 \qquad (2)$$

where $\theta_{E_{\mathcal{X}}} \in \mathbb{R}^{c \times d}$ and $\theta_{D_{\mathcal{X}}} \in \mathbb{R}^{d \times c}$ are the parameters of the encoder and the decoder for d-dimensional word embedding and c-dimensional

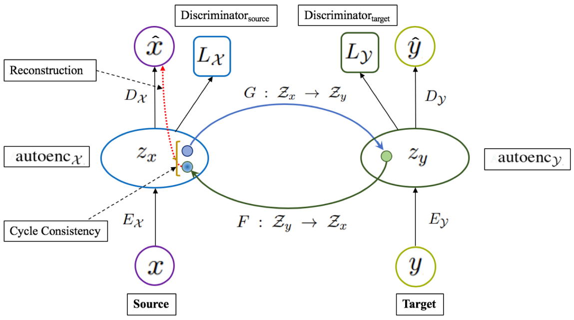

Figure 1: Our proposed adversarial autoencoder framework for unsupervised word translation.

code vector.[2] The encoder, decoder and the reconstruction loss for the other autoencoder (autoenc$_{\mathcal{Y}}$) is similarly defined.

Let $q(z_x|x)$ and $q(z_y|y)$ be the encoding distributions of the two autoencoders. We use *adversarial training* to find a mapping between $q(z_x|x)$ and $q(z_y|y)$. This is in contrast with most existing methods (*e.g.,* Conneau et al. (2018); Artetxe et al. (2017)) that directly map the distribution of the source word embeddings $p(x)$ to the distribution of the target $p(y)$. As Søgaard et al. (2018) pointed out, the *isomorphism* does not hold in general between the word embedding spaces of two languages. Mapping the latent codes gives our model more flexibility to induce the required semantic structures in its code space that could potentially yield more accurate mappings.

As shown in Figure 1, we include two linear **mappings** $G : \mathcal{Z}_x \rightarrow \mathcal{Z}_y$ and $F : \mathcal{Z}_y \rightarrow \mathcal{Z}_x$ to project the code vectors (samples from $q(.|.)$) from one language to the other. In addition, we have two language **discriminators**, $L_{\mathcal{X}}$ and $L_{\mathcal{Y}}$. The discriminators are trained to discriminate between the mapped codes and the encoded codes, while the mappers and encoders are jointly trained to fool their respective discriminator. This results in a **three-player** game, where the discriminator tries to identify the origin of a code, and the mapper and the encoder act together to prevent the discriminator to succeed by making the mapped vector and the encoded vector as similar as possible.

Discriminator Loss Let $\theta_{L_{\mathcal{X}}}$ and $\theta_{L_{\mathcal{Y}}}$ denote the parameters of the two discriminators, and W_G and W_F are the mapping weight matrices. The loss for the source discriminator $L_{\mathcal{X}}$ can be written as

$$\begin{aligned}\mathcal{L}_{L_{\mathcal{X}}}(\theta_{L_{\mathcal{X}}}|W_F, \theta_{E_{\mathcal{X}}}) = &-\frac{1}{m}\sum_{j=1}^{m}\log P_{L_{\mathcal{X}}}(\text{src} = 0|F(z_{y_j})) \\ &-\frac{1}{n}\sum_{i=1}^{n}\log P_{L_{\mathcal{X}}}(\text{src} = 1|z_{x_i}) \quad (3)\end{aligned}$$

where $P_{L_{\mathcal{X}}}(\text{src}|z)$ is the probability according to $L_{\mathcal{X}}$ to distinguish whether z is coming from the source encoder ($\text{src} = 1$) or from the target-to-source mapper F ($\text{src} = 0$). The discrimination loss $\mathcal{L}_{L_{\mathcal{Y}}}(\theta_{L_{\mathcal{Y}}}|W_G, \theta_{E_{\mathcal{Y}}})$ is similarly defined for the target discriminator $L_{\mathcal{Y}}$ using G and $E_{\mathcal{Y}}$.

Our discriminators have the same architecture as Conneau et al. (2018). It is a feed-forward network with two hidden layers of size 2048 and Leaky-ReLU activations. We apply dropout with a rate of 0.1 on the input to the discriminators. Instead of using 1 and 0, we also apply a smoothing coefficient ($s = 0.2$) in the discriminator loss.

Adversarial Loss The mappers and encoders are trained jointly with the following adversarial loss to fool their respective discriminators.

$$\begin{aligned}\mathcal{L}_{\text{adv}}(W_F, \theta_{E_{\mathcal{X}}}|\theta_{L_{\mathcal{X}}}) = &-\frac{1}{m}\sum_{i=1}^{m}\log P_{L_{\mathcal{X}}}(\text{src} = 1|F(z_{y_j})) \\ &-\frac{1}{n}\sum_{i=1}^{n}\log P_{L_{\mathcal{X}}}(\text{src} = 0|z_{x_i}) \quad (4)\end{aligned}$$

The adversarial loss for mapper G and encoder $E_{\mathcal{Y}}$ is similarly defined. Note that we consider both the mapper and the target encoder as generators. This is in contrast to existing adversarial methods, which do not use any autoencoder in the target side. The mapper and the target encoder team up to fool the discriminator. This forces the discriminator to improve its skill and vice versa for the generators, forcing them to produce indistinguishable codes through better mapping.

Cycle Consistency and Reconstruction The adversarial method introduced above maps a "bag" of source embeddings to a "bag" of target embeddings, and in theory, the mapper can match the target language distribution. However, mapping at the bag level is often insufficient to learn the individual word level mappings. In fact, there exist infinite number of possible mappings that can match the same target distribution. Thus to learn better mappings, we need to enforce more constraints to our objective.

The first form of constraints we consider is **cycle consistency** to ensure that a source code z_x

---

[2] We also experimented with a non-linear encoder, but it did not work well.

translated to the target language code space, and translated back to the original space remains unchanged, *i.e.,* $z_x \rightarrow G(z_x) \rightarrow F(G(z_x)) \approx z_x$. Formally, the cycle consistency loss in one direction:

$$\mathcal{L}_{\text{cyc}}(W_G, W_F) = \frac{1}{n} \sum_{i=1}^{n} \|z_{x_i} - F(G(z_{x_i}))\| \tag{5}$$

The loss in the other direction ($z_y \rightarrow F(z_y) \rightarrow G(F(z_y)) \approx z_y$) is similarly defined. In addition to cycle consistency, we include another constraint to guide the mapping further. In particular, we ask the decoder of the respective autoencoder to reconstruct the original input from the back-translated code. We compute this **post-cycle reconstruction loss** for the source autoencoder as follows:

$$\mathcal{L}_{\text{rec}}(\theta_{E_\mathcal{X}}, \theta_{D_\mathcal{X}}, W_G, W_F) = \frac{1}{n} \sum_{i=1}^{n} \|x_i - D_\mathcal{X}(F(G(z_{x_i})))\|^2 \tag{6}$$

The reconstruction loss at the target autoencoder is defined similarly. Apart from improved mapping, both cycle consistency and reconstruction lead to more stable training in our experiments. Specifically, they help our training to converge and get around the *mode collapse* issue (Goodfellow, 2017). Since the model now has to translate the mapped code back to the source code and reconstruct the original word embedding, the generators cannot get away by mapping all source codes to a single target code.

Total Loss The total loss for mapping a batch from source to target is

$$\mathcal{L}_{\text{src}\rightarrow\text{tar}} = \mathcal{L}_{\text{adv}} + \lambda_1 \mathcal{L}_{\text{cyc}} + \lambda_2 \mathcal{L}_{\text{rec}} \tag{7}$$

where λ_1 and λ_2 control the relative importance of the three loss components. Similarly we define the total loss for mapping in the opposite direction $\mathcal{L}_{\text{tar}\rightarrow\text{src}}$. The complete objective of our model is:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{src}\rightarrow\text{tar}} + \mathcal{L}_{\text{tar}\rightarrow\text{src}} \tag{8}$$

3.2 Training and Dictionary Construction

We present the training procedure of our model and the overall word translation process in Algorithm 1. We first pre-train the autoencoders separately on monolingual embeddings (Step 1). This pre-training is required to induce word semantics (and relations) in the latent code space.

We start adversarial training (Step 2) by updating the discriminators for $n\_critics$ (5) times, each time with a random batch. Then we update the generators (the mapper and target encoder) on the adversarial loss. The mappers then go through two more updates, one for cycle consistency and another for post-cycle reconstruction. The autoencoders (encoder-decoder) in this stage get updated only on the post-cycle reconstruction loss. We also apply the orthogonalization update to the mappers following Conneau et al. (2018) with $\beta = 0.01$.

Algorithm 1: Unsupervised word translation with cycle-consistent adversarial autoencoder

```
Input : Two sets of word embeddings: $\mathcal{X}$ and $\mathcal{Y}$
// Initial autoencoder training
1. Train autoenc$_\mathcal{X}$ and autoenc$_\mathcal{Y}$ separately for some
   epochs on monolingual embeddings (Eq. 2);
// Adversarial training
2. for n_epochs do
    for n_iterations do
        // Critic update
        for n_critics do
            (i) Sample a batch from $\mathcal{X}$ and $\mathcal{Y}$
            (ii) Update discriminators ($L_\mathcal{X}$, $L_\mathcal{Y}$) (Eq. 3)
        end
        (a) Sample a batch from $\mathcal{X}$ as source and $\mathcal{Y}$ as
            target
        (b) Update mapper $G$ and encoder $E_\mathcal{Y}$ on
            adversarial loss to fool $L_\mathcal{Y}$ (Eq. 4)
        (c) Update mappers $G$ and $F$ on cycle
            consistency loss (Eq. 5)
        (d) Update mappers ($G$, $F$) and autoenc$_\mathcal{X}$ on
            post-cycle reconstruction loss (Eq. 6)
        // Orthogonalize the mapper
        (e) Update weight matrices of mapper $G$ and $F$
            using:
                $W_G \leftarrow (1+\beta)W_G - \beta(W_G W_G^T)W_G$
                $W_F \leftarrow (1+\beta)W_F - \beta(W_F W_F^T)W_F$
        (f) Sample a batch from $\mathcal{Y}$ as source and $\mathcal{X}$ as
            target and update accordingly (symmetric to
            (b) -(e) steps).
    end
    Use validation criterion to save the best model.
end
// Iterative Procrustes/fine-tuning
3. Load the best model.
for n_iterations do
    (a) Build a synthetic dictionary (using source
        encoder, source-to-target mapper, and CSLS)
    (b) Apply the Procrustes solution on the dictionary.
end
// Test
4. Test the model on gold bilingual dictionary.
```

Our training setting is similar to Conneau et al. (2018), and we apply the same pre- and post-processing steps. We use stochastic gradient descent (SGD) with a batch size of 32, a learning rate of 0.1, and a decay of 0.98.

For selecting the best model, we use the *unsupervised validation criterion* proposed by Conneau et al. (2018), which correlates highly with the mapping quality. In this criterion, $10,000$ most frequent source words along with their nearest neighbors in the target space are considered. The average cosine similarity between these pseudo translations is considered as the validation metric.

The initial bilingual dictionary induced by adversarial training (or any other unsupervised method) is generally of lower quality than what could be achieved by a supervised method. Conneau et al. (2018) and Artetxe et al. (2018b) propose fine-tuning methods to refine the initial mappings. Similar to Conneau et al. (2018)), we fine-tune our initial mappings (G and F) by iteratively solving the *Procrustes* problem and applying a dictionary induction step. This method uses singular value decomposition or SVD of $\mathcal{Z}_y^T\mathcal{Z}_x$ to find the optimal mappings G (similarly SVD($\mathcal{Z}_x^T\mathcal{Z}_y$) for F) given the approximate alignment of words from the previous step. For generating synthetic dictionary in each iteration, we only consider the translation pairs that are mutual nearest neighbors. In our fine-tuning, we run five iterations of this process. For finding the nearest neighbors, we use the Cross-domain Similarity Local Scaling (CSLS) which works better in mitigating the hubness problem (Conneau et al., 2018).

4 Experimental Settings

Following the tradition, we evaluate our model on **word translation** (*a.k.a.* **bilingual lexicon induction**) task, which measures the accuracy of the predicted dictionary to a gold standard dictionary.

4.1 Datasets

We evaluate our model on two different datasets. The first one is from Conneau et al. (2018), which consists of FastText monolingual embeddings of (d =) 300 dimensions (Bojanowski et al., 2017) trained on Wikipedia monolingual corpus and gold dictionaries for 110 language pairs.[3] To show the generality of different methods, we consider **European**, **non-European** and **low-resource** languages. In particular, we evaluate on English (En) from/to Spanish (Es), German (De), Italian (It), Arabic (Ar), Malay (Ms), and Hebrew (He).

We also evaluate on the more challenging dataset of Dinu et al. (2015) and its subsequent extension by Artetxe et al. (2018a). We will refer to this dataset as **Dinu-Artexe** dataset. From this dataset, we choose to experiment on English from/to Italian and Spanish. English and Italian embeddings were trained on WacKy corpora using CBOW (Mikolov et al., 2013b), while the Spanish embeddings were trained on WMT News Crawl. The CBOW vectors are also of 300 dimensions.

4.2 Baselines

We compare our method with the **unsupervised** models of Conneau et al. (2018), Artetxe et al. (2018b), Alvarez-Melis and Jaakkola (2018), Xu et al. (2018a), and Hoshen and Wolf (2018).

To evaluate how our unsupervised method compares with methods that rely on a bilingual seed dictionary, we follow Conneau et al. (2018), and compute a **supervised** baseline that uses the Procrustes solution directly on the seed dictionary (5000 pairs) to learn the mapping function, and then uses CSLS to do the nearest neighbor search. We also compare with the supervised approaches of Artetxe et al. (2017, 2018a), which to our knowledge are the state-of-the-art supervised systems. For some of the baselines, results are reported from their papers, while for the rest we report results by running the publicly available codes on our machine.

For training our model on European languages, the weight for cycle consistency (λ_1) in Eq. 7 was always set to 5, and the weight for post-cycle reconstruction (λ_2) was set to 1. For non-European languages, we use different values of λ_1 and λ_2 for different language pairs. [4] The dimension of the code vectors in our model was set to 350.

5 Results

We present our results on European languages on the datasets of Conneau et al. (2018) and Dinu et al. (2015) in Tables 1 and 3, while the results on non-European languages are shown in Table 2. Through experiments, our goal is to assess:

(i) Does the unsupervised mapping method based on our proposed adversarial autoencoder model improve over the best existing adversarial method of Conneau et al. (2018) in terms of mapping accuracy and convergence (Section 5.1)?

(ii) How does our unsupervised mapping method compare with other unsupervised and supervised approaches (Section 5.2)?

---

[3] `https://github.com/facebookresearch/MUSE`

[4] We did not tune the λ values much, rather used our initial observation. Tuning λ values might yield even better results.

(iii) Which components of our adversarial autoencoder model attribute to improvements (Section 5.3)?

5.1 Comparison with Conneau et al. (2018)

Since our approach follows the same steps as Conneau et al. (2018), we first compare our proposed model with their model on European (Table 1), non-European and low-resource languages (Table 2) on their dataset. In the tables, we present the numbers that they reported in their paper (Conneau et al. (2018) (paper)) as well as the results that we get by running their code on our machine (Conneau et al. (2018) (code)). For a fair comparison with respect to the quality of the learned mappings (or induced seed dictionary), here we only consider the results of our approach that use the refinement procedure of Conneau et al. (2018).

In Table 1, we see that our **Adversarial autoencoder + Conneau et al. (2018) Refinement** outperforms Conneau et al. (2018) in all the six translation tasks involving European language pairs, yielding gains in the range 0.3 - 1.3%. Our method is also superior to theirs for the non-European and low-resource language pairs in Table 2. Here our method gives more gains ranging from 1.8 to 4.3%. Note specifically that Malay (Ms) is a low-resource language, and the FastText contains word vectors for only 155K Malay words. We found their model to be very fragile for En from/to Ms, and does not converge at all for Ms→En. We ran their code 10 times for Ms→En but failed every time. Compared to that, our method is more robust and converged most of the time we ran.

If we compare our method with Conneau et al. (2018) on the dataset of (Dinu et al., 2015; Artetxe et al., 2017) in Table 3, we see here also our method performs better than their method in all the four translation tasks involving European language pairs. In this dataset, our method shows more robustness compared to their method. For example, their method had difficulties in converging for En from/to Es translations; for En→Es, it converges only 2 times out of 10 attempts, while for Es→En it did not converge a single time in 10 attempts. Compared to that, our method was more robust, converging 4 times out of 10 attempts.

In Section 5.3, we compare our model with Conneau et al. (2018) more rigorously by evaluating them with and without fine-tuning and measuring their performance on P@1, P@5, and P@10.

5.2 Comparison with Other Methods

In this section, we compare our model with other state-of-the-art methods that do not follow the same procedure as us and Conneau et al. (2018). For example, Artetxe et al. (2018b) do the initial mapping in the similarity space, then they apply a different self-learning method to fine-tune the embeddings, and perform a final refinement with symmetric re-weighting. Instead of mapping from source to target, they map both source and target embeddings to a common space.

Let us first consider the results for European language pairs on the dataset of Conneau et al. (2018) in Table 1. Our **Adversarial autoencoder + Conneau et al. (2018) Refinement** performs better than most of the other methods on this dataset, achieving the highest accuracy for 4 out of 6 translation tasks. For De→En, our result is very close to the best system of Artetxe et al. (2018b) with only 0.2% difference.

Table 4: Conneau et al. (2018) refinement applied to the initial mappings of Artetxe et al. (2018b). ** indicates the model failed to converge.

On the dataset of Dinu et al. (2015); Artetxe et al. (2017) in Table 3, our **Adversarial autoencoder + Conneau et al. (2018) Refinement** performs better than other methods except Artetxe et al. (2018b). On average our method lags behind by about 2%. However, as mentioned, they follow a different refinement and mapping methods. For non-European and low-resource language pairs in Table 2, our **Adversarial autoencoder + Conneau et al. (2018) Refinement** exhibits better performance than others in one translation task, where the model of Artetxe et al. (2018b) performs better in the rest. One important thing to notice here is that other unsupervised models (apart from ours and Artetxe et al. (2018b)) fail to converge in one or more language pairs.

We notice that the method of Artetxe et al. (2018b) gives better results than other baselines, even in some translation tasks they achieve the highest accuracy. To understand whether the improvements of their method are due to a better initial mapping or better post-processing, we conducted two additional experiments. In our first experiment, we use their method to induce the initial seed dictionary and then apply iterative Procrustes solution (same refinement procedure of Conneau et al. (2018)) for refinement. Table 4 shows the results. Surprisingly, on both datasets their initial mappings fail to produce any reasonable results. So we suspect that the main gain in (Artetxe et al., 2018b) comes from their fine-tuning method, which they call *robust self learning*. In our second experiment, we use the initial dictionary induced by our adversarial training and then apply their refinement procedure. Here for most of the translation tasks, we achieve better results; see the model **Adversarial autoencoder + Artetxe et al. (2018b) Refinement** in Tables 1 - 3. These two experiments demonstrate that the quality of the initial dictionary induced by our model is far better than that of Artetxe et al. (2018b).

5.3 Model Dissection

We further analyze our model by dissecting it and measuring the contribution of each novel component that is proposed in this work. We achieve this by *incrementally* removing a new component from the model and evaluating it on different translation tasks. In order to better understand the contribution of each component, we evaluate each model by measuring its **P@1**, **P@5**, and **P@10 with fine-tuning** and **without fine-tuning**. In case of **without fine-tuning**, the models apply the CSLS neighbor search directly on the mappings learned from the adversarial training, *i.e.,* no Procrustes solution based refinement is done after the adversarial training. This setup allows us to compare our model directly with the adversarial model of Conneau et al. (2018), putting the effect of fine-tuning aside.

Table 5 presents the ablation results for En-Es, En-De, and En-It in both directions. The first row (**Conneau-18**) presents the results of Conneau et al. (2018) that uses adversarial training to map the *word embeddings*. The next row shows the results of **our full** model. The subsequent rows incrementally detach one component from our model. For example, **- Enc. adv** denotes the variant of our model where the target encoder is not trained on the adversarial loss ($\theta_{E_{\mathcal{X}}}$ in Eq. 4); **- - Recon** excludes the post-cycle reconstruction loss from **- Enc. adv**, and **- - - Cycle** excludes the cycle consistency from **- - Recon**. Thus, **- - - Cycle** is a variant of our model that uses only adversarial loss to learn the mapping. However, it is important

Table 5: Ablation study of our adversarial autoencoder model on the dataset of Conneau et al. (2018).

to note that in contrast to Conneau et al. (2018), our mapping is performed at the code space.

As we compare our full model with the model of Conneau et al. (2018) in the *without fine-tuning* setting, we notice large improvements in all measures across all datasets: 5.1 - 7.3% in En→Es, 3 - 6% in Es→En, 3.4 - 4.3% in En→De, 1 - 3% in De→En, 3.4 - 4.3% in En→It, and 0.3 - 3.7% in It→En. These improvements demonstrate that our model finds a better mapping compared to Conneau et al. (2018). Among the three components, the cycle consistency is the most influential one across all languages. Training the target encoder adversarially also gives a significant boost. The reconstruction has less impact. If we compare the results of - - - *Cycle* with *Conneau-18*, we see sizeable gains for En-Es in both directions. This shows the benefits of mapping at the code level.

Now let us turn our attention to the results with fine-tuning. Here also we see gains across all datasets for our model, although the gains are not as verbose as before (about 1% on average). However, this is not surprising as it has been shown that *iterative fine-tuning* with Procrustes solution is a robust method that can recover many errors made in the initial mapping (Conneau et al., 2018). Given a good enough initial mapping, the measures converge nearly to the same point even though the differences were comparatively more substantial initially; for example, notice that the scores are very similar for P@5 and P@10 measures after fine-tuning.

6 Conclusions

We have proposed an adversarial autoencoder framework to learn the cross-lingual mapping of monolingual word embeddings of two languages in a completely unsupervised way. In contrast to the existing methods that directly map word embeddings, our method first learns to transform the embeddings into latent code vectors by pretraining an autoencoder. We apply adversarial training to map the distributions of the source and target code vectors. In our adversarial training, both the mapper and the target encoder are treated as generators that act jointly to fool the discriminator. To guide the mapping further, we include constraints for cycle consistency and post-cycle reconstruction.

Through extensive experimentations on six different language pairs comprising European, non-European and low-resource languages from two different data sources, we demonstrate that our method outperforms the method of Conneau et al. (2018) for all translation tasks in all measures (P@{1,5,10}) across all settings (with and without fine-tuning). Comparison with other existing methods also shows that our method learns better mapping (not considering the fine-tuning). With an ablation study, we further demonstrated that the cycle consistency is the most important component followed by the adversarial training of target encoder and the post-cycle reconstruction. In future work, we plan to incorporate knowledge from the similarity space in our adversarial framework.

Abstract

Transfer learning approaches for Neural Machine Translation (NMT) trains a NMT model on an assisting language-target language pair (parent model) which is later fine-tuned for the source language-target language pair of interest (child model), with the target language being the same. In many cases, the assisting language has a different word order from the source language. We show that divergent word order adversely limits the benefits from transfer learning when little to no parallel corpus between the source and target language is available. To bridge this divergence, we propose to pre-order the assisting language sentences to match the word order of the source language and train the parent model. Our experiments on many language pairs show that bridging the word order gap leads to major improvements in the translation quality in extremely low-resource scenarios.

1 Introduction

Transfer learning for multilingual Neural Machine Translation (NMT) (Zoph et al., 2016; Dabre et al., 2017; Nguyen and Chiang, 2017) attempts to improve the NMT performance on the *source* to *target* language pair (child task) using an *assisting source* language (assisting to target language translation is the parent task). Here, the parent model is trained on the assisting and target language parallel corpus and the trained weights are used to initialize the child model. If source-target language pair parallel corpus is available, the child model can further be fine-tuned. The weight initialization reduces the requirement on the training data for the source-target language pair by transferring knowledge from the parent task, thereby improving the performance on the child task.

However, the divergence between the source and the assisting language can adversely impact the benefits obtained from transfer learning. Multiple studies have shown that transfer learning works best when the languages are related (Zoph et al., 2016; Nguyen and Chiang, 2017; Dabre et al., 2017). Zoph et al. (2016) studied the influence of language divergence between languages chosen for training the parent and the child model, and showed that choosing similar languages for training the parent and the child model leads to better improvements from transfer learning.

Several studies have tried to address the *lexical divergence* between the source and the target languages either by using Byte Pair Encoding (BPE) as basic input representation units (Nguyen and Chiang, 2017) or character-level NMT system (Lee et al., 2017) or bilingual embeddings (Gu et al., 2018). However, the effect of *word order divergence* and its mitigation has not been explored. In a practical setting, it is not uncommon to have source and assisting languages with different word order. For instance, it is possible to find parallel corpora between English (SVO word order) and some Indian (SOV word order) languages, but very little parallel corpora between Indian languages. Hence, it is natural to use English as an assisting language for inter-Indian language translation.

To address the word order divergence, we propose to pre-order the assisting language sentences (SVO) to match the word order of the source language (SOV). We consider an extremely resource-constrained scenario, where there is no parallel corpus for the child task. From our experiments, we show that there is a significant increase in the translation accuracy for the unseen source-target language pair.

2 Related Work

To the best of our knowledge, no work has addressed word order divergence in transfer learning

Proceedings of NAACL-HLT 2019, pages 3868–3873
Minneapolis, Minnesota, June 2 - June 7, 2019.

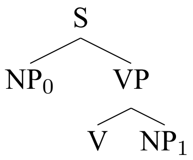
for multilingual NMT. However, some work exists for other NLP tasks in a multilingual setting. For Named Entity Recognition (NER), Xie et al. (2018) use a self-attention layer after the Bi-LSTM layer to address word-order divergence for Named Entity Recognition (NER) task. The approach does not show any significant improvements, possibly because the divergence has to be addressed before/during construction of the contextual embeddings in the Bi-LSTM layer. Joty et al. (2017) use adversarial training for cross-lingual question-question similarity ranking. The adversarial training tries to force the sentence representation generated by the encoder of similar sentences from different input languages to have similar representations.

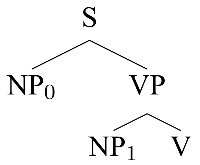
Pre-ordering the source language sentences to match the target language word order has been found useful in addressing word-order divergence for Phrase-Based SMT (Collins et al., 2005; Ramanathan et al., 2008; Navratil et al., 2012; Chatterjee et al., 2014). For NMT, Ponti et al. (2018) and Kawara et al. (2018) have explored pre-ordering. Ponti et al. (2018) demonstrated that by reducing the syntactic divergence between the source and the target languages, consistent improvements in NMT performance can be obtained. On the contrary, Kawara et al. (2018) reported drop in NMT performance due to pre-ordering. Note that these works address source-target divergence, not divergence between source languages in multilingual NMT scenario.

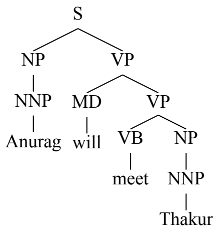
3 Proposed Solution

Consider the task of translating for an extremely low-resource language pair. The parallel corpus between the two languages, if available may be too small to train an NMT model. Similar to Zoph et al. (2016), we use transfer learning to overcome data sparsity between the source and the target languages. We choose *English* as the assisting language in all our experiments. In our resource-scarce scenario, we have no parallel corpus for training the child model. Hence, at test time, the source language sentence is translated using the parent model after performing a word-by-word translation from source to the assisting language using a bilingual dictionary.

Since the source language and the assisting language (English) have different word order, we hypothesize that it leads to inconsistencies in the contextual representations generated by the encoder for the two languages. Specifically, given an English sentence (SVO word order) and its translation in the source language (SOV word order), the encoder representations for words in the two sentences will be different due to different contexts of synonymous words. This could lead to the attention and the decoder layers generating different translations from the same (parallel) sentence in the source or assisting language. This is undesirable as we want the knowledge to be transferred from the parent model (assisting source→ target) to the child model (source→target).

Before Reordering	**After Reordering**
		






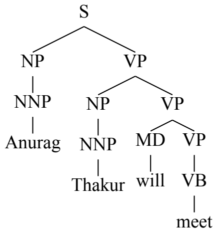


Table 1: Example showing transitive verb before and after reordering (Adapted from Chatterjee et al. (2014))

In this paper, we propose to pre-order English sentences (assisting language sentences) to match the source language word-order and train the parent model on the pre-ordered corpus. Table 1 shows one of the pre-ordering rules (Ramanathan et al., 2008) used along with an example sentence illustrating the effect of pre-ordering. This will ensure that context of words in the parallel source and assisting language sentences are similar, leading to consistent contextual representations across the source languages. Pre-ordering may also be beneficial for other word order divergence scenarios (*e.g.,* SOV to SVO), but we leave verification of these additional scenarios for future work.

4 Experimental Setup

In this section, we describe the languages experimented with, datasets used, the network hyper-parameters used in our experiments.

Languages: We experimented with English → Hindi translation as the parent task. English is the assisting source language. Bengali, Gujarati, Marathi, Malayalam and Tamil are the source languages, and translation from these to Hindi constitute the child tasks. Hindi, Bengali, Gujarati and Marathi are Indo-Aryan languages, while Malayalam and Tamil are Dravidian languages. All these languages have a canonical SOV word order.

Datasets: For training English-Hindi NMT systems, we use the IITB English-Hindi parallel corpus (Kunchukuttan et al., 2018) ($1.46M$ sentences from the training set) and the ILCI English-Hindi parallel corpus ($44.7K$ sentences). The ILCI (Indian Language Corpora Initiative) multilingual parallel corpus (Jha, 2010)[1] spans multiple Indian languages from the health and tourism domains. We use the 520-sentence dev-set of the IITB parallel corpus for validation. For each child task, we use $2K$ sentences from ILCI corpus as test set.

Network: We use OpenNMT-Torch (Klein et al., 2018) to train the NMT system. We use the standard encoder-attention-decoder architecture (Bahdanau et al., 2015) with input-feeding approach (Luong et al., 2015). The encoder has two layers of bidirectional LSTMs with 500 neurons each and the decoder contains two LSTM layers with 500 neurons each. We use a mini-batch of size 50 and a dropout layer. We begin with an initial learning rate of 1.0 and continue training with exponential decay till the learning rate falls below 0.001. The English input is initialized with pre-trained *fastText* embeddings (Grave et al., 2018) [2].

English and Hindi vocabularies consists of $0.27M$ and $50K$ tokens appearing at least 2 and 5 times in the English and Hindi training corpus respectively. For representing English and other source languages into a common space, we translate each word in the source language into English using a bilingual dictionary (we used *Google Translate* to get single word translations). In an end-to-end solution, it would be ideal to use bilingual embeddings or obtain word-by-word translations *via* bilingual embeddings (Xie et al., 2018). However, publicly available bilingual embeddings for English-Indian languages are not good enough for obtaining good-quality, bilingual representations (Smith et al., 2017; Jawanpuria et al., 2019) and publicly available bilingual dictionaries have limited coverage. The focus of our study is the influence of word-order divergence on Multilingual NMT. We do not want bilingual embeddings quality or bilingual dictionary coverage to influence the experiments, rendering our conclusions unreliable. Hence, we use the above mentioned large-coverage bilingual dictionary.

Language	BLEU			LeBLEU		
	No Pre-Order	Pre-Ordered		No Pre-Order	Pre-Ordered

Tamil	1488	1280	1252

Table 3: Number of UNK tokens generated by each model on the test set.

Pre-ordering: We use *CFILT-preorder*[3] for pre-reordering English sentences. It contains two pre-ordering configurations: (1) *generic* rules (G) that apply to all Indian languages (Ramanathan et al., 2008), and (2) *hindi-tuned* rules (HT) which improves generic rules by incorporating improvements found through error analysis of English-Hindi reordering (Patel et al., 2013). The Hindi-tuned rules improve translation for other English to Indian language pairs too (Kunchukuttan et al., 2014).

5 Results

We experiment with two scenarios: (a) an extremely resource scarce scenario with no parallel corpus for child tasks, (b) varying amounts of parallel corpora available for child task.

5.1 No Parallel Corpus for Child Task

The results from our experiments are presented in the Table 2. We report BLEU scores and LeBLEU[4]

Table 4: Sample Hindi translation generated by the Gujarati-Hindi NMT model. Text in red indicates phrase dropped by the no pre-ordered model.

scores. We observe that both the pre-ordering models significantly improve the translation quality over the no-preordering models for all the language pairs. The results support our hypothesis that word-order divergence can limit the benefits of multilingual translation. Thus, reducing the word order divergence improves translation in extremely low-resource scenarios.

An analysis of the outputs revealed that pre-ordering significantly reduced the number of UNK tokens (placeholder for unknown words) in the test output (Table 3). We hypothesize that due to word order divergence between English and Indian languages, the encoder representation generated is not consistent leading to decoder generating unknown words. However, the pre-ordered models generate better encoder representations leading to lesser number of UNK tokens and better translation, which is also reflected in the BLEU scores and Table 4.

5.2 Parallel Corpus for Child Task

We study the impact of child task parallel corpus on pre-ordering. To this end, we fine-tune the parent task model with the child task parallel corpus. Table 5 shows the results for *Bengali-Hindi*, *Gujarati-Hindi*, *Marathi-Hindi*, *Malayalam-Hindi*, and *Tamil-Hindi* translation. We observe that pre-ordering is beneficial when almost no child task corpus is available. As the child task corpus increases, the model learns the word order of the source language; hence, the non pre-ordering models perform almost as good as or sometimes better than the pre-ordered ones. The non pre-ordering model is able to forget the word-order of English and learn the word order of Indian languages. We attribute this behavior of the non pre-ordered model to the phenomenon of catastrophic forgetting (McCloskey and Cohen, 1989; French, 1999) which enables the model to learn the word-order of the source language when sufficient child task parallel corpus is available.

We also compare the performance of the fine-tuned model with the model trained only on the available source-target parallel corpus with randomly initialized weights (No Transfer Learning). Transfer learning, with and without pre-ordering, is better compared to training only on the small source-target parallel corpus.

6 Conclusion

In this paper, we show that handling word-order divergence between the source and assisting languages is crucial for the success of multilingual NMT in an extremely low-resource setting. We show that pre-ordering the assisting language to match the word order of the source language significantly improves translation quality in an extremely low-resource setting. If pre-ordering is not possible, fine-tuning on a small source-target parallel corpus is sufficient to overcome word order divergence. While the current work focused on Indian languages, we would like to validate the hypothesis on a more diverse set of languages. We

would also like to explore alternative methods to address word-order divergence which do not require expensive parsing of the assisting language corpus. Further, use of pre-ordering to address word-order divergence for multilingual training of other NLP tasks can be explored.

Abstract

Multilingual neural machine translation (NMT) enables training a single model that supports translation from multiple source languages into multiple target languages. In this paper, we push the limits of multilingual NMT in terms of the number of languages being used. We perform extensive experiments in training massively multilingual NMT models, translating up to 102 languages to and from English within a single model. We explore different setups for training such models and analyze the trade-offs between translation quality and various modeling decisions. We report results on the publicly available TED talks multilingual corpus where we show that massively multilingual many-to-many models are effective in low resource settings, outperforming the previous state-of-the-art while supporting up to 59 languages. Our experiments on a large-scale dataset with 102 languages to and from English and up to one million examples per direction also show promising results, surpassing strong bilingual baselines and encouraging future work on massively multilingual NMT.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2014; Sutskever et al., 2014) is the current state-of-the-art approach for machine translation in both academia (Bojar et al., 2016, 2017, 2018) and industry (Wu et al., 2016; Hassan et al., 2018). Recent works (Dong et al., 2015; Firat et al., 2016a; Ha et al., 2016; Johnson et al., 2017) extended the approach to support multilingual translation, i.e. training a single model that is capable of translating between multiple language pairs.

Multilingual models are appealing for several reasons. First, they are more efficient in terms of the number of required models and model parameters, enabling simpler deployment. Another benefit is transfer learning; when low-resource language pairs are trained together with high-resource ones, the translation quality may improve (Zoph et al., 2016; Nguyen and Chiang, 2017). An extreme case of such transfer learning is zero-shot translation (Johnson et al., 2017), where multilingual models are able to translate between language pairs that were never seen during training.

While very promising, it is still unclear how far one can scale multilingual NMT in terms of the number of languages involved. Previous works on multilingual NMT typically trained models with up to 7 languages (Dong et al., 2015; Firat et al., 2016b; Ha et al., 2016; Johnson et al., 2017; Gu et al., 2018) and up to 20 trained directions (Cettolo et al., 2017) simultaneously. One recent exception is Neubig and Hu (2018) who trained many-to-one models from 58 languages into English. While utilizing significantly more languages than previous works, their experiments were restricted to many-to-one models in a low-resource setting with up to 214k examples per language-pair and were evaluated only on four translation directions.

In this work, we take a step towards practical "universal" NMT – training massively multilingual models which support up to 102 languages and with up to one million examples per language-pair simultaneously. Specifically, we focus on training "English-centric" many-to-many models, in which the training data is composed of many language pairs that contain English either on the source side or the target side. This is a realistic setting since English parallel data is widely available for many language pairs. We restrict our experiments to Transformer models (Vaswani et al., 2017) as they were shown to be very effective in recent benchmarks (Ott et al., 2018), also in

Proceedings of NAACL-HLT 2019, pages 3874–3884
Minneapolis, Minnesota, June 2 - June 7, 2019.

the context of multilingual models (Lakew et al., 2018; Sachan and Neubig, 2018).

We evaluate the performance of such massively multilingual models while varying factors like model capacity, the number of trained directions (tasks) and low-resource vs. high-resource settings. Our experiments on the publicly available TED talks dataset (Qi et al., 2018) show that massively multilingual many-to-many models with up to 58 languages to-and-from English are very effective in low resource settings, allowing to use high-capacity models while avoiding overfitting and achieving superior results to the current state-of-the-art on this dataset (Neubig and Hu, 2018; Wang et al., 2019) when translating into English.

We then turn to experiment with models trained on 103 languages in a high-resource setting. For this purpose we compile an English-centric in-house dataset, including 102 languages aligned to-and-from English with up to one million examples per language pair. We then train a single model on the resulting 204 translation directions and find that such models outperform strong bilingual baselines by more than 2 BLEU averaged across 10 diverse language pairs, both to-and-from English. Finally, we analyze the trade-offs between the number of involved languages and translation accuracy in such settings, showing that massively multilingual models generalize better to zero-shot scenarios. We hope these results will encourage future research on massively multilingual NMT.

2 Low-Resource Setting: 59 Languages

2.1 Experimental Setup

The main question we wish to answer in this work is how well a single NMT model can scale to support a very large number of language pairs. The answer is not trivial: on the one hand, training multiple language pairs together may result in transfer learning (Zoph et al., 2016; Nguyen and Chiang, 2017). This may improve performance as we increase the number of language pairs, since more information can be shared between the different translation tasks, allowing the model to learn which information to share. On the other hand, adding many language pairs may result in a bottleneck; the model has a limited capacity while it needs to handle this large number of translation tasks, and sharing all parameters between the different languages can be sub-optimal (Wang et al., 2018) especially if they are not from the same typological language family (Sachan and Neubig, 2018).

We begin tackling this question by experimenting with the TED Talks parallel corpus compiled by Qi et al. (2018)[1], which is unique in that it includes parallel data from 59 languages. For comparison, this is significantly "more multilingual" than the data available from all previous WMT news translation shared task evaluations throughout the years – the latest being Bojar et al. (2016, 2017, 2018), which included 14 languages so far.[2]

We focus on the setting where we train "English-centric" models, i.e. training on all language pairs that contain English in either the source or the target, resulting in 116 translation directions. This dataset is also highly imbalanced, with language pairs including between 3.3k to 214k sentence pairs for training. Table 9 in the supplementary material details the languages and training set sizes for this dataset. Since the dataset is already tokenized we did not apply additional preprocessing other than applying joint subword segmentation (Sennrich et al., 2016) with 32k symbols.

Regarding the languages we evaluate on, we begin with the same four languages as Neubig and Hu (2018) – Azerbeijani (Az), Belarusian (Be), Galician (Gl) and Slovak (Sk). These languages present an extreme low-resource case, with as few as 4.5k training examples for Belarusian-English. In order to better understand the effect of training set size in these settings, we evaluate on four additional languages that have more than 167k training examples each – Arabic (Ar), German (De), Hebrew (He) and Italian (It).

2.2 Model Details

Using the same data, we trained three massively multilingual models: a many-to-many model which we train using all 116 translation directions with 58 languages to-and-from English, a one-to-many model from English into 58 languages, and a many-to-one model from 58 languages into English. We follow the method of Ha et al. (2016); Johnson et al. (2017) and add a target-language

[2] Chinese, Czech, English, Estonian, Finnish, French, German, Hindi, Hungarian, Latvian, Romanian, Russian, Spanish, Turkish. According to `http://www.statmt.org/wmtXX`

prefix token to each source sentence to enable many-to-many translation. These different setups enable us to examine the effect of the number of translation tasks on the translation quality as measured in BLEU (Papineni et al., 2002). We also compare our massively multilingual models to bilingual baselines and to two recently published results on this dataset (Neubig and Hu (2018); Wang et al. (2019)).

Regarding the models, we focused on the Transformer in the "Base" configuration. We refer the reader to Vaswani et al. (2017) for more details on the model architecture. Specifically, we use 6 layers in both the encoder and the decoder, with model dimension set at 512, hidden dimension size of 2048 and 8 attention heads. We also applied dropout at a rate of 0.2 in the following components: on the sum of the input embeddings and the positional embeddings, on the output of each sub-layer before added to the previous layer input (residual connection), on the inner layer output after the ReLU activation in each feed-forward sub-layer, and to the attention weight in each attention sub-layer. This results in a model with approximately 93M trainable parameters. For all models we used the inverse square root learning rate schedule from Vaswani et al. (2017) with learning-rate set at 3 and 40k warmup steps. All models are implemented in Tensorflow-Lingvo (Shen et al., 2019).

In all cases we report test results for the checkpoint that performed best on the development set in terms of BLEU. For the multilingual models we create a development set that includes examples we uniformly sample from a concatenation of all the individual language pair development sets, resulting in 13k development examples per model. Another important detail regarding multilingual training is the batching scheme. In all of our multilingual models we use heterogeneous batching, where each batch contains examples which are uniformly sampled from a concatenation of all the language pairs the model is trained on. Specifically, we use batches of 64 examples for sequences shorter than 69 tokens and batches of 16 examples for longer sequences. We did not use oversampling as the dataset is relatively small.

2.3 Results

We use tokenized BLEU in order to be comparable with Neubig and Hu (2018). Table 1 shows the results of our experiments when evaluating on the same language pairs as they did. The results under "Neubig & Hu 18" are their bilingual baselines and their best many-to-one models. Their many-to-one models use similar-language-regularization, i.e. fine-tuning a pre-trained many-to-one model with data from the language pair of interest together with data from a language pair that has a typologically-similar source language and more training data (i.e. Russian and Belarusian, Turkish and Azerbaijani). The results under "Ours" are our many-to-one and many-to-many models we trained identically in terms of model architecture and hyper-parameters.

We first note that our many-to-many model out-

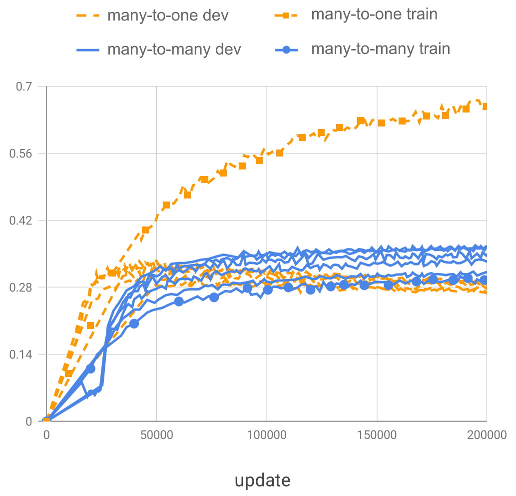

Figure 1: Development BLEU on {It,Ro,Nl,De,Ar}→En vs. training BLEU for the many-to-one and many-to-many models. Best viewed in color.

performs all other models when translating into English, with 1.82 BLEU improvement (when averaged across the four language pairs) over the best fine-tuned many-to-one models of Neubig and Hu (2018) and 2.44 BLEU improvement over our many-to-one model when averaged across the four low-resource language pairs (Table 1). This is surprising as it uses the same X→En data, model architecture and capacity as our many-to-one model, while handling a heavier burden since it also supports 58 *additional* translation tasks (*from* English *into* 58 languages). Our models also outperform the more complex models of Wang et al. (2019) which use ”Soft Decoupled Encoding” for the input tokens, while our models use a simple subword segmentation.

One possible explanation is that the many-to-one model overfits the English side of the corpus as it is multi-way-parallel: in such setting the English sentences are overlapping across the different language pairs, making it much easier for the model to memorize the training set instead of generalizing (when enough capacity is available). On the other hand, the many-to-many model is trained on additional target languages other than English, which can act as regularizers for the X→En tasks, reducing such overfitting.

To further illustrate this, Figure 1 tracks the BLEU scores on the individual development sets during training for Italian (It), Romanian (Ro), Dutch (Nl), German (De) and Arabic (Ar) into English (left), together with BLEU scores on a subset of the training set for each model. We can see that while the many-to-one model degrades in performance on the development set, the many-to-many model still improves. Note the large gap in the many-to-one model between the training set BLEU and the development set BLEU, which points on the generalization issue that is not present in the many-to-many setting. We also note that our many-to-one model is on average 0.75 BLEU behind the best many-to-one models in Neubig and Hu (2018). We attribute this to the fact that their models are fine-tuned using similar-language-regularization while our model is not.

We find an additional difference between the results on the resource-scarce languages (Table 1) and the higher-resource languages (Table 2). Specifically, the bilingual baselines outperform the many-to-one models only in the higher-resource setting. This makes sense as in the low-resource setting the baselines have very few training examples to outperform the many-to-one models, while in the higher resource setting they have access to more training data. This corroborates the results of Gu et al. (2018) that showed the sensitivity of such models to similar low resource conditions and the improvements gained from using many-to-one models (however with much fewer language pairs).

	En-Az	En-Be	En-Gl	En-Sk	Avg.

Table 3: En→X test BLEU on the TED Talks corpus

Table 3 shows the results of our massively multilingual models and bilingual baselines when evaluated out-of-English. In this case we see an opposite trend: the many-to-many model performs worse than the one-to-many model by 2.53 BLEU on average. While previous works (Wang et al., 2018; Sachan and Neubig, 2018) discuss the phenomena of quality degradation in English-to-many settings, this shows that increasing the number of *source* languages also causes additional degradation in a many-to-many model. This degradation may be due to the English-centric setting: since most of the translation directions the model is trained on are into English, this leaves less capacity for the other target languages (while still performing better than the bilingual baselines on all 8 language pairs). We also note that in this case the results are consistent among the higher and lower resource pairs – the one-to-many model is better than the many-to-many model, which outperforms the bilingual baselines in all cases. This is unlike the difference we saw in the X→ En experiments since here we do not have the multi-way-parallel overfitting issue.

2.4 Discussion

From the above experiments we learn that NMT models can scale to 59 languages in a low-resource, imbalanced, English-centric setting, with the following observations: (1) massively multilingual many-to-many models outperform many-to-one and bilingual models with similar capacity and identical training conditions when averaged over 8 language pairs into English. We attribute this improvement over the many-to-one models to the multiple target language pairs which may act as regularizers, especially in this low-resource multi-way-parallel setting that is prone to memorization. (2) many-to-many models are inferior in performance when going out-of-English in comparison to a one-to-many model. We attribute this to English being over-represented in the English-centric many-to-many setting, where it appears as a target language in 58 out of 116 trained directions, which may harm the performance on the rest of the target languages as the model capacity is limited.[3]

It is important to stress the fact that we compared the different models under *identical training conditions* and did not perform extensive hyper-parameter tuning for each setting separately. However, we believe that such tuning may improve performance even further, as the diversity in each training batch is very different between the different settings. For example, while the baseline model batches include only one language in the source and one language in the target, the many-to-many model includes 59 languages in each side with a strong bias towards English. These differences may require tailored hyper-parameter choices for each settings (i.e. different batch sizes, learning rate schedules, dropout rates etc.) which would be interesting to explore in future work.

In the following experiments we investigate whether these observations hold using (1) an even larger set of languages, and (2) a much larger, balanced training corpus that is not multi-way-parallel.

3 High-Resource Setting: 103 Languages

3.1 Experimental Setup

In this setting we scale the number of languages and examples per language pair further when training a single massively multilingual model. Since we are not aware of a publicly available resource for this purpose, we construct an in-house dataset. This dataset includes 102 language pairs which we "mirror" to-and-from English, with up to one million examples per language pair. This results in 103 languages in total, and 204 translation directions which we train simultaneously. More details about this dataset are available in Table 4, and Table 10 in the supplementary material details all the languages in the dataset.[4]

Similarly to our previous experiments, we compare the massively multilingual models to bilingual baselines trained on the same data. We tokenize the data using an in-house tokenizer and then apply joint subword segmentation to achieve an open-vocabulary. In this setting we used a vocabulary of 64k subwords rather than 32k. Since the dataset contains 24k unique characters, a 32k symbol vocabulary will consist of mostly characters, thereby increasing the average sequence length. Regarding the model, for these experiments we use a larger Transformer model with 6 layers in both the encoder and the decoder, model dimension set to 1024, hidden dimension size of 8192, and 16 attention heads. This results in a model with approximately 473.7M parameters.[5] Since the model and data are much larger in this case, we used a dropout rate of 0.1 for our multilingual models and tuned it to 0.3 for our baseline models as it improved the translation quality on the development set.

We evaluate our models on 10 languages from different typological families: *Semitic* – Arabic (Ar), Hebrew (He), *Romance* – Galician (Gl), Italian (It), Romanian (Ro), *Germanic* – German (De), Dutch (Nl), *Slavic* – Belarusian (Be), Slovak (Sk) and *Turkic* – Azerbaijani (Az) and Turkish (Tr). We evaluate both to-and-from English, where each language pair is trained on up to one million examples. As in the previous experiment, we report test results from the model that performed best in terms of BLEU on the development set.

# of language pairs	102
examples per pair	
min	63,879
max	1,000,000
average	940,087
std. deviation	188,194
total # of examples	95,888,938

Table 4: Training set details for the 103 langauges corpus, X→En data.

---

[3] This issue may be alleviated by over-sampling the non-English-target pairs, but we leave this for future work.

[4] The average number of examples per language pair is 940k, as for 13 out of the 102 pairs we had less than one million examples available.

[5] This is larger than the Transformer "Big" configuration, which includes approximately 213M trained parameters.

Table 6: En→X test BLEU on the 103-language corpus

3.2 Results

Table 5 describes the results when translating into English. First, we can see that both multilingual models perform better than the baselines in terms of average BLEU. This shows that massively multilingual many-to-many models can work well in realistic settings with millions of training examples, 102 languages and 204 jointly trained directions to-and-from English. Looking more closely, we note several different behaviors in comparison to the low-resource experiments on the TED Talks corpus. First, the many-to-one model here performs better than the many-to-many model. This shows that the previous result was indeed due to the pathologies of the low-resource dataset; when the training data is large enough and not multi-way-parallel there is no overfitting in the many-to-one model, and it outperforms the many-to-many model in most cases while they are trained identically.

One particular outlier in this case is German-to-English, where the many-to-one model is 2 BLEU points below the many-to-many model. We examine the BLEU score of this language pair on its dedicated German-English development set during training in the many-to-one model and find that it highly fluctuates. We then measure the performance on the test set for this language pair by choosing the best checkpoint on the dedicated German-English development set (instead of on the mixed multilingual development set) and find it to be 38.07, which is actually *higher* in 1 BLEU than the best result of the many-to-many model. This shows that while training many languages together, there is no "silver bullet": some languages may suffer from severe interference during training (i.e. a reduction of 3 BLEU in this case, from 38.07 to 35.05) while other languages continue to improve with more updates.

Table 6 describes the results when translating out-of-English. Again, both of the massively multilingual models perform better than the baselines when averaged across the 10 evaluated language pairs, while handling up to 102 languages to-and-from English and 204 translation tasks simultaneously. In this case the results are similar to those we observed on the TED talks corpus, where the one-to-many model performs better than the many-to-many model. Again, this advantage may be due to the one-to-many model handling a smaller number of tasks while not being biased towards English in the target side like the many-to-many model.

4 Analysis

The above results show that massively multilingual NMT is indeed possible in large scale settings and can improve performance over strong bilingual baselines. However, it was shown in a somewhat extreme case with more than 100 languages trained jointly, where we saw that in some cases the joint training may harm the performance for some language pairs (i.e. German-English above). In the following analysis we would like to better understand the trade-off between the number of languages involved and the translation accuracy while keeping the model capacity and training configuration fixed.

4.1 Multilinguality & Supervised Performance

We first study the effect of varying the number of languages on the translation accuracy in a supervised setting, where we focus on many-

	Ar-En	En-Ar	Fr-En	En-Fr	Ru-En	En-Ru	Uk-En	En-Uk	Avg.
5-to-5	**23.87**	**12.42**	**38.99**	**37.3**	29.07	**24.86**	**26.17**	16.48	**26.14**

5-to-5	1.66	4.49	3.7	3.02	3.21
25-to-25	1.83	**5.52**	**16.67**	4.31	7.08
50-to-50	**4.34**	4.72	15.14	**20.23**	**11.1**
75-to-75	1.85	4.26	11.2	15.88	8.3
103-to-103	2.87	3.05	12.3	18.49	9.17

Table 8: Zero-Shot performance while varying the number of languages involved

to-many models. We create four subsets of the in-house dataset by sub-sampling it to a different number of languages in each subset. In this way we create four additional English-centric datasets, containing 5, 25, 50 and 75 languages each to-and-from English. We make sure that each subset contains all the languages from the next smaller subsets – i.e. the 25 language subset contains the 5 language subset, the 50 language subset contains the 25 language subset and so on. We train a similar-capacity large Transformer model (with 473.7M parameters) on each of these subsets and measure the performance for each model on the 8 supervised language pairs from the smallest subset – {Arabic, French, Russian, Ukrainian}↔English. In this way we can analyze to what extent adding more languages improves or harms translation quality while keeping the model capacity fixed, testing the capacity vs. accuracy "saturation point".

Table 7 shows the results of this experiment, reporting the test results for the models that performed best on the multilingual development set. We can see that in most cases the best results are obtained using the 5-to-5 model, showing that there is indeed a trade off between the number of languages and translation accuracy when using a fixed model capacity and the same training setup. One may expect that the gaps between the different models should become smaller and even close with more updates, as the models with more languages see less examples per language in each batch, thus requiring more updates to improve in terms of BLEU. However, in our setting these gaps did not close even after the models converged, leaving 2.73 average BLEU difference between the 5-to-5 and the 103-to-103 model.

4.2 Multilinguality & Zero-Shot Performance

We then study the effect of the number of languages on zero-shot translation accuracy. Since we find zero-shot accuracy as an interesting measure for model generalization, we hypothesize that by adding more languages, the model is forced to create a more generalized representation to better utilize its capacity, which may improve zero-shot performance. We choose four language pairs for this purpose: Arabic↔French which are distant languages, and Ukrainian↔Russian which are similar. Table 8 shows the results of our models on these language pairs. For Arabic↔French the BLEU scores are very low in all cases, with the 50-to-50 and 25-to-25 models being slightly better than rest on Ar-Fr and Fr-Ar respectively. On Russian↔Ukrainian we see clear improvements when increasing the number of languages to more than five.

Figure 2 further illustrates this, showing the better generalization performance of the massively multilingual models under this zero-shot setting. While the zero-shot performance in this case is low and unstable for the 5-to-5 and 25-to-25 mod-

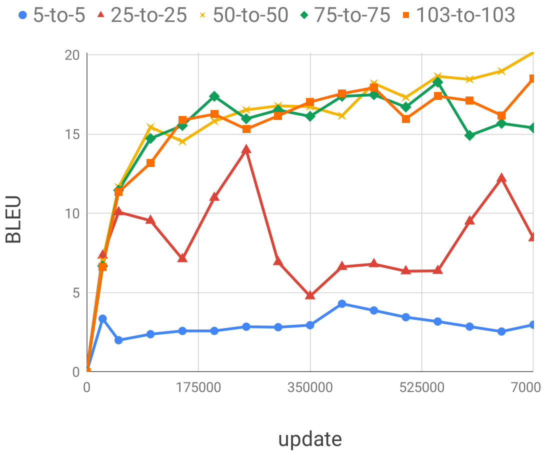

Figure 2: Zero-shot BLEU during training for Ukranian to Russian

els, it is much better for the 50-to-50, 75-to-75 and 103-to-103 models. Given these results we can say that the balance between capacity and generalization here favors the mid range 50-to-50 model, even when using models with more than 473M trained parameters. This may hint at the necessity of even larger models for such settings, which is a challenging avenue for future work. We also note that our 103 language corpus includes up to one million examples per language pair – while in real-world MT deployments, systems are trained on much more examples per pair. This again emphasizes the need for better techniques for training such massively multilingual models as we may already be hitting the capacity barrier in our setting.

5 Related Work

Dong et al. (2015) extended the NMT model of Bahdanau et al. (2014) to one-to-many translation (from English into 4 languages) by adding a dedicated decoder per target language, showing improvements over strong single-pair baselines. Firat et al. (2016a,b) proposed many-to-many models (with up to 6 languages) by using separate encoders and decoders per language while sharing the attention mechanism. They also introduced the notion of zero-resource translation, where they use synthetic training data generated through pivoting to train translation directions without available training data. Ha et al. (2016) and Johnson et al. (2017) proposed to use a shared encoder-decoder-attention model for many-to-many translation (with up to 7 languages in the latter). In order to determine the target language in such scenarios they proposed adding dedicated target-language symbols to the source. This method enabled zero-shot translation, showing the ability of the model to generalize to unseen pairs.

Recent works propose different methods for parameter sharing between language pairs in multilingual NMT. Blackwood et al. (2018) propose sharing all parameters but the attention mechanism and show improvements over sharing all parameters. Sachan and Neubig (2018) explore sharing various components in self-attentional (Transformer) models. Lu et al. (2018) add a shared "interlingua" layer while using separate encoders and decoders. Zaremoodi et al. (2018) utilize recurrent units with multiple blocks together with a trainable routing network. Platanios et al. (2018) propose to share the entire network, while using a contextual parameter generator that learns to generate the parameters of the system given the desired source and target languages. Gu et al. (2018) propose a "Universal Language Representation" layer together with a Mixture-of-Language-Experts component to improve a many-to-one model from 5 languages into English.

While the mentioned studies provide valuable contributions to improving multilingual models, they apply their models on only up to 7 languages (Johnson et al., 2017) and 20 trained directions (Cettolo et al., 2017) in a single model, whereas we focus on scaling NMT to much larger numbers of languages and trained directions. Regarding massively multilingual models, Neubig and Hu (2018) explored methods for rapid adaptation of NMT to new languages by training multilingual models on the 59-language TED Talks corpus and fine-tuning them using data from the new languages. While modeling significantly more languages than previous studies, they only train many-to-one models, which we show are inferior in comparison to our proposed massively multilingual many-to-many models when evaluated into English on this dataset.

Tiedemann (2018) trained an English-centric many-to-many model on translations of the bible including 927 languages. While this work pointed to an interesting phenomena in the latent space learned by the model where it clusters representations of typologically-similar languages together, it did not include any evaluation of the produced translations. Similarly, Malaviya et al. (2017) trained a many-to-English system including 1017 languages from bible translations, and used it to infer typological features for the different languages (without evaluating the translation quality). In another relevant work, Artetxe and Schwenk (2018) trained an NMT model on 93 languages and used the learned representations to perform cross-lingual transfer learning. Again, they did not report the performance of the translation model learned in that massively multilingual setting.

6 Conclusions and Future Work

We showed that NMT models can successfully scale to 102 languages to-and-from English with 204 trained directions and up to one million examples per direction. Such models improve the translation quality over similar single-pair baselines when evaluated to and from English by more than 2 BLEU when averaged over 10 diverse language pairs in each case. We show a similar result on the low-resource TED Talks corpus with 59 languages and 116 trained directions. We analyze the trade-offs between translation quality and the number of languages involved, pointing on capacity bottlenecks even with very large models and showing that massively multilingual models can generalize better to zero-shot settings.

We hope this work will encourage future research on massively multilingual NMT, enabling easier support for systems that can serve more people around the globe. There are many possible avenues for future work, including semi-supervised learning in such settings, exploring ways to reduce the performance degradation when increasing the number of languages, or using such models for multilingual transfer learning (McCann et al., 2017; Eriguchi et al., 2018; Artetxe and Schwenk, 2018). Understanding and improving zero-shot performance in such scenarios is also a promising direction for future work.

Acknowledgments

We would like to thank the Google Brain and Google Translate teams for their useful inputs and discussions. We would also like to thank the entire Lingvo development team for their foundational contributions to this project.

A Large-Scale Comparison of Historical Text Normalization Systems

Marcel Bollmann

Abstract

There is no consensus on the state-of-the-art approach to historical text normalization. Many techniques have been proposed, including rule-based methods, distance metrics, character-based statistical machine translation, and neural encoder–decoder models, but studies have used different datasets, different evaluation methods, and have come to different conclusions. This paper presents the largest study of historical text normalization done so far. We critically survey the existing literature and report experiments on eight languages, comparing systems spanning all categories of proposed normalization techniques, analysing the effect of training data quantity, and using different evaluation methods. The datasets and scripts are made publicly available.

1 Introduction[1]

Spelling variation is one of the key challenges for NLP on historical texts, affecting the performance of tools such as part-of-speech taggers or parsers and complicating users' search queries on a corpus. *Normalization* is often proposed as a solution; it is commonly defined as the mapping of historical variant spellings to a single, contemporary "normal form" as exemplified in Figure 1.

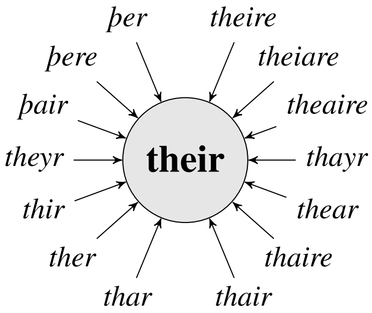

Figure 1: Historical text normalization exemplified: mapping variant spellings from historical English texts to their normalization *'their'*

Automatic normalization of historical texts has a long history, going back to at least Fix (1980). Earlier approaches often rely on hand-crafted algorithms tailored to one specific language, while more recent approaches have focused on supervised machine learning, particularly character-based statistical machine translation (SMT) and its neural equivalent (NMT). However, no clear consensus has emerged about the state of the art for this task, with papers either reporting an advantage for NMT (Hämäläinen et al., 2018), SMT (Domingo and Casacuberta, 2018), or language-specific algorithms (Schneider et al., 2017). Moreover, the quantity of annotated training data varies considerably between studies, making it difficult to obtain practical recommendations for new projects seeking to use normalization techniques.

Contributions This paper aims to provide the most comprehensive evaluation and analysis of historical text normalization systems so far. Motivated by a systematic review of previous work on this topic (Sec. 2), only publicly available normalization systems covering a wide range of proposed techniques are selected (Sec. 3) and evaluated across a diverse collection of historical datasets covering eight languages (Sec. 4). This is followed by a detailed analysis of the effect of training data quantity and a critical discussion of evaluation methods for assessing normalization quality (Sec. 5).

The datasets and code are made freely available whenever possible,[2] along with detailed instructions on how to reproduce the experiments.

2 A Brief Survey of Automatic Historical Text Normalization

The following overview is broadly organized by categories that each represent a conceptually or methodically different approach.

2.1 Substitution Lists

The conceptually simplest form of normalization is to look up each historical variant in a pre-compiled list that maps it to its intended normalization. This approach can go by many names, such as *lexical substitution*, *dictionary lookup*, *wordlist mapping*, or *memorization*. While it does not generalize in any way to variants that are not covered by the list, it has proven highly effective as a component in several normalization systems, such as the semi-automatic VARD tool (Rayson et al., 2005; Baron and Rayson, 2008) or the fully automatic Norma tool (Bollmann, 2012).

2.2 Rule-based Methods

Rule-based approaches try to encode regularities in spelling variants—e.g., historical $\langle v \rangle$ often representing modern $\langle u \rangle$—in the form of replacement rules, typically including context information to discriminate between different usages of a character. Some of the earliest approaches to normalization are rule-based, with rules being created manually for one particular language, such as Old Icelandic (Fix, 1980) or Old German (Koller, 1983).

VARD 2 uses "letter replacement rules" to construct normalization candidates, but is not necessarily concerned with precision due to its interactive nature (Baron and Rayson, 2008). Bollmann et al. (2011) describe a supervised learning algorithm to automatically derive context-aware replacement rules from training data, including "identity rules" that leave a character unchanged, then apply one rule to each character of a historical word form to produce a normalization. Porta et al. (2013) model phonological sound change rules for Old Spanish using finite-state transducers; Etxeberria et al. (2016) describe a similarly motivated model that can be trained in a supervised manner.

Rule-based methods are also commonly found when the goal is not to produce a single best normalization, but to cluster a group of spelling variants (Giusti et al., 2007) or to retrieve occurrences of variant spellings given a modern form in an information retrieval (IR) scenario (Ernst-Gerlach and Fuhr, 2006; Koolen et al., 2006).

2.3 Distance-based Methods

Approaches using edit distance measures (such as Levenshtein distance; Levenshtein, 1966) are most commonly found in an IR context, since measures that compare two word forms are a natural fit for matching a search term with relevant word forms in a historical document (e.g., Robertson and Willett, 1993). Weighted variants of distance measures can be used to assign lower costs to more likely edit operations (Kempken et al., 2006; Hauser and Schulz, 2007).

In a normalization context, distance measures can be used to compare historical variants to entries in a contemporary full-form lexicon (Kestemont et al., 2010; Jurish, 2010a). Norma includes a distance-based component whose edit weights can be learned from a training set of normalizations (Bollmann, 2012). Pettersson et al. (2013a) find a similar approach to be more effective than hand-crafted rules on Swedish. Sometimes, the line between distance-based and rule-based methods get blurred; Adesam et al. (2012) use the Levenshtein algorithm to derive "substitution rules" from training data, which are then used to link up historical Swedish forms with lexicon entries; van Halteren and Rem (2013) describe a comparable approach for Dutch.

Furthermore, distance measures also lend themselves to unsupervised approaches for clustering historical variants of the same modern form, where identifying the precise modern form is not necessarily required (Amoia and Martínez, 2013; Barteld et al., 2015).

2.4 Statistical Models

In a probabilistic view of the normalization task, the goal is to optimize the probability $p(t|s)$ that a contemporary word form t is the normalization of a historical word form s. This can be seen as a *noisy channel model*, which has been used for normalization by, e.g., Oravecz et al. (2010) and Etxeberria et al. (2016).

More commonly, *character-based statistical machine translation (CSMT)* has been applied to the normalization task. Instead of translating a sentence as a sequence of tokens, these approaches "translate" a historical word form as a sequence of characters. This has been found to be very effective for a variety of historical languages, such as Spanish (Sánchez-Martínez et al., 2013), Icelandic and Swedish (Pettersson et al., 2013b), Slovene (Scherrer and Erjavec, 2013, 2016; Ljubešić et al., 2016), as well as Hungarian, German, and English (Pettersson, 2016), where it is usually found to outperform previous approaches.
