Input: *The solution is functional human patterns and a balance between transport system capacity and land use generated travel demand.*

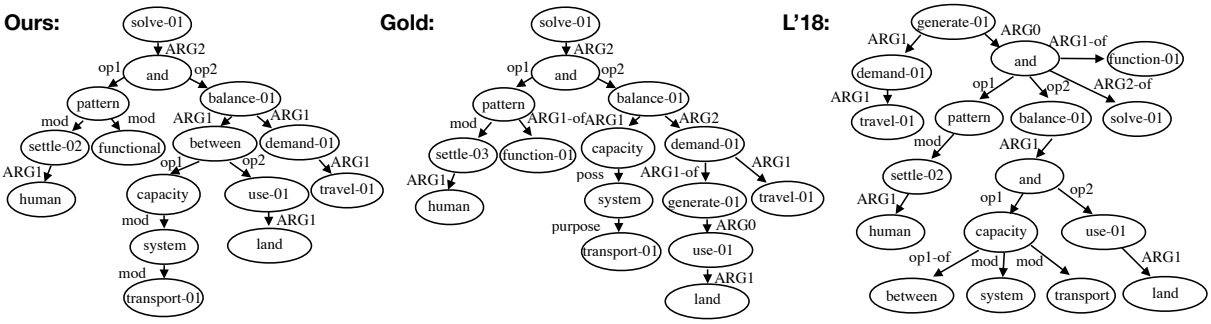

Figure 4: Case study.

method in capturing the core ideas. Besides, our model achieves the highest root-accuracy (RA) and complete-match (CM), which further confirms the usefulness of a global view and the core semantic first principle.

Even evaluated by the ordinary Smatch metric, our model yields better results than all previously reported models with the exception of Lyu and Titov (2018), which relies on a tremendous amount of manual heuristics for designing rules for graph re-categorization and adopts a pipeline approach. Note that our parser constructs the AMR graph in an end-to-end fashion with a better (quadratic) time complexity.

We present a case study in Figure 4 with comparison to the output of Lyu and Titov (2018)'s parser. As seen, both parsers make some mistakes. Specifically, our method fails to identify the concept `generated-01`. While Lyu and Titov (2018)'s parser successfully identifies it, their parser mistakenly treats it as the root of the whole AMR. It leads to a serious drawback of making the sentence meaning be interpreted in a wrong way. In contrast, our method shows a strong capacity in capturing the main idea "*the solution is about some patterns and a balance*". However, on the ordinary Smatch metric, their graph obtains a higher score (68% vs. 66%), which indicates that the ordinary Smatch is not a proper metric for evaluating the quality of capturing core semantics. If we adopt the Smatch-weighted metric, our method achieves a better score i.e. 74% vs. 61%.

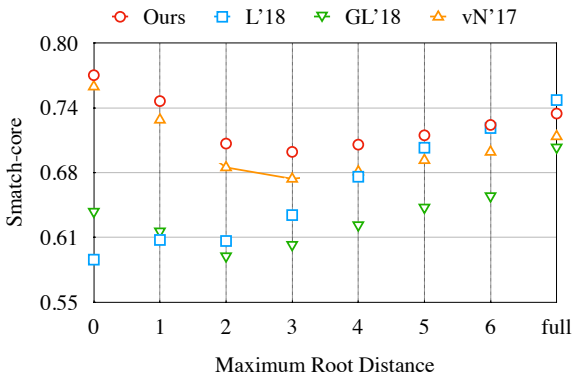

Figure 5: Smatch scores with different root distances. vN'17 is van Noord and Bos (2017)'s parser with 100K additional training pairs. GL'18 is Guo and Lu (2018)'s parser. L'18 is Lyu and Titov (2018)'s parser.

5.3 More Results

To reveal our parser's ability for grasping meanings at different levels of granularity, we plot the Smatch-core scores in Figure 5 by varying

the maximum root distance d_{max}, compared with several strong baselines and the state-of-the-art model. It demonstrates that our method is better at abstracting the core ideas of a sentence.

As discussed in § 3, there could be multiple valid generation orders for sibling nodes in an AMR graph. We experiment with the following traversal variants: (1) *random*, which sorts the sibling nodes in completely random order. (2) *relation freq.*, which sorts the sibling nodes according to their relations to the head node. We assign higher priorities to relations that occur more frequently, which drives our parser always to seek for the most common relation first. (3) *combined*, which combines the above two strategies by using *random* and *relation freq.* with equal chance. As seen in Table 2, the deterministic order strategy for training (*relation freq.*) achieves better performance than random order. Interestingly, the combined strategy significantly boosts the performance.[6] The reason is that the random order potentially produces a larger set of training pairs since each random order strategy can be considered as a different training pair. On the other hand, the deterministic order stabilizes the maximum likelihood estimate training. Therefore, the combined strategy benefits from both worlds.

Order	Smatch		
	weighted	core	ordinary
random	68.2	67.4	70.4
relation freq.	69.9	68.3	70.9
combined	71.3	70.2	73.2

Table 2: The effect of different sibling orders.

6 Conclusion and Future Work

We presented the first top-down AMR parser. Our proposed parser builds a AMR graph incrementally in a root-to-leaf manner. Experiments show that our method has a better capability of capturing the core semantics in a sentence compared with previous state-of-the-art methods. In addition, we overcome the need of heuristics for graph recategorization employed in most previous work, which makes our method much more transferable to other semantic representations or languages.

Our methods follows the intuition that humans tend to grasp the core meaning of a sentence first. However, some cognitive theories (Langacker, 2008) also suggest that human language understanding is often presented as a circular, abductive process (hermeneutic circle). It is interesting to explore the use of some revision mechanisms when the initial steps go wrong.

[6] We note there are many other ways to generate a deterministic order. For example, van Noord and Bos (2017) uses the order of aligned words in the sentence. However, we use the relation frequency method for its simplicity and not relying on external resources (e.g, an aligner).

Don't paraphrase, detect! Rapid and Effective Data Collection for Semantic Parsing

Jonathan Herzig[1] **Jonathan Berant**[1,2]

{jonathan.herzig,joberant}@cs.tau.ac.il

Abstract

A major hurdle on the road to conversational interfaces is the difficulty in collecting data that maps language utterances to logical forms. One prominent approach for data collection has been to automatically generate pseudo-language paired with logical forms, and paraphrase the pseudo-language to natural language through crowdsourcing (Wang et al., 2015). However, this data collection procedure often leads to low performance on real data, due to a mismatch between the true distribution of examples and the distribution induced by the data collection procedure. In this paper, we thoroughly analyze two sources of mismatch in this process: the mismatch in *logical form distribution* and the mismatch in *language distribution* between the true and induced distributions. We quantify the effects of these mismatches, and propose a new data collection approach that mitigates them. Assuming access to unlabeled utterances from the true distribution, we combine crowdsourcing with a paraphrase model to detect correct logical forms for the unlabeled utterances. On two datasets, our method leads to 70.6 accuracy on average on the *true distribution*, compared to 51.3 in paraphrasing-based data collection.

1 Introduction

Conversing with a virtual assistant in natural language is one of the most exciting current applications of semantic parsing, the task of mapping natural language utterances to executable logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011). Semantic parsing models rely on supervised training data that pairs natural language utterances with logical forms. Alas, such data does not occur naturally, especially in virtual assistants that are meant to support thousands of different applications and use-cases. Thus, efficient data collection is perhaps the most pressing problem for scalable conversational interfaces.

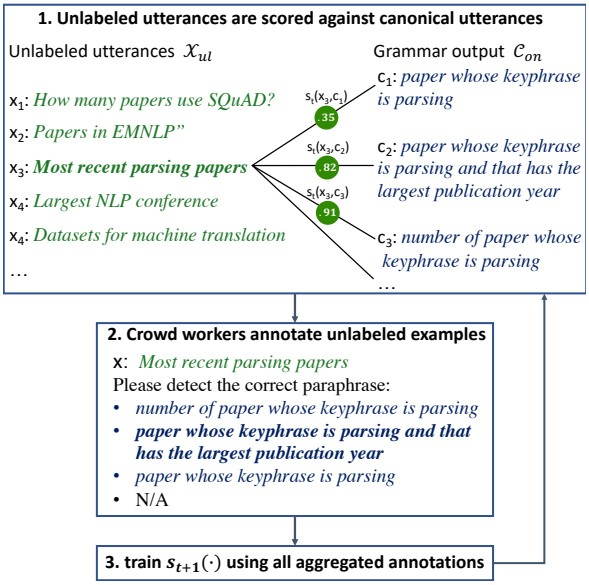

Figure 1: An overview of GRANNO, a method for annotating unlabeled utterances with their logical forms.

In recent years, many attempts aim to reduce the burden of data collection for semantic parsing, including training from denotations (Kwiatkowski et al., 2013; Artzi and Zettlemoyer, 2013), semi-supervised learning (Kociský et al., 2016; Yin et al., 2018), human in the loop (Iyer et al., 2017; Lawrence and Riezler, 2018), and training on examples from other domains (Herzig and Berant, 2017, 2018; Su and Yan, 2017). One prominent approach for data collection was introduced by Wang et al. (2015), termed OVERNIGHT. In this method, one automatically generates logical forms for an application from a grammar, paired with pseudo-language utterances. These pseudo-language utterances are then shown to crowd workers, who are able to understand them and paraphrase them into natural language, resulting

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3810–3820, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

in a supervised dataset.

The OVERNIGHT procedure has been adopted and extended both within semantic parsing (Locascio et al., 2016; Ravichander et al., 2017; Zhong et al., 2017; Cheng et al., 2018), in dialogue (Shah et al., 2018; Damonte et al., 2019) and in visual reasoning (Johnson et al., 2017; Hudson and Manning, 2019).

While the OVERNIGHT approach is appealing since it generates training data from scratch, it suffers from a major drawback – training a parser on data generated from OVERNIGHT and testing on utterances collected from a target distribution results in a significant drop in performance (Wang et al., 2015; Ravichander et al., 2017).

In this paper, we thoroughly analyze the sources of mismatch between a target distribution and the distribution induced by OVERNIGHT, and propose a new method for overcoming this mismatch. We decouple the mismatch into two terms: the *logical form mismatch*, i.e., the difference between the target distribution of logical forms and the distribution obtained when generating from a grammar, and the *language mismatch*, i.e., the difference between the natural language obtained when paraphrasing a pseudo-language utterance and the language obtained by real users of an application.

We find that the most severe problem arising from the *logical form mismatch* is insufficient coverage of logical form templates that occur in the true distribution, when generating from a grammar. We also isolate the *language mismatch* effect by paraphrasing logical forms sampled from the true logical form distribution, and find that the language mismatch alone results in a decrease of 9 accuracy points on average on two datasets.

To overcome these mismatches, we propose an alternative method to OVERNIGHT, that utilizes unlabeled utterances. Our method, named GRANNO (grammar-driven annotation), allows crowd workers to iteratively annotate unlabeled utterances by *detecting* their correct grammar generated paraphrase. Figure 1 illustrates a single iteration of this approach. An unlabeled utterance is matched using a paraphrase model against candidate pseudo-language utterances generated by the grammar (step 1). The unlabeled utterance and its top candidate paraphrases are presented to a crowd worker that detects the correct paraphrase (step 2). The paraphrase model is re-trained given all annotated utterances thus far (step 3), and is used to score the remaining unlabeled utterances.

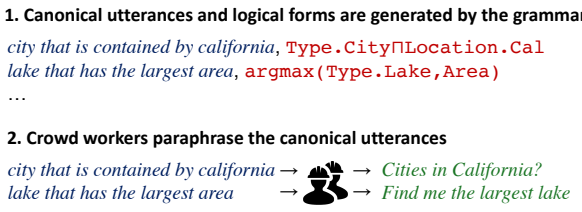

Figure 2: OVERNIGHT: Canonical utterances are generated by a grammar and paraphrased by crowd workers.

On two semantic parsing datasets, we show our procedure leads to annotation of 89% of the original training data. The accuracy of the resulting parser is 70.6 on average, well beyond the accuracy obtained through the original OVERNIGHT procedure at 51.3. This substantially closes the gap to a fully-supervised semantic parser, which obtains 84.9 accuracy. All our code and collected data is available at https://github.com/jonathanherzig/semantic-parsing-annotation.

2 The OVERNIGHT Framework

We now describe the OVERNIGHT framework for data collection, which we investigate and improve upon in this work. The starting point is a user who needs a semantic parser for some domain, but has *no data*. OVERNIGHT describes a procedure for generating training data from scratch, which comprises two steps (see Figure 2). First, a synchronous grammar is used to generate logical forms paired with *canonical utterances*, which are pseudo-language utterances that are understandable to people, but do not sound natural. Second, crowd workers paraphrase these canonical utterances into natural language utterances. This results in a training set of utterances paired with logical forms that is used to train the semantic parser. We now briefly elaborate on these two steps.

Grammar The grammar in OVERNIGHT generates logical forms paired with canonical utterances, which are understandable to crowd workers (e.g., *"number of state that borders california"*). The grammar has two parts: the *domain-*

general part contains domain-independent rules that cover logical operators (e.g., comparatives, superlatives, negation etc.). In addition, a *seed lexicon* specifies a canonical phrase (*"publication year"*) for each knowledge-base (KB) constant (`PublicationYear`), in each particular domain.

While there are many possible ways to sample data from the grammar, in OVERNIGHT logical forms and canonical utterances are exhaustively generated up to a certain maximal depth, hereafter denoted D. This follows the assumption that the semantic parser, trained from this data, should generalize to logical forms that correspond to deeper trees (we re-examine this assumption in Section 3). In addition, a typing system is used during generation, thus, semantically vacuous logical forms are not generated (e.g., `PublicationYear.Parsing`), which substantially reduces the number of generated examples.

Crowdsourcing After the above generation procedure terminates, crowd workers paraphrase each canonical utterance into a natural language utterance (e.g., the canonical utterance *"paper that has the largest publication year"* can be paraphrased to *"what is the most recent paper?"*). Finally, the framework yields a training dataset $\mathcal{D}_{\text{on}} = \{(x_i, z_i)\}_{i=1}^{N_{\text{on}}}$ consisting of pairs of natural language utterances and logical forms, which can be used to train a semantic parser.

3 Mismatch Analysis

In supervised semantic parsing, we assume access to training data of the form $\mathcal{D}_{\text{nat}} = \{(x_i, z_i)\}_{i=1}^{N_{\text{nat}}}$ sampled from the true target distribution $p_{\text{nat}}(x, z)$. Conversely, in the OVERNIGHT framework, we train from $\mathcal{D}_{\text{on}}$, which is sampled from a different distribution $p_{\text{on}}(x, z)$. Training on data sampled from $p_{\text{on}}(x, z)$ and testing on data sampled from $p_{\text{nat}}(x, z)$ leads to a substantial decrease in performance (compared to training on data sampled from $p_{\text{nat}}(x, z)$). In this section, we will analyze and quantify the causes for this degradation in performance.

By writing $p_{\text{nat}}(x, z) = p_{\text{nat}}(z)p_{\text{nat}}(x \mid z)$ and $p_{\text{on}}(x, z) = p_{\text{on}}(z)p_{\text{on}}(x \mid z)$ (mirroring the data generation procedure of OVERNIGHT), we can decouple the distribution mismatch into two terms: The first is the *logical form mismatch*, i.e., the difference between the natural distribution of logical forms $p_{\text{nat}}(z)$ and the distribution $p_{\text{on}}(z)$ of logical forms induced by OVERNIGHT. The second is the *language mismatch*, i.e., the difference between the conditional distribution of natural language $p_{\text{nat}}(x \mid z)$ and the conditional distribution $p_{\text{on}}(x \mid z)$ of natural language when performing crowdsourcing with the OVERNIGHT procedure. We will now investigate these two types of mismatch and their interaction with neural semantic parsers in the context of two popular semantic parsing datasets, GEOQUERY (Zelle and Mooney, 1996) and SCHOLAR (Iyer et al., 2017), which focus on the domains of geography and publications, respectively. For this analysis, we replicated the OVERNIGHT procedure and generated a dataset $\mathcal{D}_{\text{on}}$ for these two domains (details in Section 5).

3.1 Logical Form Mismatch

The first source of mismatch is that the natural distribution of logical forms $p_{\text{nat}}(z)$ can be quite different from the distribution $p_{\text{on}}(z)$ induced by the ad-hoc procedure for generating logical forms in OVERNIGHT.

Logical Operators Frequency A simple way to quantify the logical form mismatch, is to look whether the proportion of different logical operators, such as superlatives (e.g., `argmax`) and comparatives (e.g., `>`), substantially differs between $\mathcal{D}_{\text{on}}$ and $\mathcal{D}_{\text{nat}}$. Table 1 examines this, where hereafter we use the original training and development sets of GEOQUERY and SCHOLAR as $\mathcal{D}_{\text{nat}}$. The table shows that the frequency of logical operators is different between the two training sets $\mathcal{D}_{\text{nat}}$ and $\mathcal{D}_{\text{on}}$. For example, in $\mathcal{D}_{\text{nat}}$ of GEOQUERY, only 1% of the examples involve negation, compared to 55% of the examples in $\mathcal{D}_{\text{on}}$. Such differences may present generalization difficulties for a model trained from $\mathcal{D}_{\text{on}}$, as the real distribution we care about is $\mathcal{D}_{\text{nat}}$.

Coverage Wang et al. (2015) proposed to exhaustively generate all logical forms corresponding to a derivation tree of maximal depth D, assuming that the model will generalize to logical forms that require deeper trees. However, recent work from Finegan-Dollak et al. (2018) showed this might not be the case. In their work, Finegan-Dollak et al. (2018) consider logical form *templates*, i.e., logical forms where the KB constants are abstracted to their semantic type, and split the data such that templates in the test set are disjoint from templates in the training set. They show that neural semantic parsers struggle to generalize in this setup. Thus, *covering* the logical form

	5	4,480	76.52
	4	166	51.68

Table 2: Logical form coverage of $\mathcal{D}_{\text{nat}}$ by $\mathcal{D}_{\text{on}}$, after converting logical forms to their templates, for different values of D.

templates that appear in $\mathcal{D}_{\text{nat}}$ is important in the OVERNIGHT procedure.

Table 2 shows the number of examples generated by OVERNIGHT for different values of D, along with the proportion of examples in $\mathcal{D}_{\text{nat}}$ whose logical form template is covered by $\mathcal{D}_{\text{on}}$. Because OVERNIGHT requires paraphrasing each generated example, a reasonable value for D is 5. We observe that in this case only 63.73% of the examples in SCHOLAR are covered, as well as 76.52% of the examples in GEOQUERY.

To verify whether coverage is indeed important in our setup, we performed the following experiment. We trained a semantic parser (detailed in Section 5) on $\mathcal{D}_{\text{on}}$ for GEOQUERY and SCHOLAR (with D$=5$), and evaluated its performance on the training set of $\mathcal{D}_{\text{nat}}$ (which serves as a development set in this context). Then, we calculated the accuracy of the model with respect to examples for which their template appears in $\mathcal{D}_{\text{on}}$ (acc_{cov}), and for those their template does not appear (acc_{disj}). Table 3 shows that acc_{disj} is substantially lower

Dataset	acc_{cov}	acc_{disj}
GEOQUERY	78.73	10.71
SCHOLAR	65.58	5.24

Table 3: Denotation accuracy for the set of examples in $\mathcal{D}_{\text{nat}}$ covered by $\mathcal{D}_{\text{on}}$ (acc_{cov}), and for the set of uncovered examples (acc_{disj}).

than acc_{cov} for both datasets. This shows the importance of generating logical form templates that are likely to appear in the target distribution. Thus, our finding reinforces the conclusions in (Finegan-Dollak et al., 2018), and shows that while neural semantic parsers obtain good performance on existing benchmarks, their generalization to new compositional structures is limited.

Unlikely Logical Forms In OVERNIGHT, logical forms that are unlikely to appear in a natural interaction could be generated. For instance, the canonical utterance *"total publication year of paper whose keyphrase is semantic parsing"*, which refers to the sum of publication years of all semantic parsing papers. Although such logical forms are valid with respect to type matching, users are unlikely to produce them, and they are hard to prune automatically. To estimate the logical form mismatch caused by unlikely logical forms, we manually inspected 100 random examples from $\mathcal{D}_{\text{on}}$ with D$=5$ for GEOQUERY, and found that 31% of the examples are unlikely. While these examples are not necessarily harmful for a model, they are difficult to paraphrase, and may introduce noisy paraphrases that hurt performance.

Example 1
c: *"river that traverses california and that has the largest length"*
x_{on}: *"What river that traverses California has the largest length?"*
x_{nat}: *"What is the longest river in California?"*

Example 2
c: *"paper whose keyphrase is deep learning and that has the largest publication year"*
x_{on}: *"Name the paper with a deep learning keyphrase that has the most recent publication year."*
x_{nat}: *"Most recent deep learning papers."*

Figure 3: Examples for canonical utterances (c) generated by the grammar, their paraphrase by crowd workers (x_{on}), and their natural utterance in $\mathcal{D}_{\text{nat}}$ (x_{nat}). While the paraphrases are correct, they are biased towards the language style in c.

3.2 Language mismatch

The second mismatch in OVERNIGHT, demonstrated in Figure 3, is between the language used when naturally interacting with a conversational interface, and the language crowd workers use when elicited to generate paraphrases conditioned on a canonical utterance.

To directly measure the language mismatch, we performed the following experiment. We generated a dataset $\mathcal{D}_{\text{lang}}$ by taking the examples from $\mathcal{D}_{\text{nat}}$ and paraphrasing their logical forms using the OVERNIGHT procedure. This ensures that $p_{\text{lang}}(z) = p_{\text{nat}}(z)$, and thus the only difference between $\mathcal{D}_{\text{nat}}$ and $\mathcal{D}_{\text{lang}}$ is due to *language mismatch*. Then we measured the difference in performance when training on these two datasets.

In more detail, for every example in $\mathcal{D}_{\text{nat}}$, we extracted the corresponding canonical utterance template (since the examples are covered by the OVERNIGHT grammar), denoted by $\mathcal{C}_{\text{nat}}$. This list of canonical utterances can be viewed as an oracle output of the OVERNIGHT grammar generation procedure, since they do not exhibit any logical form mismatch. Next, 12 NLP graduate students paraphrased the examples in $\mathcal{C}_{\text{nat}}$. The students were presented with guidelines and examples for creating paraphrases, similar to the original guidelines in Wang et al. (2015). Moreover, we explicitly asked to paraphrase the canonical utterances such that the output is significantly different from the input (while preserving the meaning). After the paraphrase process was completed, we manually fixed typos in all generated paraphrases. Thus, our paraphrasing procedure yields high quality paraphrases and is an upper bound to what can be achieved by crowd workers.

Model	GEOQUERY	SCHOLAR
SUPERVISED+ELMO	86.3	83.4
OVERNIGHT-ORACLE-LF+ELMO	77.7	73.5
SUPERVISED+GLOVE	84.9	78.2
OVERNIGHT-ORACLE-LF+GLOVE	71.6	67.2

Table 4: Denotation accuracy on the test set, comparing a semantic parser trained on $\mathcal{D}_{\text{nat}}$ (SUPERVISED) and parser trained on $\mathcal{D}_{\text{lang}}$ (OVERNIGHT-ORACLE-LF).

We trained a neural semantic parser on both $\mathcal{D}_{\text{nat}}$ (named SUPERVISED) and $\mathcal{D}_{\text{lang}}$ (named OVERNIGHT-ORACLE-LF) using the original train/development split. Results in Table 4 show that for each domain, a decrease of approximately 9 points in accuracy occurs only due to the language mismatch, even with high-quality workers. This gap is likely to grow when workers are not experienced in paraphrasing, or are unfamiliar with the domain they generate paraphrases for.

We additionally observe that when we use GloVe embeddings (Pennington et al., 2014) instead of contextual ELMo embeddings (Peters et al., 2018), the gap is even higher. This shows that better representations reduce the language gap, though it is still substantial.

4 Grammar-driven Annotation

To overcome the logical form and language mismatches discussed, we propose in this section a new data generation procedure that does not suffer from these shortcomings. Our procedure, named GRANNO, relies on two assumptions. First, unlike OVERNIGHT, we assume access to unlabeled utterances $\mathcal{X}_{\text{ul}} = \{x_i\}_{i=1}^{N_{\text{ul}}}$. These can typically be found in query logs, or generated by users experimenting with a prototype. Second, we assume a scoring function $s_0(x, c)$, which provides a reasonable initial similarity score between a natural language utterance x and a canonical utterance c.

The goal of our procedure is to iteratively label $\mathcal{X}_{\text{ul}}$ with crowd workers, aided by the OVERNIGHT grammar. If we manage to label most of the dataset $\mathcal{X}_{\text{ul}}$, which is sampled from the true target distribution, we will end up with a labeled dataset $\mathcal{D}_{\text{ga}}$ that has very little distribution mismatch.

Figure 1 illustrates the procedure. First, we generate all canonical utterances $\mathcal{C}_{\text{on}}$ up to a depth D from the OVERNIGHT grammar. Because we

Algorithm 1 GRANNO

Input: unlabeled utterances $\mathcal{X}_{\text{ul}}$, grammar G
Output: $\mathcal{D}_{\text{ga}}$ - training data for a semantic parser

generate $\mathcal{C}_{\text{on}}$ from G
$\mathcal{D}_{\text{ga}} \leftarrow \emptyset$, $s_0(\cdot) \leftarrow -WMD(\cdot)$, $t \leftarrow 0$
converge $\leftarrow False$, $\mathcal{S}_{\text{pos}} \leftarrow \emptyset$, $\mathcal{S}_{\text{neg}} \leftarrow \emptyset$
while not *converge* **do**
  for x **in** $\mathcal{X}_{\text{ul}}$ **do**
    calculate $\mathcal{C}_x^K$ using $s_t(\cdot)$ ▷ top K candidates
    crowd workers annotate c_x given x and $\mathcal{C}_x^K$
    if $c_x \neq N/A$ **then**
      $\mathcal{D}_{\text{ga}} \leftarrow \mathcal{D}_{\text{ga}} \cup (x, c_x)$
      $\mathcal{X}_{\text{ul}} \leftarrow \mathcal{X}_{\text{ul}} \setminus x$
      $\mathcal{S}_{\text{pos}} \leftarrow \mathcal{S}_{\text{pos}} \cup (x, c_x)$ ▷ positive examples
      for c **in** $\mathcal{C}_x^M \setminus \{c_x\}$ **do**
        $\mathcal{S}_{\text{neg}} \leftarrow \mathcal{S}_{\text{neg}} \cup (x, c)$ ▷ negative examples
  converge $\leftarrow$ check for convergence, $t \leftarrow t + 1$
  train $s_t(\cdot)$ over $\mathcal{S}_{\text{pos}}$ and $\mathcal{S}_{\text{neg}}$
return $\mathcal{D}_{\text{ga}}$

do not paraphrase all the canonical utterances, we can generate to a higher depth D compared to OVERNIGHT and cover more of the examples in $\mathcal{X}_{\text{ul}}$ (see Table 2). Then, we iteratively label the utterances in $\mathcal{X}_{\text{ul}}$. At each iteration t, we use a paraphrase detection model $s_t(x, c)$ to present promising canonical utterances to crowd workers for each unlabeled utterance x, who label the dataset. Importantly, crowd workers in our setup do not *generate paraphrases*, they only *detect* them. We now describe GRANNO in more detail.

Iterative Annotation At each iteration t, we rely on a trained scoring function $s_t(x, c)$ that estimates the similarity between an unlabeled utterance $x \in \mathcal{X}_{\text{ul}}$ and a generated canonical utterance $c \in \mathcal{C}_{\text{on}}$. We follow the procedure described in Algorithm 1. For an utterance $x \in \mathcal{X}_{\text{ul}}$, we calculate the top-$K$ ($= 5$) most similar canonical utterances in $\mathcal{C}_{\text{on}}$, denoted by $\mathcal{C}_x^K$. We then present x along with its candidate paraphrases $\mathcal{C}_x^K$ to a worker, and ask her to choose the correct candidate paraphrase. If a paraphrase does not appear in the top-K candidates, the worker selects no candidates.

These annotations are then used to train $s_{t+1}(x, c)$, which will be used in the next iteration. For each $x \in \mathcal{X}_{\text{ul}}$ for which a worker detected a paraphrase c_x, we label (x, c_x) as a positive example. We use the top-M ($= 100$) other most similar canonical utterances $\mathcal{C}_x^M \setminus \{c_x\}$ (according to $s_t(\cdot)$) as negative examples. We train s_{t+1} from all the examples generated in iterations $0 \cdots t$. Thus, in every iteration more and more examples are labeled, and a better scoring function is trained. We stop when we meet convergence, i.e., when no new unlabeled utterances are labeled. We then output the dataset $\mathcal{D}_{\text{ga}}$ that contains every utterance x from $\mathcal{X}_{\text{ul}}$ that is now labeled, paired with the logical form that corresponds to the detected canonical utterance paraphrase c_x.

We note that an alternative modeling choice was to use the semantic parser itself as the scorer for candidate canonical utterances. However, decoupling the parser and the scorer is beneficial, as the discriminative scoring function $s_t(\cdot)$ benefits from negative examples (incorrect paraphrases), unlike the generative semantic parser.

The success of our procedure depends on a good initial scoring function $s_0(x, c)$, to be used in the first iteration, that we next describe.

Initial Scoring Function We implement $s_0(x, c)$ in an unsupervised manner, as no labeled examples are available in the first iteration. Formally, we take $s_0(x, c) = -WMD(x, c)$, where $WMD(x, c)$ is the Word Mover's Distance (WMD) (Kusner et al., 2015) between x and c, which is the minimum amount of distance that the embedded words of one utterance need to travel to reach those of the other utterance. We found WMD to perform better than cosine similarity over averaged pre-trained embeddings, as WMD performs word-level alignment, and shared words (such as entities) encourage small distance.

Implementation details We take the unlabeled utterance set to be all utterances in $\mathcal{D}_{\text{nat}}$, when ignoring logical forms: $\mathcal{X}_{\text{ul}} = \{x \mid (x, \cdot) \in \mathcal{D}_{\text{nat}}\}$. We generate all canonical utterances up to depth D= 6, resulting in roughly 350K canonical utterances in SCHOLAR and GEOQUERY, and coverage of 90% of the examples in $\mathcal{X}_{\text{ul}}$ (Table 2).

Our binary classifier $s_t(\cdot)$ is trained from paraphrases detected by workers. We utilize the ESIM neural architecture originally used for natural language inference (Chen et al., 2017). We also employ ELMo contextualized embeddings (Peters et al., 2018), and minimize the binary cross-entropy loss for each example.

5 Experiments

5.1 Experimental Setup

Datasets We experiment with two popular semantic parsing datasets: GEOQUERY (Zettlemoyer and Collins, 2005) and SCHOLAR (Iyer et al., 2017), that contain questions about US geography and academic publications, respectively.

Because we utilize the original grammar from Wang et al. (2015) that generates logical forms in lambda-DCS (Liang, 2013), we first manually annotated GEOQUERY and SCHOLAR with lambda-DCS logical forms that are translations of the original logical forms (Prolog for GEOQUERY and SQL for SCHOLAR). We only convert examples that are covered by the OVERNIGHT grammar, which results in annotating 99.3% of the examples in GEOQUERY (874 in total), and 96.7% of the examples in SCHOLAR (790 in total).

Grammar Generation To generate the training data $\mathcal{D}_{\text{on}}$ for our OVERNIGHT baseline and GRANNO, we first exhaustively generated logical form and canonical utterance pairs from the grammar up to depth $\text{D} = 5$ for OVERNIGHT and $\text{D} = 6$ for GRANNO, using type matching rules such that vacuous logical forms are not generated. Then, we further pruned unlikely logical forms that can be automatically detected (e.g., contradictions such as *"state that borders california and that not borders california"*). We additionally pruned equivalent examples: if we generated a logical form with the structure `A ⊓ B`, we pruned `B ⊓ A`.

Crowd Sourcing We gathered annotations from crowd workers by running a qualification task where we manually verified workers (annotators with at least 85% success rate were qualified). Then, qualified workers performed the tasks for the remaining examples, and for those where unqualified workers failed.

For OVERNIGHT, we gathered a single paraphrase per canonical utterance in $\mathcal{D}_{\text{on}}$ with a cost of 0.06$. For GRANNO, we detected a single paraphrase for each unlabeled utterance in $\mathcal{X}_{\text{ul}}$ that was not annotated in previous iterations, with a cost of 0.05$.

In total, we gathered 7,140 paraphrases for OVERNIGHT with a total cost of 515$, and 2,594 detections for GRANNO with a total cost of 155$. Thus, GRANNO had lower cost per task, and given the results below, benefits more from fewer tasks.

Neural Semantic Parser We use a standard semantic parser provided by AllenNLP (Gardner et al., 2017), based on a sequence-to-sequence model (Sutskever et al., 2014). The encoder is a BiLSTM that receives ELMo pre-trained embeddings (Peters et al., 2018) as input. The attention-based decoder (Bahdanau et al., 2015) is an LSTM that also employs copying (Jia and Liang, 2016).

Model	GEOQUERY	SCHOLAR
SUPERVISED	86.3	83.4
GRANNO	72.0	69.2
OVERNIGHT	61.9	40.8
OVERNIGHT-ORACLE-LF	77.7	73.5
GRANNO-ORCALE	79.1	72.5

Table 5: Denotation accuracy on the test set.

Training Scheme For both the semantic parser and the paraphrase detection model $s_t(\cdot)$ we take 10% of the training data for validation (or the official development set, if it exists). When training both models, we abstract examples to their templates, as in Dong and Lapata (2016) and Finegan-Dollak et al. (2018) inter alia. For our semantic parser, we tune the learning rate and dropout over the development set, and for $s_t(\cdot)$ we use the same hyper-parameter values as in Chen et al. (2017). We use early-stopping, and choose the model with the highest denotation accuracy and F_1 measure for the semantic parser and $s_t(\cdot)$, respectively.

5.2 Results

Main Results Table 5 shows the denotation accuracy for all experiments, when training from: $\mathcal{D}_{\text{nat}}$ (SUPERVISED); $\mathcal{D}_{\text{on}}$ (OVERNIGHT); $\mathcal{D}_{\text{lang}}$, as described in Section 3.2 (OVERNIGHT-ORACLE-LF); $\mathcal{D}_{\text{ga}}$, described in Section 4 (GRANNO); and $\mathcal{D}_{\text{ga}}$ where we simulate a perfect worker that always detects the gold paraphrase if it appears in the top-K candidates (GRANNO-ORCALE).

Results show that OVERNIGHT achieves substantially lower accuracy compared to training with examples from the target distribution (SUPERVISED), inline with the analyses presented in Section 3. For instance, SCHOLAR accuracy more than halves (40.8 for OVERNIGHT in comparison to 83.4 for SUPERVISED). Conversely, our suggested method GRANNO that directly annotates unlabeled utterances achieves much higher accuracy than OVERNIGHT. Utilizing crowd workers for detection leads to 70.6 accuracy on average, and to 75.8 when simulating perfect crowd workers (GRANNO-ORACLE).

All models performed well on the development set that was sampled from the same distribution as the training set ($> 80\%$ accuracy), and thus differences in performance are due to generalization to the true distribution. Moreover, the accuracy of the paraphrase detection model $s_t(\cdot)$ was very high ($> 95\%$ F_1 measure) on the develop-

Case	%	Natural language utterance	Gold canonical utterance	Detected canonical utterance
us	.48	*"what is the highest point in california?"*	*"place that is high point of california"*	*"high point of california"*
os	.13	*"how many citizens in california?"*	*"population of california"*	*"total population of california"*
w	.08	*"which state has the greatest density?"*	*"state that has the largest density"*	*"total density of state"*
pw	.31	*"what is the lowest elevation in california?"*	*"place that is low point of california"*	*"elevation of low point of california"*

Table 6: Examples of false positive detections by crowd workers for different cases: *under specification* (*us*), *over specification* (*os*), *wrong* (*w*) and *partially wrong* (*pw*).

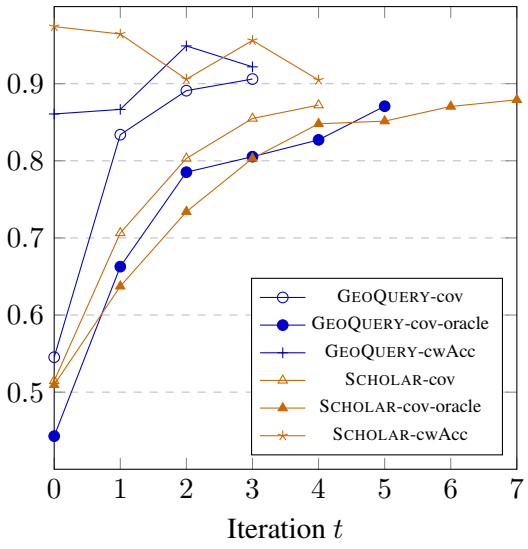

Figure 4: Analysis of GRANNO across iterations.

ment set, showing that detection is easier to model compared to generation.

We note in passing that we also implemented a baseline that uses unlabeled examples in conjunction with OVERNIGHT through self-training (Konstas et al., 2017). We trained a model with OVERNIGHT and iteratively labeled unlabeled utterances for which model confidence was high. However, we were unable to obtain good performance with this method.

GRANNO Analysis GRANNO iteratively annotates unlabeled utterances utilizing crowd workers. Figure 4 reports several metrics for GRANNO for each iteration: *cov* details the fraction of annotated utterances in $\mathcal{X}_{\text{ul}}$, where *cov-oracle* corresponds to the annotation coverage by GRANNO-ORACLE. In addition, cwAcc is the crowd workers' detection accuracy per iteration, with respect to the gold canonical utterances. The figure shows that in both datasets, GRANNO converges in a few iterations, and that workers' detection accuracy is high across all iterations ($> 85\%$).

An interesting phenomenon is that crowd workers (GRANNO) cover the unlabeled utterances faster than oracle workers (GRANNO-ORACLE). To analyze this, we inspect false positive, i.e., cases where the gold canonical utterance does *not* appear in the top-K candidates of $s_t(\cdot)$, but the crowd worker detects some candidate as the paraphrase. Table 6 presents examples for these cases and their fraction within all false positives for iteration $t = 0$, where workers cover unlabeled utterances faster than the oracle. We find that in 61% of the cases, the choice of the workers was equivalent to the gold candidate. This is due to *under specification*, when the gold paraphrase is more specific than the detected one, or *over specification*, which is the opposite case. The other 39% are indeed errors, which we split into *wrong* detections, and *partially wrong* detections, where the detected paraphrase is different than the gold one, but is reasonable choice the phrasing of the question. E.g., for *"what is the lowest elevation in California"* it is unclear whether the answer should be a location or the elevation. This shows that many false positives are in fact correct.

Limitations GRANNO relies on the unsupervised function $s_0(\cdot)$ to bootstrap the annotation procedure. In both datasets, $s_0(\cdot)$ managed to rank gold paraphrases within its top-5 candidates for roughly half of the unlabeled utterances in $\mathcal{X}_{\text{ul}}$, but this is not guaranteed.

During each iteration in GRANNO, the function $s_t(\cdot)$ is applied on all pairs of an unlabeled utterance and candidate canonical utterances, thus $s_t(\cdot)$ is applied $O(|\mathcal{X}_{\text{ul}}| \cdot |\mathcal{D}_{\text{on}}|)$ times. Empirically, we find that computation time is manageable when limiting the application of $s_t(\cdot)$ to candidates that share the same entities as the unlabeled utterance. However, this might not suffice for KBs with large schemas. In such cases, an information retrieval module could retrieve a small number of candidates, similar to Yang et al. (2019).

6 Related Work

Several works used a human in the loop for training a semantic parser. Iyer et al. (2017) incorporated user feedback to detect wrong parses and

sent them to expert annotation. Lawrence and Riezler (2018) and Berant et al. (2019) improved a supervised parser by showing its predictions to users and training from this feedback. Gupta et al. (2018) built a hierarchical annotation scheme for annotating utterances with multiple intents. Labutov et al. (2019) trained a semantic parser through interactive dialogues. Comparing to these works, our proposed method requires no supervised data or expert annotators, and is suitable for rapid development of parsers in multiple domains.

In semi-supervised learning, Konstas et al. (2017) used self-training to improve an existing AMR parser. Others used a variational autoencoder by modeling unlabeled utterances (Kociský et al., 2016) or logical forms (Yin et al., 2018) as latent variables. However, empirical gains from the unlabeled data were relatively small compared to annotating more examples.

Finally, several papers extended the OVERNIGHT procedure. Ravichander et al. (2017) replaced phrases in the lexicon with images to elicit more natural language from workers. (Cheng et al., 2018) generated more complex compositional structures by splitting the canonical utterances into multiple steps. Such work relies on workers to *generate* paraphrases, while we propose to simply *detect* them.

7 Conclusion

We address the challenge of generating data for training semantic parsers from scratch in multiple domains. We thoroughly analyze the OVERNIGHT procedure, and shed light on the factors that lead to poor generalization, namely logical form mismatch and language mismatch. We then propose GRANNO, a method that directly annotates unlabeled utterances with their logical form, by letting crowd workers detect automatically-generated canonical utterances. We demonstrate our method's success on two popular datasets, and find it substantially improves generalization to real data, compared to OVERNIGHT.

Abstract

Distantly-supervised relation extraction has proven to be effective to find relational facts from texts. However, the existing approaches treat labels as independent and meaningless one-hot vectors, which cause a loss of potential label information for selecting valid instances. In this paper, we propose a novel multi-layer attention-based model to improve relation extraction with joint label embedding. The model makes full use of both structural information from Knowledge Graphs and textual information from entity descriptions to learn label embeddings through gating integration, while avoiding the imposed noise with an *attention mechanism*. Then the learned label embeddings are used as *another attention* over the instances (whose embeddings are also enhanced with the entity descriptions) for improving relation extraction. Extensive experiments demonstrate that our model significantly outperforms state-of-the-art methods.

1 Introduction

Knowledge Graphs (KGs) such as Freebase and DBpedia have shown their strong power in many natural language processing tasks including question answering (Zhang et al., 2018) and dialog generation (Zhou et al., 2018). However, these KGs are far from complete. Relation extraction, which aims to fill this gap by extracting semantic relationships between entity pairs from plain texts, is thus of great importance.

Most existing supervised relation extraction methods require a large number of labeled training data, which is time-consuming and laborious. Distant supervision has been proposed by (Mintz et al., 2009) to address the challenge. It assumes that if two entities have a relation in KGs, then all sentences mentioning the two entities express this relation. Thus, distant supervision can automatically generate a large number of labeled data without labor cost. Simultaneously, it often suffers from wrong labeling problem (Surdeanu et al., 2012; Zeng et al., 2015).

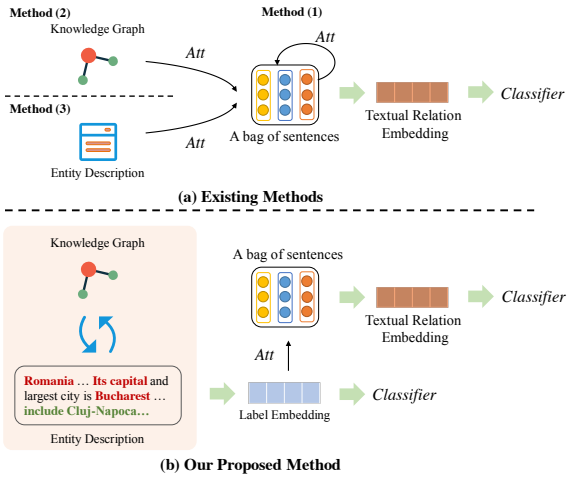

Figure 1: Illustration of comparison of existing methods and our proposed method.

Recently, significant progress has been made in applying deep neural networks for relation extraction under distant supervision (Zeng et al., 2014, 2015; Feng et al., 2017). To alleviate the wrong labeling problem in distant supervision, attention models have been proposed to select valid instances (Ji et al., 2017). As shown in Figure 1 (a), they can be divided into three categories: (1) typical attention models without external information (Lin et al., 2016; Du et al., 2018), (2) attention models using KGs (Han et al., 2018a), (3) attention models using side information such as entity descriptions (Vashishth et al., 2018; Ji et al., 2017). However, they all have flaws in selecting valid instances due to failing to exploit potential label information. They treat labels as independent and meaningless one-hot vectors, which cause a loss

of potential label information. Label embeddings aim to learn representations of labels based on related information. The label embeddings can be used to attend over the bag of instances for relation classification. Additionally, they don't take advantage of both structural information from KGs and textual information from entity descriptions and ignore the imposed noise.

In this paper, we propose a novel multi-layer attention-based model RELE (**R**elation **E**xtraction with Joint **L**abel **E**mbedding) to improve relation extraction. Our model integrates both structural information from KGs and textual information from entity descriptions with a gating mechanism to learn label embeddings, while avoiding the imposed noise (highlighted in green) in entity descriptions with an *attention mechanism*. Then the label embeddings are used as *another antention* over the bag of instances to select valid ones for improving relation extraction. Note that we also enhance the instance embedding with entity descriptions. The contributions of this paper can be summarized as follows:

- We propose a novel multi-layer attention-based model RELE to improve distantly supervised relation extraction with joint label embedding. The label embeddings can be used to attend over the bag of instances for relation classification.
- RELE makes full use of both structural information from KGs and textual information of entity descriptions to learn label embeddings through gating integration, while avoiding the imposed noise with attention.
- Extensive experiments on two benchmark datasets have demonstrated that our model significantly outperforms state-of-the-art methods on distantly-supervised relation extraction.

2 Related Work

Our work is mainly related to distant supervision, neural relation extraction and label embedding.

Distant Supervision. Most supervised relation extraction methods require large-scale labeled training data which are expensive. Distant Supervision proposed by (Mintz et al., 2009) is an effective method to automatically label large-scale training data under the assumption that if two entities have a relation in a KG, then all sentences mentioning those entities express this relation. The assumption does not work in all cases and causes the mislabeling problem.

MultiR (Hoffmann et al., 2011) and MIMLRE (Surdeanu et al., 2012) introduce multi-instance learning where the instances mentioning the same entity pair are processed at a bag level. However, these methods rely heavily on handcrafted features.

Neural Relation Extraction. With the development of deep learning, neural networks have proven to be efficient to automatically extract valid features from sentences in recent years. Some researches (Zeng et al., 2014, 2015) adopt Convolution Neural Networks (CNN) to learn sentence representations automatically. To alleviate the mislabeling problem, attention mechanisms (Lin et al., 2016; Du et al., 2018) have been employed. Apart from that, some studies apply other relevant information to improve relation extraction (Zeng et al., 2017; Vashishth et al., 2018; Han et al., 2018b,a; Ji et al., 2017). For example, RESIDE (Vashishth et al., 2018) utilizes the available side information from knowledge bases, including entity types and relation alias information. Han et al. (2018a) proposed a joint representation learning framework of KGs and instances, which leverages the KG embeddings to select valid instances. APCNN+D (Ji et al., 2017) exploits the entity descriptions as background knowledge for selection of valid instances, and ignores the imposed noise.

Different from the existing works, we propose a novel multi-layer attention-based model RELE with joint label embedding. Our model makes full use of both structural information from KGs and textual information from entity descriptions to learn label embeddings through gating integration, while avoiding the imposed noise with an *attention mechanism*. The label embeddings are then used as *another attention* over the bag of instances to select valid instances for relation classification.

Label Embedding. Label embedding has been widely exploited in computer vision including image classification (Akata et al., 2016) and text recognition (Rodriguez-Serrano et al., 2015). Recently, LEAM (Wang et al., 2018) successfully applies label embedding in text classification, which obtains each label's embedding by its corresponding text descriptions. In this work, we are the first to apply it for relation extraction. We propose

a novel multi-layer attention-based model to improve relation extraction with joint label embedding.

3 Preliminaries

In this section, we briefly introduce some notations and concepts used in this paper.

For convenience, we denote a KG as $G = \{(h, r, t)\}$, which contains considerable triplets (h, r, t) where h and t are respectively head entity and tail entity, and r denotes the relation. Their embeddings are denoted as $(\mathbf{h}, \mathbf{r}, \mathbf{t})$.

Formally, given a pair of entities (h, t) in a KG G and a bag of instances (sentences) $B = \{s_1, s_2, \cdots, s_m\}$, where each instance s_i contains (h, t), the task of *relation extraction* is to train a classifier based on B to predict the relation label y of (h, t) from a predefined relation set. If no relation exists, we simply assign NA to it.

To improve relation extraction, we make full use of both the KG G and entity descriptions $D = \{d_1, d_2, \cdots, d_n\}$ to learn label embeddings which can benefit selection of valid instances. For each entity e_i, we take the first paragraph of its corresponding Wikipedia page as its description text $d_i = \{w_1, w_2, \cdots, w_l\}$, where $w_i \in V$ denotes the description word, l is the length and V is the vocabulary.

4 Our Proposed Model

In this section, we will detail our proposed multi-layer attention-based model RELE for relation extraction with joint label embedding. Existing methods for relation extraction take labels as independent and meaningless one-hot vectors, which cause a loss of potential label information for selecting valid instances. Additionally, they don't take full advantage of both structural information from KGs and textual information from entity descriptions and ignore the imposed noisy information.

As shown in Figure 2, our model is based on a multi-layer attention, containing two parts: 1) label embedding (shown in the right) and 2) neural relation classification (shown in the left) . The former makes full use of structural information from KGs and textual information from entity descriptions to learn label embeddings through gating mechanism, while avoiding the imposed noise with an attention mechanism. The latter leverages the label embeddings as another attention over the

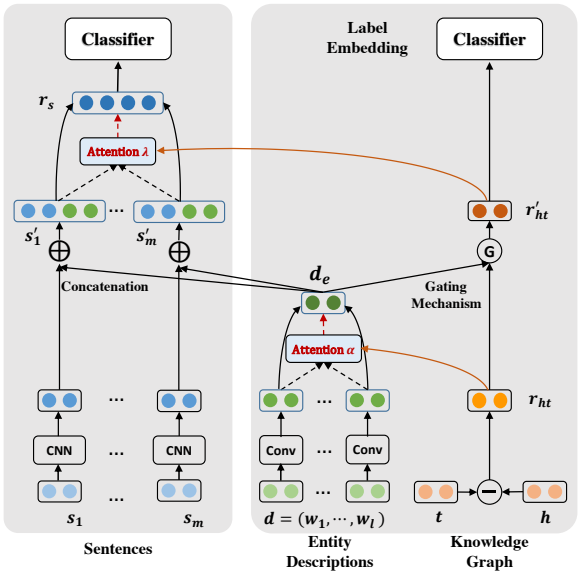

Figure 2: Illustration of our multi-layer attention based model RELE.

instances to select valid instances for improving neural relation extraction. Note that we also use the entity descriptions to enhance the representations of instances. We detail the two parts as follows.

4.1 Joint Label Embedding

Label information plays a vital role in selecting valid instances for improving relation extraction. We make full use of both structural information from KGs (Han et al., 2018a) and textual information from entity descriptions (Ji et al., 2017) to learn label embeddings via gating integration. Entity descriptions provide rich background knowledge for entities (Newman-Griffis et al., 2018) and are supposed to benefit the label embedding and relation extraction. Nevertheless, as shown in Figure 1, entity descriptions may also contain irrelevant and even misleading information. Therefore, we propose to use KG embeddings to attend over the entity descriptions, alleviating the imposed noise. Then a gating mechanism is used to integrate both the KGs and entity descriptions for learning label embeddings.

KG Embedding. We use TransE (Bordes et al., 2013) for KG embedding. Given a triplet (h, r, t), the model aims to learn low-dimensional representations vector for entities h, t and the relationship r into the same vector space, and regards a relationship r as a translation from the head entity h to tail entity t, assuming the embedding $\mathbf{t}$ should

be close to $\mathbf{h}+\mathbf{r}$ if (h, r, t) exists. The score function is defined as :

$$f(h, r, t) = -\|\mathbf{h}+\mathbf{r}-\mathbf{t}\|_2^2. \quad (1)$$

Note that since the true relations in test set are unknown, we simply represent the relation by:

$$\mathbf{r}_{ht} = \mathbf{t} - \mathbf{h}. \quad (2)$$

In this way, we can also get the relation embeddings given the entity pairs during testing.

Entity Description Embedding. Then we use the representations of relations $\mathbf{r}_{ht}$ as attention over the words of an entity description to reduce the weights of noisy words. Formally, for each entity e, we learn the representation of its description $d = (w_1, w_2, \cdots, w_l)$ as follows:

$$\mathbf{x}_i = \text{CNN}(\mathbf{w}_{i-\frac{c-1}{2}}, \cdots, \mathbf{w}_{i+\frac{c-1}{2}}), \quad (3)$$

$$\hat{\mathbf{x}}_i = \tanh(\mathbf{W}_x \cdot \mathbf{x}_i + \mathbf{b}_x), \quad (4)$$

$$\alpha_i = \frac{\exp(\hat{\mathbf{x}}_i \cdot \mathbf{r}_{ht})}{\sum_{i=1} \exp(\hat{\mathbf{x}}_i \cdot \mathbf{r}_{ht})}, \quad (5)$$

$$\mathbf{d}_e = \sum_{i=1}^{l} \alpha_i \mathbf{x}_i, \quad (6)$$

where CNN$(\cdot)$ denotes a convolution layer with window size c over the word sequence. $\mathbf{x}_i \in \mathbb{R}^{D_h}$ is the hidden representation of the word w_i. $\mathbf{W}_x$ is the weight matrix and $\mathbf{b}_x$ is the bias vector. α_i is the attention weight of the word w_i, which is computed based on the relation embedding $\mathbf{r}_{ht}$. Finally, the text description embedding $\mathbf{d}_e$ is computed by the weighted average of words.

Gating Integration. We apply a gating mechanism (Xu et al., 2016) to integrate the textual entity description embedding $\mathbf{d}_e$ and the structural information (entity embedding $\mathbf{e}$) from KGs:

$$\mathbf{e}' = \mathbf{g} \odot \mathbf{e} + (1-\mathbf{g}) \odot \mathbf{d}_e, \quad (7)$$

where $\mathbf{g} \in \mathbb{R}^{D_w}$ is a gating vector for integration, $\mathbf{e}' \in \mathbb{R}^{D_w}$ represents the final integrated entity embedding and $\odot$ represents Hadamard product. Consequently, we compute the final label embedding $\mathbf{l}$:

$$\mathbf{l} = \mathbf{t}' - \mathbf{h}'. \quad (8)$$

Label Classifier. Ideally, each label embedding is supposed to act as an "anchor" for each relation class. To achieve this goal, we consider to train the learned label embeddings $\mathbf{l}$ to be easily classified as the correct relation class. Therefore, we use softmax to get the predicted probabilities of the relation classes:

$$\text{P}(y|D, G) = \text{Softmax}(\mathbf{M}_k\mathbf{l} + \mathbf{b}_k), \quad (9)$$

where $\mathbf{M}_k$ is the transformation matrix, $\mathbf{b}_k$ is the bias.

4.2 Neural Relation Extraction

After obtaining the embeddings of labels and entity descriptions, we leverage them to advance the neural relation extraction. We first use the entity descriptions to enhance instance embeddings. Then we leverage the label embeddings to attend over the instances to select valid instances for relation classification.

Instance Embedding. We enrich the representation of an instance with the pair of entity descriptions. Firstly, for each word $w \in s = \{w_1, \cdots, w_n\}$, its embedding $\hat{\mathbf{w}}_i$ is initialized as follows:

$$\hat{\mathbf{w}}_i = \mathbf{w}_i \oplus \mathbf{p}_{i1} \oplus \mathbf{p}_{i2}, \quad (10)$$

where $\mathbf{w}_i$ is the pre-trained word vector of w_i, $\mathbf{p}_{i1}$ and $\mathbf{p}_{i2}$ are its position embeddings to incorporate relative distances to two target entities into two D_p-dimensional vectors respectively (Zeng et al., 2014). The symbol $\oplus$ represents concatenation operator.

Then, we choose CNN (Zeng et al., 2014) with window size c as our encoder to learn the instance embedding considering the text of the instance itself.

$$\mathbf{z}_i = \text{CNN}(\hat{\mathbf{w}}_{i-\frac{c-1}{2}}, \cdots, \hat{\mathbf{w}}_{i+\frac{c-1}{2}}), \quad (11)$$

$$[\mathbf{s}]_j = \max\{[\mathbf{z}_1]_j, \cdots, [\mathbf{z}_n]_j\}, \quad (12)$$

where $\mathbf{s} \in \mathbb{R}^{D_h}$ is the sentence (instance) embedding, $[\cdot]_j$ is the j-th value of a vector and function max denotes max-pooling.

Finally, we concatenate the original instance embedding $\mathbf{s}$ with the entity descriptions $(\mathbf{d}_h, \mathbf{d}_t)$, obtaining the new instance representation $\mathbf{s}'$. Formally,

$$\mathbf{s}' = \mathbf{s} \oplus \mathbf{d}_h \oplus \mathbf{d}_t. \quad (13)$$

Attention over Instances. To alleviate the wrong labeling problem of distant supervision, we leverage the label embedding $\mathbf{l}$ as attention over

instances to reduce the weights of noisy instances in the sentence bag $B = \{s_1, \cdots, s_m\}$. Then the representation of textual relation feature $\bar{\mathbf{s}}$ from the bag B can be calculated as weighted average of the instance embeddings $\mathbf{s}'_i$:

$$\hat{\mathbf{s}}_i = \tanh(\mathbf{W}_s \mathbf{s}'_i + \mathbf{b}_s), \tag{14}$$

$$\lambda_i = \frac{\exp(\mathbf{l} \cdot \hat{\mathbf{s}}_i)}{\sum_{j=1}^{m} \exp(\mathbf{l} \cdot \hat{\mathbf{s}}_i)}, \tag{15}$$

$$\bar{\mathbf{s}} = \sum_{i=1}^{m} \lambda_i \mathbf{s}'_i, \tag{16}$$

where $\mathbf{W}_s$ is the weight matrix and $\mathbf{b}_s$ is the bias vector. λ_i is the attention score of the instance s_i, computed based on the label embedding $\mathbf{l}$.

Relation Classifier. Finally, to compute the confidence of each relation class, we feed the representation of the textual relation $\bar{\mathbf{s}}$ into a softmax classifier after being processed by a linear transformation. Formally,

$$\mathrm{P}(y|B) = \mathrm{Softmax}(\mathbf{M}_s \bar{\mathbf{s}} + \mathbf{b}_s), \tag{17}$$

where $\mathbf{M}_s$ is the transformation matrix, and $\mathbf{b}_s$ is the bias.

4.3 Model Training

The objective function of our joint model RELE includes two parts, the loss of label classifier L_1 and the loss of relation classifier L_2.

Assuming that there are N bags in training set $\{B_1, B_2, \cdots, B_N\}$, and their corresponding labels $\{y_1, y_2, \cdots, y_N\}$, we exploit cross entropy for the loss function of label classifier L_1:

$$L_1 = -\sum_{i=1}^{N} \log \mathrm{P}(y_i|D, G), \tag{18}$$

The loss L_1 aims to train the label embedding to be classified to the correct relation class.

Similarly, for the loss of relation classifier L_2, we also exploit cross entropy and get:

$$L_2 = -\sum_{i=1}^{N} \log \mathrm{P}(y_i|B_i), \tag{19}$$

Finally, we aim to minimize the loss function L with L2-norm:

$$\min L = L_1 + L_2 + \eta \|\Theta\|^2, \tag{20}$$

where η is the regularization coefficient and Θ denotes the parameters in our model. Stochastic gradient descent (SGD) is used to optimize our model.

5 Experiments

5.1 Datasets

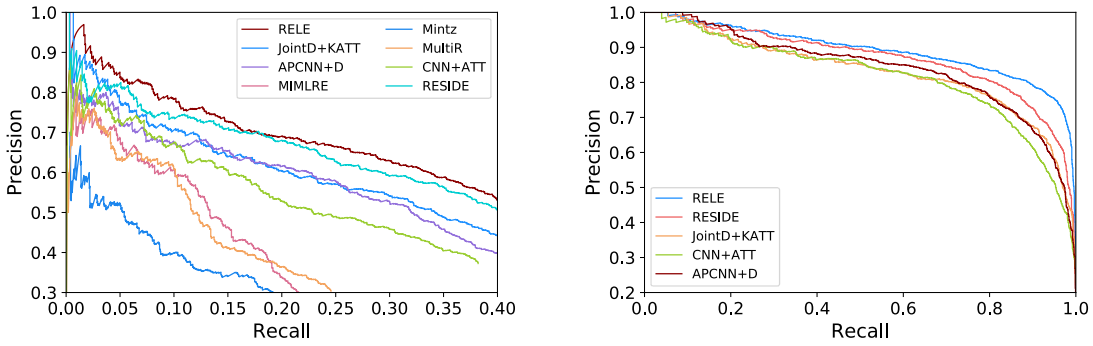
In our experiments, we evaluate our model over the NYT-FB60K dataset (Han et al., 2018a) and GIDS-FB8K dataset (Jat et al., 2018). In the following, we detail each dataset.

- NYT-FB60K. The dataset NYT-FB60K (Han et al., 2018a) includes three parts: knowledge graphs (FB60K extended from Riedel dataset (Riedel et al., 2010), containing 1,324 relations, 69,512 entities, and 335,350 facts), text corpus (whose sentences are from Riedel dataset, containing 570,088 sentences, 63,696 entities, and 56 relations) and entity descriptions (which are the first paragraphs of the entities' Wikipedia pages, containing around 80 words on average).

- GIDS-FB8K. We construct the dataset GIDS-FB8K based on GIDS dataset (Jat et al., 2018). It also contains three parts: knowledge graphs (FB8K extended from GIDS dataset, containing 208 relations, 8,917 entities, and 38,509 facts), text corpus (whose sentences are from GIDS dataset, containing 16,960 sentences, 14,261 entities, and 5 relations) and entity descriptions (which are the first paragraphs of the entities' Wikipedia pages, containing around 80 words on average).

5.2 Baselines

We compare our model with the state-of-the-art baselines:



- Mintz (Mintz et al., 2009). A multi-class logistic regression model under distant supervision.

- MultiR (Hoffmann et al., 2011). A probabilistic graphical model for multi-instance learning.

- MIMLRE (Surdeanu et al., 2012). A graphical model for multi-instance multi-label learning.

- CNN+ATT (Lin et al., 2016). A CNN model with instance-level attention.

- APCNN+D (Ji et al., 2017) A Piecewise CNN model with instance-level attention using entity descriptions. As no code available, we implemented it by ourselves.

(a) NYT-FB60K Dataset (b) GIDS-FB8K Dataset

Figure 3: Precision-recall curves for different methods. RELE achieves higher precision over the entire range of recall compared to all the baselines on both datasets.

Parameter	Value
Word/Entity/Relation Dimension D_w	50
Position Dimension D_p	5
Hidden Layer Dimension D_h	230
Kernel Size c	3
Learning Rate α	0.5
Regularization Coefficient η	0.0001
Dropout Probability p	0.5

Table 1: Parameter Settings.

- JointD+KATT (Han et al., 2018a). A joint model for knowledge graph embedding and relation extraction.

- Reside (Vashishth et al., 2018). A neural network based model which makes use of relevant side information and employs Graph Convolution Networks for encoding syntactic information of instances.

5.3 Evaluation Metrics

Following previous studies (Lin et al., 2016), our model is evaluated held-out, which compares the relations discovered from test corpus with those in Freebase. We report the Precision-Recall curve and top-N precision (P@N) metric for NYT-FB60K dataset.

For GIDS-FB8K dataset, we report the Precision-Recall curve, F1 score and Mean Average Precision (MAP). We do not use the top-N precision (P@N) metric for the dataset which is small containing only 5 relation classes.

5.4 Parameter Settings

For all the models, we use the pre-trained word embeddings with word2vec tool* on NYT corpus for initialization. The embeddings of entities mentioned in datasets are pre-trained through TransE model. We select the learning rate α among $\{0.1, 0.01, 0.005, 0.001\}$ for minimizing the loss. For other parameters, we simply follow the settings used in (Lin et al., 2016; Han et al., 2018a) so that it can be fairly compared with these baselines. Table 1 shows all the parameters used in our experiment.

5.5 Experiment Results

5.5.1 Precision-Recall Curves on Both Datasets

Figure 3 shows the comparison results in terms of Precision-Recall Curves on NYT-FB60K and GIDS-FB8K datasets. Overall, we observe that: (1) As shown in Figure 3(a), the neural network based approaches have more obvious advantages than Mintz, MultiR, and MIMLRE, illustrating the limitation of human-designed features and the advancement of neural networks in relation extraction. (2) APCNN+D using entity descriptions, and JointD+KATT exploiting KGs both outperform CNN+ATT on both datasets, showing that entity descriptions and KGs are both useful for improving the performance of relation extraction under distant supervision. RESIDE achieves better performance than APCNN+D and JointD+KATT. It is probably because that RESIDE utilizes more available side information, including entity types and relation alias information. (3) Our model

RELE	**87.0**	**76.6**	**67.0**	**76.8**	**88.0**	**73.3**	**63.2**	**78.7**	**88.0**	**78.6**	**69.8**	**78.8**

Table 2: Evaluation results P@N of different models using different number of sentences in bags on NYT-FB60K dataset. Here, **One**, **Two** and **All** represent the number of sentences randomly selected from a bag.

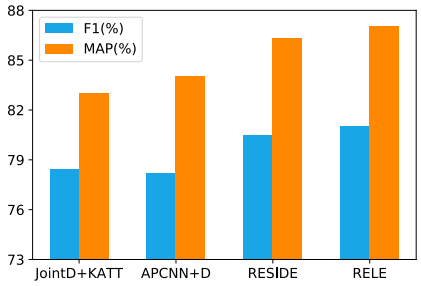

Figure 4: Comparison on GIDS-FB8K dataset.

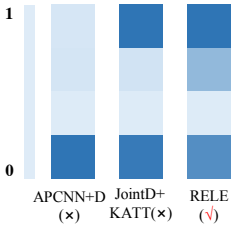
P@N(%)	100	300	500	Mean
RELE w/o LE	74.2	62.4	55.9	64.1
RELE w/o ATT$_e$	82.0	75.6	69.6	75.7
RELE w/o LC	81.0	74.0	69.0	74.7
RELE	**88.0**	**78.6**	**69.8**	**78.8**

Table 3: Evaluation results P@N of variant models on NYT-FB60K dataset.

RELE achieves the best performance compared to all the baselines. We believe the reason is that we make use of potential label information through joint label embedding. The learned label embeddings are of high quality since we fully exploit both the structural information from KGs and textual information from texts via gating integration while avoiding the imposed noise by an attention mechanism.

5.5.2 P@N Evaluation on NYT-FB60K Dataset

As shown in Table 2, we report Precision@N of different neural network based approaches on NYT-FB60K dataset. To verify the performance of our model on those entity pairs with few instances, we randomly select one, two and all instances for each entity pair, following previous studies (Du et al., 2018; Vashishth et al., 2018). As we can observe: (1) APCNN+D and JointD+KATT both outperform CNN+ATT in all cases, demonstrating the effectiveness of entity descriptions and KGs. RESIDE achieves better performance than APCNN+D and JointD+KATT by incorporating more side information (e.g., entity types). (2) Our model RELE significantly outperforms all the baselines. The reason is that our model learns high quality of label embeddings which play a critical role in relation extraction.



5.5.3 Results on GIDS-FB8K Dataset

Based on the results on the NYT-FB60K dataset, we choose APCNN+D, JointD+KATT and RESIDE as representative baselines to compare against our models on the GIDS-FB8K dataset in terms of F1 and MAP. As shown in Figure 4, our model consistently achieves better performance, which verifies the effectiveness of our model with joint label embedding. The overall results on GIDS-FB8K dataset show that our model can be well applied to smaller-scale datasets.

5.5.4 Comparison of Variant Models

In order to verify the effectiveness of different modules of our model, we design three variant models:

- **RELE w/o LE** removes the label embedding from RELE, which degenerates to CNN+ATT.
- **RELE w/o ATT$_e$** removes the attention of the KG over entity descriptions during label embedding. We use max-pooling instead, which does not consider the noise in the entity descriptions.

s_1: In **Bucharest** , **Romania** , president Traian Basescu said Sunday night that the entry into …
s_2: Last year, it opened offices in Warsaw and **Bucharest** , the capital of **Romania**.
s_3: … by the presence of two films from **Romania** , the way I spent … east of **Bucharest** …
s_4:… Ervin a of New York City , on April 18th , age 98 , formerly of **Bucharest** , **Romania** .
Triplet(*Romania, Bucharest, /location/country/capital*)

Figure 5: A case study for predicting the relation between "Bucharest" and "Romania". The baselines all predict wrongly while our model gives the right result. The left shows the weights assigned to different sentences by different models. Our model always gives higher weights to correct sentences (shown in red).

Romania is a country located at the crossroads of Central , Eastern , and Southeastern Europe . It borders the Black Sea to the southeast , … , Romania is the 12th largest country and also the 7th most populous ... Its capital and largest city is Bucharest , and other major urban areas include Cluj-Napoca ...

(a) Description text of "Romania"

Bucharest is the capital and largest city of Romania , as well as its cultural , industrial , and financial centre . It is located in the southeast of the country , … ,on the banks of the Dambovita River , less than 60 km north of the Danube River and the Bulgarian border.

(b) Description text of "Bucharest"

Figure 6: Visualization of attention values of words in the descriptions of the entities "Romania" and "Bucharest".

- **RELE w/o LC** removes the label classifier. It does not train the label embeddings to be classified to the correct classes.

As shown in Table 3, without label embedding, the performance of RELE w/o LE drops significantly (more than 10%). It demonstrates the effectiveness of our joint label embedding. If we do not consider the imposed noise in the entity descriptions, the performance of RELE w/o ATT_e decreases by around 3% on mean P@N. It demonstrates that the attention of KGs over entity descriptions is important for learning high-quality label embeddings. We also explore the performance of RELE w/o LC which does not train the label embeddings to be classified to the correct classes and find that label classifier plays a critical role in label embedding. The performance decreased by around 4% on mean P@N, without label classifier.

5.5.5 Case Study

Figure 5 illustrates an example from the test set of NYT-FB60K. As we can observe, representative attention-based baselines APCNN+D and JointD+KATT both predict wrong relation labels for the entities, while our model RELE correctly predicts the relation label "*/location/country/capital*". That is because the baselines assign relatively low weights to correct sentences (s_1 and s_2) and achieve inferior representations of the textual relation for classification. Our model RELE assigns higher weights to all the correct sentences s_1, s_2 and s_4, demonstrating that RELE learns high-quality label embeddings.

We also provide the insights of the attention of KGs over entity descriptions about "Romania" and "Bucharest". As shown in Figure 6, the words "capital", "largest". and "centre" which are related to the relation are given higher weights. It demonstrates that the attention of KGs over entity descriptions can help reduce the noise in entity descriptions and thus improve the label embeddings.

6 Conclusion

In this work, we consider leveraging potential label information to select valid instances for distantly-supervised relation extraction. We propose a novel multi-layer attention-based model RELE to improve relation extraction with joint label embedding. Our model takes full advantage of both structural information from KGs and textual information from entity descriptions to learn label embeddings, while avoiding the imposed noise with an attention mechanism. The label embeddings are trained to be classified to the correct relation classes. Then, the learned label embeddings are used as another attention over the bag to select valid instances for relation extraction. Extensive experiments have demonstrated that our model significantly outperforms state-of-the-art methods.

In the future, we will explore other useful information (e.g., correlations among the relations from KGs) available to improve the label embeddings.

Abstract

The lack of word boundaries information has been seen as one of the main obstacles to develop a high performance Chinese named entity recognition (NER) system. Fortunately, the automatically constructed lexicon contains rich word boundaries information and word semantic information. However, integrating lexical knowledge in Chinese NER tasks still faces challenges when it comes to self-matched lexical words as well as the nearest contextual lexical words. We present a Collaborative Graph Network to solve these challenges. Experiments on various datasets show that our model not only outperforms the state-of-the-art (SOTA) results, but also achieves a speed that is six to fifteen times faster than that of the SOTA model.[1]

1 Introduction

Named entity recognition (NER) aims to locate and classify certain occurrences of words or expressions in unstructured text into predefined semantic categories such as the person names, locations, organizations, etc. NER is an essential pre-processing step for many natural language processing (NLP) applications, such as relation extraction (Bunescu and Mooney, 2005), event extraction (Chen et al., 2015), question answering (Mollá et al., 2006) etc. In English NER, LSTM-CRF models (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Liu et al., 2018) leveraging word-level representations and character-level representations achieve the state-of-the-art results.

In this paper, we focus on Chinese NER. Compared with English, Chinese has no obvious word boundaries. Since without word boundaries information, it is intuitive to use character information

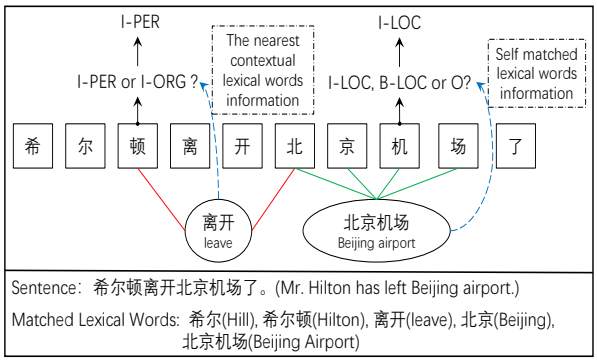

Figure 1: An example sentence integrating the nearest contextual lexical words (red line) and self-matched lexical words (green line)

only for Chinese NER (He and Wang, 2008; Liu et al., 2010; Li et al., 2014), although such methods could result in the disregard of word information. However, word information is very useful in Chinese NER, because word boundaries are usually the same as named entity boundaries. For example, as shown in Figure 1, the boundaries of the word "北京机场" (Beijing airport) are the same as the boundaries of the named entity " 北京机场" (Beijing airport). Therefore, making full use of word information would help to improve the Chinese NER performance.

There are three main ways to incorporate word information in NER. The first one is the pipeline method. The way of pipeline method is to apply Chinese Word Segmentation (CWS) first, and then to use a word-based NER model. However, the pipeline method suffers from error propagation, since the error of CWS may affect the performance of NER. The second one is to learn CWS and NER tasks jointly (Xu et al., 2013; Peng and Dredze, 2016; Cao et al., 2018; Wu et al., 2019). However, the joint models must rely on CWS annotation datasets, which are costly and are annotated under many diverse segmentation criteria (Chen

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3830–3840,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al., 2017). The third one is to leverage an automatically constructed lexicon, which is pre-trained on large automatically segmented texts. Lexical knowledge includes boundaries and semantic information. Boundaries information is provided by the lexicon word itself, and semantic information is provided by pre-trained word embeddings (Bengio et al., 2003; Mikolov et al., 2013). Compared with joint methods, a lexicon is easy to obtain and additional annotation CWS datasets are not required. Recently, Zhang and Yang (2018) propose a lattice LSTM to integrate lexical knowledge in NER. However, integrating lexical knowledge into sentences still faces two challenges.

The first challenge is to integrate self-matched lexical words. A self-matched lexical word of a character is the lexical word that contains this character. For instance, "北京**机**场" (Beijing Airport) and "**机**场" (Airport) are the self-matched words of the character "**机**" (airplane). "离开" (leave) is not the self-matched word of the character "机" (airplane), since " 机" (airplane) is not contained in the word " 离开" (leave). The lexical knowledge of self-matched word is useful in Chinese NER. For example, as shown in Figure 1, the boundaries and semantic knowledge of the self-matched word "北京机场" (Beijing Airport) can help the character "机"(airplane) to predict an "I-LOC" tag, instead of "O" or "B-LOC" tags. However, due to the limits of the word-character lattice, the lattice LSTM (Zhang and Yang, 2018) fails to integrate the self-matched word "北京机场" (Beijing Airport) into the character "机" (airplane).

The second challenge is to integrate the nearest contextual lexical words directly. The nearest contextual lexical word of a character is the word that matches the nearest past or future subsequence in the given sentence of this character. For instance, the lexical word "离开" (leave) is the nearest contextual word of the character "顿" (-ton), since the word matches the nearest future subsequence "离开" of the character, while "北京" (Beijing) is not the nearest contextual lexical word of this character. The nearest contextual lexical words are beneficial for Chinese NER. For example, as shown in Figure 1, by directly using the semantic knowledge of the nearest contextual words "离开" (leave), an "I-PER" tag can be predicted instead of an "I-ORG" tag, since "希尔顿" (Hilton Hotels) cannot be taken as the subject of the verb "离开" (leave). However, a lattice model (Zhang and Yang, 2018) only implicitly integrate the knowledge of the nearest contextual lexical words via the previous hidden state. The information of the nearest contextual lexical word may be disturbed by other information.

To solve the above challenges, we propose a character-based Collaborative Graph Network, including an encoding layer, a graph layer, a fusion layer and a decoding layer. Specifically, there are three word-character interactive graphs in the graph layer. The first one is the Containing graph (C-graph), which is designed for integrating self-matched lexical words. It models the connection between characters and self-matched lexical words. The second one is the Transition graph (T-graph), which builds the direct connection between characters and the nearest contextual matched words. It helps to handle the challenge of integrating the nearest contextual words directly. The third one is the Lattice graph (L-graph), which is inspired by the lattice LSTM (Zhang and Yang, 2018). L-graph captures partial information of self-matched lexical words and the nearest contextual lexical words implicitly by multiple hops. These graphs are built without external NLP tools, which can avoid error propagation problem. Besides, these graphs complement each other nicely and a fusion layer is designed for collaboration between these graphs.

We test our model with various Chinese NER datasets. our model not only significantly outperforms the existing state-of-the-art (SOTA) model but also is six to fifteen times faster than the speed of the SOTA model.

In summary, our main contributions are as follows:

- We propose a Collaborative Graph Network to integrate lexical knowledge directly and efficiently for Chinese NER.
- To solve the challenges of integrating self-matched lexical words and the nearest contextual lexical words, we propose three word-character interactive graphs. These interactive graphs can capture different lexical knowledge and are built without external NLP tools.
- We achieve the state-of-the-art results in various popular Chinese NER datasets, and our model achieves a 6-15x speedup over the existing SOTA model.

2 Related Work

NER. There is rich literature on NER. This includes statistic methods, such as SVM (Isozaki and Kazawa, 2002), HMMs (Bikel et al., 1997) and CRF (Lafferty et al., 2001), suffering from feature engineering. There are also a number of recent neural network approaches applied to NER, such as (Collobert et al., 2011; Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Liu et al., 2018; Akbik et al., 2018; Jie et al., 2019; Akbik et al., 2019). Compared with English, Chinese is not featured with obvious word boundaries, but it is important to leverage word boundaries and semantic information in Chinese NER. Many works use word segmentation information as extra features for Chinese NER, such as (Peng and Dredze, 2015; He and Sun, 2017a; Zhu and Wang, 2019). Peng and Dredze (2016), Cao et al. (2018) and Wu et al. (2019) propose joint models to train NER together with CWS. Our work is inspired by lattice LSTM (Zhang and Yang, 2018), which can integrate lexicon in NER.

Graph convolutional networks. There are a number of recent graph convolutional network (GCN) architectures (Kipf and Welling, 2017; Hamilton et al., 2017; Veličković et al., 2018; Qu et al., 2019) for learning over graphs. Our work is closely related to the graph attention networks (GAT), introduced by Veličković et al. (2018), leveraging masked self-attention layers to assign different importance to neighbouring nodes. In recent years, there is more and more literature about the application of GCN in NLP (Bastings et al., 2017; Marcheggiani and Titov, 2017; Zhang et al., 2018; Yao et al., 2019; Wang et al., 2018; Mishra et al., 2019; Cao et al., 2019; Zhang et al., 2019). Cetoli et al. (2017) use GCN to investigate the role of the dependency tree in English named entity recognition. However, most of the works (Bastings et al., 2017; Marcheggiani and Titov, 2017; Cetoli et al., 2017; Zhang et al., 2018) heavily rely on the dependency tree to construct a single graph, which suffer from error propagation. To capture different semantic and boundaries information, we propose a Collaborative Graph Network consisting of three automatically constructed graphs, which can avoid error propagation problem naturally. To our best knowledge, we are the first to introduce GAT and automatically constructed semantic graphs to Chinese NER tasks.

3 Approach

In this section, we first introduce the construction of graphs to integrate self-matched lexical words and the nearest contextual lexical words into sentences. We then introduce the architecture of Collaborative Graph Network as a core for solving Chinese NER tasks.

3.1 The Construction of Graphs

To integrate self-matched lexical words and the nearest contextual lexical words, we propose three word-character interactive graphs. The first is the word-character Containing graph (C-graph), which is to assist the character to capture the boundaries and semantic information of self-matched lexical words. The second is the word-character Transition graph (T-graph). The function of T-graph is to assist the character to capture the semantic information of the nearest contextual lexical words. The third is the Lattice graph (L-graph). Zhang and Yang (2018) propose a lattice structure, nested in the LSTM (Hochreiter and Schmidhuber, 1997), to integrate lexical knowledge. We free the lattice structure from the LSTM and adopt it as the third graph.

These three graphs share the same vertex set, but the edge sets of the three graphs are completely different. The vertex set is made up of the characters in the sentence and the matched lexical words, for example, as shown in Figure 1, the vertex set is V={希, 尔,..., 了, 希尔, 希尔顿, ..., 北京机场}. To represent the edge set, adjacency matrix needs to be introduced. The elements of the adjacency matrix indicate whether pairs of vertices are adjacent or not in the graph. Since the edge sets of the three graphs are totally different, the adjacency matrices of these three graphs are introduced below:

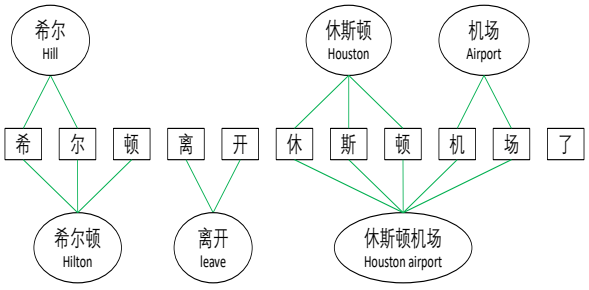

Figure 2: Word-Character Containing graph

Word-Character Containing graph

With the C-graph, the characters in the sentence can capture the boundaries and semantic information of self-matched lexical words. As shown in Figure 2, if a lexical word i contains a character j, the (i, j)-entry of the C-graph corresponding adjacency matrix $\mathbf{A}^C$ will be assigned a value of 1.

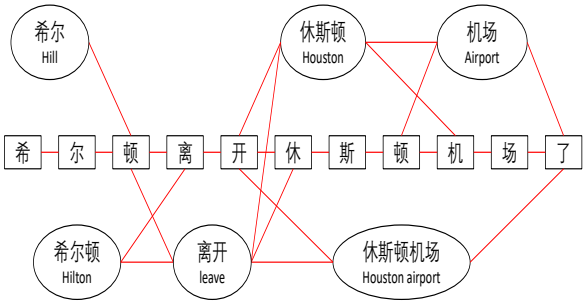

Figure 3: Word-Character Transition graph

Word-Character Transition graph

The T-graph is to assist the character to capture the semantic information of the nearest contextual lexical words. As shown in Figure 3, if a lexical word i or a character m matches the nearest preceding or following subsequence of a character j, the (i, j) or (m, j)-entry of the T-graph corresponding adjacency matrix $\mathbf{A}^T$ will be assigned a value of 1. Moreover, for capturing the context relation between lexical words, if a lexical word i is the preceding or following context of another lexical word k, we will assign "$\mathbf{A}^T_{ik} = 1$". Note that the T-graph is the same with the word cutting graph which is used in Chinese Word Segmentation.

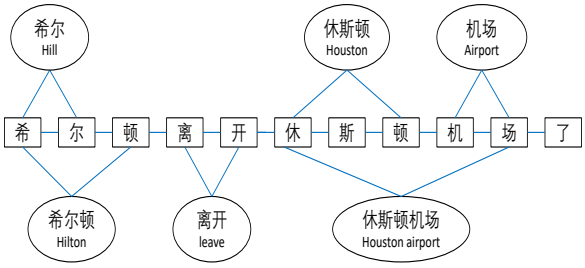

Figure 4: Word-Character Lattice graph

Word-Character Lattice graph

Zhang and Yang (2018) propose a lattice structure LSTM to exploit lexical knowledge for Chinese NER. A lattice structure can capture the information of the nearest contextual lexical words implicitly and capture some information of self-matched lexical words. As shown in Figure 4, if a character m is the nearest preceding or following character of a character j, the (m, j)-entry of the L-graph corresponding adjacency matrix $\mathbf{A}^L$ will be assigned a value of 1. Moreover, if a character j matches the lexical word i first character or end character, we will assign "$\mathbf{A}^L_{ij} = 1$".

3.2 Model

A character-based Collaborative Graph Network includes an encoding layer, a graph layer, a fusion layer, and a decoding layer. The encoding layer is to capture contextual information of the sentence and to represent the semantic information of lexical words. The graph layer is based on GAT (Veličković et al., 2018) for modeling over three word-character interactive graphs. A fusion layer is used for fusing different lexical knowledge captured by these three graphs. Finally, a standard CRF (Lafferty et al., 2001) model is used for decoding labels.

Encoding

The input of the model is a sentence and all lexical words that match consecutive subsequences of the sentence. We denote the sentence as $s = \{c_1, c_2, ..., c_n\}$, where c_i is the i-th character, and denote the matched lexical words as $l = \{l_1, l_2, ..., l_m\}$. By looking up the embedding vector from a pre-train character embedding matrix, each character c_i is represented as a vector, which denotes as $\mathbf{x}_i$.

$$\mathbf{x}_i = e^c(c_i) \tag{1}$$

e^c is a character embedding lookup table.

To capture contextual information, A bidirectional LSTM (Hochreiter and Schmidhuber, 1997) is applied to $\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$. By concatenating the left-to-right and right-to-left LSTM hidden states, we obtain the contextual representation $\mathbf{H} = \{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n\}$.

$$\overrightarrow{\mathbf{h}_i} = \overrightarrow{LSTM}(\mathbf{x}_i, \overrightarrow{\mathbf{h}_{i-1}}) \tag{2}$$

$$\overleftarrow{\mathbf{h}_i} = \overleftarrow{LSTM}(\mathbf{x}_i, \overleftarrow{\mathbf{h}_{i+1}}) \tag{3}$$

$$\mathbf{h}_i = \overrightarrow{\mathbf{h}_i} \oplus \overleftarrow{\mathbf{h}_i} \tag{4}$$

To represent the semantic information of lexical words, we look up word embeddings from a

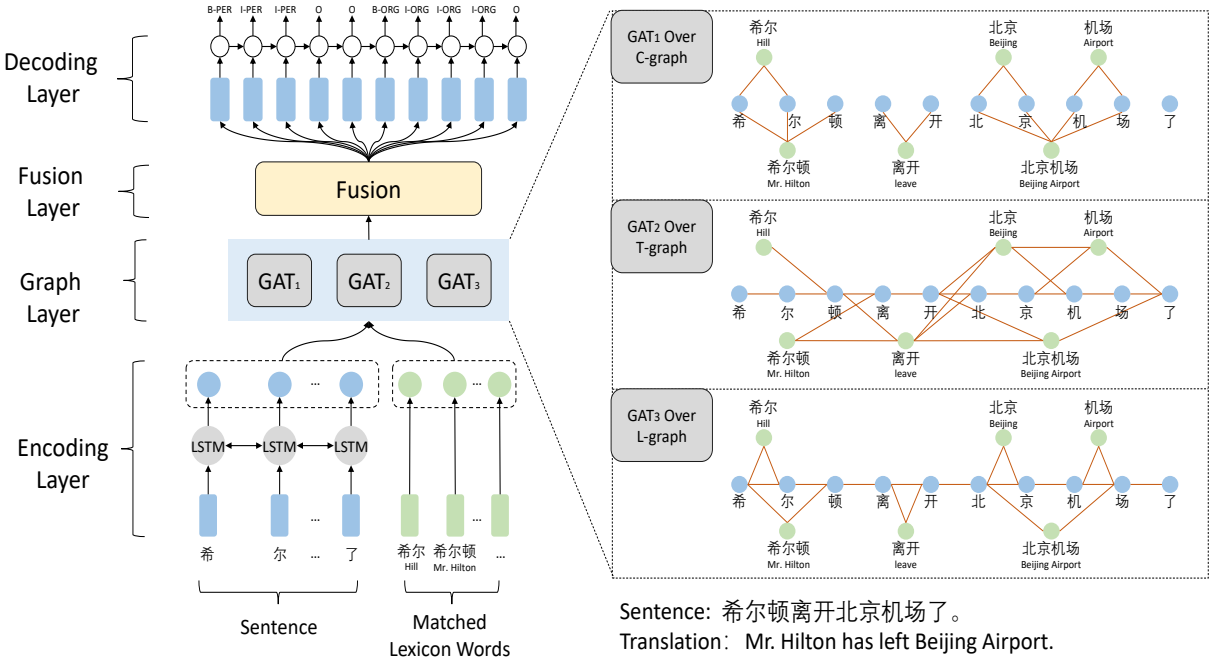

Figure 5: Main architecture of a Collaborative Graph Network for integrating lexical knowledge in Chinese NER. The left side shows the overall architecture, including an encoding layer, a graph layer, a fusion layer, and a decoding layer. On the right side, we show the details of graph attention networks over three word-character interactive graphs. We use blue to denote the characters in the sentence and use green to denote the matched lexicon words.

pre-train word embedding matrix, and each lexical words l_i is represented as a semantic vector, which denotes as $\mathbf{wv}_i$.

$$\mathbf{wv}_i = e^w(l_i) \tag{5}$$

e^w is a word embedding lookup table. We concatenate the contextual representation and the word embeddings as the output of this layer, denoting it as $\mathbf{Node}_f$.

$$\mathbf{Node}_f = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n, \mathbf{wv}_1, \mathbf{wv}_2, ..., \mathbf{wv}_m] \tag{6}$$

Graph Attention Networks over Word-Character Interactive Graphs

We use Graph Attention Networks (GAT) to model over three interactive graphs. In an M-layer GAT, the input of j-th layer is a set of node features, $\mathbf{NF}^j = \{\mathbf{f}_1, \mathbf{f}_2, ..., \mathbf{f}_N\}$, together with an adjacency matrix $\mathbf{A}$, $\mathbf{f}_i \in \mathbb{R}^F$, $\mathbf{A} \in \mathbb{R}^{N \times N}$, where N denotes the number of the nodes and F is the the dimension of features at j-th layer. The output of j-th layer is a new set of node features, $\mathbf{NF}^{(j+1)} = \{\mathbf{f}'_1, \mathbf{f}'_2, ..., \mathbf{f}'_N\}$. A GAT operation with K independent attention head can be written as :

$$\mathbf{f}'_i = \Big\Vert_{k=1}^{K} \sigma\Big(\sum_{j \in \mathcal{N}_i} \alpha_{ij}^k \mathbf{W}^k \mathbf{f}_j\Big) \tag{7}$$

$$\alpha_{ij}^k = \frac{\exp(\mathrm{LeakyReLU}(\mathbf{a}^{\mathrm{T}}[\mathbf{W}^{\mathrm{k}}\mathbf{f}_{\mathrm{i}} \| \mathbf{W}^{\mathrm{K}}\mathbf{f}_{\mathrm{j}}]))}{\Sigma_{k \in \mathcal{N}_i} \exp(\mathrm{LeakyReLU}(\mathbf{a}^{\mathrm{T}}[\mathbf{W}^{\mathrm{k}}\mathbf{f}_{\mathrm{i}} \| \mathbf{W}^{\mathrm{K}}\mathbf{f}_{\mathrm{k}}]))} \tag{8}$$

where $\|$ denotes concatenation operation, σ is a nonlinear activation function, $\mathcal{N}_i$ is the neighborhood of node i in the graph, α_{ij}^k are the attention coefficients, $\mathbf{W}^k \in \mathbb{R}^{F' \times F}$, and $\mathbf{a} \in \mathbb{R}^{2F'}$ is a single-layer feed-forward neural network. Note that, the dimension of the output $\mathbf{f}'_i$ is KF'. At the last layer, averaging will be adopted, and the dimension of final output features is F'.

$$\mathbf{f}_i^{final} = \sigma\Big(\frac{1}{K} \sum_{k=1}^{K} \sum_{j \in \mathcal{N}_i} \alpha_{ij}^k \mathbf{W}^k \mathbf{f}_j\Big) \tag{9}$$

To model three totally different word-character interactive graphs, We build three independent graph attention networks, which are denoted as GAT_1, GAT_2, and GAT_3. Since three word-character interactive graphs share the same vertex set, the input node features of all GAT are matrix $\mathbf{Node}_f$, which is shown in Equation 6. The output node features are denoted as $\mathbf{G}_1$, $\mathbf{G}_2$ and $\mathbf{G}_3$,

$$\mathbf{G}_1 = GAT_1(\mathbf{Node}_f, A^C) \tag{10}$$

$$\mathbf{G}_2 = GAT_2(\mathbf{Node}_f, A^T) \tag{11}$$

$$\mathbf{G}_3 = GAT_3(\mathbf{Node}_f, A^L) \tag{12}$$

Table 1: Main results on Weibo NER

where $\mathbf{G}_k \in \mathbb{R}^{F' \times (n+m)}$, $k \in \{1, 2, 3\}$. We keep the first n columns of these matrices and discard the last m columns, because only character representations are used to decode labels.

$$\mathbf{Q}_k = \mathbf{G}_k[:, 0{:}n], \ k \in \{1, 2, 3\} \quad (13)$$

Fusion Layer

A fusion layer is used to fuse different lexical knowledge captured by word-character interactive graphs. The input of the fusion layer is the contextual representation $\mathbf{H}$ and the output of the graph layer $\mathbf{Q}_i$, $i \in \{1, 2, 3\}$. The equation of the fusion layer is introduced below:

$$\mathbf{R} = \mathbf{W}_1\mathbf{H} + \mathbf{W}_2\mathbf{Q}_1 + \mathbf{W}_3\mathbf{Q}_2 + \mathbf{W}_4\mathbf{Q}_3 \quad (14)$$

where $\mathbf{W}_1$, $\mathbf{W}_2$, $\mathbf{W}_3$ and $\mathbf{W}_4$ are trainable matrices. Via a fusion layer, we obtain a matrix $\mathbf{R}$, $\mathbf{R} \in \mathbb{R}^{F' \times n}$, which is a new sentence representation integrating the contextual information as well as the lexical knowledge of self-matched lexical words and the nearest contextual lexical words.

Decoding and Training

We use a standard CRF (Lafferty et al., 2001) layer to capture the dependencies between successive labels. Given a sentence $s = \{c_1, c_2, ..., c_n\}$, the input of the CRF layer is $\mathbf{R} = \{\mathbf{r}_1, \mathbf{r}_2, ..., \mathbf{r}_n\}$, and the probability of the ground-truth tag sequence $y = \{y_1, y_2, ..., y_n\}$ is

$$p(y|s) = \frac{\exp(\sum_i (\mathbf{W}^{y_i}\mathbf{r}_i + \mathbf{T}_{(y_{i-1}, y_i)}))}{\sum_{y'} \exp(\sum_i (\mathbf{W}^{y'_i} r_i + \mathbf{T}_{(y'_{i-1}, y'_i)}))} \quad (15)$$

Here y' is an arbitrary label sequence, $\mathbf{W}^{y_i}$ is used for modeling emission potential for the i-th character in the sentence, and $\mathbf{T}$ is the transition matrix storing the score of transferring from one tag to another. Viterbi algorithm (Viterbi, 1967) is used to get the label sequence with the highest score. Given a manually annotated training data $\{(s_i, y_i)\}|_{i=1}^N$, we optimize the model by minimizing the negative log-likelihood loss with L_2 regularization. The loss function is defined as:

$$L = -\sum_{i=1}^{N} log(P(y_i|s_i)) + \frac{\lambda}{2}\|\Theta\|^2 \quad (16)$$

where λ denotes the L_2 regularization parameter and Θ is the all trainable parameters set

4 Experiments

In this section, we carry out extensive experiments to investigate the effectiveness of the Collaborative Graph Network.

4.1 Datasets

We evaluate our model on Weibo NER (Peng and Dredze, 2015; He and Sun, 2017a), OntoNotes 4 (Weischedel et al., 2011), and MSRA (Levow, 2006), where Weibo NER is in social domain, OntoNotes and MSRA are in the news domain. On Weibo NER, we use the same training, development and test split as Peng and Dredze (2015). On OntoNotes, we use the same data split as Che et al. (2013). Since the MSRA dataset does not have a development set, we randomly select 10% samples from the training set as the development set.

	Dataset	Ours(s)	Lattice(s)	Speedup
Training	MSRA	344	13723	×**15**
	OntoNotes	188	2561	×**13**
	Weibo NER	64	458	×**7**
Testing	MSRA	52	344	×**6**
	OntoNotes	27.1	386	×**14**
	Weibo NER	2.2	23	×**10**

Table 4: The performance of models in training and testing time. Time is measured in seconds. Lattice means the lattice LSTM (Zhang and Yang, 2018).

4.2 Experimental Settings

In our experiments, We use the same character embeddings as Zhang and Yang (2018), which is pretrained on Chinese Giga-Word. We use the lexicon provided by Li et al. (2018), including 1.3 million Chinese words. We set the dimensionality of LSTM hidden states to 300 and set the initial learning rate to 0.001. Since the scale of each dataset varies, we set different training batch size for different datasets. Specifically, we set batch sizes of MSRA, OntoNotes and Weibo NER as 64, 20 and 10. We use stochastic gradient Descent (SGD) algorithm to optimize parameters in OntoNotes and WeiboNER, and use Adam (Kingma and Ba, 2014) algorithm to optimize parameters in MSRA. We stop the training when we find the best result in the development set.

4.3 Overall Performance

Weibo NER. Table 1 shows the results on Weibo NER. Zhu and Wang (2019) propose a Convolutional Attention Network using segmentation information, which is the existing state-of-the-art (SOTA) model. Our model outperforms SOTA model by 3.78%, 1.07% and 5.34% in F1 score on Overall, Named Entity, and Nominal Mention. Zhang and Yang (2018) propose a lattice LSTM to integrate lexical knowledge. Our model outperforms the lattice LSTM by 4.3%, 3.41% and 6.07% in F1 score on Overall, Named Entity, and Nominal Mention.

OntoNotes. Table 2 shows the results on OntoNotes. Compared with lattice LSTM (Zhang and Yang, 2018), Our model gains a 0.91% improvement in F1 score. Compared with the best result (Yang et al., 2016), our model doesn't rely on gold-standard segmentation, which is not available in the real world. Note that our model even outperforms the model proposed by (Wang et al., 2013; Yang et al., 2016; Zhu and Wang, 2019), which uses the information of gold-standard segmentation.

MSRA. Results on the MSRA dataset are shown in Table 3. By leveraging hand crafted features (Chen et al., 2006; Zhang et al., 2006; Zhou et al., 2013) and character embeddings (Lu et al., 2016), statistical models achieve good results on MSRA dataset. Dong et al. (2016) integrate LSTM-CRF with radical features and Zhang and Yang (2018) propose a lattice LSTM to integrate lexical knowledge. Our model outperforms the lattice LSTM by 0.29% in F1 score on MSRA datasets.

Speed. As an essential preprocessing NLP tool, NER tasks require high speeds of both training and testing. Since aligning word-character lattice structure for batch training is usually non-trivial, the lattice LSTM (Zhang and Yang, 2018) suffers from slow speeds in training and testing. However, both LSTM and GAT in our model can compute efficiently by batch training.

For fair comparison, both the lattice LSTM and our model are implemented under PyTorch[2]. By using a single NVIDIA GeForce GTX 1080 Ti GPU, We randomly select 10 training and testing epoch as samples. The average time of training and testing is shown in Table 4. Our model can achieve a 6-15x speedup over the lattice LSTM.

4.4 Effectiveness of Three Word-Character Interactive Graphs

We conduct ablation experiments to demonstrate the effectiveness of these three word-character interactive graphs.

Comparison Setting. We design ablation studies as follow: 1) w/o C: without word-character Containing graph(C-graph). 2) w/o T: without word-character Transition graph (T-graph). 3) w/o L: without word-character Lattice graph (L-graph). 4)w/o C & T: without C-graph and T-graph, only keep L-graph. 5)w/o C & L : without C-graph and L-graph, only keep T-graph. 6) w/o

w/o C & T	70.53	58.51	92.72
w/o C & L	65.81	58.65	91.98
w/o T & L	71.41	58.72	92.80
BiLSTM+CRF	61.84	52.77	88.05

Table 5: Ablation study on reducing word-character interactive graphs, For example, ”w/o C” means removing word-character containing graph from the complete model.

T & L : without T-graph and L-graph, only keep L-graph. 7) BiLSTM+CRF: baseline model.

Comparison Results. Table 5 shows the results of ablation experiments. We can clearly see that removing any graph causes obvious performance degradation, but the importance of different graphs varies from dataset to dataset. Specifically, on OntoNotes and MSRA, ’w/o T-graph’ obtains worse performance than others, showing that T-graph is important. However, T-graph performs poorly without cooperating with other graphs. We guess that “T-graph” graph can only capture the information of the nearest contextual lexical words, and it is not enough to rely solely on T-graph. On Weibo NER, these graphs show equal importance. Since dialects slangs and irregular phrases are very common in social domain, we must rely on C-graph, T-graph, and L-graph jointly to handle the informal and complex contexts. In conclusion, from ablation experiments, we can find that each graph can be implemented independent of the other, but together they can achieve the best result, showing that all these three graphs are essential to our model.

5 Case Study

To show visually that our model can solve the challenges when integrating self-matched lexical words and the nearest contextual lexical words, a case study comparing without C-graph, without T-graph and the complete model is shown in Table 6. In the first case, there is an entity “ 西安电子科技大学”(Xidian University) with nested “西安” (Xi’an) and “ 电子科技大学” (UESTC). These common entities are all in the lexicon. Without C-graph, the model can’t integrate the information of the self-matched lexical word ‘西安电子科技大学” (Xidian University) into the characters “ 电” and “安”. Influenced by another lexical word “ 电子科技大学” (UESTC), the predicted label of the character “ 电” is “B-ORG”, and the label of the character “安” is predicted to be “I-ORG”, affect by the lexical word “西安” (Xi’an). In the second case, there is an entity “ 联想” (Lenovo), which can also be a common verb (“Associate”) in Chinese. Without T-graph, the model can’t integrate the information of the nearest contextual lexical words “ 腾讯” (Tencent) and “联合” (Joint) into the characters “ 联” and “ 想”, so the predicted labels of the characters “联” and “ 想” are ”O”s. However, with the help of T-graph, the model can use the information of the nearest contextual lexical words “腾讯” (Tencent) and “ 联合” (Joint) to predict the correct labels.

6 Conclusion

In this paper, we propose a Collaborative Graph Network for integrating lexical knowledge in Chinese NER. The core of the network is three lexical word-character interactive graphs. These interactive graphs can capture different lexical knowledge and are built without external NLP tools. We show through various experiments that our model has complementary strengths to the SOTA model and these interactive graphs are effective.

Abstract

In recent years there is a surge of interest in applying distant supervision (DS) to automatically generate training data for relation extraction (RE). In this paper, we study the problem *what limits the performance of DS-trained neural models*, conduct thorough analyses, and identify a factor that can influence the performance greatly, *shifted label distribution*. Specifically, we found this problem commonly exists in real-world DS datasets, and without special handing, typical DS-RE models cannot automatically adapt to this shift, thus achieving deteriorated performance. To further validate our intuition, we develop a simple yet effective adaptation method for DS-trained models, *bias adjustment*, which updates models learned over the source domain (*i.e.*, DS training set) with a label distribution estimated on the target domain (*i.e.*, test set). Experiments demonstrate that bias adjustment achieves consistent performance gains on DS-trained models, especially on neural models, with an up to 23% relative F1 improvement, which verifies our assumptions. Our code and data can be found at https://github.com/INK-USC/shifted-label-distribution.

1 Introduction

Aiming to identify the relation among an entity pair, relation extraction (RE) serves as an important step towards text understanding and is a long-standing pursuit by many researchers. To reduce the reliance on human-annotated data, especially for data-hungry neural models (Zeng et al., 2014; Zhang et al., 2017), there have been extensive studies on leveraging *distant supervision* (DS) in conjunction with external knowledge bases to automatically generate large-scale training data (Mintz et al., 2009; Zeng et al., 2015).

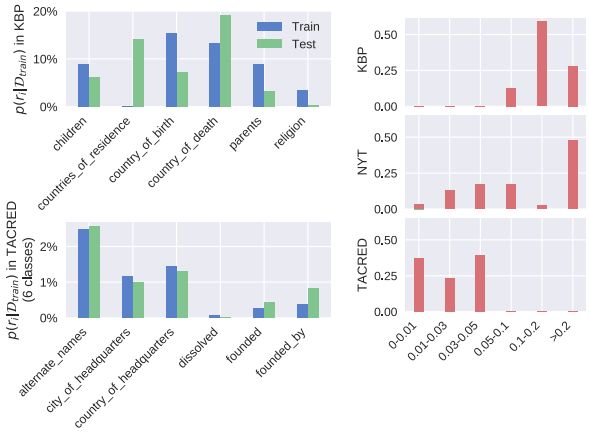

Figure 1: Left: Label distributions of KBP (distantly supervised dataset) are shifted, while those of TACRED (human-annotated dataset, 6 classes for illustration) are consistent. Full distributions for NYT and TACRED can be found in Appendix B. **Right:** Each relation r_i is categorized into intervals along x-axis according to $|p(r_i|\mathcal{D}_{train}) - p(r_i|\mathcal{D}_{test})|$; height of the bars indicates proportion of test instances that fall into each category, revealing that the shift is severe in DS datasets such as KBP and NYT.

While recent DS-based relation extraction methods focus on handling *label noise* (Riedel et al., 2010; Hoffmann et al., 2011; Lin et al., 2016), *i.e.*, false labels introduced by error-prone DS process, other factors may have been overlooked. Here, we observe model behaviors to be different on DS datasets and clean dataset, which implies existence of other challenges that restrict performance of DS-RE models. In this paper, we conduct thorough analyses over both real-world and synthetic datasets to explore the question — *what limits the performance of DS-trained neural models*.

Our analysis starts with a performance comparison among recent relation extraction methods on both DS datasets (*i.e.*, KBP (Ellis et al., 2012), NYT (Riedel et al., 2010)) and human-annotated dataset (*i.e.*, TACRED (Zhang et al., 2017)), with the goal of seeking models that can consistently yield strong results. We observe that, on human-

*Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3841–3850, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

annotated dataset, neural relation extraction models outperform feature-based models by notable gaps, but these gaps diminish when the same models are applied to DS datasets—neural models merely achieve performance comparable with feature-based models. We endeavor to analyze the underlying problem that leads to this unexpected "diminishing" phenomenon.

Inspired by two heuristic threshold techniques that prove to be effective on DS datasets, and further convinced by comprehensive analysis on synthetic datasets, we reveal an important characteristic of DS datasets—*shifted label distribution*, the issue that the label distribution of training set does not align with that of test set. There often exists a large margin between label distributions of *distantly-supervised training set* and that of *human-annotated test set*, as shown in Fig 1. Intuitively, this is mainly caused by "false positive" and "false negative" labels generated by error-prone DS processes, and the imbalanced data distribution of external knowledge bases.

To some extent, such distortion is a special case of domain shift — *i.e.*, training the model on a source domain and applying the learned model to a different target domain. To further verify our assumption, we develop a simple domain adaption method, *bias adaptation*, to address the shifted label distribution issue. It modifies the bias term in softmax classifiers and explicitly fits models along the shift. Specifically, the proposed method estimates the label distribution of target domain with a small development set sampled from test set, and derives the adapted predictions under reasonable assumptions. In our experiments, we observe consistent performance improvement, which validates that model performance may be severely hindered by label distribution shift.

In the rest of the paper, we first introduce the problem setting in Section 2 and report the inconsistency of model performance with human annotations and DS in Section 3. Then, we present two threshold techniques which are found to be effective on DS datasets and further lead us to the discovery of shifted label distribution. We explore its impact on synthetic datasets in Section 4, and introduce the bias adjustment method in Section 5. In addition, comparison of denoising method, heuristic threshold and bias adjustment is conducted in Section 6. We discuss related work in Section 7 and conclude our findings in Section 8.

Dataset	Distantly Supervised		Human-annotated
	KBP	NYT	TACRED
#Relation Types	7	25	42
#Train Sentences	23,784	235,982	37,311
#Test Sentences	289	395	6,277

Table 1: Statistics of Datasets Used in Our Study.

2 Experiment Setup

In this paper, we conduct extensive empirical analyses on distantly supervised relation extraction (DS-RE). For a meaningful comparison, we ensure the same setup in all experiments. In this section, we provide a brief introduction on the setting, while more details could be found in Appendix A. All implementations are available at https://github.com/INK-USC/shifted-label-distribution.

2.1 Problem Setting

Following previous works (Ren et al., 2017; Liu et al., 2017), we conduct relation extraction at *sentence level*. Formally speaking, the basic unit is the relation mention, which is composed of one sentence and one ordered entity pair within the sentence. The relation extraction task is to categorize each relation mention into a given set of relation types, or a Not-Target-Type (NONE).

2.2 Datasets

We select three popular relation extraction datasets as benchmarks. Specifically, two of them are distantly supervised and one is human-annotated.

KBP (Ling and Weld, 2012) uses Wikipedia articles annotated with Freebase entries as train set, and manually-annotated sentences from 2013 KBP slot filling assessment results (Ellis et al., 2012) as test set.

NYT (Riedel et al., 2010) contains New York Times news articles and has been already heuristically annotated. Test set is constructed manually by (Hoffmann et al., 2011).

TACRED (Zhang et al., 2017) is a large-scale crowd-sourced dataset, and is sufficiently larger than previous manually annotated datasets.

2.3 Pre-processing

We leverage pre-trained GloVe (Pennington et al., 2014) embedding[1], and use the StanfordNLP toolkit (Manning et al., 2014) to get part of speech

Table 2: Performance Comparison of RE Models. 5-time average and standard deviation of F1 scores are reported.

(POS) tags, named-entity recognition (NER) tags, and dependency parsing trees.

For the development sets, we use the provided development set on TACRED, and randomly split 10% of training set on KBP and NYT. This development set is also refered to as *noisy dev*, as we will introduce a *clean dev* to deal with shifted label distribution in the later parts.

2.4 Models

We consider two classes of relation extraction methods, *i.e.*, feature-based and neural models.

Specifically, Feature-based models include Logistic Regression (Mintz et al., 2009), CoType-RM (Ren et al., 2017) and ReHession (Liu et al., 2017). Neural models include Bi-LSTMs and Bi-GRUs (Zhang et al., 2017), Position-Aware LSTM (Zhang et al., 2017), CNNs and PCNNs (Zeng et al., 2014, 2015).

For each relation mention, these models will first construct a representation vector $\mathbf{h}$, and then make predictions with softmax based on $\mathbf{h}$[2]:

$$p(y = r_i|\mathbf{h}) = \frac{\exp(\mathbf{r}_i^T\mathbf{h} + b_i)}{\sum_{r_j}\exp(\mathbf{r}_j^T\mathbf{h} + b_j)}, \quad (1)$$

where $\mathbf{r}_i$ and b_i are the parameters corresponding to *i*-th relation type. More details on these models can be found in Appendix A.

3 The Diminishing Phenomenon

Neural models alleviate the reliance on handcrafted features and have greatly advanced the state-of-the-art, especially on datasets with human annotations. Meanwhile, we observe such performance boost starts to diminish on distantly supervised datasets. Specifically, we list the performance of all tested models in Table 2 and summarize three popular models in Figure 2.

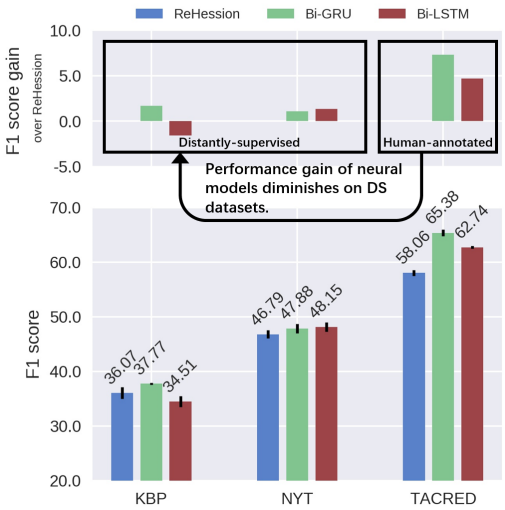

Figure 2: F1 score comparison among three models. Bi-GRU outperforms ReHession with a significant gap on TACRED, but only has comparable performance (with ReHession) on KBP and NYT. Similar gap diminishing phenomenon happens to Bi-LSTM.

On TACRED, a human annotated dataset, complex neural models like Bi-LSTM and Bi-GRU significantly outperform feature-based ReHession, with an up to 13% relative F1 improvement. On the other hand, on distantly supervised datasets (KBP and NYT), the performance gaps between the aforementioned methods diminishes to within 5% (relative improvement). We refer to this observation as "diminishing" phenomenon. Such observation implies a lack of handling of the underlying difference between human annotations and distant supervision.

After a broad exploration, we found two heuristic techniques that we believe capture problems exclusive to distantly supervised RE, and are potentially related to "diminishing" phenomenon. We found they can greatly boost the performance on distantly supervised datasets, but fail to do so

[2]CoType-RM and logistic regression are exceptions as they don't adopt softmax to generate output.

on human-annotated dataset. To get deeper insights, we analyze the diminishing phenomenon and the two heuristic methods.

3.1 Heuristic Threshold Techniques

Max threshold and entropy threshold are designed to identify the "ambiguous" relation mentions (*i.e.*, predicted with a low confidence) and label them as the NONE type (Ren et al., 2017; Liu et al., 2017). In particular, referring to the original predictions as $r^* = \arg\max_{r_i} p(y = r_i|\mathbf{h})$, we formally introduce these two threshold techniques:

- **Max Threshold** introduces an additional hyper-parameter T_m, and adjusts the prediction as (Ren et al., 2017):

$$predict(\mathbf{h}) = \begin{cases} r^*, & p(y = r^*|\mathbf{h}) > T_m \\ \text{NONE}, & \text{Otherwise} \end{cases}.$$

- **Entropy Threshold** introduces an additional hyper-parameter T_e. It first calculates the entropy of prediction:

$$e(\mathbf{h}) = -\sum_{r_k} p(y = r_k|\mathbf{h}) \log p(y = r_k|\mathbf{h}),$$

then it adjusts prediction as (Liu et al., 2017):

$$predict(\mathbf{h}) = \begin{cases} r^*, & e(\mathbf{h}) < T_e \\ \text{NONE}, & \text{Otherwise} \end{cases}.$$

To estimate T_e or T_m, 20% instances are sampled from the test set as an additional development set, and used to tune the value of T_e and T_m with grid search. After that, we evaluate the model performance on the remaining 80% of the test set. We refer to this new dev set as *clean dev* and refer to the original dev set used for tuning other parameters as *noisy dev*. We would like to highlight that tuning threshold on this clean dev is necessary as it acts as a bridge between distantly supervised train set and human-annotated test set.

3.2 Results and Discussion

Results of three representative models (ReHession, Bi-GRU and Bi-LSTM) using threshold techniques are summarized in Figure 3. Full results are listed in Table 3. We observe significant improvements on distantly supervised datasets (*i.e.*, KBP and NYT), with a up to 19% relative F1 improvement (Bi-GRU from 37.77% to 45.01% on KBP). However, on the human-annotated corpus, the performance gain can be hardly noticed. Such inconsistency implies that these heuristics may capture some important but overlooked factors for distantly supervised relation extraction, while we are still unclear about their underlying mechanisms.

Intuitively, annotations provided by distant supervision differ from human annotations in two ways: (1) **False Positive:** falsely annotating unrelated entities in one sentence as a certain relation type; (2) **False Negative:** neglecting related entities by marking their relationship as NONE. The terms, false positive and false negative, are commonly used to describe wrongful predictions. Here we only borrow the terms for describing label noises. These label noises distort the true label distribution of train corpora, creating a gap between the label distribution of train and test set (*i.e.*, shifted label distribution). With existing denoising methods, the effect of noisy training instances may be reduced; still, it would be infeasible to recover the original label, and thus label distribution shift remains an unsolved problem.

In our experiments, we notice that in distantly supervised datasets, instances labeled as NONE have a larger portion in test set than in train set. It is apparent that the strategy of rejecting "ambiguous" predictions would guide the model to predict more NONE types, leading the predicted label distribution towards a favorable direction. Specifically, in the train set of KBP, 74.25% instances are annotated as NONE and 85.67% in the test set. The original Bi-GRU model would annotate 75.72% instances to be NONE, which is close to 74.25%; after applying the max-threshold and entropy-threshold, this proportion becomes 86.18% and 88.30%, which are close to 85.67%.

Accordingly, we believe part of the underlying mechanism of heuristic threshold is to better handle the label distribution difference between train and test set. We try to further verify this hypothesis with experiments in next section.

4 Shifted Label Distribution

In this section, we first summarize our observation on shifted label distribution, and then conduct empirical analysis to study its impact on model performance using synthetic datasets. These datasets are carefully created so that label distribution is the only variable and other factors are controlled.

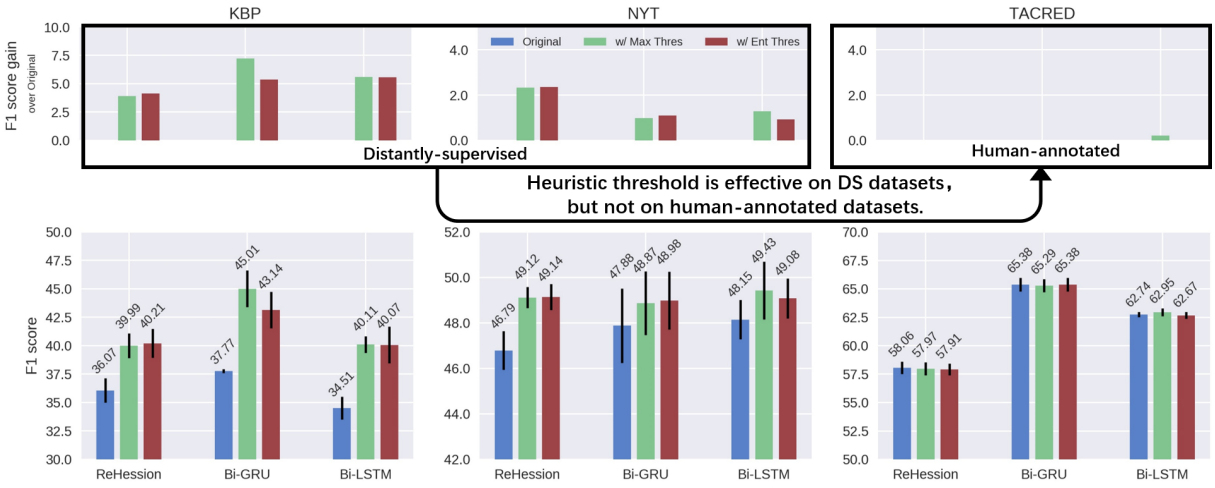

Figure 3: F1 scores on three datasets when (a) no threshold (original) (b) max threshold (c) entropy threshold are applied, respectively. A clear boost is observed on distantly supervised datasets (*i.e.*KBP and NYT) after applying threshold; however, performance n human-annotated dataset (*i.e.*TACRED) remains almost the same with thresholding. Heuristic threshold techniques may capture some important but overlooked problems in distantly supervised relation extraction.

4.1 Shifted Label Distribution

Shifted label distribution refers to the problem that the label distribution of train set does not align with the test set. This problem is related to but different from "learning from imbalanced data", where the data distribution is imbalanced, but consistent across train and test set. Admittedly, one relation may appear more or less than another in natural language, creating distribution skews; however, this problem widely occurs in both supervised and distantly supervised settings, and is not our focus in this paper.

Our focus is the *label distribution difference between train and test set*. This problem is critical to distantly supervised relation extraction, where the train set is annotated with distant supervision and the test set is manually annotated. As previously mentioned in Section 3.2, distant supervision differs from human annotations by introducing "false positive" and "false negative" labels. The label distribution of train set is subject to existing entries in KBs, and thus there exists a gap between label distributions of train and test set.

We visualize the distribution of KBP (DS dataset) and a truncated 6-class version of TACRED (human-annotated dataset) in Fig 1. Also, proportions of instances categorized into $\delta = |p(r_i|\mathcal{D}_{train}) - p(r_i|\mathcal{D}_{test})|$ bins are shown. It is observed that KBP and NYT both have shifted label distributions (most instances fall into $\delta > 0.05$ bins); while TACRED has consistent label distributions (all instances fall into $\delta < 0.05$ bins).

4.2 Impact of Shifted Label Distribution

In order to quantitatively study the impact of label distribution shift, we construct synthetic datasets by sub-sampling instances from the human-annotated TACRED dataset. In this way, the only variable is the label distribution of synthetic datasets, and the impact of other factors such as label noise is excluded.

Synthetic Dataset Generation. We create five synthetic train sets, by sampling sentence-label pairs from original TACRED train set with label distributions S1-S5. S5 is a randomly generated label distribution (see Fig 7 in Appendix B). S0 is TACRED's original train set label distribution. S1 – S4 are created with linear interpolation between S0 and S5, *i.e.*, $\text{Si} = \frac{5-i}{5}\text{S0} + \frac{i}{5}\text{S5}$. We apply disproportionate stratification to control the label distribution of synthetic datasets. In this way, we ensure that the number of sampled instances in each synthetic train set is kept constant within 10000 ± 3, and the label distribution of each set satisfies S1-S5 respectively.

Results and Discussion. We conduct experiments with three typical models (*i.e.*, Bi-GRU, Bi-LSTM and ReHession) and summarize their results in Fig 4. We observe that, from S1 to S5, the performance of all models consistently drops. This phenomenon verifies that shifted label distribution is making a negative influence on model performance. The negative effect expands as the train set label distribution becomes more twisted.

At the same time, we observe that feature-based ReHession is more robust to such shift. The gap

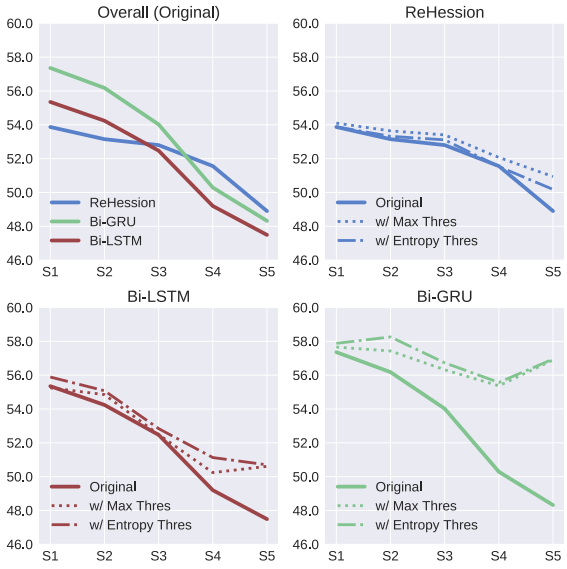

Figure 4: F1 scores on synthesized datasets S1-S5. We observe that (a) performance consistently drops from S1 to S5, demonstrating the impact of shifted label distributions; (b) ReHession is more robust to such distribution shift, outperforming Bi-LSTM and Bi-GRU on S4 and S5; (c) threshold is an effective way to handle such shift.

between ReHession and Bi-GRU stably decreases, and eventually ReHession starts to outperform the other two at S4. This could be the reason accounting for "diminishing" phenomenon — neural models such as Bi-GRU is supposed to outperform ReHession by a huge gap (as with S1); however on distantly supervised datasets, shifted label distribution seriously interfere the performance (as with S4 and S5), and therefore it appears as the performance gap diminishes.

Applying Threshold Techniques. We also applied the two threshold techniques on the synthetic datasets and summarize their performance in Fig 4. The three models become more robust to the label distribution shift when threshold is applied. Threshold techniques are consistently making improvements, and the improvements are more significant with S5 (most shifted) than with S0 (least shifted). This observation verifies that the underlying mechanism of threshold techniques help the model better handle label distribution shift.

5 Bias Adjustment: An Adaptation Method for Label Distribution Shift

Investigating the probabilistic nature of softmax classifier, we present a principled domain adaptation approach, *bias adjustment* (BA), to deal with label distribution shift. This approach explicitly fits the model along such shift by adjusting the bias term in softmax classifier.

5.1 Bias Adjustment

We view corpora with different label distributions as different domains. Denoting distantly supervised corpus (train set) as $\mathcal{D}_d$ and human-annotated corpus (test set) as $\mathcal{D}_m$, our task becomes to calculate $p(y = r_i|\mathbf{h}, \mathcal{D}_m)$ based on $p(y = r_i|\mathbf{h}, \mathcal{D}_d)$.

We assume the only difference between $p(y = r_i|\mathbf{h}, \mathcal{D}_m)$ and $p(y = r_i|\mathbf{h}, \mathcal{D}_d)$ to be the label distribution, and the semantic meaning of each label is unchanged. Accordingly, we assume $p(\mathbf{h}|r_i)$ is universal, *i.e.*,

$$p(\mathbf{h}|r_i, \mathcal{D}_m) = p(\mathbf{h}|r_i, \mathcal{D}_d) = p(\mathbf{h}|r_i). \quad (2)$$

As distantly supervised relation extraction models are trained with $\mathcal{D}_d$, its prediction in Equation 1 can be viewed as $p(y = r_i|\mathbf{h}, \mathcal{D}_d)$, *i.e.*,

$$\begin{aligned} p(y = r_i|\mathbf{h}, \mathcal{D}_d) &= p(y = r_i|\mathbf{h}) \\ &= \frac{\exp(\mathbf{r}_i^T\mathbf{h} + b_i)}{\sum_{r_j} \exp(\mathbf{r}_j^T\mathbf{h} + b_j)}. \end{aligned} \quad (3)$$

Based on the Bayes Theorem, we have:

$$p(y = r_i|\mathbf{h}, \mathcal{D}_m) = \frac{p(\mathbf{h}|r_i, \mathcal{D}_m)p(r_i|\mathcal{D}_m)}{\sum_{r_j} p(\mathbf{h}|r_j, \mathcal{D}_m)p(r_j|\mathcal{D}_m)}. \quad (4)$$

Based on the definition of conditional probability and Equation 2, we have:

$$\begin{aligned} p(\mathbf{h}|r_i, \mathcal{D}_m) &= p(\mathbf{h}|r_i) = p(\mathbf{h}|r_i, \mathcal{D}_d) \\ &= \frac{p(\mathbf{h}, r_i, \mathcal{D}_d)}{p(r_i, \mathcal{D}_d)} \\ &= \frac{p(r_i|\mathbf{h}, \mathcal{D}_d) \cdot p(\mathbf{h}|\mathcal{D}_d)}{p(r_i|\mathcal{D}_d)}. \end{aligned} \quad (5)$$

With Equation 3, 4 and 5, we can derive that

$$\begin{aligned} & p(y = r_i|\mathbf{h}, \mathcal{D}_m) \\ =& \frac{p(y = r_i|\mathbf{h}, \mathcal{D}_d)\frac{p(r_i|\mathcal{D}_m)}{p(r_i|\mathcal{D}_d)}}{\sum_{r_j} p(y = r_j|\mathbf{h}, \mathcal{D}_d)\frac{p(r_j|\mathcal{D}_m)}{p(r_j|\mathcal{D}_d)}} \\ =& \frac{\exp(\mathbf{r}_i^T\mathbf{h} + b_i')}{\sum_j \exp(\mathbf{r}_j^T\mathbf{h} + b_j')}, \end{aligned} \quad (6)$$

where

$$b_i' = b_i + \ln p(r_i|\mathcal{D}_m) - \ln p(r_i|\mathcal{D}_d). \quad (7)$$

Dataset	Model	Original	Max-thres	Δ	Ent-thres	Δ	BA-Set	Δ	BA-Fix	Δ

Table 3: F1 score of RE Models with Threshold and Bias Adaptation. 5-time average and standard deviation of F1 scores are reported. Δ denotes the F1 improvement over original. On DS datasets, the four methods targeting label distribution shift achieve consistent performance improvement, with averagely 3.83 F1 improvement on KBP and 1.72 on NYT. However, the same four methods fail to improve performance on human-annotated TACRED.

With this derivation we now know that, under certain assumptions (Equation 2), we can adjust the prediction to fit a target label distribution given $p(r_i|\mathcal{D}_d)$ and $p(r_i|\mathcal{D}_m)$. Accordingly, we use Equation 6 and 7 to calculate the adjusted prediction as:

$$r^* = \arg\max_{r_i} \exp(\mathbf{r}_i^T \mathbf{h} + b'_i). \quad (8)$$

Label distribution estimation. The source domain (train) label distribution, $p(r_i|\mathcal{D}_d)$ can be easily estimated on train set. As for target domain (test) distribution $p(r_i|\mathcal{D}_m)$, we use maximum likelihood estimation on a held-out *clean dev* set, which is a 20% sample from test set. This setting is similar to heuristic threshold techniques.

Implementation details. The bias adjustment model are implemented in two ways:

- **BA-Set** directly replaces the bias term in Equation 1 with b'_i in Equation 7 during evaluation. No modification to model training is required.
- **BA-Fix** fixes the bias term in Equation 1 as $b_i = \ln p(r_i|\mathcal{D}_d)$ during training and replaces it with $b'_i = \ln p(r_i|\mathcal{D}_m)$ during evaluation. Intuitively, BA-Fix would encourage the model to fit our assumption better (Equation 2); still, it needs special handling during model training, which is a minor disadvantage of BA-Fix compared with BA-Set.

5.2 Results and Discussion

We conduct experiments to explore the effectiveness of BA-Set and BA-Fix and summarize their performance in Table 3. Also, F1 improvements

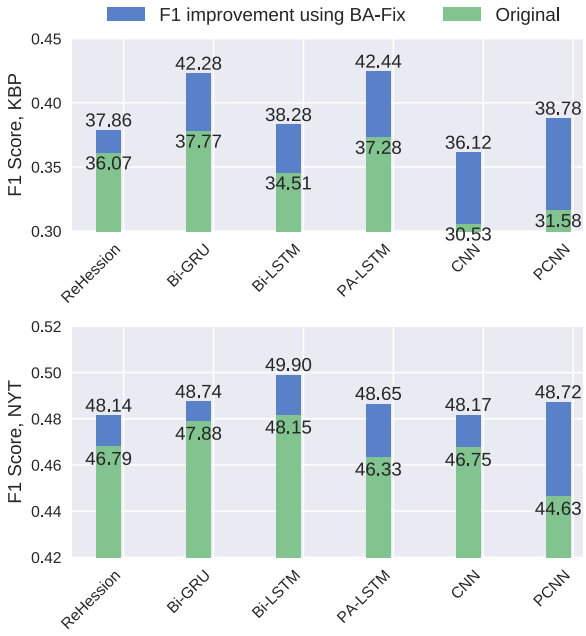

Figure 5: F1 Improvement using BA-Fix. BA-Fix consistently improves performance in compared models.

when BA-Fix is used is shown in Fig 5. We find that these two technologies bring consistent improvements to all RE models on both distantly supervised datasets. Especially, in the case of PCNN on KBP dataset, a 23% relative F1 improvement is observed. At the same time, the same technology fails to achieve performance improvements on TACRED, the human annotated dataset. In other words, we found that, by explicitly adapting the model along label distribution shift, consistent improvements can be achieved on distant supervision but not on human annotations. This observation again supports our assumption that shifted label distribution is an unique factor for distantly super-

vised RE that needs special handling.

Summary of all four methods. Compared with heuristic threshold techniques, bias adjustment methods directly address shifted label distribution issue by adjusting bias term in classifier, and is more principled and explainable. Though both threshold and bias adjustment methods require an extra clean dev sampled from test set, threshold techniques require predicting on the instances in the clean dev and tune T_m or T_e based on the output probability. Bias adjustment only needs the label distribution estimated on clean dev, and is more efficient in computation. As for performance, there is no clear indication that one method is consistently stronger than another. However, all four methods (2 threshold and 2 bias adjustment) achieve similar results when applied to RE models – we observe relatively significant performance improvements on DS datasets, but only marginal improvements on human-annotated dataset.

Comments on neural RE models. On average, bias adjustment methods results in 3.66 F1 improvement on KBP and 2.05 on NYT for neural models. BA-Fix gains a suprising 7.20 with PCNN on KBP. Noting that only bias terms in softmax classifier are modified and only a small piece of extra information is used, it is implied that shifted label distribution is severely hindering model performance and capabilities of state-of-the-art neural models are not fully described with traditional evaluation. Hidden representations $\mathbf{h}$ learned by neural models indeed capture semantic meanings more accurately than feature-based model, while the bias in classifier becomes the major obstacle towards better performance.

6 Comparison with Denoising Methods

In this section, we conduct analyses about shifted label distribution and its relation with label noise. We apply a popular label noise reduction method– selective attention (Lin et al., 2016), which groups all sentences with the same entity pair into one bag, conducts multi-instance training and tries to place more weight on high-quality sentences within the bag. This method, along with threshold techniques and bias adjustment introduced in previous sections, is applied to two different models (*i.e.*, PCNN and Bi-GRU).

We summarize their improvements over the original model in Figure 6. We find that selective attention is indeed effective and improves the performance; meanwhile, heuristic threshold and bias adaption approaches boost the performance, and in some cases the boost is even more significant than that of selective attention. This observation is reasonable since both heuristics and bias adaption approaches are able to access additional information from clean dev (20% of test set). Still, it is surprising that such small piece of information brings about huge difference, demonstrating the importance of handling shifted label distribution. It also shows that there exists much space for improving distantly supervised RE models from a shifted label distribution perspective.

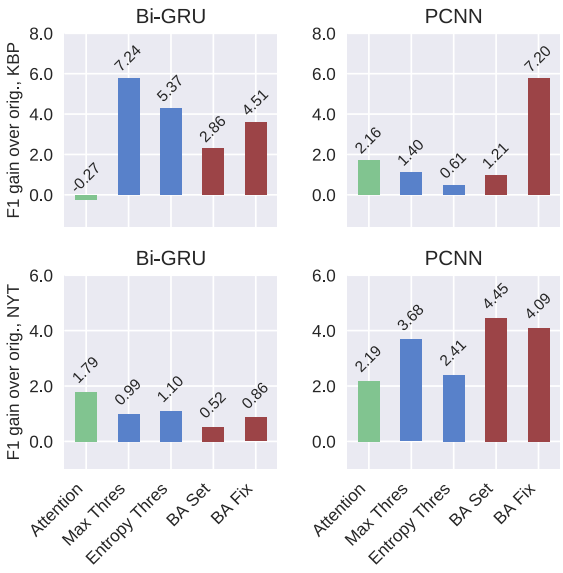

Figure 6: Comparison among selective attention, threshold heuristics and bias adaption approaches. Threshold heuristics and bias adaption approaches bring more significant improvements in some cases, indicating that shifted label distribution is a non-negligible problem.

7 Related Work

7.1 Relation Extraction

Relation extraction is to identify the relationship between a pair of entity mentions. The task setting slightly varies as the relation can be either extracted from a bag of sentences (corpus-level) or one single sentence (sentence-level). In this paper, we focus on sentence-level RE. That is, prediction should be purely based on the information provided within the sentence, instead of external knowledge or commonsense.

Recent approaches follow the supervised learning paradigm and rely on considerable amounts of labeled instances to train effective models. Zeng et al. (2014) proposed using CNN for relation ex-

traction, which could automatically capture features from texts. Zeng et al. (2015) further extended it with piecewise max-pooling, *i.e.*, splitting the sentence into three pieces with the object and subject entity, doing max-pooling over the three pieces separately, and finally concatenating the hidden representations. Lin et al. (2016) applied selective attention over sentences for learning from multiple instances. This method was originally designed for corpus-level setting. It organizes sentences into bags and assign lower weights to those less relevant sentences in the bag. Zhang et al. (2017) proposed position-aware LSTM network which incorporates entity position information into encoding and enables attention mechanism to simultaneously exploit semantic and positional information.

7.2 Distant Supervision

In supervised relation extraction paradigm, one longstanding bottleneck is the lack of large-scale labeled training data. In order to alleviate the dependency on human supervision, Mintz et al. (2009) proposed distant supervision, namely constructing large datasets automatically by aligning text to an existing knowledge bases (*e.g.*, Freebase). Also, distantly supervised relation extraction is formulated into a reinforcement learning problem by Feng et al. (2018) for selecting high-quality instances. Similar annotation generation strategy using distant supervision has also been used for other NLP tasks, such as named entity recognition (Shang et al., 2018) and sentiment classification (Go et al., 2009).

Though this strategy lightens annotation burdens, distant supervision inevitably introduces label noises. As the relation types are annotated merely according to entity mentions in the sentence, the local context may be annotated with labels that are not expressed in the sentence, In recent years, researchers mainly focus on dealing with label noises, and proposed the following methods: Riedel et al. (2010) use multi-instance single-label learning paradigm; Hoffmann et al. (2011); Surdeanu et al. (2012) propose multi-instance multi-label learning paradigm. Recently, with the advance of neural network techniques, deep learning methods (Zeng et al., 2015; Lin et al., 2016) are applied to distantly supervised datasets, with powerful automatic feature extraction and advanced label noised reducing techniques such as selective attention. Liu et al. (2017) proposed a general framework to consolidate heterogeneous information and refine the true labels from noisy labels.

Label noise is certainly an important factor limiting the performance of DS-RE models. Meanwhile, we argue that shifted label distribution is also a performance-limiting aspect. It is long-overlooked and should be handled properly.

8 Conclusion and Future Work

In this paper, we first present the observation of inconsistent performance when models are trained with human annotations and distant supervision in the task of relation extraction. It leads us to explore the underlying challenges for distantly supervised relation extraction. Relating two effective threshold techniques to label distribution, we reveal an important yet long-overlooked issue – *shifted label distribution*. The impact of this issue is further demonstrated with experiments on five synthetic train sets. We also consider this issue from a domain adaptation perspective, introducing a theoretically-sound bias adjustment method to recognize and highlight label distribution shift. The bias adjustment methods achieve significant performance improvement on distantly-supervised datasets. All of these findings support our argument that shifted label distribution can severely hinder model performance and should be handled properly in future research.

Based on these observations, we suggest that in addition to label noise, more attention be paid to the shifted label distribution in distantly supervised relation extraction research. We hope that the analysis presented will provide new insights into this long-overlooked factor and encourage future research of creating models robust to label distribution shift. We also hope that methods such as threshold techniques and bias adjustment become useful tools in future research.

Abstract

Many existing relation extraction (RE) models make decisions globally using integer linear programming (ILP). However, it is nontrivial to make use of integer linear programming as a blackbox solver for RE. Its cost of time and memory may become unacceptable with the increase of data scale, and redundant information needs to be encoded cautiously for ILP. In this paper, we propose an easy first approach for relation extraction with information redundancies, embedded in the results produced by local sentence level extractors, during which conflict decisions are resolved with domain and uniqueness constraints. Information redundancies are leveraged to support both easy first collective inference for easy decisions in the first stage and ILP for hard decisions in a subsequent stage. Experimental study shows that our approach improves the efficiency and accuracy of RE, and outperforms both ILP and neural network-based methods.

1 Introduction

Relation extraction (RE) has been extensively studied due to its crucial role for many knowledge based applications (Fan et al., 2012; Zhang et al., 2012; Chen et al., 2014a), such as question answering and knowledge graph. There are two types of relation extractors: local and global. The former identify relationships between entity pairs individually according to the local features of sentences, *e.g.,* lexical and syntactic features (Bunescu and Mooney, 2007; Mintz et al., 2009; Surdeanu et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016). The latter make decisions by further considering joint features of the entire corpus (Yao et al., 2010; Li et al., 2011, 2013; de Lacalle and Lapata, 2013; Chen et al., 2014a). Global relation extractors are able to resolve conflict decisions, and to utilize the dependencies among extracted facts to improve the performance (Li et al., 2011; Chen et al., 2014a), commonly by formalizing RE as a constrained optimization problem and solving RE with integer linear programming (ILP) (Roth and Yih, 2004; Choi et al., 2006; Roth and Yih, 2007; Li et al., 2011; Ji et al., 2013; Chen et al., 2014a,b). However, global optimization remains dominated by the ILP solvers, suffering from heavy time expenses.

Using integer linear programming for RE as a blackbox solver is a challenging task. First, with the increase of entity pairs and candidate relations, the variables and constraints encoded for ILP increase dramatically, which in return may consume too much computing time and memory. Second, redundant information needs to be encoded cautiously. Consider <United States, *capital : 0.6*, New York>, <United States, *capital : 0.7*, New York> and <United States, *capital : 0.96*, Washington D.C.> in Table 1. Simple statistical methods, such as confidence summation, may easily lead to a wrong decision in this case.

To address the above issues, we propose to make easy (most confident) decisions first, and then to make hard decisions with ILP. The rationale lies in that easy decisions should be made early, and eliminating conflicts with constraints aids hard decision making. We leverage information redundancies, embedded in the results produced by sentence level extractors, to compute the confidences of candidate relations for entity pairs. Redundancy commonly exists in various corpora, *e.g.,* subject "United States" and object "New York" appear multiple times in Table 1. Even if there exists a specific relation between a subject and an object, the relation may not be reflected in certain mentions due to the lack of embedded evidence in single mentions, and *information redundancies are essentially to alleviate such insufficiency for decision making*.

ID	Entity Pair	Top-3 Candidate Relations		
1	Australia, Canberra	*capital : 0.7*	*locationCity : 0.2*	*nationality : 0.1*
2	United States, New York	*capital : 0.6*	*birthPlace : 0.35*	*nationality : 0.05*
3	United States, New York	*capital : 0.7*	*country : 0.23*	*deathPlace : 0.07*
4	United States, Washington D.C.	*capital : 0.96*	*country : 0.03*	*birthPlace : 0.01*
5	Australia, Sydney	*locationCountry : 0.6*	*capital : 0.2*	*largestCity : 0.2*
6	University of Sydney, Sydney	*locationCity : 0.7*	*locationCountry : 0.2*	*city : 0.1*
7	Geoff Ogilvy, Australia	*nationality : 0.4*	*locationCountry : 0.3*	*city : 0.3*

Table 1: Example entity pairs and their candidate relations.

When making easy decisions, we keep the consistency among candidate relations by making use of constraints (*i.e.,* domain and uniqueness constraints) to eliminate conflicts directly, instead of implicitly encoding constraints in ILP (Yao et al., 2010; de Lacalle and Lapata, 2013; Chen et al., 2014a; Koch et al., 2014; Chen et al., 2014b). As a result, the number of variables and constraints to be encoded in ILP is significantly reduced, which speeds up the entire decision making process.

In short, our approach employs an easy-first strategy with information redundancies to make most confident decisions first during which conflict candidate relations are resolved directly by domain and uniqueness constraints, and it only makes the remaining hard decisions with ILP. Our approach is an important improvement of ILP-models, and it is not a new RE model, but an efficient and effective approach to fully exploiting the results of (any) local RE extractors. As shown in the experiments, our approach improves the performance, on average (4.58%, 17.90%) more accurate and (21, 37) times faster than existing ILP and neural network-based methods, respectively.

In the rest, we first introduce constraints and redundancies in Section 2, then present our detailed approach in Section 3, followed by experimental study in Section 4, related work in Section 5, and conclusions in Section 6.

2 Constraints and Redundancies

Consider a set M of mentions and a set R of predefined relations $\{r_1, \ldots, r_k\}$. For each mention m, a sentence level extractor produces an entity pair (subject s and object o) and a confidence score c_i for each relation r_i ($i \in [1, k]$), which represents the probability that s and o have relation r_i (Berger et al., 1996; Hoffmann et al., 2011). Here an NA (unknown) relation is typically included in R.

A mention m preprocessed by a sentence level extractor is essentially a $k+2$ tuple $(s, o, r_1 : c_1, \ldots, r_k : c_k)$, as illustrated in Table 1, where $1 \geq c_i \geq c_j \geq 0$ for any $i > j \in [1, k]$ and $\sum_{i=1}^{k} c_i = 1$. Observe that an entity pair (subject s and object o) with a relation $r \in R$ can be treated as an SRO triple (s, r, o), and a mention m contains k SRO triples. For convenience, given a mention m and a relation $r \in R$, we also denote the score of relation r in m as $m[r].c$.

Given a set M of mentions preprocessed by a sentence level extractor, our task for relation extraction is to determine the set of correct relations for each entity pair in M, and our approach adopts an easy-first strategy to make fast and accurate decisions, by leveraging constraints and redundancies that are to be introduced below.

In the following, a mention is referred to the one preprocessed by a sentence level extractor.

2.1 Constraints

We consider two types of constraints: domain and uniqueness constraints, commonly used to enforce agreements on decisions for RE (Yao et al., 2010; de Lacalle and Lapata, 2013; Chen et al., 2014a; Koch et al., 2014; Chen et al., 2014b).

Domain constraints. This type of constrains enforces constraints among the subject and object domains of relations. Given relations r_i and r_j ($1 \leq i, j \leq k$), (1) an *S-S domain constraint* ensures that r_i and r_j share no common entities between their subjects, *i.e.,* $r_i.subject \cap r_j.subject = \emptyset$, (2) an *O-O domain constraint* ensures that r_i and r_j share no common entities between their objects, *i.e.,* $r_i.object \cap r_j.object = \emptyset$, and (3) an *S-O domain constraint* ensures that r_i and r_j share no common entities between the subject of r_i and the object of r_j, *i.e.,* $r_i.subject \cap r_j.object = \emptyset$.

For example, (1) relations *largestCity* and *locationCity* have their subjects as countries (*e.g.,* "Australia") and organizations (*e.g.,* "University of Sydney"), respectively. They hold an *S-S* domain constraint; (2) relations *locationCity* and *locationCountry* have their objects as cities and countries, respectively. They hold an *O-O* domain constraint; (3) *locationCity* has its subjects as or-

# of mentions	# of entity pairs	# of subjects	# of objects	# / ratio of entity pairs mentioned multiple times		# / ratio of subjects mentioned multiple times		# / ratio of objects mentioned multiple times		Top 3 relation precision (%)
				≥ 3	≥ 5	≥ 3	≥ 5	≥ 3	≥ 5	
53162	30864	11360	9709	2754/ 8.92%	1225/ 3.97%	2914/ 25.65%	1591/ 14.01%	2442/ 25.15%	1351/ 13.91%	DB_me: 77.3/ 11.8/ 5.0 DB_nn: 76.5/ 10.6/ 5.0

Table 2: Redundancy statistics of DBpedia - (see Section 4 for details about the datasets).

ganizations and *nationality* has its objects as countries. It holds an *S-O* domain constraint.

Uniqueness constraints. This type of constrains enforces the uniqueness of the subjects and objects of relations. Given a relation r_i $(1 \leq i \leq k)$, (1) an *S uniqueness constraint* ensures that there exist no subject s and objects $o_h \neq o_l$ such that both (s, r_i, o_h) and (s, r_i, o_l) hold, and (2) an *O uniqueness constraint* ensures that there exist no object o and subjects $s_h \neq s_l$ such that both (s_h, r_i, o) and (s_l, r_i, o) hold, respectively.

For example, relation *capital* holds both *S* and *O* uniqueness constraints, since a country as the subject of *capital* has only one capital, and a city as the object of *capital* can only be the capital of one country.

We refer to the total set of relations with *S-S* (resp. *O-O* and *S-O*) domain constraints as DC_{ss} (resp. DC_{oo} and DC_{so}). We also refer to the total set of relations with *S* (resp. *O*) uniqueness constraints as UC_s (resp. UC_o).

2.2 Information Redundancies

Redundancies are used to pick up hidden information (Downey et al., 2005; Banko et al., 2007; Li et al., 2011), and are very common in the corpus, as revealed by the statistics in Table 2. They are essentially the statistical characteristics (knowledge) of the results produced by local sentence level extractors, and are very important for global predictions. In this study, we introduce and leverage four classes of information redundancies: S-O, S-R, O-R and R redundancies.

S-O redundancies are introduced to aid the decision making of the top-one relations of mentions with the same subjects and objects. For a mention $m = (s, o, r_1 : c_1, \ldots, r_k : c_k)$ preprocessed by a sentence level extractor, its certainty degree $\mathsf{ent}(\mathsf{m})$ is defined as follows.

$$\mathsf{ent}(\mathsf{m}) = -\sum_{i=1}^{k} c_i \ln c_i. \quad (1)$$

The redundancy score $\mathsf{RC}(\mathsf{s}, \mathsf{r}_1, \mathsf{o})$ of the top-one relation r_1 for subject s and object o in m, based on its S-O redundancies, is defined as

$$\mathsf{RC}(\mathsf{s}, \mathsf{r}_1, \mathsf{o}) = \sum_{m' \in M_{s,o,r_1}} \alpha^{\mathsf{ent}(\mathsf{m}')}, \quad (2)$$

where M_{s,o,r_1} is the set of mentions in M whose subjects are s, objects are o, and top-one relations are r_1, and α is a small positive number in $(0, 1)$ (set to 0.05 by default) to enforce that $\alpha^{\mathsf{ent}(\mathsf{m}')}$ falls into $(0, 1)$. Informally, $\mathsf{RC}(\mathsf{s}, \mathsf{r}_1, \mathsf{o})$ is a collective score based on its S-O redundancies, which makes use of *information entropy* to judge the confidence, and considers both the relative confidence scores and repeated times.

S-R redundancies are introduced to aid the decision making whether a subject meets the domain requirement of a relation. The likelihood score $\mathsf{LC}(\mathsf{s}, \mathsf{r})$ for subject s and relation r, based on its S-R redundancies, is

$$\mathsf{LC}(\mathsf{s}, \mathsf{r}) = \frac{\sum_{m \in M_s} m[r].c}{\sum_{m \in M_s} \sum_{r' \in R \setminus \{NA\}} m[r'].c}, \quad (3)$$

where M_s is the set of mentions with the same subject s. Informally, $\mathsf{LC}(\mathsf{s}, \mathsf{r})$ measures the probability that relation r has a subject s among all relations except NA.

O-R redundancies are introduced to aid the decision making whether an object meets the domain requirement of a relation. The likelihood score $\mathsf{LC}(\mathsf{o}, \mathsf{r})$ for object o and relation r, based on its O-R redundancies, is

$$\mathsf{LC}(\mathsf{o}, \mathsf{r}) = \frac{\sum_{m \in M_o} m[r].c}{\sum_{m \in M_o} \sum_{r' \in R \setminus \{NA\}} m[r'].c}, \quad (4)$$

where M_o is the set of mentions with the same object o. Informally, $\mathsf{LC}(\mathsf{o}, \mathsf{r})$ measures the probability that relation r has an object o among all relations except NA.

R redundancies are introduced to aid the decision making whether a subject and an object have a non-NA relation. The likelihood score $\mathsf{LC}(\mathsf{s}, \mathsf{o})$ for subject s and object o, based on its R redundancies, is

$$\mathsf{LC}(\mathsf{s}, \mathsf{o}) = \max_{m \in M_{s,o}} \sum_{r \in R \setminus \{NA\}} m[r].c, \quad (5)$$

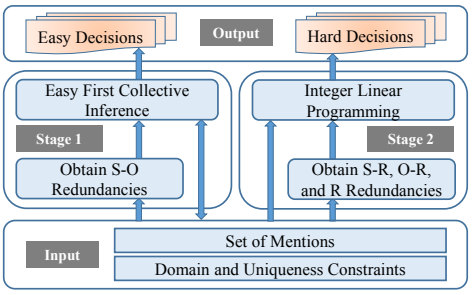

Figure 1: Framework of our approach eFIRE.

Input: a set M of mentions, a set of domain and uniqueness constraints, and a threshold ϵ.
Output: a set E of decision and updated M.
1. $E := \emptyset$;
2. Compute redundancy scores and sort with a max-heap MH;
3. **while** MH.Max() $> \epsilon$ **do**
4. $\quad (s, r, o, c) :=$ MH.popMax();
5. $\quad E := E \cup \{(s, r, o, c)\}$;
6. $\quad$ Conflict resolving by updating MH and M;
7. **return** E, M.

Figure 2: Algorithm for making easy decisions.

where $M_{s,o}$ is the set of mentions with the same subject s and object o. Informally, $\mathsf{LC(s, o)}$ selects prominent information from local decisions to measure the probability of having at least one non-NA relation between s and o.

As will be seen in the next section, redundancy scores $\mathsf{RC(s, r_1, o)}$ are used for making easy decisions, and likelihood scores $\mathsf{LC(s, r)}$, $\mathsf{LC(o, r)}$ and $\mathsf{LC(s, o)}$ are used for hard decisions, respectively.

3 Easy First Relation Extraction

We propose a novel easy FIrst approach for Relation Extraction with information redundancies, referred to as eFIRE. As shown by the framework in Figure 1, our approach obtains S-O redundancies, and makes easy decisions with easy first collective inference in the first stage. Then it derives S-R, O-R and R redundancies, and makes hard decisions with ILP in the second stage. We next introduce our approach in detail.

3.1 Easy First Collective Inference

In the first stage, decisions must be highly accurate to avoid error propagation. As revealed by Table 2, the decisions produced by local extractors are only reliable for top-one relations. Hence, eFIRE first makes decisions for entity pairs using their top-one relations only. The confidences are the redundancy scores obtained with the S-O redundancies (Section 2.2). Once a decision is made, disagreements are resolved immediately with domain and uniqueness constraints directly (Section 2.1).

Confidence computing and ordering. It computes the redundancy scores $\mathsf{RC(s, r_1, o)}$ of all the entity pairs (s, o) with their top-one relations r_1 in mentions M, using S-O redundancies. The higher the redundancy scores $\mathsf{RC(s, r_1, o)}$ are, the more confident subject s and object o have a relation r_1. Hence, entity pairs with their top-one relations are sorted in a descending order of their redundancy scores. As updating operations happen very often during the process of decision making, we introduce a max-heap MH to maintain all the entity pairs with their top-one relations and redundancy scores for the sake of efficiency.

Decision making and conflict resolving. It first makes a decision for the entity pair (s, o) by choosing its top-one relation r_1 such that the redundancy score $\mathsf{RC(s, r_1, o)}$ is the highest in MH.

Then it resolves conflicts accordingly. (1) For any relation $r \in R$ having an S-S domain constraint with r_1, all entity pairs with subject s and top-one relation r are deleted from MH, and for entity pairs with subject s in M, their scores of relation r are set to zeroes. It is similar for O-O and S-O domain constraints. (2) If relation r_1 has an S uniqueness constraint, all entity pairs with subject s and top-one relation r_1 are deleted from MH, and for entity pairs with subject s and object $o' \neq o$ in M, their scores of relation r_1 are set to zeroes. It is similar for O uniqueness constraints.

The above process is repeated until the highest redundancy score in the max-heap MH is less than a predefined threshold ϵ, which is to ensure the correctness of decisions. For the benefit of efficiency, we also index mentions by subjects, by objects and by entity pairs, separately.

The intention of threshold ϵ is to distinguish easy decisions from hard ones based on S-O redundancies. This indeed can be reflected from the redundancy scores. Consider an extreme case when there is only one mention m in M with subject s, object o and top-one relation r_1 whose score is 1.0, *i.e.,* there are no S-O redundancies for mention m. In this case, we have $\mathsf{RC(s, r_1, o)} = 1.0$. However, for cases when multiple mentions with the same subject s, object o and top-one relation r_1, it is likely that the redundancy score is less than 1.0. Hence, threshold ϵ is typically set to a value a

little less than 1.0.

Our approach makes a better use of information redundancies in the corpus to aid the decision making process. Recall the example on determining whether the capital of "United States" is "New York" or "Washington D.C." in Section 1. With the S-O redundancies, "Washington D.C." is chosen as the capital of "United States", as $\mathsf{RC}(\mathsf{United\ States}, \textit{capital}, \mathsf{New\ York}) = 0.18$ and $\mathsf{RC}(\mathsf{United\ States}, \textit{capital}, \mathsf{Washington\ D.C.}) = 0.57$, which justifies the rationale of introducing the certainty degree $\mathsf{ent}(\mathsf{m})$ for mentions m.

Complete algorithm for easy first inference. The complete algorithm is presented in Figure 2.

It first initializes the set E of easy decisions empty (line 1). It then computes the redundancy scores of all the entity pairs with their top-one relations in mentions M, using S-O redundancies, and these entity pairs with their top-one relations are sorted in a descending order of their redundancy scores with a max heap MH (line 2). It repeatedly deals with entity pairs and their top-one relations in MH one by one until the highest redundancy score in MH is no more than ϵ (lines 3-6). Once a decision is made (lines 4, 5), conflicts are resolved immediately by updating MH and M (line 6). Finally, the modified mentions M and a set E of easy decisions are returned (line 7).

Time and space complexity analyses. The algorithm runs in $O(|M|^2(|R| + \log|M|))$ time, where $|M|$ and $|R|$ are the numbers of mentions and predefined relations, respectively. Observe the following. For a mention, (1) it takes $O(|R| + \log|M|)$ time to compute the redundancy scores for all entity pairs with their top-one relations, (2) maintaining MH can be done in $O(\log|M|)$ time, and (3) decision making and conflict resolving take $O(|M|(|R|+\log|M|))$ time. As there are in total $|M|$ mentions, we have the conclusion.

It is easy to see that the algorithm takes a space in the linear size of the set M of mentions.

3.2 Integer Linear Programming

In the second stage, our goal is to find an optimal configuration for the remaining mentions, making use of S-R, O-R and R redundancies, solving the disagreements by domain and uniqueness constraints, and maximizing the overall confidence of the made decisions. This is an NP-hard optimization problem, and many optimization models can be used to obtain approximate solutions. The tricky part is the design of the objective functions. Here, we adopt the ILP tool "IBM ILOG CPLEX".

More specifically, for each mention m and each of its candidate relations r in the set M of remaining mentions returned in the first stage, we define a binary decision variable v_m^r indicating whether relation r is chosen for the entity pair (s, o) in m by the solver. For each mention m in M, we choose its top three relations with scores no less than 0.1 as the candidate relations. As revealed by Table 2, candidates beyond top-3 are very unreliable.

Our objective is to maximize the total confidence of all the selected candidates based on the S-R, O-R and R redundancies, and the objective function can be written as:

$$\max \sum_{m\in M, r\in R^m} \big(\mathsf{LC}(\mathsf{s},\mathsf{r})+\mathsf{LC}(\mathsf{o},\mathsf{r})+\mathsf{LC}(\mathsf{s},\mathsf{o}) + \sum_{m'\in M_m} m'[r].c\big) v_m^r, \tag{6}$$

where s and o are the subject and object in m, R^m is the set of candidate relations for s and o in m, and M_m is the set of mentions in M having the same subject and object as m. The first component is the sum of S-R, O-R, and R redundancies of the selected candidates, and the second one is the sum of the original confidence scores of the selected candidates. The former is designed to encourage the model to select candidates meeting the domain requirements of relations, and the latter is designed to give consideration to decisions produced by sentence level extractors. That is, although the sentence level extractors may make wrong decisions, the global statistics of their decisions are reliable, and should be preserved.

The domain and uniqueness constraints are encoded to avoid conflict decisions as follows.

$$v_{m_i}^{r^{m_i}} + v_{m_j}^{r^{m_j}} \le 1, \tag{7}$$

where m_i and m_j have the same subject, $r^{m_i} \in R^{m_i}$, $r^{m_j} \in R^{m_j}$, and r^{m_i} and r^{m_j} have an S-S domain constraint in DC_{ss}.

$$v_{m_i}^{r^{m_i}} + v_{m_j}^{r^{m_j}} \le 1, \tag{8}$$

where m_i and m_j have the same object, $r^{m_i} \in R^{m_i}$, $r^{m_j} \in R^{m_j}$, and r^{m_i} and r^{m_j} have an O-O domain constraint in DC_{oo}.

$$v_{m_i}^{r^{m_i}} + v_{m_j}^{r^{m_j}} \le 1, \tag{9}$$

Datasets	Methods	Running time(s)	# of ILP variables	# of ILP constraints
DB_me	baseline	52.70	12353	293361

	PCNN+ATT	34.55	-	-

Table 3: Efficiency of eFIRE and comparison methods.

where the subject of m_i is the object of m_j, $r^{m_i} \in R^{m_i}$, $r^{m_j} \in R^{m_j}$, and r^{m_i} and r^{m_j} have an S-O domain constraint in DC_{so}.

$$\sum_{m \in M_{r,s}} v_m^r \leq 1, \tag{10}$$

where $M_{r,s}$ is the set of mentions with candidate relation r, subject s and pairwise distinct objects, and r has an S uniqueness constraint in UC_s.

$$\sum_{m \in M_{r,o}} v_m^r \leq 1, \tag{11}$$

where $M_{r,o}$ is the set of mentions with candidate relation r, object o and pairwise distinct subjects, and r has an O uniqueness constraint in UC_o.

By adopting ILP, eFIRE combines the scores refined in the first stage and the constraints to make hard decisions. After the optimization problem is solved, together with the easy decisions obtained in the first stage, eFIRE finally produces a list of selected candidate relations for each entity pair.

4 Experimental Study

In this section, we present an extensive experimental study of our easy first approach eFIRE.

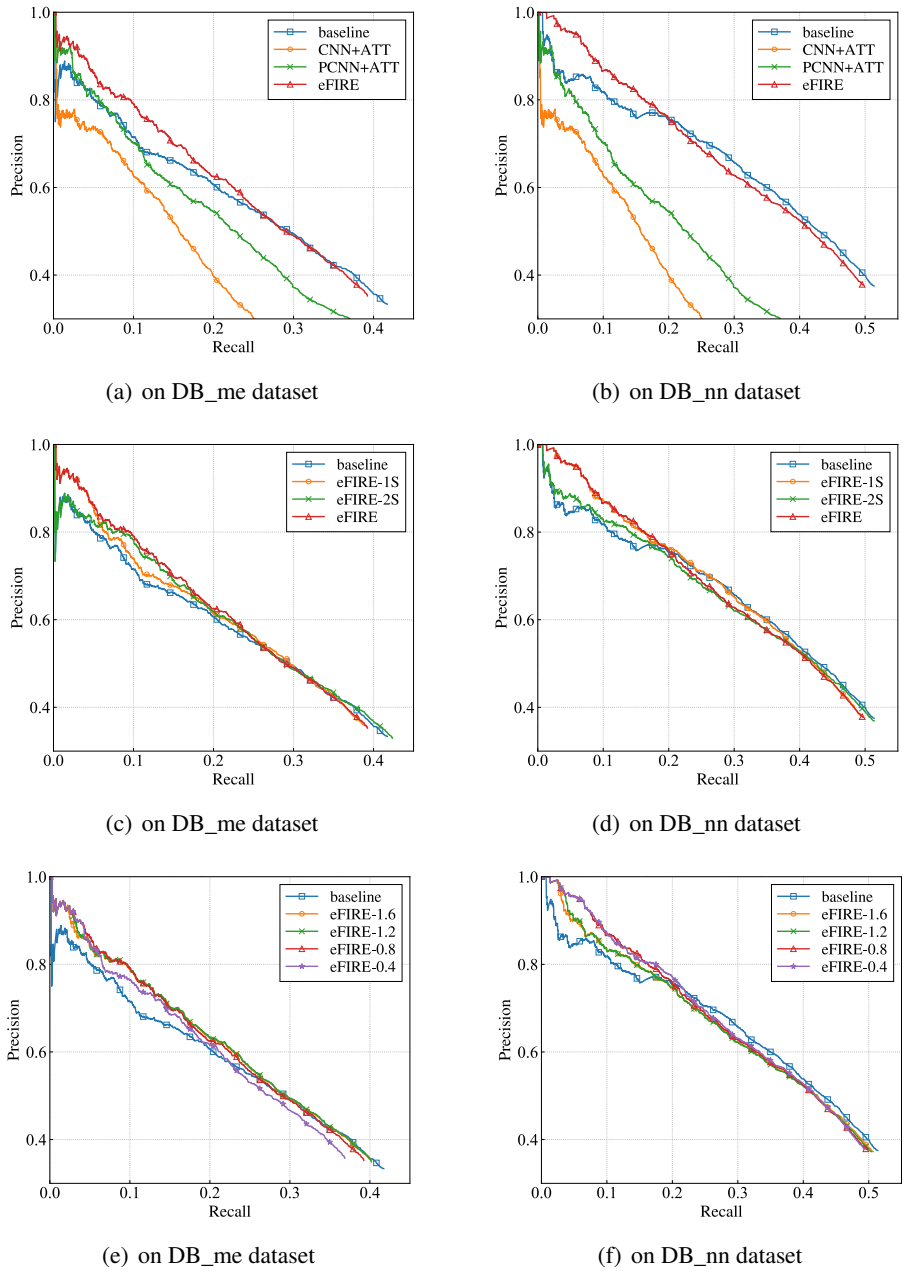
4.1 Experimental Settings

We first present our experimental settings.

Datasets. The two datasets, DB_me and DB_nn, stem from DBpedia (Bizer et al., 2009), mapping the triples in DBpedia to sentences in the New York Time corpus. We map 51 different relations to the dataset. We use both a maximum entropy model MaxEnt (Chen et al., 2014a) and neural network model NN (Lin et al., 2016) as the sentence level extractors to output confidence scores, denoted as DB_me and DB_nn, respectively. The features of these two datasets are reported in Table 2. There are 53162 mentions in each dataset, including 38654 mentions with NA relations. We learn domain and uniqueness constraints from Freebase as knowledge base (KB).

Algorithms for comparison. To evaluate our approach, we compare with three methods: the ILP based global method for RE in (Chen et al., 2014a) as baseline that use the global clues to help resolve the disagreements, and CNN+ATT and PCNN+ATT in (Lin et al., 2016) that are neural network-based methods with attention mechanism to use all informative sentences.

Implementation. All algorithms were implemented with C++. All experiments were run on a PC with 2 Intel(R) Xeon(R) E5ÍC2640 2.6GHz CPUs and 64 GB of memory. When running time is measured, the test was repeated over 5 times and the average is reported.



4.2 Experimental Results

We next present our findings of the effectiveness and efficiency of our easy first approach eFIRE. Following previous work, we also use the precision in the low recall portion of the P-R curve as the effectiveness criterion.

Exp-1: Overall performance. In the first set of tests, we evaluated the effectiveness and efficiency, and the results are reported in Figures 3(a), 3(b) and Table 3, respectively.

Our approach eFIRE outperforms the methods for comparison. eFIRE is on average (4.80%, 4.36%), (17.99%, 28.10%) and (7.69%, 17.82%) more accurate than baseline, CNN+ATT and PCNN+ATT on (DB_me, DB_nn) in the low-recall portion $[0, 0.25]$ of the P-R curves, respectively. eFIRE consistently outperforms CNN+ATT and PCNN+ATT over the entire range of recall. While baseline tends to have results with a higher recall, it has a weakness of low precision, which is alleviated by eFIRE that is able to obtain more correct decisions. It is difficult to guarantee high precision and recall at the same time. For most KB population applications, only the high precision part is considered for the effectiveness evaluation. It is worth pointing out that we only compare the testing time of CNN+ATT and PCNN+ATT here.

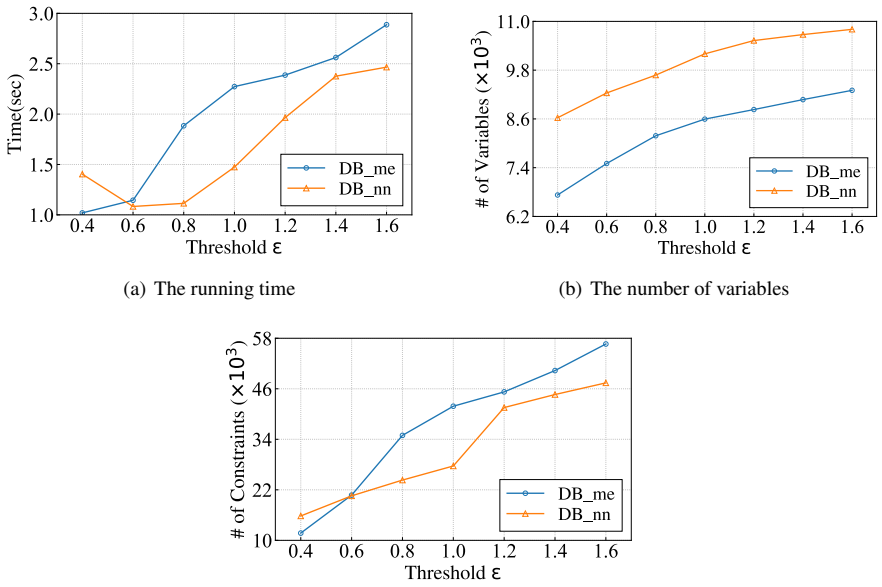
Our method eFIRE also reduces the running time on all datasets. eFIRE is on average (28, 14), (37, 63) and (18, 31) times faster than baseline, CNN+ATT and PCNN+ATT on (DB_me, DB_nn), respectively. This is because the easy-first strategy of eFIRE significantly re-

(a) on DB_me dataset (b) on DB_nn dataset

(c) on DB_me dataset (d) on DB_nn dataset

(e) on DB_me dataset (f) on DB_nn dataset

Figure 3: Overall performances: eFIRE vs. its variants vs. baseline vs. CNN+ATT vs. PCNN+ATT.



duces the number of variables and constraints encoded in the ILP solver, as shown in Table 3.

Note that the running time has no obvious linear relationships with the number of variables and constraints among different datasets. In addition to the number of variables and constraints, objective functions have a impact on the running time of ILP too. Further, CPLEX is used as a black box, which makes it hard to have a precise analysis.

These results tell us that the easy-first strategy for RE, by making use of the redundancy information embedded in the local results of sentence level extractors, is an effective and efficient complement for RE using ILP solvers.

Exp-2: Performance of easy first collective inference with S-O redundancies. In the second set of tests, in order to evaluate the impacts of S-O redundancies, we implemented a variant of our approach, referred to as eFIRE-1S, that makes easy decisions with the easy first collective inference, and then adopts the same ILP method in baseline for making the rest decisions. The results are reported in Figures 3(c), 3(d), and Table 3.

Method eFIRE-1S outperforms baseline in the

(a) The running time

(b) The number of variables

(c) The number of constraints

Figure 4: Impacts of threshold ϵ on time, variables and constraints.

low-recall portions of the P-R curves on all two datasets. These results tell us that the easy first collective inference using S-O redundancies can not only improve the effectiveness of decision making for RE, but also improve the efficiency, as it significantly reduces the constraints and variables encoded in the ILP solver.

Exp-3: Performance of ILP with S-R, O-R and R redundancies. In the third set of tests, to evaluate the impacts of S-R, O-R and R redundancies, we implemented a variant of eFIRE, referred to as eFIRE-2S, that only consists of the second stage of eFIRE. That is, all decisions of eFIRE-2S are made by the ILP solver. The results are reported in Figures 3(c), 3(d) and Table 3.

Method eFIRE-2S outperforms baseline on all two datasets. It essentially improves the precision without sacrificing the recall. For ILP based methods, their key differences are the objective functions. eFIRE-2S incorporates more reliable statistics of sentence level extractors, *i.e.,* S-R, O-R and R redundancies, while baseline only uses maximal scores to encourage choosing the candidates with higher individual sentence level confidence scores. So, S-R, O-R and R redundancies benefit the decision making of ILP solvers. The efficiency of eFIRE-2S and baseline are comparable, which implies that the efficiency benefit of eFIRE comes from its first stage easy first collective inference.

Exp-4: Setting verification of threshold ϵ. In the last set of tests, to verify the setting of threshold ϵ, we varied its values to $[0.4, 1.6]$. The results of effectiveness and running time are reported in Figures 3(e), 3(f) and Figure 4, respectively.

The results show that our approach eFIRE is effective and efficient when ϵ falls into $[0.5, 0.9]$, during which eFIRE outperforms baseline in the low-recall portion. This justifies our setting for threshold ϵ, which is typically a little less than 1.0 to distinguish easy decisions from hard ones (Section 3.1). Threshold ϵ obviously has an impact on the running time, as the smaller ϵ is, the more running time eFIRE has in the first stage, and the less it has in the second stage.

Summary. From these tests, we find followings.

(1) Our approach eFIRE is both effective and efficient. It is more accurate than baseline in the low-recall portion $[0, 0.25]$ and CNN+ATT and PCNN+ATT consistently. eFIRE is on average (4.58%, 23.05%, 12.76%) more accurate in the low-recall portion and (21, 50, 25) times faster than baseline, CNN+ATT and PCNN+ATT, respectively. (2) The use of the easy-first strategy and S-O redundancies both improves the accuracy of RE and reduces the running time, and the use of S-R, O-R and R redundancies improves the accuracy of RE. (3) The setting of threshold ϵ is flexible in a range of $[0.5, 0.9]$ for our approach eFIRE.

5 Related Work

Relation extraction has been studied extensively in recent years, and can be divided into local re-

lation extractors (Mintz et al., 2009; Surdeanu et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Søgaard et al., 2015) using the lexical features, syntactic features, and other local features of sentences, and global relation extractors utilizing the corpus features and relationships among local decisions (Kate and Mooney, 2010; Yao et al., 2010; Li et al., 2011; Singh et al., 2013; Li and Ji, 2014; Nguyen et al., 2017; Su et al., 2017). Global relation extractors leverage more information to resolve conflict decisions, which typically leads to more accurate decisions than local ones.

Recently, neural network-based models (Zeng et al., 2014; Ji et al., 2017) have been proposed for RE. Lin et al. (2016) proposes an attention mechanism to calculate weights for all sentences of one entity pair and selects plausible sentences from noisy sentences. Different from these are supervised methods that need label data for training, we propose an unsupervised method in this study.

Disagreements among decisions can be resolved by constraints. Yao et al. (2010) propose a relation extraction model that captures selectional preferences and functionality constraints to integrate information across documents. Fader et al. (2011) implement syntactic and lexical constraints on binary relations expressed by verbs in Open IE systems. Koch et al. (2014) impose type (or domain) constraints to only allow relations over appropriately typed mentions for relation extraction. Similar to (Chen et al., 2014a), our approach utilizes both domain and uniqueness constraints to resolve disagreements.

Many global relation extractors use integer linear programming as a blackbox solver (Roth and Yih, 2004; Choi et al., 2006; Roth and Yih, 2007; Li et al., 2011; Ji et al., 2013; Chen et al., 2014a,b; Wang et al., 2015). The ILP solver derives decisions through a well designed objective function, and resolves conflict decisions by encoding constraints into ILP. Our easy first approach is complimentary to these methods with each other, as these methods can take the easy first collective inference of our approach for making easy decisions as a first step, and our approach can make use of any of these methods as its solution for making hard decisions in its second stage.

Redundancies in the corpus have been used to pick up hidden information. Downey et al. (2005) consider redundant extractions for judging the correctness of extractions. Li et al. (2011) take advantage of redundant information to conduct reasoning across documents based on the information network structure. We introduce four classes of information redundancies: S-O, S-R, O-R and R redundancies, and we leverage S-O redundancies for making easy decisions, and the others to aid hard decision making.

Easy-first strategy relies on the intuition that "easy decisions should be made early, while harder decisions should be left for later when more information is available (Stoyanov and Eisner, 2012)". Their method makes easy decisions first for coreference resolution, and further makes use of the information from coreference clusters in the form of features to make later decisions. In this study, we propose to make easy (most confident) decisions first for relation extraction, and then to make hard decisions with ILP, where easy decisions are distinguished from hard ones with redundance scores based on S-O redundancies.

Data dependencies have well studied for improving data quality (Ma, 2011; Ma et al., 2015; Fan and Geerts, 2012), which essentially make use of data redundancies and dependencies. Our approach is partially inspired by these studies. Indeed, the uniqueness constraints defined in this study can be treated as functional dependencies (Abiteboul et al., 1995).

6 Conclusions

In this paper, we have proposed a fast easy first approach for relation extraction by making use of information redundancies, embedded in the results produced by local sentence level extractors, under domain and uniqueness constraints. We have introduced four classes of information redundancies to aid both easy first collective inference for easy decisions in the first stage and ILP for hard decisions in the second stage. Finally, using datasets processed by sentence level extractors with different models, we have experimentally verified that our easy first approach is both effective and efficient compared with state-of-the-art both ILP and neural network-based methods.

Dependency-Guided LSTM-CRF for Named Entity Recognition

Zhanming Jie and **Wei Lu**
StatNLP Research Group
Singapore University of Technology and Design
zhanming_jie@mymail.sutd.edu.sg, luwei@sutd.edu.sg

Abstract

Dependency tree structures capture long-distance and syntactic relationships between words in a sentence. The syntactic relations (e.g., *nominal subject*, *object*) can potentially infer the existence of certain named entities. In addition, the performance of a named entity recognizer could benefit from the long-distance dependencies between the words in dependency trees. In this work, we propose a simple yet effective *dependency-guided* LSTM-CRF model to encode the complete dependency trees and capture the above properties for the task of named entity recognition (NER). The data statistics show strong correlations between the entity types and dependency relations. We conduct extensive experiments on several standard datasets and demonstrate the effectiveness of the proposed model in improving NER and achieving state-of-the-art performance. Our analysis reveals that the significant improvements mainly result from the dependency relations and long-distance interactions provided by dependency trees.

1 Introduction

Named entity recognition (NER) is one of the most important and fundamental tasks in natural language processing (NLP). Named entities capture useful semantic information which was shown helpful for downstream NLP tasks such as coreference resolution (Lee et al., 2017), relation extraction (Miwa and Bansal, 2016) and semantic parsing (Dong and Lapata, 2018). On the other hand, dependency trees also capture useful semantic information within natural language sentences. Currently, research efforts have derived useful discrete features from dependency structures (Sasano and Kurohashi, 2008; Cucchiarelli and Velardi, 2001; Ling and Weld, 2012) or structural constraints (Jie et al., 2017) to help the NER task. However, how to make good use of the rich relational information as well as complex long-distance interactions among words as conveyed by the complete dependency structures for improved NER remains a research question to be answered.

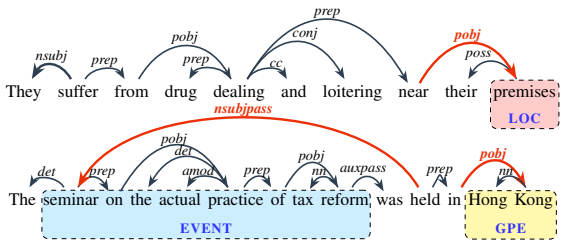

Figure 1: Example sentences annotated with named entiteis and dependencies in the OntoNotes 5.0 dataset.

The first example in Figure 1 illustrates the relationship between a dependency structure and a named entity. Specifically, the word "*premises*", which is a named entity of type LOC (location), is characterized by the incoming arc with label "*pobj*" (prepositional object). This arc reveals a certain level of the semantic role that the word "*premises*" plays in the sentence. Similarly, the two words "*Hong Kong*" in the second example that form an entity of type GPE are also characterized by a similar dependency arc towards them.

The long-distance dependencies capturing non-local structural information can also be very helpful for the NER task (Finkel et al., 2005). In the second example of Figure 1, the long-distance dependency from "*held*" to "*seminar*" indicates a direct relation "*nsubjpass*" (passive subject) between them, which can be used to characterize the existence of an entity. However, existing NER models based on linear-chain structures would have difficulties in capturing such long-distance relations (i.e., non-local structures).

One interesting property, as highlighted in the work of Jie et al. (2017), is that most of the en-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3862–3872,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tities form subtrees under their corresponding dependency trees. In the example of the EVENT entity in Figure 1, the entity itself forms a subtree and the words inside have rich complex dependencies among themselves. Exploiting such dependency edges within the subtrees allows a model to capture non-trivial semantic-level interactions between words within long entities. For example, "*practice*" is the prepositional object (*pobj*) of "*on*" which is a preposition (*prep*) of "*seminar*" in the EVENT entity. Modeling these grandchild dependencies (GD) (Koo and Collins, 2010) requires the model to capture some higher-order long-distance interactions among different words in a sentence.

Inspired by the above characteristics of dependency structures, in this work, we propose a simple yet effective dependency-guided model for NER. Our neural network based model is able to capture both contextual information and rich long-distance interactions between words for the NER task. Through extensive experiments on several datasets on different languages, we demonstrate the effectiveness of our model, which achieves the state-of-the-art performance. To the best of our knowledge, this is the first work that leverages the complete dependency graphs for NER. We make our code publicly available at `http://www.statnlp.org/research/information-extraction`.

2 Related Work

NER has been a long-standing task in the field of NLP. While many recent works (Peters et al., 2018a; Akbik et al., 2018; Devlin et al., 2019) focus on finding good contextualized word representations for improving NER, our work is mostly related to the literature that focuses on employing dependency trees for improving NER.

Sasano and Kurohashi (2008) exploited the syntactic dependency features for Japanese NER and achieved improved performance with a support vector machine (SVM) (Cortes and Vapnik, 1995) classifier. Similarly, Ling and Weld (2012) included the head word in a dependency edge as features for fine-grained entity recognition. Their approach is a pipeline where they extract the entity mentions with linear-chain conditional random fields (CRF) (Lafferty et al., 2001) and used a classifier to predict the entity type. Liu et al. (2010) proposed to link the words that are associated with selected typed dependencies (e.g., "*nn*", "*prep*") using a skip-chain CRF (Sutton and McCallum, 2004) model. They showed that some specific relations between the words can be exploited for improved NER. Cucchiarelli and Velardi (2001) applied a dependency parser to obtain the syntactic relations for the purpose of unsupervised NER. The resulting relation information serves as the features for potential existence of named entities. Jie et al. (2017) proposed an efficient dependency-guided model based on the semi-Markov CRF (Sarawagi and Cohen, 2004) for NER. The purpose is to reduce time complexity while maintaining the non-Markovian features. They observed certain relationships between the dependency edges and the named entities. Such relationships are able to define a reduced search space for their model. While these previous approaches do not make full use of the dependency tree structures, we focus on exploring neural architectures to exploit the complete structural information conveyed by the dependency trees.

3 Model

Our dependency-guided model is based on the state-of-the-art BiLSTM-CRF model proposed by Lample et al. (2016). We first briefly present their model as background and next present our dependency-guided model.

3.1 Background: BiLSTM-CRF

In the task of named entity recognition, we aim to predict the label sequence $\mathbf{y} = \{y_1, y_2, \cdots, y_n\}$ given the input sentence $\mathbf{x} = \{x_1, x_2, \cdots, x_n\}$ where n is the number of words. The labels in $\mathbf{y}$ are defined by a label set with the standard IOBES[1] labeling scheme (Ramshaw and Marcus, 1999; Ratinov and Roth, 2009). The CRF (Lafferty et al., 2001) layer defines the probability of the label sequence $\mathbf{y}$ given $\mathbf{x}$:

$$P(\mathbf{y}|\mathbf{x}) = \frac{\exp(score(\mathbf{x}, \mathbf{y}))}{\sum_{\mathbf{y}'} \exp(score(\mathbf{x}, \mathbf{y}'))} \quad (1)$$

Following Lample et al. (2016), the score is defined as the sum of transitions and emissions from the bidirectional LSTM (BiLSTM):

$$score(\mathbf{x}, \mathbf{y}) = \sum_{i=0}^{n} A_{y_i, y_{i+1}} + \sum_{i=1}^{n} F_{\mathbf{x}, y_i} \quad (2)$$

[1] "S-" indicates the entity with a single word and "E-" indicates the end of an entity.

where $\mathbf{A}$ is a transition matrix in which $A_{y_i,y_{i+1}}$ is the transition parameter from the label y_i to the label y_{i+1}[2]. $\mathbf{F}_{\mathbf{x}}$ is an emission matrix where $F_{\mathbf{x},y_i}$ represents the scores of the label y_i at the i-th position. Such scores are provided by the parameterized LSTM (Hochreiter and Schmidhuber, 1997) networks. During training, we minimize the negative log-likelihood to obtain the model parameters including both LSTM and transition parameters.

3.2 Dependency-Guided LSTM-CRF

Input Representations The word representation $\mathbf{w}$ in the BiLSTM-CRF (Lample et al., 2016; Ma and Hovy, 2016; Reimers and Gurevych, 2017) model consists of the concatenation of the word embedding as well as the corresponding character-based representation. Inspired by the fact that each word (except the root) in a sentence has exactly one *head* (i.e., *parent*) word in the dependency structure, we can enhance the word representations with such dependency information. Similar to the work by Miwa and Bansal (2016), we concatenate the word representation together with the corresponding head word representation and dependency relation embedding as the input representation. Specifically, given a dependency edge (x_h, x_i, r) with x_h as parent, x_i as child and r as dependency relation, the representation at position i can be denoted as:

$$\mathbf{u}_i = [\mathbf{w}_i; \mathbf{w}_h; \mathbf{v}_r], \quad x_h = parent(x_i) \qquad (3)$$

where $\mathbf{w}_i$ and $\mathbf{w}_h$ are the word representations of the word x_i and its parent x_h, respectively. We take the final hidden state of character-level BiLSTM as the character-based representation (Lample et al., 2016). $\mathbf{v}_r$ is the embedding for the dependency relation r. These relation embeddings are randomly initialized and fine-tuned during training. The above representation allows us to capture the direct long-distance interactions at the input layer. For the word that is a root of the dependency tree, we treat its parent as itself[3] and create a root relation embedding. Additionally, contextualized word representations (e.g., ELMo) can also be concatenated into $\mathbf{u}$.

Neural Architecture Given the dependency-encoded input representation $\mathbf{u}$, we apply the LSTM to capture the contextual information and model the interactions between the words and their corresponding parents in the dependency trees. Figure 2 shows the proposed dependency-guided LSTM-CRF (**DGLSTM-CRF**) with 2 LSTM layers for the example sentence "*Abramov had an accident in Moscow*" and its dependency structure. The corresponding label sequence is {S-PER, O, O, O, O, S-GPE}. Followed by the first BiLSTM, the hidden states at each position will propagate to the next BiLSTM layer and its child along the dependency trees. For example, the hidden state of the word "*had*", $\mathbf{h}_2^{(1)}$, will propagate to its child "*Abramov*" at the first position. For the word that is root, the hidden state at that specific position will propagate to itself. We use an *interaction function* $g(\mathbf{h}_i, \mathbf{h}_{p_i})$ to capture the interaction between the child and its parent in a dependency. Such an interaction function can be concatenation, addition or a multilayer perceptron (MLP). We further apply another BiLSTM layer on top of the interaction functions to produce the context representation for the final CRF layer.

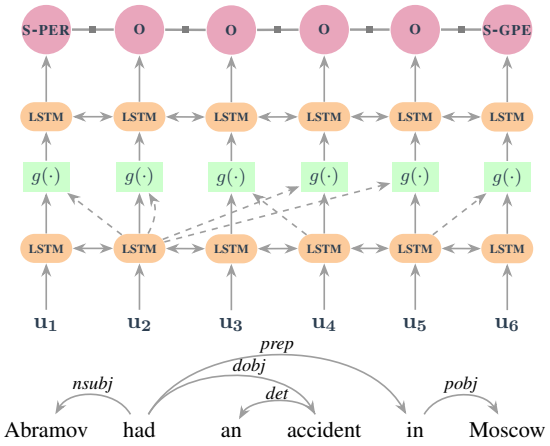

Figure 2: Dependency-guided LSTM-CRF with 2 LSTM Layers. Dashed connections mimic the dependency edges. "$g(\cdot)$" represents the interaction function.

The architecture shown in Figure 2 with a 2-layer BiLSTM can effectively encode the grandchild dependencies because the input representations encode the parent information and the interaction function further propagate the grandparent information. Such propagations allow the model to capture the indirect long-distance interactions from the grandchild dependencies between the words in the sentence as mentioned in Section 1. In general, we can stack more interaction functions and BiLSTMs to enable deeper reasoning over the dependency trees. Specifically, the hid-

[2] y_0 and y_{n+1} are `start` and `end` labels.

[3] We also tried using a root word embedding but the performance is similar.

Interaction Function	$g(\mathbf{h}_i, \mathbf{h}_{p_i})$
Self connection	$\mathbf{h}_i$
Concatenation	$\mathbf{h}_i \bigoplus \mathbf{h}_{p_i}$
Addition	$\mathbf{h}_i + \mathbf{h}_{p_i}$
MLP	$\text{ReLU}(\mathbf{W}_1\mathbf{h}_i + \mathbf{W}_2\mathbf{h}_{p_i})$

Table 1: List of interaction functions.

den states of the $(l+1)$-th layer $\mathbf{H}^{(l+1)}$ can be calculated from the hidden state of the previous layer $\mathbf{H}^{(l)}$:

$$\mathbf{H}^{(l+1)} = \text{BiLSTM}\Big(f\big(\mathbf{H}^{(l)}\big)\Big)$$
$$\mathbf{H}^{(l)} = \Big[\mathbf{h}_1^{(l)}, \mathbf{h}_2^{(l)}, \cdots, \mathbf{h}_n^{(l)}\Big]$$
$$f\big(\mathbf{H}^{(l)}\big) = \Big[g(\mathbf{h}_1^{(l)}, \mathbf{h}_{p_1}^{(l)}), \cdots, g(\mathbf{h}_n^{(l)}, \mathbf{h}_{p_n}^{(l)})\Big]$$

where p_i indicates the parent index of the word x_i. $g(\mathbf{h}_i^{(l)}, \mathbf{h}_{p_i}^{(l)})$ represents the interaction functions between the hidden state at the i-th and p_i-th positions under the dependency edges (x_{p_i}, x_i). The number of layers L can be chosen according to the performance on the development set.

Interaction Function The interaction function between the parent and child representations can be defined in various ways. Table 1 shows the list of interaction function considered in our experiments. The first one returns the hidden state itself, which is equivalent to stacking the LSTM layers. The concatenation and addition involve no parameter, which are straightforward ways to model the interactions. The last one applies an MLP to model the interaction between parent and child representations. With the rectified linear unit (ReLU) as activation function, the $g(\mathbf{h}_i, \mathbf{h}_{p_i})$ function is analogous to a graph convolutional network (GCN) (Kipf and Welling, 2017) formulation. In such a graph, each node has a self connection (i.e., $\mathbf{h}_i$) and a dependency connection with parent (i.e., $\mathbf{h}_{p_i}$). Similar to the work by Marcheggiani and Titov (2017), we adopt different parameters $\mathbf{W}_1$ and $\mathbf{W}_2$ for self and dependency connections.

4 Experiments

Datasets The main experiments are conducted on the large-scale OntoNotes 5.0 (Weischedel et al., 2013) English and Chinese datasets. We chose these datasets because they contain both constituency tree and named entity annotations. There are 18 types of entities defined in the OntoNotes dataset. We convert the constituency trees into the Stanford dependency (De Marneffe and Manning, 2008) trees using the rule-based tool (De Marneffe et al., 2006) by Stanford CoreNLP (Manning et al., 2014). For English, Pradhan et al. (2013) provided the train/dev/test split[4] and the split has been used by several previous works (Chiu and Nichols, 2016; Li et al., 2017; Ghaddar and Langlais, 2018). For Chinese, we use the official splits provided by Pradhan et al. (2012)[5].

Dataset	Train		Dev		Test		ST	GD
	# Sent.	# Entity	# Sent.	# Entity	# Sent.	# Entity	(%)	(%)
OntoNotes 5.0 - English	59,924	81,828	8,528	11,066	8,262	11,057	98.5	41.1
OntoNotes 5.0 - Chinese	36,487	62,543	6,083	9,104	4,472	7,494	92.9	49.1
SemEval2010T1 - Catalan	8,709	15,278	1,445	2,431	1,698	2,910	100.0	28.6
SemEval2010T1 - Spanish	9,022	17,297	1,419	2,615	1,705	3,046	100.0	29.8

Table 2: Dataset statistics. "ST" is the ratio of entities that form subtrees. "GD" is the ratio of entities that have grandchild dependencies within their subtrees.

Besides, we also conduct experiments on the Catalan and Spanish datasets from the SemEval-2010 Task 1[6] (Recasens et al., 2010)[7]. The SemEval-2010 task was originally designed for the task of coreference resolution in multiple languages. Again, we chose these corpora primarily because they contain both dependency and named entity annotations. Following Finkel and Manning (2009) and Jie et al. (2017), we select the most dominant three entity types and merge the rest into one general a entity type "*misc*". Table 2 shows the statistics of the datasets used in main experiments. To further evaluate the effectiveness of the dependency structures, we also conduct additional experiments under a low-resource setting for NER (Cotterell and Duh, 2017).

The last two columns of Table 2 show the relationships between the dependency trees and named entities with length larger than 2 for the complete dataset. Specifically, the penultimate column shows the percentage of entities that can form a complete subtree (ST) under their dependency tree structures. Apparently, most of the entities form subtrees, especially for the Catalan and Spanish datasets where 100% entities form subtrees. This observation is consistent with the findings reported in Jie et al. (2017). The last column in Table 2 shows the percentage of the grandchild

[6]http://stel.ub.edu/semeval2010-coref/download
[7]This dataset also has English portion but it is a subset of the OntoNotes English.

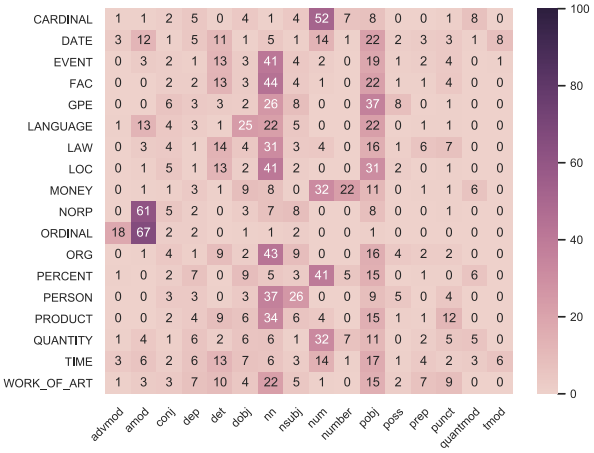

Figure 3: Percentage of entity words (y axis) with respect to dependency relations (x axis) in the OntoNotes English dataset. Columns with percentage less than 5% are ignored for brevity.

dependencies (Koo and Collins, 2010) (GD) that exist in these subtrees (i.e., entities). Such grandchild dependencies could be useful for detecting certain named entities, especially for long entities. As we will see later in Section 5, the performance of long entities can be significantly improved with our dependency-guide model.

The heatmap table in Figure 3 shows the correlation between the entity types and the dependency relations in the OntoNotes English dataset. Specifically, each entry denotes the percentage of the entities that have a parent dependency with a specific dependency relation. For example, at the row with GPE entity, 37% of the entity words[8] have a dependency edge whose label is "*pobj*". When looking at column of "*pobj*" and "*nn*", we can see that most of the entities relate to the prepositional object (*pobj*) and noun compound modifier (*nn*) dependencies. Especially for the NORP (i.e., *nationalities or religious or political groups*) and ORDINAL (e.g., "*first*", "*second*") entities, more than 60% of the entity words have the dependency with adjectival modifier (*amod*) relation. Furthermore, every entity type (i.e., row) has a most related dependency relation (with more than 17% occurrences). Such observations present useful information that can be used to categorize named entities with different types.

Baselines We implemented the state-of-the-art NER model **BiLSTM-CRF** (Lample et al., 2016) as the first baseline with different number of LSTM layers ($L = \{0, 1, 2, 3\}$). $L = 0$ indicates the model only relies on the input representation. Following Zhang et al. (2018), the complete dependency trees are considered bidirectional and encoded with a contextualized GCN (BiLSTM-GCN). We further add the relation-specific parameters (Marcheggiani and Titov, 2017) and a CRF layer for the NER task. The resulting baseline is **BiLSTM-GCN-CRF** [9]. We use the bootstrapping paired t-test (Berg-Kirkpatrick et al., 2012) for significance test when comparing the results of different models.

Experimental Setup We choose MLP as the interaction function in our DGLSTM-CRF according to performance on the development set. The hidden size of all models (i.e., LSTM, GCN) is set to 200. We use the Glove (Pennington et al., 2014) 100-d word embeddings, which was shown to be effective in English NER task (Ma and Hovy, 2016; Peters et al., 2018a). We use the publicly available FastText (Grave et al., 2018) word embeddings for Chinese, Catalan and Spanish. The ELMo (Peters et al., 2018a), deep contextualized word representations[10] are used for all languages in our experiments since Che et al. (2018) provides ELMo for many other languages[11], including Chinese, Catalan and Spanish. We use the average weights over all layers of the ELMo representations and concatenate them with the input representation $\mathbf{u}$. Our models are optimized by mini-batch stochastic gradient descent (SGD) with learning rate 0.01 and batch size 10. The L_2 regularization parameter is 1e-8. The hyperparameters are selected according to the performance on the OntoNotes English development set.

4.1 Main Results

OntoNotes English Table 3 shows the performance comparison between our work and previous work on the OntoNotes English dataset. Without the LSTM layers (i.e., $L = 0$), the proposed model with dependency information significantly improves the NER performance with more than 2 points in F_1 compared to the baseline BiLSTM-CRF ($L = 0$), which demonstrate the effective-

[8] The words that are annotated with entity labels.

[9] Detailed description of this baseline can also be found in the supplementary material.

[10] We also tried BERT (Devlin et al., 2019) in preliminary experiments and obtained similar performance as ELMo. The NER performance using BERT without fine-tuning reported in Peters et al. (2019) is consistent with the one reported by ELMo (Peters et al., 2018a).

Table 4: Performance comparison on the OntoNotes 5.0 Chinese Dataset.

ness of dependencies for the NER task. Our best performing BiLSTM-CRF baseline (with Glove) achieves a F_1 score of 87.78 which is better than or on par with previous works (Chiu and Nichols, 2016; Li et al., 2017; Ghaddar and Langlais, 2018) with extra features. This baseline also outperforms the CNN-based models (Strubell et al., 2017; Li et al., 2017). The BiLSTM-GCN-CRF model outperforms the BiLSTM-CRF model but achieves inferior performance compared to the proposed DGLSTM-CRF model. We believe it is challenging to preserve the surrounding context information with stacking GCN layers while contextual information is important for NER (Peters et al., 2018b). Overall, the 2-layer DGLSTM-CRF model significantly (with $p < 0.01$) outperforms the best BiLSTM-CRF baseline and the BiLSTM-GCN-CRF model. As we can see from the table, increasing the number of layers (e.g., L = 3) does not give us further improvements for both BiLSTM-CRF and DGLSTM-CRF because such third-order information (e.g., the relationship among a words parent, its grandparent, and great-grandparent) does not play an important role in indicating the presence of named entities.

We further compare the performance of all models with ELMo (Peters et al., 2018a) representations to investigate whether the effect of dependency would be diminished by the contextualized word representations. With $L = 0$, the ELMo representations largely improve the performance of BiLSTM-CRF compared to the BiLSTM-CRF model with word embeddings only but is still 1 point below our DGLSTM-CRF model. The 2-layer DGLSTM-CRF model outperforms the best BilSTM-CRF baseline with 0.9 points in F_1 ($p < 0.001$). Empirically, we found that among the entities that are correctly predicted by DGLSTM-CRF but wrongly predicted by BiLSTM-CRF, 47% of them are with length more than 2. Our finding shows the 2-layer DGLSTM-CRF model is able to accurately recognize long entities, which can lead to a higher precision. In addition, 51.9% of the entities that are correctly retrieved by DGLSTM-CRF have the dependency relations "*pobj*", "*nn*" and "*nsubj*", which have strong correlations with certain named entity types (Figure 3). Such a result demonstrates the effectiveness of dependency relations in improving the recall of NER.

OntoNotes Chinese Table 4 shows the performance comparison on the Chinese datasets. We compare our models against the state-of-the-art

Table 5: Results on the SemEval-2010 Task 1 datasets.

NER model on this dataset, Lattice LSTM (Zhang and Yang, 2018)[12]. Our implementation of the strong BiLSTM-CRF baseline achieves comparable performance against the Lattice LSTM. Similar to the English dataset, our model with L = 0 significantly improves the performance compared to the BiLSTM-CRF (L = 0) model. Our DGLSTM-CRF model achieves the best performance with L = 2 and is consistently better ($p < 0.02$) than the strong BiLSTM-CRF baselines. As we can see from the table, the improvements of the DGLSTM-CRF model mainly come from recall ($p < 0.001$) compared to the BiLSTM model, especially in the scenario with word embeddings only. Empirically, we also found that those correctly retrieved entities of the DGLSTM-CRF (compared against the baseline) mostly correlate with the following dependency relations: "*nn*", "*nsubj*", "*nummod*". However, DGLSTM-CRF achieves lower precisions against BiLSTM-CRF, which indicates that the DGLSTM-CRF model makes more false-positive predictions. The reason could be the relatively lower ratio of ST(%)[13] as shown in Table 2, which means some of the entities do not form subtrees under the complete dependency trees. In such a scenario, the model may not correctly identify the boundary of the entities, which results in lower precision.

[12]We run their code on the OntoNotes 5.0 Chinese dataset.

[13]Percentage of entities that can form a subtree.

SemEval-2010 Table 5 shows the results of our models on the SemEval-2010 Task 1 datasets. Overall, we observe substantial improvements of the DGLSTM-CRF on the Catalan and Spanish datasets (with $p < 0.001$ marked in bold against the best performing BiLSTM-CRF baseline), especially for DGLSTM-CRF with ELMo and L larger than 1. With word embeddings, the best DGLSTM-CRF model outperforms the best performing BiLSTM-CRF baseline with more than 10 and 9 points in F_1 on the Catalan and Spanish datasets, respectively. The BiLSTM-GCN-CRF model also performs much better than the BiLSTM-CRF baselines but is worse than the DGLSTM-CRF model with $L \geq 2$. Both precision and recall significantly improve with a large margin compared to the best performing BiLSTM-CRF, especially for the recall (with more than 10 points improvement) on these two datasets. With ELMo, the best performing DGLSTM-CRF model outperforms the BiLSTM-CRF baseline with about 6 and 7 points in F_1 on these two datasets, respectively. The substantial improvements show that the structural dependency information is extremely helpful for these two datasets.

With ELMo representations, we observe about 2 and 3 points improvements in F_1 compared with the 1-layer DGLSTM-CRF model on these two datasets, respectively. Empirically, more than 50% of the entities that are correctly predicted by the

– with gold dependency	**52.13**	**33.26**	**40.61**	**52.14**	**35.59**	**42.30**

Table 7: Low-resource NER performance on the SemEval-2010 Task 1 datasets.

2-layer model but not the 1-layer model are with length larger than 2. Also, most of these entities contain the grandchild dependencies "(*sn, sn*)" and "(*spec, sn*)" where *sn* represents noun phrase and *spec* represents specifier (e.g., determiner, quantifier) in both datasets. Such a finding shows that the 2-layer model is able to capture the interactions given by the grandchild dependencies.

4.2 Additional Experiments

CoNLL-2003 English Table 6 shows the performance on the CoNLL-2003 English dataset. The dependencies are predicted from Spacy (Honnibal and Montani, 2017). With the contextualized word representations, DGLSTM-CRF outperforms BiLSTM-CRF with 0.2 points in F_1 ($p < 0.09$). The improvement is not significant due to the relatively lower equality of the dependency trees. To further study the effect of the dependencies, we modified the predicted dependencies to ensure each entity form a subtree in the complete dataset. Such modification improves the F_1 to 92.7, which is significantly better ($p < 0.05$) than the BiLSTM-CRF.

Low-Resource NER Following Cotterell and Duh (2017), we emulate truly low-resource condition with 100 sentences for training. We assume that the contextualized word representations are not available and dependencies are predicted. Table 7 shows the NER performance on the SemEval-2010 Task 1 datasets under the low-resource setting. With limited amount of training data, BiLSTM-CRF suffers from low recall and the DGLSTM-CRF largely improves it on these two datasets. Using gold dependencies further significantly improves the precision and recall.

–w/o dependency relation	88.92	89.99	89.46

Table 9: Ablation study of the DGLSTM-CRF model on the OntoNotes English dataset.

Effect of Dependency Quality To evaluate how the quality of dependency trees affect the performance, we train a state-of-the-art dependency parser (Dozat and Manning, 2017) using our training set and make prediction on the development/test set. We implemented the dependency parser using the AllenNLP package (Gardner et al., 2017). Table 8 shows the performance (LAS) of the dependency parser on four languages (i.e., OntoNotes English, OntoNotes Chinese, Catalan and Spanish) and the performance of DGLSTM-CRF against the best performing BiLSTM-CRF with ELMo. DGLSTM-CRF even with predicted dependencies is able to consistently outperform the BiLSTM-CRF on four languages. However, the performance is still worse than the DGLSTM-CRF with gold dependencies, especially on the Catalan and Spanish. Such results suggest that it is essential to have high-quality dependency annotations available for the proposed model.

Ablation Study Table 9 shows the ablation study of the 2-layer DGLSTM-CRF model on the OntoNotes English dataset. With self connection as interaction function, the F_1 drops 0.3 points. The model achieves comparable performance with concatenation as interaction function but F_1 drops about 0.4 points with the addition interaction function. We believe that the addition potentially leads to certain information loss. Without the depen-

dency relation embedding $\mathbf{v}_r$ in the input representation, the F_1 drops about 0.4 points.

5 Analysis

5.1 Effectiveness of Dependency Relations

To demonstrate whether the model benefits from the dependency relations, we first select the entities that are correctly predicted by the 2-layer DGLSTM-CRF model but not by the best performing baseline 2-layer BiLSTM-CRF on the OntoNotes English dataset. We draw the heatmap in Figure 4 based on these entities. Comparing Figure 3 and 4, we can see that they are similar in terms of the density. Both of them show consistent relationships between the entity types and the dependency relations. The comparison shows that the improvements partially result from the effect of dependency relations. We also found from our model's predictions that some entity types have strong correlations with the relation pairs on grandchild dependencies[14].

5.2 Entity with Different Lengths

Table 10 shows the performance comparison with different entity lengths on all datasets. As mentioned earlier, the dependencies as well as the grandchild relations allow our models to capture the long-distance interactions between the words. As shown in the table, the performance of entities with lengths more than 1 consistently improves with DGLSTM-CRF for all languages except Chinese. As we pointed out in the dataset statistics (Table 2), the number of entities that form subtrees in OntoNotes Chinese is relatively smaller compared to other datasets. The performance gain is more significant for entities with longer length on the other three languages. We found that, among the improvements of entities with length larger than 2 in English, 85% of them have long-distance dependencies and 30% of them have grandchild dependencies within the entity boundary. The analysis shows that our model that exploits the dependency tree structures is helpful for recognizing long entities.

[14]The corresponding heatmap visualization is provided in supplementary material.

6 Conclusions and Future Work

Motivated by the relationships between the dependency trees and named entities, we propose a dependency-guided LSTM-CRF model to encode the complete dependency tree and capture such relationships for the NER task. Through extensive experiments on several datasets, we demonstrate the effectiveness of the proposed model in improving the NER performance. Our analysis shows that NER benefits from the dependency relations and long-distance dependencies, which are able to capture the non-local interactions between the words.

As statistics shows that most of the entities form subtrees under the dependency trees, future work includes building a model for joint NER and dependency parsing which regards each entity as a single unit in a dependency tree.

Ackowledgements

Abstract

Large training datasets are required to achieve competitive performance in most natural language tasks. The acquisition process for these datasets is labor intensive, expensive, and time consuming. This process is also prone to human errors. In this work, we show that cross-cultural differences can be harnessed for natural language text classification. We present a transfer-learning framework that leverages widely-available unaligned bilingual corpora for classification tasks, using no task-specific data. Our empirical evaluation on two tasks – formality classification and sarcasm detection – shows that the cross-cultural difference between German and American English, as manifested in product review text, can be applied to achieve good performance for formality classification, while the difference between Japanese and American English can be applied to achieve good performance for sarcasm detection – both without any task-specific labeled data.

1 Introduction

The collection of large, task-specific labeled datasets poses a major challenge to the application of supervised text classification in many domains. Acquiring these datasets is expensive, time-consuming, and error-prone.

In this work, we propose leveraging bilingual datasets for classification tasks. The large-scale availability of such datasets counteracts the low availability of task-specific labeled data. The cross-cultural differences expressed in these bilingual datasets can be learned and then transferred for text classification tasks with no labeled data. Our work, thus, extends the idea of *distant supervision* (Mintz et al., 2009) to tasks for which no relevant large-scale curated datasets exist.

Culture was defined by Hofstede et al. (2010) as "*the collective programming of the mind, which distinguishes the members of one group of people from another*." Shweder et al. (2006) defines membership in a cultural group as "*thinking and acting in a certain way, in the light of particular goals, values, pictures of the world*." Based on these definitions we can reasonably expect members of a specific cultural group to think and act in ways that are distinct from others. For example, Hedderich (2010), who investigated cross-cultural differences at the workplace, found that the overall interaction of employees in Germany is more *formal* than their American counterparts. House (1997) found that "*German subjects tended to interact in ways that were more direct, more explicit, more self-referenced, and more content-oriented*".

Similarly, several works have studied cross-cultural differences between Japanese and English (both American and British variants) (Koga and Pearson, 1992; Minami, 1994; Martinsons, 2001; Adachi, 2010). Specifically, Adachi (1996) and Ziv (1988) investigated sarcasm in Japanese and the latter showed that American students are more sarcastic than their Japanese counterparts.

The main thesis underlying this work is that texts composed by members of a specific cultural group are distinct from those composed by members of another. Observational studies on cultural differences, such as those described in the examples above, allow us to identify the high-level semantics of these differences.

We present a transfer learning algorithm which learns a model encapsulating cross-cultural differences from bilingual data, and applies the learned model to text classification tasks. We study this idea using two natural language classification tasks: (1) *Formality classification* – by learning the difference between the writing style of Germans compared to Americans; and (2) *Sarcasm detection* – by learning the difference between the writing style of Japanese compared to Americans.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3873–3883,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Our approach requires only a bilingual dataset without the need for any alignments, special labels, or task-specific training data. Our empirical evaluation demonstrates that such cross-cultural distinction can be successfully transferred to those tasks. We present an algorithm that, given two unaligned corpora of texts written in two languages, transforms the two document classes into a common representation. A binary classifier is then trained to distinguish between representation of documents originating from one language as compared to the other. The classifier can be subsequently applied to a binary text classification task. For example, if the document is deemed by the American-Japanese classifier as American, we will infer that the text is sarcastic.

We study various representations of both words and documents and present a novel document representation algorithm adapted to our task. Our empirical results suggest that our transfer-learning approach based on cross-cultural differences achieves comparable performance to direct learning approaches trained on task-specific labeled data. Additional results demonstrate the contribution of our proposed representation approach.

The contributions of this work can be summarized as follows: (1) We propose a transfer learning framework to enable text classification using cross-cultural differences learned on bilingual data; (2) We propose a representation scheme for documents, designed for the task of text classification based on bilingual data; (3) We perform an empirical evaluation of our approach and contribute our labeled datasets to the community.

2 Related Work

Cross-cultural differences have been studied extensively in the social science literature (Shweder, 1991; Weber and Hsee, 1998; Liu and McClure, 2001; Boroditsky et al., 2003; Yin et al., 2011; Hong et al., 2012). Specifically, Paul and Girju (2009); Garimella et al. (2016) explored differences through language analysis.

Text classification approaches have traditionally used distributed representation of texts (e.g. TF-IDF) and applied supervised models to these representations (Joachims, 1998; Wang and Manning, 2012). More recent work has pursued improved representations (Joulin et al., 2017) and novel neural architectures (Conneau et al., 2017).

Algorithm 1 Cross-Cultural Transfer Learning

Input: C_0 (documents from language L_0)
Input: C_1 (documents from language L_1)
Input: T (transformation method)
Input: D_t (binary classification task dataset)
Output: $\hat{\mathbf{y}}_t$ (predictions)

$C_0^T, C_1^T \leftarrow \text{TRANSFORM_DOCUMENTS}(T, C_0, C_1)$
$h \leftarrow \text{TRAIN_CLASSIFIER}(C_0^T, C_1^T)$
$D_t^T \leftarrow \text{TRANSFORM_DOCUMENTS}(T, D_t)$
$\hat{\mathbf{y}}_t \leftarrow \text{TRANSFER_LEARNING}(h, D_t^T)$

Transfer learning in natural language processing has recently moved beyond pre-trained word embeddings (Howard and Ruder, 2018) to more advanced approaches (Peters et al., 2018; Radford et al., 2018).

Cross-lingual word embedding seeks a mapping between embedding spaces representing different languages (Ruder et al., 2019). This goal is most often achieved by training monolingual word embeddings for multiple languages independently, and then learning a transformation between them using either supervised or unsupervised methods.

Cross-lingual language understanding (XLU) is an area of research that has recently gained much attention. Related methods seek to learn a joint-embedding space for multiple languages (Conneau et al., 2018; Devlin et al., 2019) .

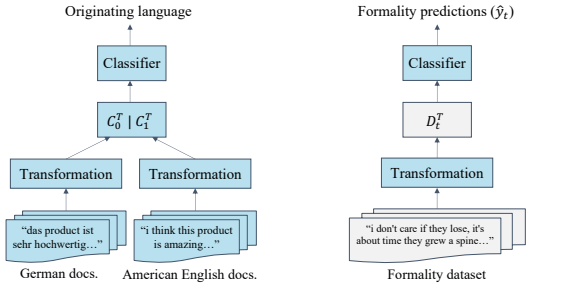
This work, to the best of our knowledge, is the first to leverage cross-cultural differences in bilingual text data to perform inference on monolingual data.

3 Cross-Cultural Transfer Learning

In this section we describe our approach for text classification tasks such as formality classification and sarcasm detection, using transfer learning from bilingual data. A supervised learning model is trained to differentiate between a pair of languages based on their cross-cultural differences, as manifested in the available text data. Specifically, the training data contains a corpus of text documents collected from two distinct languages, with the assumption that the language of each document is known. Note that, the bilingual data needed for this approach is coarsely taken from the same domain. However, the texts need not be aligned beyond this coarse level. That is, full alignment between specific documents across the two languages is not required. Algorithm 1 summarizes the steps of our method.

3.1 Formal Framework

Given two collections of documents from languages L_0 and L_1 denoted as C_0 and C_1, respectively, the following are the steps to applying our framework:



1. Using a transformation, denoted T, transform the two document classes into a common representation. The resulting transformed collections of documents are denoted C_0^T and C_1^T, respectively.

2. Train a binary classifier, denoted h, to discriminate document representations in C_0^T from those in C_1^T. That is, the classifier is trained to classify representations of documents as originating from either L_0 or L_1.

3. Given a binary classification task dataset, denoted D_t, which consists of text documents (with a known language), transform all texts in D_t using transformation T, to obtain a set of document representations denoted D_t^T.

4. Finally, apply the classifier h, trained on the bilingual data, to the document representations in D_t^T to obtain predictions for each member of this set, denoted $\hat{\mathbf{y}}_t$.

Figure 1 summarizes the process.

(a) Train on transformed bilingual data (b) Apply to a binary classification task

Figure 1: Illustration of the cross-cultural transfer learning framework through the example of the formality classification task. (a) The classifier is trained on document representations of the German-American bilingual data ($C_0^T \mid C_1^T$) to distinguish documents as originating from either German or American English (L_0 or L_1). (b) The trained classifier is applied to a formality task.

3.2 Transformations

The effectiveness of the framework described above depends in large part on the choice of transformation T. In general, transformation T transforms documents from languages L_0 and L_1 into a common representation. A well chosen transformation should enable the supervised learning in subsequent steps to focus on cross-cultural differences between the original documents rather than superficial differences between the texts.

In our construction, we used compound transformations composed of the following parts: (1) Translation of the texts to a common language (Section 3.2.1); (2) Mapping the tokens in the text to word embeddings (Section 3.2.2); (3) Combining the word embeddings to form document-level vector representations (Section 3.2.3).

3.2.1 Translation

The first part of our document transformation involves translating the documents. We chose to translate documents from L_0 to L_1, so that documents authored in language L_1 (those documents denoted C_1 above), require no translation.

The motivation for choosing L_1 as the "target" language may involve the reliability of the translation to this language, the availability of high quality word embeddings in this language, or the fore-knowledge that downstream tasks will involve datasets written in this language.

Under this framework we evaluate two different translation approaches: (1) A state of the art machine translation system we denote as **MT**. Following preliminary experiments with both the method by Vaswani et al. (2017) and with Google cloud translation[1], we focused on the latter as it achieved better results. (2) A word-by-word nearest-neighbor search, denoted as **NN**, where we use the method of Lample et al. (2018), adapted to our task. These choices represent a complexity-accuracy trade-off. We expect the **MT** system to give high-quality translation, but at the cost of higher complexity. Conversely, the **NN** approach is simple to implement, but may produce lower-quality translations.

In order to implement **NN** some notion of distance between words in language L_0 and words in L_1 is needed. We used cross-lingual word embeddings for this purpose. For a given language pair, the embedding of the joint vector space representation of many words from both languages is known. For implementing nearest neighbor search for a particular word in L_0, we simply compare the embedding vector representation of this word

[1] https://cloud.google.com/translate/docs

with all known embedding vectors of words in language L_1, and select the one that maximizes their similarity, as suggested by Lample et al. (2018) (and done efficiently by employing the method of Johnson et al. (2019)). For translating German to English such an embedding dataset is available for download.[2] For Japanese to English, we trained our own such model (following Lample et al. (2018)), as this language pair is not available for download. Note that the embeddings used in this step may or may not be related to the embeddings described in the next section.

3.2.2 Word Embeddings

Once our documents are converted to a single language using one of the translation methods above, we represent each word in the document as an embedding vector, which is a dense distributed version of the corresponding word.

We experiment with several types of word embeddings, including: pre-trained embedding models trained on large corpora of general English language text, publicly available for download (Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and FastText (Bojanowski et al., 2017)).

3.2.3 Document Representation

After applying translation and mapping tokens to word embeddings, our documents are represented as a variable-length list of vectors (each corresponding to word). In the following we examine various methods for combining these vectors into a single uniform length representation, and derive a document representation scheme that uses label information to achieve better discrimination, which we conjecture increases the ability to encode the cross-cultural difference.

The methods we explore produce weighted combinations of the word vectors in the document, normalized to unit length. A model that captures the intuition that text is composed of both local and global context is proposed by Arora et al. (2017). Applying maximum likelihood estimation to this model obtains the representation:

$$\mathbf{c}_d = \sum_i^n \frac{a}{\mathcal{U}(w_i) + a} \mathbf{v}_{w_i} \tag{1}$$

where $\mathbf{c}_d \in \mathbb{R}^k$ is the resulting document representation vector and $\mathbf{v}_{w_i} \in \mathbb{R}^k$ is the embedding vector corresponding to the i-th of n words in document d; $\mathcal{U}(w)$ denotes the unigram distribution; and $a>0$ is a free parameter that controls smoothing. This equation expresses the intuitive approach of averaging the word embeddings, each weighted inversely to the word's frequency. Thus, very popular words are down-weighted. This is also related to an inverse document frequency (IDF) weighting proposed in De Boom et al. (2016).

In our application we seek a document embedding to assist in solving a binary classification task. In other words, we seek a context vector $\mathbf{c}_d$ that is most discriminative, taking advantage of additional information about some binary label. More specifically, we assume that we have a conditional model for the probability of each token given the class.

Formalizing this idea, we seek an embedding that will maximize the *expected log-probability of a document*:

$$\mathbb{E}\left[\log\left(P\left(L|w_1, w_2, \ldots, w_n\right)\right)\right] = \mathbb{E}\left[\log \textstyle\prod_{i=1}^n P\left(w_i \mid \mathbf{c}_d, L\right)\right] + C$$

where we have used Bayes rule and C is constant w.r.t $\mathbf{c}_d$. As the notation suggests, we now have a generative model for each class:

$$P\left(w_i \mid \mathbf{c}_d, L_0\right) = \alpha \cdot P\left(w_i \mid L_0\right) + (1-\alpha) \cdot \left(\frac{\exp\left(\mathbf{v}_{w_i}^\top \mathbf{c}_d\right)}{Z}\right)$$
$$P\left(w_i \mid \mathbf{c}_d, L_1\right) = \alpha \cdot P\left(w_i \mid L_1\right) + (1-\alpha) \cdot \left(\frac{\exp\left(\mathbf{v}_{w_i}^\top \mathbf{c}_d\right)}{Z}\right)$$

where $P\left(w_i \mid L_0\right)$ and $P\left(w_i \mid L_1\right)$ are the conditional unigram models, and Z denotes a normalization constant.

Focusing on the probability of a single token:

$$\begin{aligned} f\left(\mathbf{c}_d\right) &= \mathbb{E}\left[\log P\left(w_i \mid \mathbf{c}_d, L\right)\right] \\ &= \frac{1}{2}\left[\log P\left(w_i \mid \mathbf{c}_d, L_0\right) + \log P\left(w_i \mid \mathbf{c}_d, L_1\right)\right] \end{aligned} \tag{2}$$

under the assumption that $P\left(L_0\right) = P\left(L_1\right) = \frac{1}{2}$.

This expression has the following gradient (w.r.t. $\mathbf{c}_d$):

$$\begin{aligned} &\nabla f\left(\mathbf{c}_d\right) = \\ &\frac{1}{2} a \cdot e_{i,d} \left[\frac{P\left(w_i \mid L_0\right) + P\left(w_i \mid L_1\right) + 2a e_{i,d}}{\left(P\left(w_i \mid L_0\right) + a e_{i,d}\right) \cdot \left(P\left(w_i \mid L_1\right) + a e_{i,d}\right)}\right] \mathbf{v}_{w_i} \end{aligned} \tag{3}$$

where $a = \frac{(1-\alpha)}{\alpha Z}$ and $e_{i,d} = \exp\left(\mathbf{v}_{w_i}^\top \mathbf{c}_d\right)$. Note that when we evaluate Equation (3) with $\mathbf{c}_d = 0$ the expression becomes:

$$\nabla f\left(0\right) = \frac{1}{2} a \left[\frac{P(w_i|y) + P(w_i|L_1) + 2a}{(P(w_i|L_0)+a)\cdot(P(w_i|L_1)+a)}\right] \mathbf{v}_{w_i}$$

[2] https://github.com/facebookresearch/MUSE

Thus, maximizing the Taylor approximation $f(\mathbf{c}_d) \approxeq f(0) + \nabla f(0)^\top \mathbf{c}_d$ w.r.t. $\mathbf{c}_d$ (following Arora et al. (2017)) yields the following estimator:

$$\mathbf{c}_d = \frac{1}{2} \sum_{i=1}^{n} a \left[\frac{P(w_i|L_0)+P(w_i|L_1)+2a}{(P(w_i|L_0)+a)\cdot(P(w_i|L_1)+a)} \right] \mathbf{v}_{w_i} \quad (4)$$

Examining the expression above, we can see that for a fixed value of a, the numerator of the of the ratio grows with the frequency of w_i in *either* language L_0 or L_1. The denominator of the ratio grows when w_i is frequent in *both* languages. Hence, the weighting scheme gives more weight to vectors corresponding to words that are frequent in either language, but not both. Further, similarly to Equation 1, the expression gives a larger weight to words that have low frequency in either language.

Note that the representations above define an *unnormalized* quantity, so that the absolute values of the vector weights are less important than their relative values. The final document representation is given by $\frac{\mathbf{c}_d}{||\mathbf{c}_d||}$.

4 Evaluation

In order to evaluate our setup, we consider the application of the above framework to two binary text classification tasks: formality classification and sarcasm detection. For each such task we require a bilingual dataset containing texts drawn from two languages for training and another (one or more) dataset to use for evaluation. Table 1 summarizes the characteristics of both the bilingual and evaluation datasets.

4.1 Formality Classification Task

The formality classification task (Heylighen and Dewaele, 1999) aims to classify a document as either formal or informal. For evaluating this task we used the following datasets:

Amazon Product Descriptions and Reviews Product descriptions and their corresponding user reviews from the Motors and Fashion categories of Amazon e-commerce website (He and McAuley, 2016). We consider the description texts to be examples of formal writing and the reviews to be examples of informal writing (Novgorodov et al., 2019). We filter documents that are not in English or shorter than 10 terms. We then sample one review per description document to result with a balanced dataset in terms of class labels.

New York Times Article snippets and Comments Article-snippets and their corresponding user comments from the New York Times (Kesarwani, 2018). We consider article-snippet texts to be examples of formal writing and the comment texts to be examples of informal writing. We focus on the news section, and filter documents shorter than 10 terms. We then sample one comment per article-snippet to result with a balanced dataset in terms of class labels.

Formality in Online Communication Texts annotated for formality, originating from four types of online communication: News, Blog, Email, and community question answering forums (denoted as Answers) (Lahiri, 2015; Pavlick and Tetreault, 2016). The mean formality score for each document (across all annotators) ranges from -3 (very informal) and 3 (very formal). To make this dataset suitable for our binary classification framework, we only consider documents with a mean formality score in the highest and lowest 20^{th} percentile per communication type as formal and informal, respectively.

Surrogate Bilingual Dataset for Formality Based on prior research by Hedderich (2010), who investigated cross-cultural differences between Germans and Americans and identified the former to be more formal, we selected German and American English (Ger-Am) as the language pair to serve as a surrogate for the formality task. The German language is chosen to represent the formal class and the American English language is chosen to represent the informal class. We use the eBay Fashion product review bilingual data to learn the cross-culture differences. The data is extracted from the German and American sites of eBay e-commerce website, and the reviews originate from 24 sub-categories (e.g, "Jewelry").

4.2 Sarcasm Detection Task

The sarcasm detection task (Tepperman et al., 2006) aims to classify a document as either non-sarcastic or sarcastic. For evaluating the sarcasm detection task, we used the following dataset:

Sarcasm Corpus V2 The Sarcasm Corpus version 2 (Oraby et al., 2016)[3] includes response text from quote-response pairs annotated for sarcasm. Each sample consists of the form of sarcasm (Gen for general sarcasm, RQ for rhetorical question or

Hyp for hyperbole), a class label (either sarcastic or non-sarcastic), a quote text, and a response text (the text annotated for sarcasm).

Surrogate Bilingual Dataset for Sarcasm Based on prior research on cross-cultural differences between Japanese and American (Koga and Pearson, 1992; Minami, 1994; Martinsons, 2001; Adachi, 2010), and specifically Adachi (1996) and Ziv (1988) who addressed sarcasm in Japanese, we selected Japanese and American English (Jp-Am) as the language pair to serve as a surrogate for the sarcasm task. The Japanese language is chosen to represent the non-sarcastic class and the American English language is chosen to represent the sarcastic class. We use the Amazon Japanese and American reviews as the bilingual data to learn the cross-culture difference. The data originates from the Japanese and American marketplaces of the Amazon Customer Reviews Dataset [4], and the reviews originate from 39 categories (e.g. "Books").

4.3 Surrogate Bilingual Datasets Pre-processing

To allow the classifier to learn cross-cultural differences during training, and before transferring to the specific task, we seek to remove from the bilingual datasets used for training any other sources of information that may incidentally distinguish between the two language corpora: (1) We filter documents containing fewer than 10 or more than 250 terms; (2) We apply language detection (Shuyo, 2010) to remove documents in languages outside the surrogate languages; (3) We sample the same number of documents per each sub-category, document length and review-rating. This enables us to remove any bias towards a topic; (4) We sample the same number of documents from both languages to result with a balanced dataset in terms of class labels. We draw the reader's attention to the fact that the documents in the bilingual datasets are plain reviews which have not gone through any formality classification or sarcasm detection as part of their pre-processing. We publicly release the surrogate datasets.[5]

4.4 Classification Algorithms

We experiment with both Logistic Regression and XGBoost classifiers (McCullagh, 2018; Chen and Guestrin, 2016), and report the results of the former as it yielded superior performance. For Logistic Regression, we tune both the regularization norm ($L1$ or $L2$), and the regularization coefficient (C). For XGBoost, we tune the learning-rate, maximum tree depth, number of rounds (trees), minimum loss reduction required for partitioning, sub-sample ratio of features per tree, and both the $L1$ and $L2$ regularization coefficients. The configurations empirically chosen (based on grid search experiments on the validation set) were (1) $L2$ regularization with $C = 10^4$ for models trained on bilingual data; (2) $L2$ regularization with $C = 1$ for models trained on task-specific data. We also experimented with the following neural network architectures for the classification: LSTM-RNN (Hochreiter and Schmidhuber, 1997), HAN (Yang et al., 2016), QRNN (Bradbury et al., 2017), and VDCNN (Conneau et al., 2017). However, these models did not achieve any substantial performance gain to justify their additional complexity.

4.5 Evaluation Metrics

We report the AUC scores of stratified, five-fold cross-validation experiments on the formality classification and sarcasm detection tasks. For each fold of each experiment, the evaluation dataset is partitioned into train, validation and test splits. Task-specific models use all three splits for training, hyper-parameter tuning and evaluation, respectively, while models trained on bilingual data only use the test split for evaluation (so

that both types of models are evaluated on the same test set). Statistical significance is measured using one-way paired t-test (Casella and Berger, 2002) with $p<0.01$.

5 Results and Discussion

Our empirical evaluation explores the following main research questions: (1) How effective is the approach of using bilingual data as described in Section 3 on our chosen tasks? (2) How does the choice of transformation impact the performance of the approach? Specifically, we consider the choice of machine translation and document representation.

Comparison to Models Trained on Task-specific Data In order to determine the overall effectiveness of our approach as described in Section 3, we consider the result of training a model using task-specific labeled data. We expect that if our approach is effective, we can achieve performance close to that of a model trained on this task-specific data. Table 2 reports the cross-validation AUC comparing our approach to the model trained on task-specific data. The table considers both tasks across the various evaluation datasets described in Section 4. The final column reports the percent difference between the two methods.

Examining the table, we observe that our method is within 10% of the AUC of the model trained on task-specific data, on all datasets and tasks, and as close as 4% on four of the datasets. Our model was trained entirely on bilingual data with no examples from the task it was evaluated on. The comparison with a model that was trained on data specific to the target task yields only a small improvement over our method. The comparable performance supports our thesis that cross-cultural information which exists within the bilingual data can be leveraged to achieve performance that is nearly equal to that achieved by collecting expensive task-specific labels.

Effect of Translation Component Table 3 considers the effect of the translation component of the compound transformation described in Section 3.2.1. Recall we considered two approaches for translation which represent a complexity-accuracy trade-off. We expect the **MT** approach to provide a higher quality translation, but it is substantially more complex to train and deploy. Conversely, the **NN** approach is simple to deploy at the cost of overall translation quality. The table illustrates that the difference in translation quality does have an impact on the down-stream task performance. However, the magnitude of the impact varies widely across the datasets in our experiments. For the formality task, the <8% gap between the methods may justify the reduced complexity of the **NN** approach. It is interesting to note that the model performs well even with a very simple word-by-word translation scheme.

Effect of Document Representation Table 4 considers the effect of the document representation component of the transformation discussed in Section 3.2.3 across the tasks, datasets, and translation methods. The first result column shows the

Table 4: AUC performance for various representation methods. AVG refers to a simple unweighted average of word vectors, IDF refers to a document-frequency-based weighting according to equation 1. LANG refers to a weighting scheme that takes the language of origin into consideration, based on Equation 4. The best result per dataset is marked in bold, "*" indicates statistically significant difference of the leading method from both other methods.

performance of a simple unweighted average of the word vectors. The second result column shows a document-frequency-based weighting according to Equation 1. The third result column shows the performance of a weighting scheme that takes the language of origin into consideration, based on Equation 4.

Examining the table, we observe that using a non-uniform weighting scheme generally gives improved performance over the naive unweighted baseline. The effect of the document representation method is significant when paired with the **NN** translation approach. Thus, the translation and document representation components of the compound transformation are complementary in the sense that when translation is of high quality, a naive document representation suffices. Conversely, when translation quality is sub-optimal, the choice of document representation can significantly impact performance.

We also studied the effect of the choice of word embeddings as discussed in Section 3.2.2, but there were no statistical significant differences.

(a) Formality classification: Two documents from the Amazon Fashion and the New York Times evaluation datasets classified as *informal*, respectively. Orange color indicates contribution to the document being classified as *informal* and blue color otherwise.

(b) Sarcasm detection: Two documents from the Sarcasm Corpus evaluation dataset classified as *sarcastic*. Green color indicates contribution to the document being classified as *sarcastic* and red color otherwise.

Figure 2: Documents from the evaluation datasets of both the formality classification, and sarcasm detection tasks and their corresponding LIME interpretation (Ribeiro et al., 2016). Color intensity is in proportion with the word's contribution to the classification according to the LIME algorithm.

Qualitative Examples To better understand what the models trained on bilingual data actually learn, we utilize the LIME algorithm (Ribeiro et al., 2016) to attain each word's gravity to the classification of the document. Figure 2 provides visual explanations of documents from the evaluation datasets of both the formality classification, and sarcasm detection tasks and their corresponding LIME interpretation. Specifically, Figure 2a showcases documents from the Amazon Fashion and the New York Times datasets classified as *informal*, respectively, while Figure 2b showcases documents from the Sarcasm Corpus dataset classified as *sarcastic*. Examining the formality visualization (2a), we observe that words that affect the formality of the document, such as `awesome` in the first example and `treasure` in the second one, are indeed assigned with a higher weight by the LIME algorithm. Similarly for the sarcasm visualization (2b), we observe that words that contribute to the document being sarcastic, such as `perfect` and `amazing` in the first example, and `rolex` and `right` followed immediately by `back` in the second example, are indeed assigned with a higher weight by the LIME algorithm.

Most Discriminating Words To further demonstrate qualitatively the formality discriminating in-

German (Translated)		American English	
long	original	love	cute
high	broken	one	another
well	material	loved	going
good	handy	excellent	lovely
even	narrow	amazing	overpowering
cut	time	perfect	wanted
quality	clear	wearing	wonderful
cheap	ok	favorite	incredible
chic	flowery	like	overwhelming
hand	fake	comfortable	back
alternative	optimal	new	tiny
woody	waterproof	terrible	glad

Table 5: Most discriminative unigrams between German and American English according to their $wc(w_i, L_j)$ scores, based on the eBay Ger-Am product reviews dataset.

formation latent in German and American data, we seek the words that are most helpful in discriminating between the two languages. This notion is made concrete using the relative contribution of word w_i to the Kullback-Leibler divergence (Berger and Lafferty, 2017) between the languages, applied to all words, separately for each language:

$$wc\left(w_i, L_j\right) = P\left(w_i \mid L_j\right) \log\left(\frac{P(w_i|L_j)}{P\left(w_i|L_{(1-j)}\right)}\right)$$

Table 5 presents the unigrams that achieve the highest values for the expression above as computed on the eBay bilingual dataset of German and American English reviews. We can see that terms conveying information, such as `long`, `high`, `quality`, `cheap`, `woody`, and `clear` are more common in translated German documents, while terms conveying emotion, such as `love`, `amazing`, `favorite`, `wonderful`, `terrible`, and `overwhelming` are more common in American English documents.

6 Conclusions

In this work, we show that cross-cultural differences can be harnessed for natural language text classification. We present a transfer-learning framework that leverages bilingual corpora for classification tasks using no task-specific data, and evaluate its performance on formality classification and sarcasm detection tasks. We show that our approach achieves comparable performance to task-specific methods directly trained on the two tasks, and propose a document representation scheme designed for bilingual training data. Such a representation can improve performance substantially when a low-quality translation method is used. In future work, we would like to generalize our approach to the multilingual case of multiple languages and a multi-class target task, explore applications beyond text classification, and study transformations that eliminate the need for a translation system.

Abstract

Supervised learning models often perform poorly at *low-shot* tasks, i.e. tasks for which little labeled data is available for training. One prominent approach for improving low-shot learning is to use unsupervised pre-trained neural models. Another approach is to obtain richer supervision by collecting annotator *rationales* (explanations supporting label annotations). In this work, we combine these two approaches to improve low-shot text classification with two novel methods: a simple bag-of-words embedding approach; and a more complex context-aware method, based on the BERT model. In experiments with two English text classification datasets, we demonstrate substantial performance gains from combining pre-training with rationales. Furthermore, our investigation of a range of train-set sizes reveals that the simple bag-of-words approach is the clear top performer when there are only a few dozen training instances or less, while more complex models, such as BERT or CNN, require more training data to shine.

1 Introduction

When trained on large amounts of labeled data, supervised machine learning models demonstrate impressive performance in various domains ranging from text classification to image recognition (Yogatama et al., 2017; Krizhevsky et al., 2012). In many domains, however, labeled data is difficult to obtain. This might be due to annotation cost, or simply because there are no available instances to annotate before the system has to make the next classification decision. Imagine, for example, a personalized email tagger, where new tag types can be created and then used for annotation by the user at any time. When only little training is available, model performance drops dramatically.

Various methods have been proposed to optimize machine learning models trained on little data with the goal of improving performance for a given train set size or reducing the number of training instances that need to be collected. One of the most prominent for text classification (and other NLP tasks) is transfer learning from unsupervised data, or unsupervised pre-training. This approach has been widely adopted with the introduction of pre-trained word embeddings (Mikolov et al., 2013; Joulin et al., 2017). Word type representations have subsequently been extended with pre-trained, context-dependent representations achieving strong results across a wide range of NLP tasks (Melamud et al., 2016; Peters et al., 2018; Howard and Ruder, 2018). A recent strong performer in this line of research is BERT (Devlin et al., 2018), a multi-layer attention-based neural model that is pre-trained on large amounts of plain text and then fine tuned to specific tasks. Systems using BERT have achieved state-of-the-art performance on various NLP tasks, including short text classification.

Another approach for training text classifiers with few labeled instances is to supplement the class labels with annotation rationales. Annotation rationales for text are usually specific subsequences of words within a text instance that the annotator considers to be evidence supporting the label assignment. Zaidan et al. (2007) were the first to investigate the use of annotator rationales for training text classifiers. They obtained manual rationales for an IMDB movie review dataset (Pang et al., 2002) and showed that an SVM classifier can be modified to obtain improved accuracy using these rationales. The bold text in the movie review snippet "*perhaps **the greatest element to the film** is its constant surprises and unpredictability*" is one example of an annotated rationale in this dataset. Abedin et al. (2011) showed similar results using SVM and rationales for classifying

cause identifiers in aviation safety reports from the Aviation Safety Reporting System (ASRS).

In this work, we combine the power of unsupervised pre-training with the fine-grained guidance from rationales to propose two novel low-shot text classification methods. Both methods promote rationale-like features in the input to improve the classification outcome. The first method uses rationale supervision to bias a simple bag-of-words text embedding towards the more discriminative features. In the second method, we show how to fine-tune a pre-trained BERT model with both instance labels and rationales jointly. An investigation across a range of train-set sizes on the IMDB and ASRS text classification datasets reveals that our bag-of-words approach substantially outperforms all baselines for train sets of up to a few dozen instances. For larger sizes, our BERT-based model and a CNN baseline perform the best. Our code is publicly available. [1]

2 Related Work

As mentioned in the Introduction, Zaidan et al. (2007) was the first work to show how manual rationales annotated for movie reviews (Pang et al., 2002) can be used to improve classifier accuracy. They also investigated the annotation effort ramifications and found that the additional annotation of a few rationales per instance on top of the standard label annotation roughly doubled annotation time. When enough instances are readily available for annotation, this information is important to assess the trade-off between obtaining annotator rationales and obtaining standard labeled instances. However, we note that there are cases where more unlabeled instances may not be available and then obtaining annotator rationales may be the only way to improve the classifier accuracy.

The model most closely related to our rationale-biased bag-of-words is the one proposed by Sharma and Bilgic (2018) (denoted RA-SVM in Section 5.2). It biases the input representation by adjusting feature weights in a way that is agnostic to the type of classifier used. More specifically, it uses one-hot word features and performs simple fixed discounting of non-rationale word feature weights during training only. In contrast, our model learns a rationale-biased embedded representation of texts and this representation is used both at train and test time.

The model most closely related to our rationale-biased BERT model is the one proposed by Zhang et al. (2016) (denoted RA-CNN in Section 5.2). This model uses a CNN sentence encoder with pre-trained word embeddings. It follows a two-step approach, where one sentence classifier is trained to identify sentences containing rationales and weigh them higher in an overall 'weighted-average-of-sentences' document representation. Then a second classifier is trained to make the final label prediction based on that representation. They showed improved accuracy compared to non-rationale-augmented CNNs as well as to rationale-augmented SVM models. Our main contributions relative to that work are the introduction of the joint-learning technique, which learns text classification and rationale words identification concurrently, and the adaptation of the entire approach to BERT. The ability of our model to identify rationale spans within sentences also seems useful for interpretability. Tepper et al. (2013) also chose a two-step approach similar to Zhang et al. (2016) using more traditional classifiers with sparse features. They train one classifier to identify rationale-like pieces of text and then a second classifier is trained to label input instances taking only the rationale-like texts into account.

Finally, *few-shot* learning methods attempt to learn how to effectively train classifiers for new classes with only few labeled instances, using techniques commonly referred to as *meta-learning* (Snell et al., 2017; Yu et al., 2018). Snell et al. (2017), for example, learn an embedding function that is used to represent the input instances such that simple nearest-prototype classifiers can be trained effectively to recognise instances of a new target class after being exposed to a small number of labeled examples. Although a new class is learned from few labeled instances as in our work, the preceding meta-learning process relies on a large number of labeled instances aggregated over many closely related classes or tasks. This is an important distinction from our low-shot setting.

3 Rationale-biased Bag-of-words

In this section, we describe our proposed rationale-biased bag-of-words method for performing low-shot text classification with rationales.

[1] https://github.com/mihaela-bornea/low-shot-text-classification

3.1 Rationale-biased representation

Let $\vec{v}$ be a vector representation of word v (either one-hot or a low-dimensional embedding). We represent a text instance $t = (v_1, .., v_n)$ as an L2-normalized, weighted average of its words giving the text embedding function:

$$emb(t) = \vec{t} = \frac{1}{Z} \sum_{v_i \in t} w_i \vec{v_i} \quad (1)$$

where Z is the normalization factor.

This embedding is a standard bag-of-words approach to representing texts, where weights, such as TF-IDF, are typically used to bias the representation towards words that carry more important information. We hypothesize that since rationales highlight support for annotator classification decisions, biasing this text embedding function towards *rationale-like* words would expose the more discriminative features. To this end, given a rationale-bias function $f_{rb}(v)$ that estimates the similarity between a word v and the annotated rationale texts in the training dataset, the rationale biased representation could be computed using Eq. (1) with $w_i = f_{rb}(v_i)$. The remainder of this section describes how we compute $f_{rb}(v)$.

Let the *prototype* representation of a collection of text instances $T = (t_1, .., t_m)$ be the L2-normalized centroid of its text instance vectors:

$$prot(T) = \frac{1}{Z} \sum_{t_i \in T} \vec{t_i} \quad (2)$$

where Z is the normalization factor.

A rationale for a text instance t and class label c is any word subsequence r of t that was annotated as evidence for the assignment of c to t. A *class rationale prototype* $\vec{R_i} = prot(R_i)$ is the prototype representation of the rationales $R_i = (r_1, .., r_l)$ annotated for class c_i, where each rationale instance r is embedded using Eq. (1) with uniform weights. We define the following rationale-bias function $f_{rb}(v)$:

$$f_{rb}(v) = (\exp sim_{rb}(v))^{\alpha} \quad (3)$$

$$sim_{rb}(v) = \max_{i \in \{1..k\}} cosine(\vec{v}, \vec{R_i})$$

That is, $sim_{rb}(v)$ is the maximum cosine similarity of the word vector to any of the class rationale prototypes, and $f_{rb}(v)$ is an always positive derivative of $sim_{rb}(v)$ that is controlled by the hyperparameter $\alpha \geq 0$. Higher values of α mean stronger magnification of the impact of the rationale biases; $\alpha = 0$ means that the rationale bias is completely ignored. With this rationale-bias function, we can now compute rationale-biased representations for text instances using Eq. (1), and these representations can be used as inputs to any classifier.

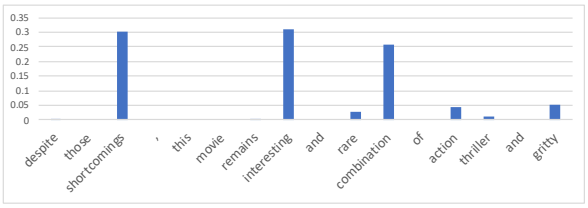

Figure 1: The bias weights generated by a rationale-biased model trained on 20 instances, to a snippet from an example movie review.

In early experiments, we noticed that many *non-discriminating*, common words in the target domain (e.g., *movie*, *certainly*, *guy*) tended to get high rationale biases. This is presumably due to the fact that rationales in these datasets often have spans that include multiple rationale words along with other words. To compensate, we adjusted the class rationale prototype representation to:

$$adjusted(R_i) = prot(R_i) - prot(T_{all}) \quad (4)$$

where T_{all} is the collection of all training instances across all classes. That is, we subtract the entire training-set prototype vector from each class rationale prototype. We L2-normalize this representation as well.

Figure 1 is an example illustrating actual bias weights generated by our model. As can be seen in this case, the most positive and negative indicative words are 'picked up' as indicated by the high respective bias. However, it should also be noted that this model misses the sentiment polarity inversion expressed by the word *despite*, due to its simple sequence-agnostic nature.

3.2 Classifiers

Various types of classifiers can be trained to perform text classification on top of the rationale-biased text representations described in the previous section. We chose to experiment with a standard SVM classifier as well as a simple, nearest-prototype classifier similar to the approach taken in prior few-shot learning work (Snell et al., 2017). Before training and applying these classifiers, we compute the class rationale prototypes to determine the rationale-bias function f_{rb}. We then use

that function to embed all of the dataset text instances and use these text embeddings as inputs to the classifiers. More specifically, for our nearest-prototype classifier, given a training set of text instance collections $T_1, .., T_k$ labeled with classes $c_1, .., c_k$, we represent each class c_i by the *class prototype* $\vec{T_i} = prot(T_i)$. To classify a new text instance t' we simply choose the closest class prototype using cosine similarity:

$$class(t') = \arg\max_{i \in \{1..k\}} cosine(\vec{t'}, \vec{T_i}) \quad (5)$$

Our hypothesis is that this proposed method would do comparatively well with very little training data because (a) with the guidance of the rationale bias it could pick up individual discriminative words more quickly (e.g., *good* or *bad* for sentiment tasks); (b) combining the use of pre-trained word embeddings as the underlying word representation with rationale bias would help generalize to words unseen in the training data (e.g. to *best* from *good*) and would facilitate an effective rationale bias similarity function $sim_{rb}(v)$; and (c) the training regimen is simple with a relatively small number of parameters to be learned compared to some more complex neural models such as the one discussed in the following section.

4 Rationale-biased BERT

BERT (Devlin et al., 2018) is a context-aware neural network model that has shown excellent results when used as a basis for various supervised NLP systems. Its power comes from transferring context-aware language modeling information learned from unsupervised training over very large amounts of plain text. In this section, we show how we adapt BERT to handle long texts and then to incorporate rationale supervision together with standard instance labels.

4.1 Fine-tuning BERT

Presented with a sequence of word tokens[2] $s = (a_1, ..a_n)$ as input, a BERT model outputs contextualized vector encodings for each token $B(s) = (h_0, h_1, .., h_n)$,[3] where h_0 is a special encoding for the entire sequence. Pre-trained versions of this model were trained by Devlin et al. (2018) against language modeling and sentence prediction objectives on large corpora of text allowing them to capture valuable contextualized information in these encodings. Devlin et al. (2018) applied dropout followed by a simple linear layer, $L_{tok}(drop(B(s)_i))$ where $i > 0$ to perform token-level classification and $L_{text}(drop(B(s)_0))$ for sentence-level classification. They fine-tuned the entire model on task-specific labels using a standard cross-entropy loss function. With this approach, they achieved state-of-the-art results on various NLP tasks, such as Named Entity Recognition (token-level) and single-sentence sentiment classification (sentence-level).

4.2 Averaged BERT classifier for long texts

While BERT proved to be very effective for classifying short texts such as individual sentences, its computational complexity is quadratic with the length of the input text yielding long run times for texts longer than a few sentences. Since our input texts may be long, we split them into sentences, apply BERT to each of the sentences separately and average the outputs as follows.

Given a text instance comprising the set of sentences $t = (s_1, ..., s_m)$, we encode it as the weighted average of the individual sentences:

$$B_{avg}(t) = \vec{t} = \sum_{i \in 1..m} w_i \cdot drop(B(s_i)_0) \quad (6)$$

where w_i are the weights used in the weighted average. We experiment with uniform weights and also with learning weights as learned attention, using a linear layer L_{attn}:

$$w_i = softmax(L_{attn}(drop(B(s_i)_0))) \quad (7)$$

Finally, similar to the original BERT approach, to fine tune a classifier for long text instances, we apply a linear layer to the text encoding $L_{text}(B_{avg}(t))$ and train the whole model to predict the target labels with the loss function:

$$S_{target}(t, l_t) = CE(L_{text}(B_{avg}(t)), l_t) \quad (8)$$

where l_t is the training label for text instance t and CE is the cross-entropy loss function. Figure 2 illustrates our architecture.

4.3 Rationale-biased BERT classifiers

We propose two methods to incorporate rationale supervision into our averaged BERT text classifier. The first is based on straightforward multi-task learning, where rationale word prediction is considered an auxiliary task that is jointly trained

[2] BERT breaks words into subword units called *word pieces* (Wu et al., 2016).

[3] We refer here to the top-most output layer of BERT.

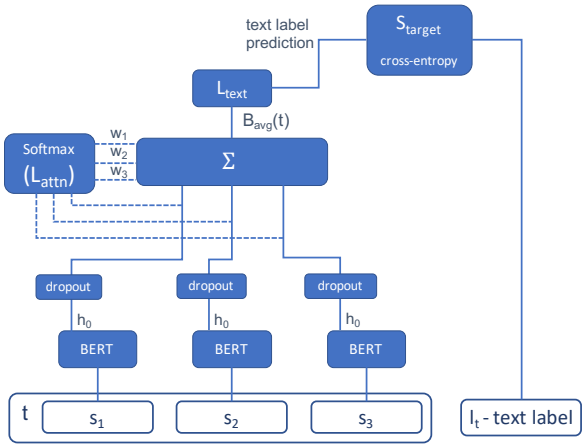

Figure 2: Averaged BERT model architecture. The three BERT boxes refer to the same single instance of the model. L_{attn} is the optional sentence attention learning component from Eq. (7).

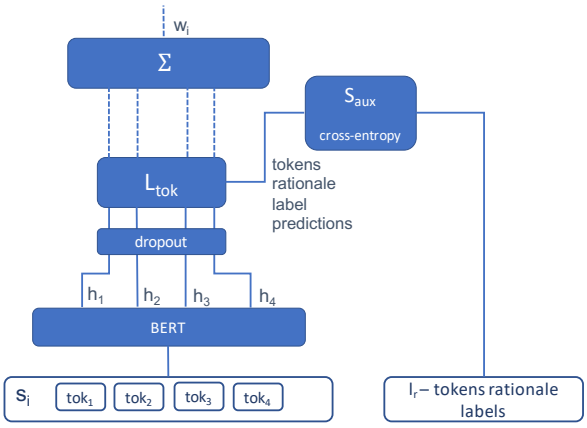

Figure 3: Rationale-bias auxiliary model component. The BERT model here is the same one used for the main target task. w_i is the average probability that a token in the sentence is part of a rationale, which can be used as sentence attention in the averaged BERT.

with the main text label prediction task. The second extends the first by using rationale supervision to estimate the attention to each sentence. It then uses that attention (or importance measure) to inform the weighted average from Eq. (6).

Simple joint learning. Figure 3 illustrates the auxiliary model added to the averaged BERT. The same BERT model is trained to perform two classification tasks: (1) predicting the label of each text instance (target text classification task); and (2) predicting for every input token in every input sentence whether it is part of an annotated rationale subsequence (auxiliary task). This is achieved by introducing the auxiliary loss function:

$$S_{aux}(t, l_r) = \frac{1}{n} \sum_{i,j} CE(L_{tok}(drop(B(s_i)_j)), l_r^{i,j}) \quad (9)$$

where $l_r^{i,j}$ is the rationale label of token j in sentence i, L_{tok} is a linear layer for learning to classify tokens and n is the total number of tokens in text t. Finally, the multi-task objective function per input text t is:

$$S_{joint}(t, l_t, l_r) = S_{target}(t, l_t) + S_{aux}(t, l_r) \quad (10)$$

Our hypothesis is that the auxiliary task will infuse lower-level information regarding the relevance of input words into the BERT model, which will help boost the main task classifier.[4]

[4]In early experiments, we also tried infusing this information to lower layers of the BERT model (i.e., to an internal layer rather than the output layer) following Søgaard and Goldberg (2016), but that did not improve the performance.

Rationale-biased Attention. The dotted lines in Figure 3 illustrate our proposed approach to extend simple joint-learning by using the rationale signal to learn how to identify the more important sentences in the input text. To train this model, we use the same multi-task loss function in Eq. (10). However, this time, instead of using uniform weights in the averaged BERT, we consider the attention weight of a sentence to be the average of the probabilities that each of its tokens is in a rationale span. These weights are used to compute the final weighted average representation of the text input in Eq. (6). In our experiments, we found that it was better not to backpropagate the error from S_{target} towards the token-level rationale classifier (i.e. along the dotted lines). Therefore, the rationale classifier is still trained only based on S_{aux}.

The hypothesis here is that this model could be successful by infusing more explicitly the inductive bias that sentences with rationale words are more important than others for the final classification task. Incorporating more inductive bias is particularly important with little training data. Compared to the bag-of-words approach presented in the previous section, however, we presume that both BERT-based methods presented here might be more challenged with extremely little training data because of the more complex underlying models and training regimen.

Figure 4 shows an example of sentence attentions and word rationale probabilities computed by our rationale-biased attention BERT model.

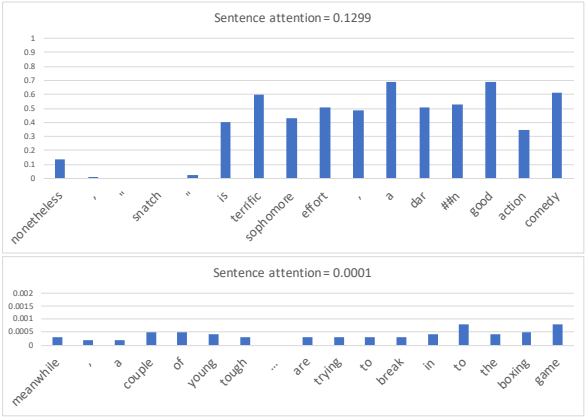

Figure 4: Excerpts from the sentence that got the highest attention (top) and lowest attention (bottom) in an IMDB movie review, by our rationale-biased attention BERT model. Bars indicate the probability the model assigns for every word of being part of a rationale.

Being context-aware, this model captures relevant sequences of words rather than just spotting key words. In addition to being useful for the classification task, these sentence and token weights also seem useful for model interpretability.

5 Experimental Settings

We conducted experiments with two English text classification datasets. Zaidan et al. (2007) added rationales supporting the positive/negative class labels on 1800 movie reviews from the Internet Movie Database (IMDB) dataset (Pang et al. (2002)). We used 900 reviews for training, 450 for development and 450 for testing, and maintained the original even positive/negative balance in every split.

The Aviation Safety Reporting System (ASRS) dataset contains reports of aviation safety incidents. We used the version from Abedin et al. (2011), which has 1233 reports in the training set, 100 for development and 1000 for testing. Reports are labeled with one or more of 14 safety incident cause categories. To create a binary classification dataset comparable to the IMDB dataset, we extracted a balanced subset of reports that were labeled with the 'Proficiency' label or the 'Physical Environment' label (but not both). We chose these particular two labels because they have a similar number of instances and are among the top most frequent labels in the dataset. This resulted in 386 reports for training and 392 reports for testing. Table 1 provides some additional statistics regarding these two datasets.

	IMDB	ASRS
sentences per instance	33.8	15.3
words per instance	736.6	262.1
rationales per instance	8.6	3.0
words per rationale	7.2	2.2

Table 1: Dataset statistics

5.1 Experimental protocol

To test the hypothesis that our proposed rationale-biased methods can improve classification with little training data, we ran experiments varying the amount of training data used from 2 instances up to roughly 400. For each training size n, we sampled n training instances to train the models and tested on the entire dev/test set. We repeated this experiment 30 times (for each n) and report average accuracies. We fixed all parameters based on tuning on only the IMDB development set prior to running on the IMDB and ASRS test data (no tuning was done on ASRS data).

5.2 Compared methods

RA-SVM is the Rationale-Augmented SVM by Sharma and Bilgic (2018) that biases the text representation to rationales by discounting non-rationale word features by a fixed discount ratio during training. All words are TF-IDF weighted prior to discounting. We experimented with different discounts on the IMDB development set and found that 0.1 gave the best results. And while Sharma and Bilgic (2018) use a one-hot word representation, we also experimented with giving it dense word embeddings, but this yielded degraded performance. We also report results with no rationale discount - a plain ***SVM*** baseline.

RA-CNN is the Rationale-Augmented CNN by Zhang et al. (2016), described in section 2. We used the authors' implementation with pre-trained word2vec Google News word embeddings with 300 dimensions for 3 million words.[5] We tuned batch size, dropout, learning rate and number of epochs on our development set. We also report results with no rationale weighting - a plain ***CNN*** baseline.

RB-BOW-SVM and ***RB-BOW-PROTO*** are the SVM and nearest-prototype classifiers running on top of our proposed rationale-biased bag-of-words (BOW) text representation (Section 3). We tuned

[5] https://code.google.com/archive/p/word2vec/

the hyperparameter α on the dev set, obtaining the best results with $\alpha = 6$ for both classifiers. ***BOW-PROTO*** is the prototype classifier based on a BOW with no rationale bias ($\alpha = 0$). We tried both one-hot word representations and word embeddings using the same word2vec embeddings as for CNN and RA-CNN.

AVG-BERT and ***ATTN-WAVG-BERT*** are our proposed BERT-based models trained without rationales using a uniform-weight average and an attention-based weighted average of sentences, respectively (Section 4.2). ***RB-AVG-BERT*** is the joint model that uses rationale prediction as an auxiliary task, and ***RB-WAVG-BERT*** is the method that also uses rationales to estimate sentence-level attention (Section 4.3). For all of the above, we used the pre-trained models 'bert-base-uncased' and 'bert-base-cased' for the IMDB and ASRS datasets, respectively. We used default hyperparameters, except for using learning rate of 5e-6 and 10 epochs for fine-tuning, which we found to work better for AVG-BERT with light tuning. To fit the computation graphs into the GPU memory (NVIDIA Tesla V100) we trimmed sentences longer than 48 word pieces, and texts containing more than 64 sentences. We implemented our models using a PyTorch implementation of BERT.[6]

ULMFiT (Howard and Ruder, 2018) is a recent method achieving state-of-the-art text classification results on several datasets. It is trained in three steps: (1) training a general-domain recurrent neural network language model on a large corpus (WikiText-103); (2) fine-tuning the language model to the domain data of the target task disregarding class labels; and (3) fine-tuning a classifier for the task using the encoder of the learned fine-tuned language model as a starting point. We used the *fast.ai*[7] implementation of ULMFiT, tuning batch size, dropout multiplication factor, learning rates and number of epochs on our development set. ULMFiT does not currently have a rationale-augmented version.

6 Results

In this section, we start by investigating the performance of different variants of our proposed models on the IMDB dev set. The most promising configurations are then evaluated on the IMDB and ASRS test sets. Since both of our datasets are binary and balanced we note that the random baseline accuracy is 50%.

6.1 Development set investigation

To demonstrate the contribution of various components of our rationale-biased bag-of-words approach, we performed several ablation experiments on the development set, shown in Figure 5. The compared variants include: ***RB-BOW-PROTO***: our full method with pre-trained word embeddings; ***BOW-PROTO***: no rationale-bias; ***OH***: RB-BOW-PROTO with one-hot word representations instead of word embeddings; ***NO-ADJUST***: RB-BOW-PROTO without discounting common words by subtracting the general prototype vector (Eq. (4)); ***SINGLE***: RB-BOW-PROTO with just a single rationale prototype representing all rationales instead of one rationale prototype for each class (Eq. (3)); and ***INSTANCE***: RB-BOW-PROTO with a rationale prototype for every individual text instance instead of one per class. As can be seen, combining the use of pre-training and rationales is critical to the success of our full method. First, the importance of using pre-trained word embeddings is evident by the significant drop in performance when using one-hot encodings with train-sets with 60 instances or fewer. Second, the importance of rationale-biasing can be seen by the large performance drop with BOW-PROTO across all train-set sizes. With those two components in place, we see that the RB-BOW-PROTO is able to perform significantly above the 50% random baseline with very few training instances. We note that RB-BOW-SVM demonstrated similar performance to RB-BOW-PROTO. For brevity, we don't include a detailed report here, but do include RB-BOW-SVM in the test results section.

To illustrate the potential merit in using our proposed rationale-biased embedding function we show 2-dimensional plots of text embeddings with and without rationale-bias in Figure 7. We randomly sampled a train-set of size 60 from the IMDB dataset and used it to learn the rationale-biased embedding function. We plotted the positive and negative class prototypes as learned from the training set as well as the embeddings of the IMDB dev set instances. We used T-SNE to reduce those 300-dimensional embeddings down to

two dimensions for visualization. The rationale-biased representation appears to discriminate better between positive and negative instances. In particular, we notice an increase in the distance between the representations of class prototypes and a clearer clustering of the development set instances around their respective class prototypes. For this data subset, the nearest prototype classifier achieves accuracy of 78.1% when using the rationale-biased embedding compared to 69.7% with an unbiased representation.

Next, we investigate the performance of the BERT-based models on the IMDB dataset. Figure 6 shows the results on the dev set. First we note that unlike the simpler bag-of-words methods, all of these models require at least 20 training instances before they meaningfully improve on the random 50% baseline. On the other hand, with 200 training instances or more, all of the BERT-based models significantly outperform the bag-of-words methods. More specifically, we see that RB-AVG-BERT and RB-WAVG-BERT, which use rationale supervision, significantly outperform AVG-BERT and ATTN-WAVG-BERT, which only use text label supervision, by up to 10 accuracy points. Between RB-AVG-BERT and RB-WAVG-BERT, the latter, which incorporates more inductive bias, performs more robustly.

6.2 Test set results

Figure 8 and Table 2 show the IMDB test-set results of our best rationale-biased methods and their non-rationale counterparts (chosen based on dev set performance), as well as all of the baselines.[8] Our bag-of-words models, RB-BOW-PROTO and RB-BOW-SVM, which combine rationale-biasing with pre-trained word embeddings, outperform all other baselines by a large margin of up to more than 20 absolute accuracy points for training sets of size 20 or smaller. On these particularly small datasets, the other rationale-aware baselines, RA-SVM and RA-CNN, do not perform as well. For larger training sets of size 60 and more, all systems perform better, as expected. In particular, the more complex CNN and BERT-based models have significantly improved performance with more supervision. Both RA-CNN and our RB-BERT, which combine pre-training with rationales, benefit substantially from rationale supervision, with up to more than 30 absolute accuracy points improvement. In absolute terms, our BERT models outperform their CNN counterparts and every other baseline in this training size range.

Finally, Figure 9 and Table 3 show results on the ASRS test set. The trends here are similar, showing the robust merit in our rationale-bias approach. The only striking difference is that in this dataset, the CNN methods outperform our BERT-based

methods both in their rationale and non-rationale versions. We note that the RA-CNN baseline takes a similar approach to ours in the sense that it also combines pre-training (pre-trained word embeddings) with rationales. The reasons for one method being better than the other on a particular dataset could be related to the compatibility between the pre-training corpus and the test dataset or sensitivity to hyperparameter tuning (we did not do any tuning on the ASRS dev set).

7 Conclusions

In this work, we addressed an important challenge in supervised machine learning, namely the dependency on large amounts of labeled training data. We demonstrated that substantial performance gains in low-shot text classification can be obtained by combining unsupervised pre-training with annotator rationales across various methods. To this end, we presented two novel methods that together provide strong results on a range of train set sizes. We performed experiments using various baselines, data sizes and ablations to help understand what works best for varying amounts of available training data. Most notably, we showed that simple bag-of-words methods with pre-trained word embeddings work best for very small train sets, while more complex methods based on pre-trained language models excel when more data is available.

Abstract

We propose a novel on-device sequence model for text classification using recurrent projections. Our model ProSeqo uses dynamic recurrent projections without the need to store or look up any pre-trained embeddings. This results in fast and compact neural networks that can perform on-device inference for complex short and long text classification tasks.

We conducted exhaustive evaluation on multiple text classification tasks. Results show that ProSeqo outperformed state-of-the-art neural and on-device approaches for short text classification tasks such as dialog act and intent prediction. To the best of our knowledge, ProSeqo is the first on-device long text classification neural model. It achieved comparable results to previous neural approaches for news article, answers and product categorization, while preserving small memory footprint and maintaining high accuracy.

1 Introduction

In the last decade, research in deep neural networks has lead to tremendous advances and state-of-the-art performance on wide range of Natural Language Processing (NLP), speech and vision applications. Coupled with the tremendous growth and adoption of smart devices such as mobile phones, watches, Internet of Things, conversational AI devices like Alexa and Google Home, these deep learning improvements have resulted in text and speech becoming the primary modes of communication (Cohen, 2008). To date, the majority of the models run on the server side by taking user input, sending the data to the server (or cloud) for processing and returning the results back to the user. This often results in latency delays, inconsistent user experiences and concerns over user privacy.

One way to surmount these challenges is to develop and deploy text and speech models that run inference entirely on-device and return accurate predictions in real-time. To make this work, the on-device models have to be very small in size (few kilobytes or megabytes) to fit on-devices like mobile phone, watch and IoT; to have low latency and be as accurate as server side models. These on-device challenges opened up new active area of research, which recently has shown promising results for speech (Lin et al., 2018), wake word detection (He et al., 2017), dialog act (Ravi and Kozareva, 2018) and intent prediction short text classification (Ravi and Kozareva, 2019).

Previous attempts for on-device text classification used hashed <*input_text*, *output_class*> pairs. Unfortunately, such models cannot handle examples that are not part of the lookup table and cannot generalize to more complex tasks like the ones we solve in this paper – long text classification, conversational intent prediction. (Bui et al., 2018) combined graphs with neural networks to improve the robustness of the model, but this resulted in large model sizes that cannot fit on-device. The most successful work is the self-governing neural network (SGNN) from (Ravi and Kozareva, 2018) and (SGNN++) from (Ravi and Kozareva, 2019), which use locality-sensitive projections (Ravi, 2017, 2019) to encode short text into low-dimensional representations. SGNN reached state-of-the-art results on dialog acts outperforming recurrent networks. While successful, SGNN's static projections make it hard to generalize to longer sequences.

In this work, we take one step further by developing a novel embedding free on-device neural model that combines *dynamic projections* with recurrent operations to learn powerful representations that can more powerfully encode text representations and can be equally efficient at short and long text classification tasks. The main contributions of our work are:

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3894–3903,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- We propose novel on-device dynamic projection sequence network ProSeqo for short and long text classification; To the best of our knowledge, this is the first on-device neural network for long text classification;
- Unlike SGNN which uses static projections and fully connected networks, ProSeqo is the first work to introduce embedding-free LSTMs that combine *dynamic projections* with recurrent operations to learn powerful yet compact neural networks applicable for on-device scenarios;
- We conduct exhaustive evaluations and comparisons against state-of-the-art on-device and deep learning models for short and long text classification;
- Our results show that ProSeqo outperformed state-of-the-art on-device SGNN network (Ravi and Kozareva, 2018) with up to +8.9% accuracy on short text classification and +35.9% accuracy on long document classification. This shows that ProSeqo's dynamic recurrent projections are more powerful than the static ones used in SGNN;
- Similarly, our results show that ProSeqo outperformed the non-on-device neural models like RNN (Khanpour et al., 2016), CNN (Lee and Dernoncourt, 2016) for dialog acts and intent prediction; as well as LSTMs (Zhang et al., 2015), character CNNs (Zhang et al., 2015; Bui et al., 2018) for long document classification of news, answers and product reviews. This is a significant advancement given ProSeqo's small model size compared to these widely used approaches;
- Finally, we conduct a series of ablation studies to demonstrate the effect of ProSeqo's projection size on accuracy and the ability of ProSeqo to produce small model sizes while retaining high accuracy.

2 ProSeqo: Projection Sequence Networks for On-device Text Classification

We introduce a neural architecture, *ProSeqo*, a projection-based sequence network, that is designed to (a) be efficient and learn compact *embedding-free* neural representations of text at the semantic level, (b) capture contextual and morphological information at the character-level, and (c) model longer context across words and sentences that is suited for both short and long-text classification tasks.

The key differences to prior work (e.g., RNNs, CNNs) are that we use context information to *dynamically* compute text representations and learn compact neural networks for text classification that are suited for on-device applications. Our work departs significantly from recent on-device work (Ravi and Kozareva, 2018) and (Ravi and Kozareva, 2019) which leverage projection operations to learn efficient networks that can even be transferred to other tasks (Sankar et al., 2019b). However, they are limited to short-text classification tasks. In contrast, our model effectively uses contextual information and combines *recurrent* and *projection* operations to achieve efficiency and enable learning more powerful neural networks that generalize well and can solve more complex language classification tasks. As a result, our projection sequence network is able to dynamically project and learn efficient neural classifier models that are competitive with state-of-the-art RNNs and CNNs without the need to store or lookup any pre-trained embeddings.

2.1 Model Overview

The overall architecture of ProSeqo is shown in Figure 1. It consists of multiple parts: a word context projector, a recurrent projector, a projection sequence encoder, and a classification layer. Next, we describe in details each component.

2.2 Word Context Projector

Given an input text x_i (sentence or document) with sequence of words w_{it}, where w_{it} refers to t-th word in the input, we first project the input x_i to a vector representation $\mathbb{P}(x_i)$. Majority of the neural models used in NLP rely on embedding matrices (word or character level) to achieve this. Instead, we dynamically compute word vector representations using *context* and locality-sensitive projections (Ravi, 2017).

2.2.1 Character and Morphology Projection

Each word contains characters and morphological information that can be informative for the task. For example, the words `amaze` and `amazing`, may appear slightly different but capture similar semantics for a review classification task. It

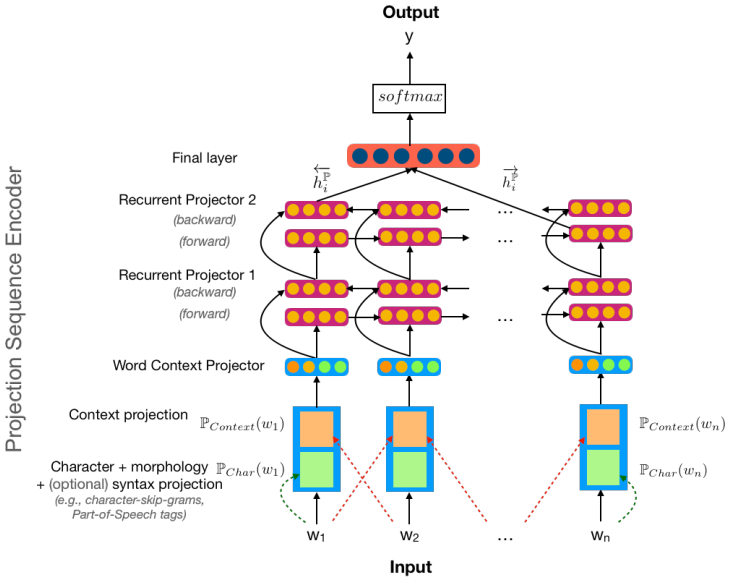

Figure 1: Model architecture for ProSeqo: On-device Projection Sequence Neural Networks.

is particularly challenging for NLP tasks to handle large vocabularies and model *unknown* words missing from training data. Previous methods have proposed to overcome this by relying on character-level embeddings and other neural models like character-CNNs. However, these methods are often complex and slow to compute for long text (e.g., convolution kernels on devices without significant computational capacity) and still require explicitly storing character or sub-word sequences. For example, even simple character trigrams over 26 characters in the English alphabet requires storing and looking up $V = 26^3 = 18K$ entries in character embedding table and complexity of $O(V \cdot d)$, where d is the dimensionality of the embedding. For word embeddings, V can be as large as 100K to millions of entries.

We extract character-level sequence information (i.e., character sequences) and use locality-sensitive projections (Ravi, 2017, 2019) to dynamically project them to a vector representation $\mathbb{P}_{Char}(w_{it})$ with just $O(T \cdot d)$ complexity, where $T << V$.

$$\mathbb{P}_{Char}(w_{it}) = \mathbb{P}(w_{itc_{1\ldots C}}) \quad (1)$$
$$= \mathbb{P}(\overrightarrow{w_{it}}) \quad (2)$$

where, $w_{itc_{1\ldots C}}$ is the sequence of characters $c \in [1, C]$ in word w_{it} and $\overrightarrow{w_{it}}$ is a sparse vector comprised of character-level features (character skip-grams) extracted from the word w_{it}. We can also extend this to include other morphological (e.g., stemming) or syntax features (e.g., Part-of-Speech) but this adds further complexity and requires lexicons or further pre-processing steps (e.g., stemmers, taggers) which may not be available on device during inference. Hence, we only use simple raw features like character skip-grams in the projector.

$$\mathbb{P}(\overrightarrow{w_{it}}) = \texttt{LSH}_{proj}(\overrightarrow{w_{it}}, \overrightarrow{\mathbb{P}_{T,d}}) \quad (3)$$
$$= [\ sgn(\overrightarrow{w_{it}} \cdot \overrightarrow{\mathbb{P}_{1,1}}), \ldots, \quad (4)$$
$$\ldots, sgn(\overrightarrow{w_{it}} \cdot \overrightarrow{\mathbb{P}_{T,d}})\ ]$$

We then apply LSH projections that dynamically compute locality-sensitive projections and transform the extracted sparse vector $\overrightarrow{w_{it}}$ (character sequence features) into a compact, low-dimensional binary representation $\mathbb{P}(\overrightarrow{w_{it}})$. The projection functions $\overrightarrow{\mathbb{P}}$ used to compute the binary vector are dynamically generated from observed features in $\overrightarrow{w_{it}}$ and a random seed. T, d represents the number of projection functions and dimensonality of each binary vector produced by each projection function. So, the output of the character-level projector is a $T \cdot d$ binary vector.

The locality-sensitive nature of the projections help learn a compact representation that capture semantic similarity (Sankar et al., 2019a) (i.e., words with similar character or morphology are mapped to the same binary representation) with a small memory footprint. For more details on LSH projections, refer to (Ravi, 2017).

2.2.2 Context Projection

In addition to characters, the surrounding context also contains important information useful to represent in the word vector. Unlike characters though, word context is typically not fixed in language and changes across sentences and documents. To address this, we extend the projection mechanism to capture word meaning using contextual information.

$$\begin{aligned}
\mathbb{P}_{Context}(w_{it}) &= \mathbb{P}(context(w_{it})) && (5)\\
&= \mathbb{P}(w_{it-\Delta}...w_{it-1}, && (6)\\
&\quad\ w_{it+1}...w_{it+\Delta})\\
&= \mathbb{P}(\overrightarrow{w_{it,\Delta}}) && (7)\\
&= \texttt{LSH}_{proj}(\overrightarrow{w_{it,\Delta}}, \overrightarrow{\mathbb{P}_{T,d}}) && (8)
\end{aligned}$$

where, Δ represents the context size around the current word w_{it}, $\overrightarrow{w_{it,\Delta}}$ is the context features extracted from neighboring context. We use simple raw features like word unigrams to model the context and apply dynamic projections on the sparse context feature vector to transform this to a binary context projection vector.

2.3 Recurrent Projector

We use LSTM to model the state of word projection sequences within a sentence or document. This allows the model to capture words appearing in different parts of the input text, and use the projection space to learn an efficient neural representation for the task. At each time-step t, we compute the word projection by combining both character and context information, and transforming them via projections.

$$\mathbb{P}(x_t) = [\ \mathbb{P}_{Char}(x_t),\ \mathbb{P}_{Context}(x_t)\ ] \quad (9)$$

The LSTM-projector $\mathbb{P}_{\text{RNN}}$ then computes the new state $h_t^{\mathbb{P}}$ using the projector output as follows

$$\begin{aligned}
f_t^{\mathbb{P}} &= \sigma(W_f \cdot [h_{t-1}, \mathbb{P}(x_t)] + b_f) && (10)\\
i_t^{\mathbb{P}} &= \sigma(W_i \cdot [h_{t-1}, \mathbb{P}(x_t)] + b_i) && (11)\\
\widetilde{C_t^{\mathbb{P}}} &= \tanh(W_C \cdot [h_{t-1}, \mathbb{P}(x_t)] + b_C) && (12)\\
C_t^{\mathbb{P}} &= f_t^{\mathbb{P}} * C_{t-1}^{\mathbb{P}} + i_t^{\mathbb{P}} * \widetilde{C_t^{\mathbb{P}}} && (13)\\
o_t^{\mathbb{P}} &= \sigma(W_o \cdot [h_{t-1}, \mathbb{P}(x_t)] + b_o) && (14)\\
h_t^{\mathbb{P}} &= o_t^{\mathbb{P}} * \tanh(C_t^{\mathbb{P}}) && (15)
\end{aligned}$$

where, $f^{\mathbb{P}}, i^{\mathbb{P}}, o^{\mathbb{P}}$ represent the projection forget, input and output gates respectively, σ is a non-linearity (ReLu) and W, b are the weight and bias parameters. $h_t^{\mathbb{P}}$ is the new state computed from previous state $h_{t-1}^{\mathbb{P}}$. Note that we can replace LSTM with GRU (Cho et al., 2014) or other variants to control the gating mechanism and derive other recurrent projector model variants.

2.4 Projection Sequence Encoder

We use a bidirectional recurrent projector $\mathbb{P}_{\text{RNN}}$ that encodes the input word sequence by summarizing information from both directions for word projections. The sequence encoder captures both character-level and contextual information across time steps through the projection space $\Omega_{\mathbb{P}}$.

The projection sequence encoder contains a forward encoder $\overrightarrow{\mathbb{P}_{\text{RNN}}}$ that processes the sentence (or document) from w_{i1} to w_{iT} and the backward encoder $\overleftarrow{\mathbb{P}_{\text{RNN}}}$ which reads the input text in reverse.

$$\begin{aligned}
\overrightarrow{xh_i^{\mathbb{P}}} &= \overrightarrow{\mathbb{P}_{\text{RNN}}}(x_i) && (16)\\
\overleftarrow{h_i^{\mathbb{P}}} &= \overleftarrow{\mathbb{P}_{\text{RNN}}}(x_i) && (17)\\
h_i &= [\ \overrightarrow{h_i^{\mathbb{P}}},\ \overleftarrow{h_i^{\mathbb{P}}}\ ] && (18)
\end{aligned}$$

We concatenate the two states to model the state h_i and transition of word projection sequences within a sentence or document.

Stacked Recurrent Projections: We also stack the recurrent projections to create deeper, multi-layered ProSeqo. Each layer is a bidirectional recurrent projection encoder with information from the forward and backward states passed to the next layer. In our work, we train ProSeqo with 2 layers.

2.5 Text Classifier

The final state of the projection sequence encoder h_{iF} is combined with an output layer to learn a classifier for a given task.

$$y_i = \texttt{softmax}(W_F \cdot h_{iF} + b_F) \quad (19)$$

We train ProSeqo via backpropagation using stochastic gradient descent with negative log likelihood of correct labels as the loss.

3 Text Classification Tasks

In this section, we describe the tasks and datasets for our experimental evaluation. We choose the datasets to compare against prior state-of-the-art on-device work (Ravi and Kozareva, 2018), and also to test the generalizability of our on-device model on short and long texts.

Text Classification Task		#Classes	Vocabulary	Avg. Length	Train	Test
SWDA	Dialog Act	42	20,000	7	193,000	5,000
MRDA	Dialog Act	6	12,000	8	78,000	15,000
ATIS	Intent Prediction	21	950	11	4,478	893
SNIPS	Intent Prediction	7	11,241	10	13,084	700
AG	News Categorization	4	156,000	38	120,000	7,600
Y!A	Yahoo! Answers Categorization	10	1,554,607	108	1,400,000	60,000
AMZN	Product Review Prediction	5	1,919,336	92	3,000,000	650,000

Table 1: Text Classification Tasks and Dataset Characteristics

3.1 Dataset Description

• **SWDA:** Switchboard Dialog Act Corpus is a popular open domain dialog corpus between two speakers with 42 dialog acts (Godfrey et al., 1992; Jurafsky et al., 1997). The dataset is used in the on-device work of (Ravi and Kozareva, 2018).

• **MRDA:** Meeting Recorder Dialog Act is a dialog corpus of multiparty meetings annotated with 6 dialog acts (Adam et al., 2003; Shriberg et al., 2004). The dataset was also used by on-device work of (Ravi and Kozareva, 2018). We used the same data split as (Lee and Dernoncourt, 2016; Ortega and Vu, 2017; Ravi and Kozareva, 2018).

• **ATIS:** The Airline Travel Information Systems dataset (Tür et al., 2010) is widely used in dialog and speech research. The dataset contains audio recordings of people making flight reservations (Tür et al., 2010; Goo et al., 2018).

• **SNIPS:** To test the generalizability of our model, we use another NLU dataset with custom intent-engines collected by Snips personal voice assistant. We used the data from (Goo et al., 2018). Compared to the single-domain ATIS dataset, Snips is more complicated mostly because of the rich and diverse intent repository combined with the larger vocabulary.

• **AG:** AG News corpus is a collection of news articles on the web, where each document has a title and a description field. We used the dataset from (Zhang et al., 2015).

• **Y!A:** Yahoo! Answers is a text classification task with 10 diverse classes: *Society & Culture*, *Science & Mathematics*, *Health*, *Education & Reference*, *Computers & Internet*, *Sports*, *Business & Finance*, *Entertainment & Music*, *Family & Relationships* and *Politics & Government*. Each document contains a question title, question context and best answers. We obtained the data from (Zhang et al., 2015). Note that (Yang et al., 2016) used a smaller test sample for evaluation. To present fair results, we will not compare to (Yang et al., 2016).

• **AMZN:** Amazon review dataset is obtained from (Zhang et al., 2015). Resolving this task can be very helpful for product categorization (Kozareva, 2015). The corpora has reviews with ratings ranging from 1 to 5. Following prior work, we use 3,000,000 reviews for training and 650,000 reviews for testing.

3.2 Dataset Characteristics

Table 1 shows the datasets characteristics such as the type of the task, number of classes, vocabulary size, average text length, train and test sizes. As shown in Table 1, the datasets are very diverse, some have few thousand training examples, while others have millions. The test sizes also differ. Similarly, there are tasks with small and huge vocabularies. These diverse characteristics help validate and capture the ability of our on-device model ProSeqo to generalize to different tasks, data constraints, settings and vocabulary. With respect to the text length, we have two major categories: short text tasks such as dialog act and intent prediction, and long text tasks such as news, product reviews and answer categorization.

3.3 Experimental Setup & Model Parameters

We setup our experiments as given a classification task and dataset, we apply ProSeqo to train an on-device model. For each task, we report *Accuracy* on the test set. Unlike typical NLP approaches including baseline neural methods, we do **not** apply any vocabulary pruning or pre-processing at all to the input sentences and documents, except for splitting tokens by space.

We use a 2-layer *ProSeqo* neural network with recurrent projections of size $T = 60, d = 14$ and 256 hidden dimensions to represent state in each bidirectional LSTM-projection layer. We use character 7-grams (with 1-skip) and context size of 1 to model the projector described in Section 2.2. ProSeqo network is trained with SGD and Adam

Model	SWDA	MRDA	ATIS	SNIPS
ProSeqo (our on-device model)	**88.3**	**90.1**	**97.8**	**97.9**

Table 2: Short Text Classification On-device Results & Comparisons to Prior Work

optimizer (Kingma and Ba, 2014) over shuffled mini-batches of size 100. We did not do any additional dataset-specific tuning or processing.

4 STC: Short Text Classification Results

This section focuses on the multiple short text classification experiments we have conducted. Table 2 shows the results on the dialog act and intent prediction tasks for SWDA, MRDA, ATIS and SNIPS datasets. Overall, ProSeqo reached the highest performance and significantly improved upon prior state-of-the-art on-device neural approaches (Ravi and Kozareva, 2018). Similarly, ProSeqo outperformed non-on-device neural models like RNN (Khanpour et al., 2016), CNN (Lee and Dernoncourt, 2016) and joint neural approaches (Goo et al., 2018; Hakkani-Tur et al., 2016).

4.1 STC: Comparison with On-Device Work

We compare our on-device model against state-of-the-art on-device short text classification approach SGNN (Ravi and Kozareva, 2018). SGNN was evaluated only on the SWDA and MRDA dialog act tasks (Ravi and Kozareva, 2018) and reached state-of-the-art performance against prior non-on-device neural approaches (Khanpour et al., 2016). We directly compare performance on the same SWDA and MRDA datasets. As shown in Table 2 ProSeqo reaches +5.3% improvement for SWDA and +3.4% accuracy improvement for MRDA.

Since we want to compare on-device performance on a wider spectrum of tasks and datasets, we re-implemented SGNN with the same parameters (Ravi and Kozareva, 2018). We run experiments on ATIS and SNIPS intent prediction tasks and reported results in Table 2 in italic to indicate that this is a re-implementation of (Ravi and Kozareva, 2018) and previously these on-device results were not reported. As shown in Table 2, SGNN consistently performs well on dialog act and intent prediction tasks. Overall, ProSeqo reached +8.9% accuracy improvements on ATIS and +4.5% accuracy improvements on SNIPS compared to SGNN. This shows that ProSeqo's recurrent dynamic projections learn more powerful representations than the static SGNN ones, this also leads to significant performance improvements on multiple tasks.

4.2 STC: Comparison with Non-On-Device

The main objective of on-device work is to develop small and efficient models that fit on devices with limited memory and capacity. In contrast, the non-on-device models do not have any constraints and can use all resources available on server side. Therefore, it is not fair to directly compare the on-device and non-on-device models. Taking these differences in consideration, we show in Table 2 results from non-on-device models with the objective to highlight the power of on-device models and their capability to produce small memory footprint models, which are competitive in accuracy to those using pre-trained embeddings and unconstrained resources.

As shown in Table 2, prior work focused on developing the best approach for a specific task and dataset, resulting in not having a single model across all tasks. ProSeqo is the only approach spanning across all tasks and datasets. In terms of SWDA and MRDA, ProSeqo significantly improves with +8.2% accuracy and +3.3% accuracy the best performing non-on-device neural approach (Khanpour et al., 2016). For ATIS and SNIPs, the most recent state-of-art approaches use joint intent and slot prediction model (Hakkani-Tur et al., 2016; Liu and Lane, 2016; Goo et al., 2018), where the slot model recognizes the enti-

Model	AG	Y!A	AMZN
ProSeqo (our on-device model)	**91.5**	**72.4**	**62.3**
SGNN (Ravi and Kozareva, 2018)(**on-device**)	*57.6*	*36.5*	*39.3*
FastText-full(Joulin et al., 2016)	**92.5**	72.3	60.2
CharCNNLargeWithThesau.(Zhang et al., 2015)	90.6	71.2	59.6
CNN+NGM(Bui et al., 2018)	86.9	-	-
LSTM-full(Zhang et al., 2015)	86.1	70.8	59.4
Hier.-Attention(Yang et al., 2016)	-	-	**63.6**
Hier.-AVE(Yang et al., 2016)	-	-	**62.9**

Table 3: Long Text Classification On-device Results & Comparisons to Prior Work

ties and their semantic categories in the text, and the intent prediction model uses the slot information. (Liu and Lane, 2016) showed that joint intent and slot model improves upon the individual ones. While the entities and their semantic types are useful, ProSeqo does not rely on such additional information. ProSeqo simply uses the text and different context to learn compact semantic projection representations on-the-fly to make the intent prediction. ProSeqo improves with +3.7% the best approach for ATIS, which is a gated intent attention (Goo et al., 2018), and with +1% the best approach for SNIPS, which is gated full attention (Goo et al., 2018). (Goo et al., 2018) developed two complimentary approaches one with full attention and one with gated intent attention, yet they do not have consistent improvements on both datasets and tasks. In our case, our on-device ProSeqo model consistently improved upon both tasks, and reached state-of-the-art performance over prior non-on-device neural approaches. This is a significant improvement given the small size of ProSeqo and the fact that it does not store or lookup any pre-trained embedding matrices.

5 LDC: Long Document Classification Results

This section focuses on long document classification results. Table 3 shows the results on three tasks and datasets (AG, Y!A, AMZN). Overall, ProSeqo significantly improved upon the on-device neural model SGNN (Ravi and Kozareva, 2018) with +23% to +35.9% accuracy. ProSeqo also reached comparable performance to prior non-on-device neural LSTMs and character CNNs approaches (Zhang et al., 2015; Bui et al., 2018).

5.1 LDC: Comparison with On-Device Work

To the best of our knowledge, ProSeqo is the first on-device neural approach for long document classification. Since prior on-device work focused mostly on short text, we re-implemented the on-device state-of-the-art neural approach SGNN (Ravi and Kozareva, 2018) and run it on multiple long text tasks and datasets. Similarly to the short text section, we reported SGNN results in Table 3 in italic to indicate that this is a re-implementation of (Ravi and Kozareva, 2018) and previously results on these datasets and tasks were not reported.

As shown in Table 3, SGNN performed well on short texts, but it did not reach high performance on long documents. It it important to highlight that ProSeqo maintained consistent performance across all short and long document classification tasks. For long texts, ProSeqo improved SGNN with +33.9% accuracy on AG news, with +35.9% accuracy on Y!A and with +23% accuracy on Amazon product review classification. These are significant improvements and further show the importance of ProSeqo's recurrent dynamic projections for short and long text classification.

5.2 LDC: Comparison with Non-On-Device

Similarly to the short text classification, we also conduct a comparison of non-on-device model for long document classification. As highlighted before, such comparison is not fair due to the fact that non-on-device models do not have to comply with small memory, small size and low latency constraints. Bearing this in mind, we show results in Table 3. As it can be seen, only FastText (Joulin et al., 2016), CharCNN with Thesaurus (Zhang et al., 2015) and LSTM-full (Zhang et al., 2015) have been evaluated on all datasets, while CNN+NGM (Bui et al., 2018) focused on reaching the best performance for AG news. ProSeqo outperforms (Joulin et al., 2016; Zhang et al., 2015,?; Bui et al., 2018), and reaches comparable results to FastText (Joulin et al., 2016) on AG news. The hierarchical attention and hierarchi-

cal average models of (Yang et al., 2016) were evaluated only on the Amazon reviews and Y!A datasets. However, we noticed that the test set of the Y!A dataset in (Yang et al., 2016) was smaller compared to the data used in (Zhang et al., 2015; Joulin et al., 2016) and our experiments. To make consistent and fair comparisons, we did not include (Yang et al., 2016). For Amazon reviews, ProSeqo reached comparable performance to hierarchical average and hierarchical attention models (Yang et al., 2016). Overall, ProSeqo reached similar performance to non-on-device neural approaches, which use pre-trained embeddings while ProSeqo does not store or lookup any pre-trained embedding matrices.

6 ProSeqo Ablation Studies

This section shows two ablation studies focusing on the: (1) effect of the projection size on accuracy and (2) model size on accuracy.

6.1 Effect of Projection Size on Accuracy

During series of evaluations on multiple short and long text classification tasks, and comparing results against prior state-of-the-art neural networks and on-device neural models, ProSeqo achieved robust performance irrespective of the task, vocabulary size, training and test datasets. This is significant improvement given the small memory size of the model and the fact that we used the same model, configuration and model parameters across all seven NLP tasks unlike prior work which fine-tuned on specific data.

We also evaluated ProSeqo with different number of parameters T, d used in the recurrent projection. Table 4 shows the performance of ProSeqo on the AG News classification task and indicates that even if we reduce the projection size by 3x, we still achieve 90% accuracy with a small drop in performance of 1.4% (91.5 $\rightarrow$ 90.09).

Projection Size ($T \cdot d$)	300	600	800
Compression Ratio ($\frac{S_1}{S_2}$)	15×10^4	7.5×10^4	5.6×10^4
Accuracy	90.0	91.0	**91.5**

Table 4: Effect of ProSeqo's Recurrent Projection Size on Accuracy for AG News Classification. *Compression Ratio* is computed wrt ProSeqo model size (S_1) vs. LSTM baseline (S_2) with word embeddings (vocabulary size=150K, embedding size=300).

6.2 ProSeqo's Model Size

In addition to the quality evaluations, comparisons and results, we also highlight how compact and fast our on-device model is, which is very important for fitting the model on small memory-constrained devices such as mobile phones and watches. For this purpose, we measure the current size of our ProSeqo model. We do not have the exact parameter counts and model sizes from the previous neural approaches such as RNNs, BiLSTMs, and Hierarchical Attention models. But we make an observation that number of parameters in the recurrent layers of these baseline networks are similar to the parameters encoded in the recurrent projector layers in the ProSeqo model. Hence we can approximately compute the difference in model sizes between ProSeqo and other neural models by taking into consideration the size of embeddings fed into the recurrent layers along with the training data vocabulary size.

As highlighted in the main contributions of our approach ProSeqo is an embedding-free method, which means that it does not have to store or look up any embedding matrices. This makes the model small in comparison to existing neural approaches. For instance, to calculate the model size of ProSeqo as explained in Section 2 we need to consider $(T \cdot d)$ where d is the number of LSH bits specified for each projection vector, and T is the number of projection functions used resulting in $(T \cdot d) = 60 \times 14$ parameters shared across all time-steps. Independent of the task, length of the text (*short* vs *long*) and vocabulary sizes, ProSeqo's model size remains constant $(T \cdot d)$ across all seven tasks and datasets. Comparing ProSeqo's model size against a neural approach that uses Glove (or word2vec) word embeddings with 300 dimensions and vocabulary size V for the datasets, we can easily see that the neural models will have bigger sizes and their model size also varies depending on the task and vocabulary size. For instance, the vocabulary size in AG dataset is $150K$ resulting in $150K \times 300$ more model parameters than ProSeqo. For Yahoo this is $1.5M \times 300$ and for Amazon model size is $1.9M \times 300$. As it can be seen, ProSeqo produces models that are orders of magnitude smaller compared to prior neural approaches. On AG dataset, ProSeqo model has $5 \cdot 10^4$x fewer parameters for the first layer which is equivalent to just 3.3KB in size using `float32` parameters compared to 180MB for other neural methods. ProS-

eqo's size remains constant independent of the text lengths, vocabulary size and classification tasks. Even with neural models like charCNN that use character-level embeddings which is typically applied in conjunction with word embeddings, ProSeqo still yields an order or two magnitude smaller model sizes. The computation within ProSeqo is fast, $O(T \cdot d \cdot n)$ `multiply-add` operations for n-length words regardless of word/character vocabulary sizes.

7 Conclusion

We proposed a novel Projection Sequence Neural Network (ProSeqo) for on-device text classification. Evaluations on multiple text classification tasks show that ProSeqo significantly improved accuracy compared to state-of-the-art on-device neural network SGNN (Ravi and Kozareva, 2018) on short text with +3.4% for MRDA, +4.5% on SNIPS, +5.3% on SWDA and +8.9% on ATIS; and long documents with +23% on Amazon product reviews, +33.9% on AG news, +35.9% on Y!A. Similarly, ProSeqo improved non-on-device neural RNN, CNN and joint approaches (Khanpour et al., 2016; Lee and Dernoncourt, 2016; Hakkani-Tur et al., 2016; Goo et al., 2018) on short text and reached comparable results on long documents (Joulin et al., 2016; Zhang et al., 2015; Bui et al., 2018). This is significant improvement given ProSeqo's small network size, and the fact that we used the same architecture and parameters across all seven NLP tasks, while prior work tuned depending on the task and dataset.

Abstract

Text classification tends to struggle when data is deficient or when it needs to adapt to unseen classes. In such challenging scenarios, recent studies have used meta-learning to simulate the few-shot task, in which new queries are compared to a small support set at the sample-wise level. However, this sample-wise comparison may be severely disturbed by the various expressions in the same class. Therefore, we should be able to learn a general representation of each class in the support set and then compare it to new queries. In this paper, we propose a novel Induction Network to learn such a generalized class-wise representation, by innovatively leveraging the dynamic routing algorithm in meta-learning. In this way, we find the model is able to induce and generalize better. We evaluate the proposed model on a well-studied sentiment classification dataset (English) and a real-world dialogue intent classification dataset (Chinese). Experiment results show that on both datasets, the proposed model significantly outperforms the existing state-of-the-art approaches, proving the effectiveness of class-wise generalization in few-shot text classification.

1 Introduction

Deep learning has achieved a great success in many fields such as computer vision, speech recognition and natural language processing (Kuang et al., 2018). However, supervised deep learning is notoriously greedy for large labeled datasets, which limits the generalizability of deep models to new classes due to annotation cost. Humans on the other hand are readily capable of rapidly learning new classes of concepts with few examples or stimuli. This notable gap provides a fertile ground for further research.

Few-shot learning is devoted to resolving the data deficiency problem by recognizing novel classes from very few labeled examples. The limitation of only one or very few examples challenges the standard fine-tuning method in deep learning. Early studies (Salamon and Bello, 2017) applied data augmentation and regularization techniques to alleviate the overfitting problem caused by data sparseness, only to a limited extent. Instead, researchers have explored meta-learning (Finn et al., 2017) to leverage the distribution over similar tasks, inspired by human learning. Contemporary approaches to few-shot learning often decompose the training procedure into an auxiliary meta-learning phase, which includes many meta-tasks, following the principle that the testing and training conditions must match. They extract some transferable knowledge by switching the meta-task from mini-batch to mini-batch. As such, few-shot models can classify new classes with just a small labeled support set.

However, existing approaches for few-shot learning still confront many important problems, including the imposed strong priors (Fei-Fei et al., 2006), complex gradient transfer between tasks (Munkhdalai and Yu, 2017), and fine-tuning the target problem (Qi et al., 2018). The approaches proposed by Snell et al. (2017) and Sung et al. (2018), which combine non-parametric methods and metric learning, provide potential solutions to some of those problems. The non-parametric methods allow novel examples to be rapidly assimilated, without suffering from catastrophic overfitting. Such non-parametric models only need to learn the representation of the samples and the metric measure. However, instances in the same class are interlinked and have their uniform fraction and their specific fractions. In previous studies, the class-level representations are calculated by simply summing or averaging represen-

tations of samples in the support set. In doing so, essential information may be lost in the noise brought by various forms of samples in the same class. Note that few-shot learning algorithms do not fine-tune on the support set. When increasing size of the support set, the improvement brought by a bigger data size will also be diminished by more sample level noises.

Instead, we explore a better approach by performing induction at the class-wise level: ignoring irrelevant details and encapsulating general semantic information from samples with various linguistic forms in the same class. As a result, there is a need for a perspective architecture that can reconstruct hierarchical representations of support sets and dynamically induce sample representations to class representations.

Recently, capsule network (Sabour et al., 2017) has been proposed, which possesses the exciting potential to address the aforementioned issue. A capsule network uses "capsules" that perform dynamic routing to encode the intrinsic spatial relationship between parts and whole that constitutes viewpoint invariant knowledge. Following a similar spirit, we can regard samples as parts and class as a *whole*. We propose the Induction Networks, which aims to model the ability of learning generalized class-level representation from samples in a small support set, based on the dynamic routing process. First, an Encoder Module generates representations for a query and support samples. Next, an Induction Module executes a dynamic routing procedure, in which the matrix transformation can be seen as a map from the sample space to the class space, and then the generation of the class representation is all depending on the routing-by-agreement procedure other than any parameters, which renders a robust induction ability to the proposed model to deal with unseen classes. By regarding the samples' representations as input capsules and the classes' as output capsules, we expect to recognize the semantics of classes that is invariant to sample-level noise. Finally, the interaction between queries and classes is modelled—their representations are compared by a Relation Module to determine if the query matches the class or not. Defining an episode-based meta-training strategy, the holistic model is meta-trained end-to-end with the generalizability and scalability to recognize unseen classes.

The specific contributions of our work are listed as follows:

- We propose the Induction Networks for few-shot text classification. To deal with sample-wise diversity in the few-shot learning task, our model is the first, to the best of our knowledge, that explicitly models the ability to induce class-level representations from small support sets.
- The proposed Induction Module combines the dynamic routing algorithm with typical meta-learning frameworks. The matrix transformation and routing procedure enable our model to generalize well to recognize unseen classes.
- Our method outperforms the current state-of-the-art models on two few-shot text classification datasets, including a well-studied sentiment classification benchmark and a real-world dialogue intent classification dataset.

2 Related Work

2.1 Few-Shot Learning

The seminal work on few-shot learning dates back to the early 2000s (Fe-Fei et al., 2003; Fei-Fei et al., 2006). The authors combined generative models with complex iterative inference strategies. More recently, many approaches have used a meta-learning (Finn et al., 2017; Mishra et al., 2018) strategy in the sense that they extract some transferable knowledge from a set of auxiliary tasks, which then helps them to learn the target few-shot problem well without suffering from overfitting. In general, these approaches can be divided into two categories.

Optimization-based Methods This type of approach aims to learn to optimize the model parameters given the gradients computed from the few-shot examples. Munkhdalai and Yu (2017) proposed the Meta Network, which learnt the meta-level knowledge across tasks and shifted its inductive biases via fast parameterization for rapid generalization. Mishra et al. (2018) introduced a generic meta-learning architecture called SNAIL which used a novel combination of temporal convolutions and soft attention.

Distance Metric Learning These approaches are different from the above approaches that entail some complexity when learning the target few-

shot problem. The core idea in metric-based few-shot learning is similar to nearest neighbours and kernel density estimation. The predicted probability over a set of known labels is a weighted sum of labels of support set samples. Vinyals et al. (2016) produced a weighted K-nearest neighbour classifier measured by the cosine distance, which was called Matching Networks. Snell et al. (2017) proposed the Prototypical Networks which learnt a metric space where classification could be performed by computing squared Euclidean distances to prototype representations of each class. Different from fixed metric measures, the Relation Network learnt a deep distance metric to compare the query with given examples (Sung et al., 2018).

Recently, some studies have been presented focusing specifically on few-shot text classification problems. Xu et al. (2018) studied lifelong domain word embeddings via meta-learning. Yu et al. (2018) argued that the optimal meta-model may vary across tasks, and they employed the multi-metric model by clustering the meta-tasks into several defined clusters. Rios and Kavuluru (2018) developed a few-shot text classification model for multi-label text classification where there was a known structure over the label space. Xu et al. (2019) proposed a open-world learning model to deal with the unseen classes in the product classification problem. We solve the few-shot learning problem from a different perspective and propose a dynamic routing induction method to encapsulate the abstract class representation from samples, achieving state-of-the-art performances on two datasets.

2.2 Capsule Network

The Capsule Network was first proposed by Sabour et al. (2017), which allowed the network to learn robustly the invariants in part-whole relationships. Lately, Capsule Network has been explored in the natural language processing field. Yang et al. (2018) successfully applied Capsule Network to fully supervised text classification problem with large labeled datasets. Unlike their work, we study few-shot text classification. Xia et al. (2018) reused the supervised model similar to that of Yang et al. (2018) for intent classification, in which a capsule-based architecture is extended to compute similarity between the target intents and source intents. Unlike their work, we propose Induction Networks for few-shot learning, in which we propose to use capsules and dynamic routing to learn generalized class-level representation from samples based. The dynamic routing method makes our model generalize better in the few-shot text classification task.

3 Problem Definition

3.1 Few-Shot Classification

Few-shot classification (Vinyals et al., 2016; Snell et al., 2017) is a task in which a classifier must be adapted to accommodate new classes not seen in training, given only a few examples of each of these new classes. We have a large labeled training set with a set of classes C_{train}. However, after training, our ultimate goal is to produce classifiers on the testing set with a disjoint set of new classes C_{test}, for which only a small labeled support set will be available. If the support set contains K labeled examples for each of the C unique classes, the target few-shot problem is called a C-way K-shot problem. Usually, the K is too small to train a supervised classification model. Therefore, we aim to perform meta-learning on the training set, and extract transferable knowledge that will allow us to deliver better few-shot learning on the support set and thus classify the test set more accurately.

3.2 Training Procedure

The training procedure has to be chosen carefully to match inference at test time. An effective way to exploit the training set is to decompose the training procedure into an auxiliary meta-learning phase and mimic the few-shot learning setting via episode-based training, as proposed in Vinyals et al. (2016). We construct an meta-episode to compute gradients and update our model in each training iteration. The meta-episode is formed by randomly selecting a subset of classes from the training set first, and then choosing a subset of examples within each selected class to act as the support set S and a subset of the remaining examples to serve as the query set Q. The meta-training procedure explicitly learns to learn from the given support set S to minimise a loss over the query set Q. We call this strategy as episode-based meta training, and the details are shown in Algorithm 1. It is worth noting that there are exponentially many possible meta tasks to train the model on, making it hard to overfit. For example, if a dataset contains 159 training classes, this leads to

Algorithm 1 Episode-Based Meta Training

1: **for** each *episode iteration* **do**
2: Randomly select C classes from the class space of the training set;
3: Randomly select K labeled samples from each of the C classes as support set $S = \{(x_s, y_s)\}_{s=1}^{m}$ $(m = K \times C)$, and select a fraction of the reminder of those C classes' samples as query set $Q = \{(x_q, y_q)\}_{q=1}^{n}$;
4: Feed the support set S to the model and update the parameters by minimizing the loss in the query set Q;
5: **end for**

$$\begin{pmatrix} 159 \\ 5 \end{pmatrix} = 794,747,031 \text{ possible } 5-way \text{ tasks.}$$

4 The Models

Our Induction Networks, depicted in Figure 1 (the case of 3-way 2-shot model), consists of three modules: Encoder Module, Induction Module and Relation Module. In the rest of this section, we will show how these modules work in each meta-episode.

4.1 Encoder Module

This module is a bi-direction recurrent neural network with self-attention as shown in Lin et al. (2017). Given an input text $x = (w_1, w_2, ..., w_T)$, represented by a sequence of word embeddings. We use a bidirectional LSTM to process the text:

$$\overrightarrow{h_t} = \overrightarrow{LSTM}(w_t, h_{t-1}) \quad (1)$$

$$\overleftarrow{h_t} = \overleftarrow{LSTM}(w_t, h_{t+1}) \quad (2)$$

And we concatenate $\overrightarrow{h_t}$ with $\overleftarrow{h_t}$ to obtain a hidden state h_t. Let the hidden state size for each unidirectional LSTM be u. For simplicity, we note all the T $h_t s$ as $H = (h_1, h_2, ..., h_T)$. Our aim is to encode a variable length of text into a fixed size embedding. We achieve that by choosing a linear combination of the T $LSTM$ hidden vectors in H. Computing the linear combination requires the self-attention mechanism, which takes the whole LSTM hidden states H as input, and outputs a vector of weights a:

$$a = softmax(W_{a2} tanh(W_{a1} H^T)) \quad (3)$$

here $W_{a1} \in R^{d_a \times 2u}$ and $W_{a2} \in R^{d_a}$ are weight matrices and d_a is a hyperparameter. The final representation e of the text is the weighted sum of H:

$$e = \sum_{t=1}^{T} a_t \cdot h_t \quad (4)$$

4.2 Induction Module

This section introduces the proposed dynamic routing induction algorithm. We regard these vectors e obtained from the support set S by Eq 4 as sample vectors e^s, and the vectors e from the query set Q as query vectors e^q. The most important step is to extract the representation for each class in the support set. The main purpose of the induction module is to design a non-linear mapping from sample vector e_{ij}^s to class vector c_i:

$$\left\{e_{ij}^s \in R^{2u}\right\}_{i=1,...C, j=1...K} \mapsto \left\{c_i \in R^{2u}\right\}_{i=1}^{C}.$$

We apply the dynamic routing algorithm (Sabour et al., 2017) in this module, in the situation where the number of the output capsule is one. In order to accept any-way any-shot inputs in our model, a weight-sharable transformation across all sample vectors in the support set is employed. All of the sample vectors in the support set share the same transformation weights $W_s \in R^{2u \times 2u}$ and bias b_s, so that the model is flexible enough to handle the support set at any scale. Each sample prediction vector $\hat{e}_{ij}^s$ is computed by:

$$\hat{e}_{ij}^s = squash(W_s e_{ij}^s + b_s) \quad (5)$$

where $squash$ is a non-linear squashing function through the entire vector, which leaves the direction of the vector unchanged but decreases its magnitude. Given input vector x, $squash$ is defined as:

$$squash(x) = \frac{\|x\|^2}{1 + \|x\|^2} \frac{x}{\|x\|} \quad (6)$$

Eq 5 encodes important invariant semantic relationships between lower level sample features and higher level class features (Hinton et al., 2011). To ensure the class vector encapsulates the sample feature vectors of this class automatically, dynamic routing is applied iteratively. In each iteration, the process dynamically amends the connection strength and makes sure that the coupling coefficients d_i sum to 1 between class i and all support samples in this class by a "routing softmax":

$$d_i = softmax\left(b_i\right) \quad (7)$$

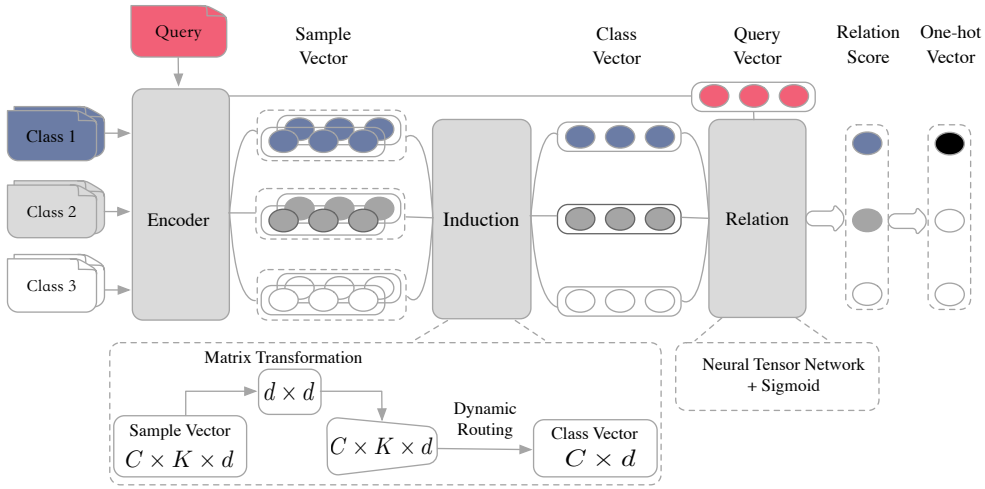

Figure 1: Induction Networks architecture for a C-way K-shot ($C = 3$, $K = 2$) problem with one query example

where b_i is the logits of coupling coefficients, and initialized by 0 in the first iteration. Given each sample prediction vector $\hat{e}^s_{ij}$, each class candidate vector $\hat{c}_i$ is a weighted sum of all sample prediction vectors $\hat{e}^s_{ij}$ in class i:

$$\hat{c}_i = \sum_j d_{ij} \cdot \hat{e}^s_{ij} \tag{8}$$

then a non-linear "squashing" function is applied to ensure that the length of the vector output of the routing process will not exceed 1:

$$c_i = squash(\hat{c}_i) \tag{9}$$

The last step in every iteration is to adjust the logits of coupling coefficients b_{ij} by a "routing by agreement" method. If the produced class candidate vector has a large scalar output with one sample prediction vector, there is a top-down feedback which increases the coupling coefficient for that sample and decreases it for other samples. This type of adjustment is very effective and robust for the few-shot learning scenario because it does not need to restore any parameters. Each b_{ij} is updated by:

$$b_{ij} = b_{ij} + \hat{e}^s_{ij} \cdot c_i \tag{10}$$

Formally, we call our induction method as dynamic routing induction and summarize it in Algorithm 2.

Algorithm 2 Dynamic Routing Induction

Require: sample vector e^s_{ij} in support set S and initialize the logits of coupling coefficients $b_{ij} = 0$

Ensure: class vector c_i

for all samples $j = 1, ..., K$ in class i:
  $\hat{e}^s_{ij} = squash(W_s e^s_{ij} + b_s)$
for *iter* iterations **do**
  $d_i = softmax(b_i)$
  $\hat{c}_i = \sum_j d_{ij} \cdot \hat{e}^s_{ij}$
  $c_i = squash(\hat{c}_i)$
  for all samples $j = 1, ..., K$ in class i:
    $b_{ij} = b_{ij} + \hat{e}^s_{ij} \cdot c_i$
end for
Return c_i

4.3 Relation Module

After the class vector c_i is generated by the Induction Module and each query text in the query set is encoded to a query vector e^q by the Encoder Module, the next essential procedure is to measure the correlation between each pair of query and class. The output of the Relation Module is called the relation score, representing the correlation between c_i and e^q, which is a scalar between 0 and 1. Specifically, we use the neural tensor layer (Socher et al., 2013) in this module, which has shown great advantages in modeling the relationship between two vectors (Wan et al., 2016; Geng et al., 2017). We choose it as an interaction function in this paper. The tensor layer outputs a relation vector as follows:

$$v(c_i, e^q) = f\left({c_i}^T M^{[1:h]} e^q\right) \tag{11}$$

where $M^k \in R^{2u \times 2u}, k \in [1, ..., h]$ is one slice of the tensor parameters and f is a non-linear activation function called RELU (Glorot et al., 2011).

The final relation score r_{iq} between the i-th class and the q-th query is calculated by a fully connected layer activated by a sigmoid function.

$$r_{iq} = sigmoid(W_r v(c_i, e^q) + b_r) \quad (12)$$

4.4 Objective Function

We use the mean square error (MSE) loss to train our model, regressing the relation score r_{iq} to the ground truth y_q: matched pairs have similarity 1 and the mismatched pair have similarity 0. Given the support set S with C classes and query set $Q = \{(x_q, y_q)\}_{q=1}^{n}$ in an episode, the loss function is defined as:

$$L(S, Q) = \sum_{i=1}^{C} \sum_{q=1}^{n} (r_{iq} - \mathbf{1}(y_q == i))^2 \quad (13)$$

conceptually we are predicting relation scores, which can be considered as a regression problem and the ground truth is within the space $\{0, 1\}$.

All parameters of the three modules are trained jointly by backpropagation. The Adagrad (Duchi et al., 2011) is used on all parameters in each training episode. Our model does not need any fine-tuning on the classes it has never seen due to its generalization nature. The induction and comparison ability are accumulated in the model along with the training episodes.

5 Experiments

We evaluate our model by conducting experiments on two few-shot text classification datasets. All the experiments are implemented with Tensorflow.

5.1 Datasets

Amazon Review Sentiment Classification (ARSC) Following Yu et al. (2018), we use the multiple tasks with the multi-domain sentiment classification (Blitzer et al., 2007) dataset. The dataset comprises English reviews for 23 types of products on Amazon. For each product domain, there are three different binary classification tasks. These buckets then form $23 \times 3 = 69$ tasks in total. Following Yu et al. (2018), we select $12(4 \times 3)$ tasks from 4 domains (Books, DVD, Electronics and Kitchen) as the test set, and there are only five examples as support set for each label in the test set. We create 5-shot learning models on this dataset.

	Training Set	Testing Set
Class Num	159	57
Data Num	195,775	2,279
Data Num/Class	≥ 77	$20 \sim 77$

Induction Networks (ours)	**85.63**

Table 2: Comparison of mean accuracy (%) on ARSC

Open Domain Intent Classification for Dialog System (ODIC) We create this dataset by fetching the log data on a real-world conversational platform. The enterprises submit various dialogue tasks with a great number of intents, but many intents have only a few labeled samples, which is a typical few-shot classification application. Following the definition of the few-shot learning task, we divide the ODIC into a training set and a testing set and ensure that the labels of the two sets have no intersection. The details of the set partition are shown in Table 1.

5.2 Experiment Setup

Baselines In this section, the baseline models in our experiments are introduced as follows.

- Matching Networks: a few-shot learning model using a metric-based attention method (Vinyals et al., 2016).
- Prototypical Networks: a deep metric-based method using sample average as class prototypes (Snell et al., 2017).
- Graph Network: a graph-based few-shot learning model that implements a task-driven message passing algorithm on the sample-wise level (Garcia and Bruna, 2017).
- Relation Network: a few-shot learning model which uses a neural network as the distance metric and sums up sample vectors in the support set as class vectors (Sung et al., 2018).
- SNAIL: a class of simple and generic meta-learner architectures that use a novel combi-

Model	5-way Acc.		10-way Acc.

Table 3: Comparison of mean accuracy (%) on ODIC

nation of temporal convolutions and soft attention (Mishra et al., 2018).

- ROBUSTTC-FSL: This approach combines several metric-based methods by clustering the tasks (Yu et al., 2018).

The baseline results on ARSC are reported in Yu et al. (2018) and we implemented the baseline models on ODIC with the same text encoder module.

Implementation Details We use 300-dimension Glove embeddings (Pennington et al., 2014) for ARSC dataset and 300-dimension Chinese word embeddings trained by Li et al. (2018) for ODIC. We set the hidden state size of LSTM $u = 128$ and the attention dimension $d_a = 64$. The iteration number $iter$ used in dynamic routing algorithm is 3. The relation module is a neural tensor layer with $h = 100$ followed by a fully connected layer activated by sigmoid. We build 2-way 5-shot models on ARSC following Yu et al. (2018), and build episode-based meta training with $C = [5, 10]$ and $K = [5, 10]$ for comparison on ODIC. In addition to K sample texts as support set, the query set has 20 query texts for each of the C sampled classes in every training episode. This means, for example, that there are $20 \times 5 + 5 \times 5 = 125$ texts in one training episode for the 5-way 5-shot experiments.

Evaluation Methods We evaluate the performance by few-shot classification accuracy following previous studies in few-shot learning (Snell et al., 2017; Sung et al., 2018). To evaluate the proposed model with the baselines objectively, we compute mean few-shot classification accuracies on ODIC over 600 randomly selected episodes from the testing set. We sample 10 test texts per class in each episode for evaluation in both 5-shot and 10-shot scenarios. Note that for ARSC, the support set for testing is fixed by Yu et al. (2018). Consequently, we just need to run the test episode once for each of the target tasks. The mean accuracy of the 12 target task is compared to the baseline models following Yu et al. (2018).

5.3 Experiment Results

Overall Performance Experiment results on ARSC are presented in Table 2. The proposed Induction Networks achieves a 85.63% accuracy, outperforming the existing state-of-the-art model, ROBUSTTC-FSL, by a notable 3% improvement. We due the improvement to the fact that ROBUSTTC-FSL builds a general metric method by integrating several metrics at the sample level, which faces the difficulty of getting rid of the noise among different expressions in the same class. In addition to that, the task-clustering-based method used by ROBUSTTC-FSL must be found on the relevance matrix, which is inefficient when applied to real-world scenarios where the tasks change rapidly. Our Induction Networks, however, is trained in the meta-learning framework with more flexible generalization and its induction ability can hence be accumulated through different tasks.

We also evaluate our method with a real-world intent classification dataset ODIC. The experiment results are listed in Table 3. We can see that our proposed Induction Networks achieves best classification performances on all of the four experiments. In the distance metric learning models (Matching Networks, Prototypical Networks, Graph Network and Relation Network), all the learning occurs in representing features and measuring distances at the sample-wise level. Our work builds an induction module focusing on the class-wise level of representation, which we claim to be more robust to variation of samples in the support set. Our model also outperforms the latest optimization-based method—SNAIL. The difference between Induction Networks and SNAIL shown in Table 3 is statistically significant under the paired at the 99% significance level. In

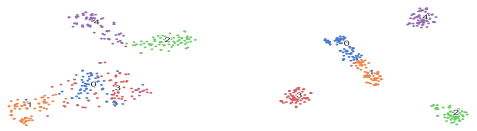
	Iteration	Accuracy
Routing+Relation	3	**85.63**
Routing+Relation	2	85.41
Routing+Relation	1	85.06
Routing + Cosine	3	84.67
Sum +Relation	-	83.07
Attention + Relation	-	85.15

Table 4: Ablation study of Induction Networks on ARSC dataset

addition, the performance difference between our model and other baselines in the 10-shot scenario is more significant than in the 5-shot scenario. This is because in the 10-shot scenario, for the baseline models the improvement brought by a bigger data size is also diminished by more sample level noises.

Ablation Study To analyze the effect of varying different components of the Induction Module and Relation Module, we further report the ablation experiments on the ARSC dataset as shown in Table 4. We can see that the best performance is achieved when we used 3 iterations, corresponding to the best result reported in Table 2 (more rounds of iterations did not further improve the performance), and the table shows the effectiveness of the routing component. We also changed the Induction Module with sum and self-attention and changed Relation Module with cosine distance. Changes in the performances validate the benefit of both the Relation Module and Induction Module. The Attention+Relation models the induction ability by self-attention mechanism, but the ability is limited by the learnt attention parameters. Conversely, the proposed dynamic routing induction method captures class-level information by automatically adjusting the coupling coefficients according to inputted support sets, which is more suitable for the few-shot learning task.

5.4 Further Analysis



We further analyze the effect of transformation and visualize query text vectors to show the advantage of the Induction Networks.

Effect of Transformation Figure 2 shows the t-SNE (Maaten and Hinton, 2008) visualization of support sample vectors before and after matrix transformation under the 5-way 10-shot scenario. We randomly select a support set with 50 texts (10 texts per class) from the ODIC testing set, and obtain the sample vectors $\left\{e^s_{ij}\right\}_{i=1,...5,j=1...10}$ after the encoder module and the sample prediction vector $\left\{\hat{e}^s_{ij}\right\}_{i=1,...5,j=1...10}$ after transformation. We can see that the vectors after matrix transformation are more separable, demonstrating the effectiveness of matrix transformation to encode semantic relationships between lower-level sample features and higher-level class features.

(a) Before transformation (b) After transformation

Figure 2: Effect of Transformation under the 5-way 10-shot scenario. (a) The support sample vectors before matrix transformation. (b) The support sample vectors after matrix transformation.

(a) Relation Network (b) Induction Networks

Figure 3: Query text vector visualization learnt by (a) Relation Network and (b) Induction Networks.

Query Text Vector Visualization We also find out that our induction module does not only work well in generating effective class-level features, but also helps the encoders to learn better text vectors, as it can give different weights to instances and features during backpropagation. Figure 3 shows the t-SNE (Maaten and Hinton, 2008) visualization of text vectors from the same randomly selected five classes, learnt by the Relation Network and our Induction Networks. It is clear that the text vectors learnt by Induction Networks are better separated semantically than those of Relation Network.

6 Conclusion

In this paper, we propose the Induction Networks, a novel neural model for few-shot text classification. We propose to induce the class-level representations from support sets to deal with sample-wise diversity in few-shot learning tasks. The Induction Module combines the dynamic routing algorithm with a meta-learning framework, and the

routing mechanism makes our model more general to recognize unseen classes. The experiment results show that the proposed model outperforms the existing state-of-the-art few-shot text classification models. We found that both the matrix transformation and routing procedure contribute consistently to the few-shot learning tasks.

Benchmarking Zero-shot Text Classification: Datasets, Evaluation and Entailment Approach

Wenpeng Yin, Jamaal Hay, Dan Roth

Abstract

Zero-shot text classification (0SHOT-TC) is a challenging NLU problem to which little attention has been paid by the research community. 0SHOT-TC aims to associate an appropriate label with a piece of text, irrespective of the text domain and the aspect (e.g., topic, emotion, event, etc.) described by the label. And there are only a few articles studying 0SHOT-TC, all focusing only on topical categorization which, we argue, is just the tip of the iceberg in 0SHOT-TC. In addition, the chaotic experiments in literature make no uniform comparison, which blurs the progress.

This work benchmarks the 0SHOT-TC problem by providing unified datasets, standardized evaluations, and state-of-the-art baselines. Our contributions include: i) The datasets we provide facilitate studying 0SHOT-TC relative to conceptually different and diverse aspects: the "topic" aspect includes "sports" and "politics" as labels; the "emotion" aspect includes "joy" and "anger"; the "situation" aspect includes "medical assistance" and "water shortage". ii) We extend the existing evaluation setup (*label-partially-unseen*) – given a dataset, train on some labels, test on all labels – to include a more challenging yet realistic evaluation *label-fully-unseen* 0SHOT-TC (Chang et al., 2008), aiming at classifying text snippets without seeing task specific training data at all. iii) We unify the 0SHOT-TC of diverse aspects within a textual entailment formulation and study it this way. [1]

1 Introduction

Supervised text classification has achieved great success in the past decades due to the availability of rich training data and deep learning techniques. However, zero-shot text classification (0SHOT-TC) has attracted little attention despite its great potential in real world applications, e.g., the intent recognition of bank consumers. 0SHOT-TC is challenging because we often have to deal with classes that are compound, ultra-fine-grained, changing over time, and from different aspects such as topic, emotion, etc.

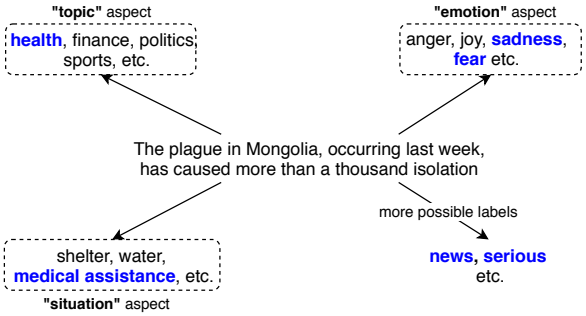

Figure 1: A piece of text can be assigned labels which describe the different aspects of the text. Positive labels are in blue.

Existing 0SHOT-TC studies have mainly the following three problems.

First problem. The 0SHOT-TC problem was modeled in a too restrictive vision. Firstly, most work only explored a single task, which was mainly topic categorization, e.g., (Pushp and Srivastava, 2017; Yogatama et al., 2017; Zhang et al., 2019). We argue that this is only the tiny tip of the iceberg for 0SHOT-TC. Secondly, there is often a precondition that a part of classes are seen and their labeled instances are available to train a model, as we define here as *Definition-Restrictive*:

*Definition-Restrictive (*0SHOT-TC*).* Given labeled instances belonging to a set of seen classes S, 0SHOT-TC aims at learning a classifier $f(\cdot) : X \rightarrow Y$, where $Y = S \cup U$; U is a set of unseen classes and belongs to the same aspect as S.

In this work, we formulate the 0SHOT-TC in a

broader vision. As Figure 1 demonstrates, a piece of text can be assigned labels which interpret the text in different aspects, such as the "topic" aspect, the "emotion" aspect, or the "situation" aspect described in the text. Different aspects, therefore, differ in interpreting the text. For instance, by "topic", it means "this text is about {health, finance $\cdots$}"; by "emotion", it means "this text expresses a sense of {joy, anger, $\cdots$}"; by "situation", it means "the people there need {shelter, medical assistance, $\cdots$}". Figure 1 also shows another essential property of 0SHOT-TC – the applicable label space for a piece of text has no boundary, e.g., "this text is news", "the situation described in this text is serious", etc. Therefore, we argue that we have to emphasize a more challenging scenario to satisfy the real-world problems: seeing no labels, no label-specific training data. Here is our new 0SHOT-TC definition:

*Definition-Wild (*0SHOT-TC*).* 0SHOT-TC aims at learning a classifier $f(\cdot) : X \rightarrow Y$, where classifier $f(\cdot)$ never sees Y-specific labeled data in its model development.

Second problem. Usually, conventional text classification denotes labels as indices {0,1,2, $\cdots$, n} without understanding neither the aspect's specific interpretation nor the meaning of the labels. This does not apply to 0SHOT-TC as we can not pre-define the size of the label space anymore, and we can not presume the availability of labeled data. Humans can easily decide the truth value of any upcoming labels because humans can interpret those aspects correctly and understand the meaning of those labels. The ultimate goal of 0SHOT-TC should be to develop machines to catch up with humans in this capability. To this end, making sure the system can understand the described aspect and the label meanings plays a key role.

Third problem. Prior work is mostly evaluated on different datasets and adopted different evaluation setups, which makes it hard to compare them fairly. For example, Rios and Kavuluru (2018) work on medical data while reporting R@K as metric; Xia et al. (2018) work on SNIPS-NLU intent detection data while only unseen intents are in the label-searching space in evaluation.

In this work, we benchmark the datasets and evaluation setups of 0SHOT-TC. Furthermore, we propose a textual entailment approach to handle the 0SHOT-TC problem of diverse aspects in a unified paradigm. To be specific, we contribute in the following three aspects:

Dataset. We provide datasets for studying three aspects of 0SHOT-TC: topic categorization, emotion detection, and situation frame detection – an event level recognition problem. For each dataset, we have standard split for *train*, *dev*, and *test*, and standard separation of seen and unseen classes.

Evaluation. Our standardized evaluations correspond to the *Definition-Restrictive* and *Definition-Wild*. i) *Label-partially-unseen evaluation*. This corresponds to the commonly studied 0SHOT-TC defined in *Definition-Restrictive*: for the set of labels of a specific aspect, given training data for a part of labels, predicting in the full label set. This is the most basic setup in 0SHOT-TC. It checks whether the system can generalize to some labels in the same aspect. To satisfy *Definition-Wild*, we define a new evaluation: ii) *Label-fully-unseen evaluation*. In this setup, we assume the system is unaware of the upcoming aspects and can not access any labeled data for task-specific training.

Entailment approach. Our *Definition-Wild* challenges the system design – how to develop a 0SHOT-TC system, without accessing any task-specific labeled data, to deal with labels from diverse aspects? In this work, we propose to treat 0SHOT-TC as a textual entailment problem. This is to imitate how humans decide the truth value of labels from any aspects. Usually, humans understand the problem described by the aspect and the meaning of the label candidates. Then humans mentally construct a hypothesis by filling a label candidate, e.g., "sports", into the aspect-defined problem "the text is about ?", and ask ourselves if this hypothesis is true, given the text. We treat 0SHOT-TC as a textual entailment problem so that our model can gain knowledge from entailment datasets, and we show that it applies to both *Definition-Restrictive* and *Definition-Wild*.

Overall, this work aims at benchmarking the research of 0SHOT-TC by providing standardized datasets, evaluations, and a state-of-the-art entailment system. All datasets and codes are released.

2 Related Work

ZERO-STC was first explored by the paradigm "Dataless Classification" (Chang et al., 2008).

Dataless classification first maps the text and labels into a common space by Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007), then picks the label with the highest matching score. Dataless classification emphasizes that the representation of labels takes the equally crucial role as the representation learning of text. Then this idea was further developed in (Song and Roth, 2014; Chen et al., 2015; Li et al., 2016a,b; Song et al., 2016).

With the prevalence of word embeddings, more and more work adopts pretrained word embeddings to represent the meaning of words, so as to provide the models with the knowledge of labels (Sappadla et al., 2016; Yogatama et al., 2017; Rios and Kavuluru, 2018; Xia et al., 2018). Yogatama et al. (2017) build generative LSTM to generate text given the embedded labels. Rios and Kavuluru (2018) use label embedding to attend the text representation in the developing of a multi-label classifier. But they report R@K, so it is unclear whether the system can really predict unseen labels. Xia et al. (2018) study the zero-shot intent detection problem. The learned representations of intents are still the sum of word embeddings. But during testing, the intent space includes only new intents; seen intents are not covered. All of these studies can only meet the definition in *Definition-Restrictive*, so they do not really generalize to open aspects of 0SHOT-TC.

Zhang et al. (2019) enrich the embedding representations by incorporating class descriptions, class hierarchy, and the word-to-label paths in ConceptNet. Srivastava et al. (2018) assume that some natural language explanations about new labels are available. Then those explanations are parsed into formal constraints which are further combined with unlabeled data to yield new label oriented classifiers through posterior regularization. However, those explanatory statements about new labels are collected from crowd-sourcing. This limits its application in real world 0SHOT-TC scenarios.

There are a few works that study a specific zero-shot problem by indirect supervision from other problems. Levy et al. (2017) and Obamuyide and Vlachos (2018) study zero-shot relation extraction by converting it into a machine comprehension and textual entailment problem respectively. Then, a supervised system pretrained on an existing machine comprehension dataset or textual entailment dataset is used to do inference. Our work studies the 0SHOT-TC by formulating a broader vision: datasets of multiple apsects and evaluations.

Other zero-shot problems studied in NLP involve entity typing (Zhou et al., 2018), sequence labeling (Rei and Søgaard, 2018), etc.

3 Benchmark the dataset

In this work, we standardize the datasets for 0SHOT-TC for three aspects: topic detection, emotion detection, and situation detection.

For each dataset, we insist on two principles: i) **Label-partially-unseen**: A part of labels are unseen. This corresponds to *Definition-Restrictive*, enabling us to check the performance of unseen labels as well as seen labels. ii) **Label-fully-unseen**: All labels are unseen. This corresponds to *Definition-Wild*, enabling us to check the system performance in test-agnostic setups.

3.1 Topic detection

Yahoo. We use the large-scale Yahoo dataset released by Zhang et al. (2015). Yahoo has 10 classes: {"Society & Culture", "Science & Mathematics", "Health", "Education & Reference", "Computers & Internet", "Sports", "Business & Finance", "Entertainment & Music", "Family & Relationships", "Politics & Government"}, with original split: 1.4M/60k in train/test (all labels are balanced distributed).

We reorganize the dataset by first fixing the *dev* and *test* sets as follows: for *dev*, all 10 labels are included, with 6k labeled instances for each; For *test*, all 10 labels are included, with 10k instances for each. Then training sets are created on remaining instances as follows.

For *label-partially-unseen*, we create two versions of Yahoo *train* for 0SHOT-TC:

- *Train-v0*: 5 classes: {"Society & Culture", "Health", "Computers & Internet", "Business & Finance", "Family & Relationships"} are included; each is equipped with 130k labeled instances.
- *Train-v1*: 5 classes: { "Science & Mathematics", "Education & Reference", "Sports", "Entertainment & Music", "Politics & Government"} are included; each is equipped with 130k labeled instances.

We always create two versions of *train* with non-overlapping labels so as to get rid of the

		emotions										
		sad	joy	anger	disgust	fear	surp.	shame	guilt	love	none	sum

Table 2: Emotion *dev* in 0SHOT-TC

model's over-fitting on one of them.

Label-fully-unseen share the same *test* and *dev* with the *label-partially-unseen* except that it has no training set. It is worth mentioning that our setup of *label-partially-unseen* and *label-fully-unseen* enables us to compare the performance mutually; it can show the system's capabilities while seeing different sizes of classes.

3.2 Emotion detection

UnifyEmotion. This emotion dataset was released by Bostan and Klinger (2018). It was constructed by unifying the emotion labels of multiple public emotion datasets[2]. This dataset consists of text from multiple domains: tweet, emotional events, fairy tale and artificial sentences, and it contains 9 emotion types {"sadness", "joy", "anger", "disgust", "fear", "surprise", "shame", "guilt", "love"} and "none" (if no emotion applies). We remove the multi-label instances (appro. 4k) so that the remaining instances always have a single positive label. The official evaluation metric is *label-weighted* F1.

Since the labels in this dataset has unbalanced distribution. We first directly list the fixed *test* and *dev* in Table 1 and Table 2, respectively. They are shared by following *label-partial-unseen* and *label-fully-unseen* setups of *train*.

Label-partial-unseen has the following two versions of *train*:

- *Train-v0*: 5 classes: {"sadness", "anger", "fear", "shame", "love"} are included.
- *Train-v1*: 4 classes: { "joy", "disgust", "surprise", "guilt"} are included.

For *label-fully-unseen*, no training set is provided.

3.3 Situation detection

The situation frame typing is one example of an event-type classification task. A situation frame studied here is a *need* situation such as the need for water or medical aid, or an *issue* situation such as crime violence (Strassel et al., 2017; Muis et al., 2018). It was originally designed for low-resource situation detection, where annotated data is unavailable. This is why it is particularly suitable for 0SHOT-TC.

We use the Situation Typing dataset released by Mayhew et al. (2019). It has 5,956 labeled instances. Totally 11 situation types: "food supply", "infrastructure", "medical assistance", "search/rescue", "shelter", "utilities, energy, or sanitation", "water supply", "evacuation", "regime change", "terrisms", "crime violence" and an extra type "none" – if none of the 11 types applies. This dataset is a *multi-label* classification, and *label-wise weighted F1* is the official evaluation.

The *train*, *test* and *dev* are listed in Table 3.

[2]Please refer to (Bostan and Klinger, 2018) for more details about the constituent datasets.

Summary of 0SHOT-TC datasets. Our three datasets covers single-label classification (i.e., "topic" and "emotion") and multi-label classification (i.e., "situation"). In addition, a "none" type is adopted in "emotion" and "situation" tasks if no predefined types apply – this makes the problem more realistic.

4 Benchmark the evaluation

How to evaluate a 0SHOT-TC system? This needs to review the original motivation of doing 0SHOT-TC research. As we discussed in Introduction section, ideally, we aim to build a system that works like humans – figuring out if a piece of text can be assigned with an open-defined label, without any constrains on the domains and the aspects described by the labels. Therefore, we challenge the system in two setups: *label-partially-unseen* and *label-fully-unseen*.

Label-partially-unseen. This is the most common setup in existing 0SHOT-TC literature: for a given dataset of a specific problem such as topic categorization, emotion detection, etc, train a system on a part of the labels, then test on the whole label space. Usually all labels describe the same aspect of the text.

Label-fully-unseen. In this setup, we push "zero-shot" to the extreme – no annotated data for any labels. So, we imagine that learning a system through whatever approaches, then testing it on 0SHOT-TC datasets of open aspects.

This *label-fully-unseen* setup is more like the dataless learning principle (Chang et al., 2008), in which no task-specific annotated data is provided for training a model (since usually this kind of model fails to generalize in other domains and other tasks), therefore, we are encouraged to learn models with open-data or test-agnostic data. In this way, the learned models behave more like humans.

5 An entailment model for 0SHOT-TC

As one contribution of this work, we propose to deal with 0SHOT-TC as a textual entailment problem. It is inspired by: i) text classification is essentially a textual entailment problem. Let us think about how humans do classification: we mentally think "whether this text is about sport?", or "whether this text expresses a specific feeling?", or "whether the people there need water supply?" and so on. The reason that conventional text classification did not employ entailment approach is it always has pre-defined, fixed-size of classes equipped with annotated data. However, in 0SHOT-TC, we can neither estimate how many and what classes will be handled nor have annotated data to train class-specific parameters. Textual entailment, instead, does not preordain the boundary of the hypothesis space. ii) To pursue the ideal generalization of classifiers, we definitely need to make sure that the classifiers understand the problem encoded in the aspects and understand the meaning of labels. Conventional supervised classifiers fail in this aspect since label names are converted into indices – this means the classifiers do not really understand the labels, let alone the problem. Therefore, exploring 0SHOT-TC as a textual entailment paradigm is a reasonable way to achieve generalization.

Convert labels into hypotheses. The first step of dealing with 0SHOT-TC as an entailment problem is to convert labels into hypotheses. To this end, we first convert each aspect into an *interpretation* (we discussed before that generally one aspect defines one interpretation). E.g., "topic" aspect to interpretation "the text is about the topic". Table 4 lists some examples for the three aspects: "topic", "emotion" and "situation".

In this work, we just explored two simple methods to generate the hypotheses. As Table 4 shows, one is to use the label name to complete the interpretation, the other is to use the label's definition in WordNet to complete the interpretation. In testing, once one of them results in an "entailment" decision, then we decide the corresponding label is positive. We can definitely create more natural hypotheses through crowd-sourcing, such as "food" into "the people there are starving". Here we just set the baseline examples by automatic approaches, more explorations are left as future work, and we welcome the community to contribute.

Convert classification data into entailment data. For a data split (*train*, *dev* and *test*), each input text, acting as the premise, has a positive hypothesis corresponding to the positive label, and all negative labels in the data split provide negative hypotheses. Note that unseen labels do not provide negative hypotheses for instances in *train*.

		situations											
		search	evac	infra	utils	water	shelter	med	food	reg.	terr.	crim.	none
	total size	327	278	445	412	492	659	1,046	810	80	348	983	1,868
split	test	190	166	271	260	289	396	611	472	51	204	590	1,144
	dev	137	112	174	152	203	263	435	338	29	144	393	724
	train-v0	327	–	445	–	492	–	1,046	–	80	–	983	–
	train-v1	–	278	–	412	–	659	–	810	–	348	–	–

Table 3: Situation *train*, *dev* and *test* split for 0SHOT-TC.

aspect	labels	interpretation	example hypothesis	
			word	wordnet definition
topic	sports etc.	this text is about ?	"?"= sports	"?" = an active diversion requiring physical exertion and competition
emotion	anger etc.	this text expresses ?	"?"= anger	"?" = a strong emotion; a feeling that is oriented toward some real or supposed grievance
situation	shelter etc.	The people there need ?	"?"= shelter	"?" = a structure that provides privacy and protection from danger

Table 4: Example hypotheses we created for modeling different aspects of 0SHOT-TC.

Entailment model learning. In this work, we make use of the widely-recognized state of the art entailment technique – BERT (Devlin et al., 2019), and train it on three mainstream entailment datasets: MNLI (Williams et al., 2018), GLUE RTE (Dagan et al., 2005; Wang et al., 2019) and FEVER[3] (Thorne et al., 2018), respectively. We convert all datasets into binary case: "entailment" vs. "non-entailment", by changing the label "neutral" (if exist in some datasets) into "non-entailment".

For our *label-fully-unseen* setup, we directly apply this pretrained entailment model on the test sets of all 0SHOT-TC aspects. For *label-partially-unseen* setup in which we intentionally provide annotated data, we first pretrain BERT on the MNLI/FEVER/RTE, then fine-tune on the provided training data.

Harsh policy in testing. Since seen labels have annotated data for training, we adopt different policies to pick up seen and unseen labels. To be specific, we pick a seen label with a harsher rule: i) In single-label classification, if both seen and unseen labels are predicted as positive, we pick the seen label only if its probability of being positive is higher than that of the unseen label by a hyper-parameter α. If only seen or unseen labels are predicted as positive, we pick the one with the highest probability; ii) In multi-label classification, if both seen and unseen labels are predicted as positive, we change the seen labels into "negative" if their probability of being positive is higher than that of the unseen label by less than α. Finally, all labels labeled positive will be selected. If no positive labels, we choose "none" type.

$\alpha = 0.05$ in our systems, tuned on *dev*.

6 Experiments

6.1 Label-partially-unseen evaluation

In this setup, there is annotated data for partial labels as *train*. So, we report performance for unseen classes as well as seen classes. We compare our entailment approaches, trained separately on MNLI, FEVER and RTE, with the following baselines.

Baselines.

- *Majority*: the text picks the label of the largest size.
- *ESA*: A dataless classifier proposed in (Chang et al., 2008). It maps the words (in text and label names) into the title space of Wikipedia articles, then compares the text with label names. This method does not rely on *train*.

[3]FEVER is an evidential claim verification problem: given a hypothesis, the system needs to identify evidence sentences as premise, then gives the entailment decision. We use the ground truth evidence as premises in this work.

		topic				emotion				situation			
		v0		v1		v0		v1		v0		v1	
		s	u	s	u	s	u	s	u	s	u	s	u
w/o *train*	Majority	0.0	10.0	10.0	0.0	0.0	13.3	18.5	0.0	0.0	19.7	0.0	16.4
	Word2Vec	28.1	43.3	43.3	28.1	8.1	5.4	6.2	7.3	10.3	24.7	8.6	23.1

Wiki-based	**52.1**	21.2	27.7	101.0
our entail.				
MNLI	37.9	22.3	15.4	75.6
FEVER	40.1	24.7	21.0	85.8
RTE	43.8	12.6	37.2	93.6
ensemble	45.7	**25.2**	**38.0**	**108.9**

Table 6: Label-fully-unseen evaluation.

We implemented ESA based on 08/01/2019 Wikipedia dump[4]. There are about 6.1M words and 5.9M articles.

- *Word2Vec*[5] (Mikolov et al., 2013): Both the representations of the text and the labels are the addition of word embeddings element-wisely. Then cosine similarity determines the labels. This method does not rely on *train* either.

- *Binary-BERT*: We fine-tune BERT[6] on *train*, which will yield a binary classifier for entailment or not; then we test it on *test* – picking the label with the maximal probability in single-label scenarios while choosing all the labels with "entailment" decision in multi-label cases.

[4] https://dumps.wikimedia.org/enwiki/

[5] https://code.google.com/archive/p/word2vec/

[6] We always use "bert-base-uncased" version.

Discussion. The results of *label-partially-unseen* are listed in Table 5. "ESA" performs slightly worse than "Word2Vec" in topic detection, mainly because the label names, i.e., topics such as "sports", are closer than some keywords such as "basketball" in Word2Vec space. However, "ESA" is clearly better than "Word2Vec" in situation detection; this should be mainly due to the fact that the label names (e.g., "shelter", "evaculation", etc.) can hardly find close words in the text by Word2Vec embeddings. Quite the contrary, "ESA" is easier to make a class such as "shelter" closer to some keywords like "earthquake". Unfortunately, both Word2Vec and ESA work poorly for emotion detection problem. We suspect that emotion detection requires more entailment capability. For example, the text snippet "when my brother was very late in arriving home from work", its gold emotion "fear" requires some common-knowledge inference, rather than just word semantic matching through Word2Vec and ESA.

The supervised method "Binary-BERT" is indeed strong in learning the seen-label-specific models – this is why it predicts very well for seen classes while performing much worse for unseen classes.

Our entailment models, especially the one pretrained on MNLI, generally get competitive performance with the "Binary-BERT" for *seen* (slightly worse on "topic" and "emotion" while clearly better on "situation") and improve the performance regarding *unseen* by large margins. At this stage, fine-tuning on an MNLI-based pre-

	topic				emotion				situation				sum			
	RTE	FEV.	MN.	ens.	RTE	FEV.	MN.	ens.	RTE	FEV.	MN.	ens.	RTE	FEV.	MN.	ens.
word	44.9	42.0	43.4	48.4	12.4	26.7	21.2	18.3	37.7	24.5	14.7	38.3	95.0	93.2	79.3	105.0
def	14.5	25.3	17.2	26.0	3.4	18.7	16.8	9.0	14.1	19.2	11.8	14.4	32.0	63.2	45.8	49.4
comb.	43.8	40.1	37.9	45.7	12.6	24.7	22.3	25.2	37.2	21.0	15.4	38.0	93.6	85.8	81.2	**108.9**

Table 7: Fine-grained *label-fully-unseen* performances of different hypothesis generation approaches "word", "def" (definition) and "comb" (word&definition) on the three tasks ("topic", "emotion" and "situation") based on three pretrained entailment models (RTE, FEVER, MNLI) and the ensemble approach (ens.). The last column *sum* contains the addition of its preceding three blocks element-wisely.

trained entailment model seems more powerful.

6.2 Label-fully-unseen evaluation

Regarding this *label-fully-unseen* evaluation, apart from our entailment models and three unsupervised baselines "Majority", "Word2Vec" and "ESA", we also report the following baseline:

Wikipedia-based: We train a *binary* classifier based on BERT on a dataset collected from Wikipedia. Wikipedia is a corpus of general purpose, without targeting any specific 0SHOT-TC task. Collecting categorized articles from Wikipedia is popular way of creating training data for text categorization, such as (Zhou et al., 2018). More specifically, we collected 100K articles along with their categories in the bottom of each article. For each article, apart from its attached positive categories, we randomly sample three negative categories. Then each article and its positive/negative categories act as training pairs for the binary classifier.

We notice "Wikipedia-based" training indeed contributes a lot for the topic detection task; however, its performances on emotion and situation detection problems are far from satisfactory. We believe this is mainly because the Yahoo-based topic categorization task is much closer to the Wikipedia-based topic categorization task; emotion and situation categorizations, however, are relatively further.

Our entailment models, pretrained on MNLI/FEVER/RTE respectively, perform more robust on the three 0SHOT-TC aspects (except for the RTE on emotion). Recall that they are not trained on any text classification data, and never know the domain and the aspects in the *test*. This clearly shows the great promise of developing textual entailment models for 0SHOT-TC. Our ensemble approach[7] further boosts the performances on all three tasks.

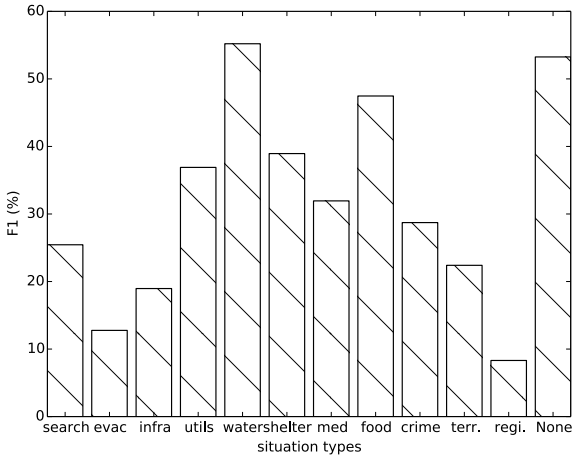

Figure 2: Performance of different situation classes in *label-fully-unseen, predicted by the ensemble model.*

An interesting phenomenon, comparing the *label-partially-unseen* results in Table 5 and the *label-fully-unseen* results in Table 6, is that the pretrained entailment models work in this order for *label-fully-unseen* case: RTE > FEVER >MNLI; on the contrary, if we fine-tune them on the label-partially-unseen case, the MNLI-based model performs best. This could be due to a possibility that, on one hand, the constructed situation entailment dataset is closer to the RTE dataset than to the MNLI dataset, so an RTE-based model can generalize well to situation data, but, on the other hand, it could also be more likely to over-fit the training set of "situation" during fine-tuning. A deeper exploration of this is left as future work.

6.3 How do the generated hypotheses influence

In Table 4, we listed examples for converting class names into hypotheses. In this work, we only tried to make use of the class names and their defini-

[7]For each input pair of the entailment model, we sum up their probabilities after softmax, then do softmax to get new probabilities.

tions in WordNet. Table 7 lists the fine-grained performance of three ways of generating hypotheses: "word", "definition", and "combination" (i.e., word&definition).

This table indicates that: i) Definition alone usually does not work well in any of the three tasks, no matter which pretrained entailment model is used; ii) Whether "word" alone or "word&definition" works better depends on the specific task and the pretrained entailment model. For example, the pretrained MNLI model prefers "word&definition" in both "emotion" and "situation" detection tasks. However, the other two entailment models (RTE and FEVER) mostly prefer "word". iii) Since it is unrealistic to adopt only one entailment model, such as from {RTE, FEVER, MNLI}, for any open 0SHOT-TC problem, an ensemble system should be preferred. However, the concrete implementation of the ensemble system also influences the strengths of different hypothesis generation approaches. In this work, our ensemble method reaches the top performance when combining the "word" and "definition". More ensemble systems and hypothesis generation paradigms need to be studied in the future.

To better understand the impact of generated hypotheses, we dive into the performance of each labels, taking "situation detection" as an example. Figure 2 illustrates the separate F1 scores for each situation class, predicted by the ensemble model for *label-fully-unseen* setup. This enables us to check in detail how easily the constructed hypotheses can be understood by the entailment model. Unfortunately, some classes are still challenging, such as "evacuation", "infrastructure", and "regime change". This should be attributed to their over-abstract meaning. Some classes were well recognized, such as "water", "shelter", and "food". One reason is that these labels mostly are common words – systems can more easily match them to the text; the other reason is that they are situation classes with higher frequencies (refer to Table 3) – this is reasonable based on our common knowledge about disasters.

7 Summary

In this work, we analyzed the problems of existing research on zero-shot text classification (0SHOT-TC): restrictive problem definition, the weakness in understanding the problem and the labels' meaning, and the chaos of datasets and evaluation setups. Therefore, we are benchmarking 0SHOT-TC by standardizing the datasets and evaluations. More importantly, to tackle the broader-defined 0SHOT-TC, we proposed a textual entailment framework which can work with or without the annotated data of *seen* labels.

A Logic-Driven Framework for Consistency of Neural Models

Tao Li, Vivek Gupta, Maitrey Mehta, Vivek Srikumar
School of Computing, University of Utah

Abstract

While neural models show remarkable accuracy on individual predictions, their internal beliefs can be inconsistent *across* examples. In this paper, we formalize such inconsistency as a generalization of prediction error. We propose a learning framework for constraining models using logic rules to regularize them away from inconsistency. Our framework can leverage both labeled and unlabeled examples and is directly compatible with off-the-shelf learning schemes without model redesign. We instantiate our framework on natural language inference, where experiments show that enforcing invariants stated in logic can help make the predictions of neural models both accurate and consistent.

1 Introduction

Recent NLP advances have been powered by improved representations (e.g., ELMo, BERT— Peters et al., 2018; Devlin et al., 2019), novel neural architectures (e.g., Cheng et al., 2016; Seo et al., 2017; Parikh et al., 2016; Vaswani et al., 2017), and large labeled corpora (e.g., Bowman et al., 2015; Rajpurkar et al., 2016; Williams et al., 2018). Consequently, we have seen progressively improving performances on benchmarks such as GLUE (Wang et al., 2018). But, are models really becoming better? We take the position that, while tracking performance on a leaderboard is necessary to characterize model quality, it is not sufficient. Reasoning about language requires that a system has the ability not only to draw correct inferences about textual inputs, but also to be consistent its beliefs across various inputs.

To illustrate this notion of consistency, let us consider the task of natural language inference (NLI) which seeks to identify whether a premise entails, contradicts or is unrelated to a hypothesis (Dagan et al., 2013). Suppose we have three sentences P, H and Z, where P entails H and H contradicts Z. Using these two facts, we can infer that P contradicts Z. In other words, these three decisions are not independent of each other. Any model for textual inference should not violate this invariant defined over any three sentences, *even if they are not labeled*.

Neither are today's models trained to be consistent in this fashion, nor is consistency evaluated. The decomposable attention model of Parikh et al. (2016) updated with ELMo violates the above constraint for the following sentences:[1]

P: John is on a train to Berlin.
H: John is traveling to Berlin.
Z: John is having lunch in Berlin.

Highly accurate models can be inconsistent in their beliefs over groups of examples. For example, using a BERT-based NLI model that achieves about 90% F-score on the SNLI test set (Bowman et al., 2015), we found that in about 46% of *unlabeled* sentence triples where P entails H and H contradicts Z, the first sentence does not contradict the third. Observations of a similar spirit were also made by Minervini and Riedel (2018), Glockner et al. (2018) and Nie et al. (2018).

To characterize and eliminate such errors, first, we define a method to measure the inconsistency of models with respect to invariants stated as first-order logic formulas over model predictions. We show that our definition of inconsistency strictly generalizes the standard definition of model error.

Second, we develop a systematic framework for mitigating inconsistency in models by compiling the invariants into a differentiable loss functions using t-norms (Klement et al., 2013; Gupta and Qi, 1991) to soften logic. This allows us

[1] We used the model available through the Allen NLP online demo: http://demo.allennlp.org/textual-entailment.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3924–3935, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

to take advantage of unlabeled examples and enforce consistency of model predictions over them. We show that the commonly used cross-entropy loss emerges as a specific instance of our framework. Our framework can be easily instantiated with modern neural network architectures.

To show the effectiveness of our approach, we instantiate it on the NLI task. We show that even state-of-the-art models can be highly inconsistent in their predictions, but our approach significantly reduces inconsistency.

In summary, our contributions are:

1. We define a mechanism to measure model inconsistency with respect to declaratively specified invariants.
2. We present a framework that compiles knowledge stated in first-order logic to loss functions that mitigate inconsistency.
3. We show that our learning framework can reduce prediction inconsistencies even with small amount of annotated examples without sacrificing predictive accuracy.[2]

2 A Framework for (In)consistency

In this section, we will present a systematic approach for measuring and mitigating inconsistent predictions. A prediction is *incorrect* if it disagrees with what is known to be true. Similarly, predictions are *inconsistent* if they do not follow a known rule. Therefore, a model's errors can be defined by their concordance with declarative knowledge. We will formalize this intuition by first developing a uniform representation for both labeled examples and consistency constraints (§2.1). Then, we will present a general definition of errors in the context of such a representation (§2.2). Finally, we will show a logic-driven approach for designing training losses (§ 2.3).

As a running example, we will use the NLI task whose goal is to predict one of three labels: *Entailment* (E), *Contradiction* (C), or *Neutral* (N).

2.1 Representing Knowledge

Suppose x is a *collection* of examples (perhaps labeled). We write constraints about them as a conjunction of statements in logic:

$$\bigwedge_{(L,R)} L(x) \rightarrow R(x) \tag{1}$$

Here, L and R are Boolean formulas, *i.e.* antecedents and consequents, constructed from model predictions on examples in x.

One example of such an invariant is the constraint from §1, which can be written as $E(P,H) \wedge C(H,Z) \rightarrow C(P,Z)$, where, e.g., predicate $E(P,H)$ denotes that model predicted label E. We can also represent labeled examples as constraints: *"If an example is annotated with label $Y^\star$, then model should predict so."* In logic, we write $\top \rightarrow Y^\star(x)$.[3] Seen this way, the expression (1) could represent labeled data, unlabeled groups of examples with constraints between them, or a combination.

2.2 Generalizing Errors as Inconsistencies

Using the representation defined above, we can define how to evaluate predictors. We seek two properties of an evaluation metric: It should 1) quantify the inconsistency of predictions, and 2) also generalize classification error. To this end, we define two types of errors: *global* and *conditional* violation. Both are defined for a dataset D consisting of example collections x as described above.

Global Violation (ρ) The global violation is the fraction of examples in a dataset D where any constraint is violated. We have:

$$\rho = \frac{\sum_{x \in D} \left[\bigvee_{(L,R)} \neg \left(L(x) \rightarrow R(x) \right) \right]}{|D|} \tag{2}$$

Here, $[\cdot]$ is the indicator function.

Conditional Violation (τ) For a conditional statement, if the antecedent is not satisfied, the statement becomes trivially true. Thus, with complex antecedents, the number of examples where the constraint is true can be trivially large. To only consider those examples where the antecedent holds, we define the conditional violation as:

$$\tau = \frac{\sum_{x \in D} \left[\bigvee_{(L,R)} \neg \left(L(x) \rightarrow R(x) \right) \right]}{\sum_{x \in D} \left[\bigvee_{(L,R)} L(x) \right]} \tag{3}$$

Discussion The two metrics are complementary to each other. On one hand, to lower the global metric ρ, a model could avoid satisfying the antecedents. In this case, the conditional metric τ is

[2] Our code to replay our experiments is archived at https://github.com/utahnlp/consistency.

[3] The symbol $\top$ denotes the Boolean `true`.

more informative. On the other hand, the global metric reflects the impact of domain knowledge in a given dataset, while the conditional one does not. Ideally, both should be low.

Both violations strictly generalize classification error. If all the knowledge we have takes the form of labeled examples, as exemplified at the end of §2.1, both violation metrics are identical to model error. The appendix formally shows this.

2.3 Learning by Minimizing Inconsistencies

With the notion of errors, we can now focus on how to train models to minimize them. A key technical challenge involves the unification of discrete declarative constraints with the standard loss-driven learning paradigm.

To address this, we will use relaxations of logic in the form of t-norms to deterministically compile rules into differentiable loss functions.[4] We treat predicted label probabilities as soft surrogates for Boolean decisions. In the rest of the paper, we will use lower case for model probabilities—e.g., $e(P, H)$, and upper case—e.g., $E(P, H)$—for Boolean predicates.

Different t-norms map the standard Boolean operations into different continuous functions. Table 1 summarizes this mapping for three t-norms: product, Gödel, and Łukasiewicz. Complex Boolean expressions can be constructed from these four operations. Thus, with t-norms to relax logic, we can systematically convert rules as in (1) into differentiable functions, which in turn serve as learning objectives to minimize constraint violations. We can use any off-the-shelf optimizer (e.g., ADAM Kingma and Ba, 2015). We will see concrete examples in the NLI case study in §3.

Picking a t-norm is both a design choice and an algorithmic one. Different t-norms have different numerical characteristics and their comparison is a question for future research.[5] Here, we will focus on the product t-norm to allow comparisons to previous work: as we will see in the next section, the product t-norm strictly generalizes the widely used cross entropy loss.

[4] A full description of t-norms is beyond the scope of this paper; we refer the interested reader to Klement et al. (2013).

[5] For example, the Gödel t-norm, used by Minervini and Riedel (2018), has a discountinuous but semi-differentiable residuum. The Łukasiewicz t-norm can lead to zero gradients for large disjunctions, rendering learning difficult.

3 Case Study: NLI

We study our framework using the NLI task as a case study. First, in §3.1, we will show how to represent a training set as in (1). We will also introduce two classes of domain constraints that apply to groups of premise-hypothesis pairs. Next, we will show how to compile these declaratively stated learning objectives to loss functions (§3.2). Finally, we will end this case study with a discussion about practical issues (§3.3).

3.1 Learning Objectives in Logic

Our goal is to build models that minimize inconsistency with domain knowledge stated in logic. Let us look at three such consistency requirements.

Annotation Consistency For labeled examples, we expect that a model should predict what an annotator specifies. That is, we require

$$\forall(P, H), Y^\star \in D, \quad \top \rightarrow Y^\star(P, H) \qquad (4)$$

where $Y^\star$ represents the ground truth label for the example (P, H). As mentioned at the end of §2.2, for the annotation consistency, both global and conditional violation rates are the same, and minimizing them is maximizing accuracy. In our experiments, we will report accuracy instead of violation rate for annotation consistency (to align with the literature).

Symmetry Consistency Given any premise-hypothesis pair, the grounds for a model to predict *Contradiction* is that the events in the premise and the hypothesis cannot coexist simultaneously. That is, a (P, H) pair is a contradiction if, and only if, the (H, P) pair is also a contradiction:

$$\forall(P, H) \in D, \quad C(P, H) \leftrightarrow C(H, P) \qquad (5)$$

Transitivity Consistency This constraint is applicable to any three related sentences P, H and Z. If we group the sentences into three pairs, namely (P, H), (H, Z) and (P, Z), the label definitions mandate that not all of the $3^3 = 27$ assignments to these three pairs are allowed. The example in §1 is an allowed label assignment. We can enumerate all such valid labels as the conjunction:

$$\begin{aligned}
&\forall(P, H, Z) \in D, \\
&\quad (E\,(P, H) \wedge E\,(H, Z) \rightarrow E\,(P, Z)) \\
&\wedge\,(E\,(P, H) \wedge C\,(H, Z) \rightarrow C\,(P, Z)) \\
&\wedge\,(N\,(P, H) \wedge E\,(H, Z) \rightarrow \neg C\,(P, Z)) \\
&\wedge\,(N\,(P, H) \wedge C\,(H, Z) \rightarrow \neg E\,(P, Z))
\end{aligned} \qquad (6)$$

Name	Boolean Logic	Product	Gödel	Łukasiewicz
Negation	$\neg A$	$1-a$	$1-a$	$1-a$
T-norm	$A \wedge B$	ab	$\min(a,b)$	$\max(0, a+b-1)$
T-conorm	$A \vee B$	$a+b-ab$	$\max(a,b)$	$\min(1, a+b)$
Residuum	$A \rightarrow B$	$\min\left(1, \frac{b}{a}\right)$	$\begin{cases} 1, \text{ if b} \geq \text{a}, \\ b, \text{ else} \end{cases}$	$\min(1, 1-a+b)$

Table 1: Mapping discrete statements to differentiable functions using t-norms. Literals are upper-cased (e.g. A) while real-valued probabilities are lower-cased (e.g. a). In this paper, we focus on the product t-norm.

3.2 Inconsistency Losses

Using the consistency constraints stated in §3.1, we can now derive the inconsistency losses to minimize. For brevity, we will focus on the annotation and symmetry consistencies.

First, let us examine annotation consistency. We can write the universal quantifier in (4) as a conjunction to get:

$$\bigwedge_{(P,H),Y^\star \in D} \top \rightarrow Y^\star(P,H) \tag{7}$$

Using the product t-norm from Table 1, we get the learning objective of maximizing the probability of the true labels:

$$\prod_{(P,H),Y^\star \in D} y^\star_{(P,H)} \tag{8}$$

Or equivalently, by transforming to the negative log space, we get the annotation loss:

$$L_{ann} = \sum_{(P,H),Y^\star \in D} -\log y^\star_{(P,H)}. \tag{9}$$

We see that we get the familiar cross-entropy loss function using the definition of inconsistency with the product t-norm!

Next, let us look at symmetry consistency:

$$\bigwedge_{(P,H) \in D} C(P,H) \leftrightarrow C(H,P). \tag{10}$$

Using the product t-norm, we get:

$$\prod_{(P,H) \in D} \min\left(1, \frac{c_{(H,P)}}{c_{(P,H)}}\right) \min\left(1, \frac{c_{(P,H)}}{c_{(H,P)}}\right) \tag{11}$$

Transforming to the negative log space as before, we get the symmetry loss:

$$L_{sym} = \sum_{(P,H) \in D} |\log c_{(P,H)} - \log c_{(H,P)}| \tag{12}$$

The loss for transitivity L_{tran} can also be similarly derived. We refer the reader to the appendix for details.

The important point is that we can systematically convert logical statements to loss functions and cross-entropy is only one of such losses. To enforce some or all of these constraints, we add their corresponding losses. In our case study, with all constraints, the goal of learning is to minimize:

$$L = L_{ann} + \lambda_{sym} L_{sym} + \lambda_{tran} L_{tran} \tag{13}$$

Here, the λ's are hyperparameters to control the influence of each loss term.

3.3 Training Constrained Models

The derived loss functions are directly compatible with off-the-shelf optimizers. The symmetry/transitivity consistencies admit using unlabeled examples, while annotation consistency requires labeled examples. Thus, in §4, we will use both labeled and unlabeled data to power training.

Ideally, we want the unlabeled dataset to be absolutely informative, meaning a model learns from *every* example. Unfortunately, obtaining such a dataset remains an open question since new examples are required to be both linguistically meaningful and difficult enough for the model. Minervini and Riedel (2018) used a language model to generate unlabeled adversarial examples. Another way is via pivoting through a different language, which has a long history in machine translation (e.g., Kay, 1997; Mallinson et al., 2017).

Since our focus is to study inconsistency, as an alternative, we propose a simple method to create unlabeled examples: we randomly sample sentences from the same topic. In §4, we will show that even random sentences can be surprisingly informative because the derived losses operate in real-valued space instead on discrete decisions.

BERT w/ SNLI+MultiNLI^2	22.1	67.1	4.1	13.7	19.3	59.7	4.5	15.2
LSTM w/ SNLI+MultiNLI	25.8	69.5	9.9	21.0	16.8	53.6	5.3	16.0

Table 2: Inconsistencies (%) of models on our 100k evaluation dataset. Each number represents the average of three random runs. Models are trained using 5% and 100% of the train sets. SNLI+MultiNLI^2: finetuned twice. ρ_S and τ_S: symmetry consistency violations. ρ_T and τ_T: transitivity consistency violations.

4 Experiments

In this section, we evaluate our framework using (near) state-of-the-art approaches for NLI, primarily based on BERT, and also compare to an LSTM model. We use the SNLI and MultiNLI (Wang et al., 2018) datasets to define annotation consistency. Our LSTM model is based on the decomposable attention model with a BiLSTM encoder and GloVe embeddings (Pennington et al., 2014). Our BERT model is based on the pretrained BERT$_{base}$, finetuned on SNLI/MultiNLI. The constrained models are initialized with the finetuned BERT$_{base}$ and finetuned again with inconsistency losses.[6] For fair comparison, we also show results of BERT$_{base}$ models finetuned twice.

Our constrained models are trained on both labeled and unlabeled examples. We expect that the different inconsistencies do not conflict with each other. Hence, we select hyperparameters (e.g., the λ's) using development accuracy only (*i.e.*, annotation consistency). We refer the reader to the appendix for details of our experimental setup.

4.1 Datasets

To be comprehensive, we will use both of the SNLI and MultiNLI to train our models, but we also show individual results.

We study the impact of the amount of label supervision by randomly sampling different percentages of labeled examples. For each case, we also sample the same percentages from the corresponding development sets for model selection. For the MultiNLI dataset, we use the `matched` dev for validation and `mismatched` dev for evaluation.

Mirrored Instances (M) Given a labeled example, we construct its mirrored version by swapping the premise and the hypothesis. This results in the same number of unlabeled sentence pairs as the annotated dataset. When sampling by percentage, we will only use the sampled examples to construct mirrored examples. We use this dataset for symmetry consistency.

Unlabeled Instance Triples (T) For the transitivity constraint, we sample 100k sentence triples from MS COCO (Lin et al., 2014) captions. From these, we construct three examples as in §3.1: sentences (P, H, Z) gives the pairs (P, H), (H, Z), and (P, Z). In all, we have 100k example *unlabeled* triples for the transitivity constraint.

Unlabeled Instance Pairs (U) For each sentence triple in the dataset T, we take the first example (P, H) and construct mirrored examples, *i.e.* (H, P). This yields 100k *unlabeled* instance pairs for training with the symmetry loss.

Evaluation Dataset We sample a different set of 100k example triples for measuring transitivity consistency. For symmetry consistency, we follow the above procedure for the dataset U to construct evaluation instance pairs. Recall that the definition of inconsistency allows measuring model quality with unlabeled data.

4.2 Inconsistency of Neural Models

In Table 2, we report the impact of the amount of annotated data on symmetry/transitivity consistencies by using different percentages of labeled examples. We see that both LSTM and BERT models have symmetry consistency violations, while the transitivity consistency has lower violations. Surprisingly, the LSTM model performed on par with BERT in terms of symmetry/transitivity consistency; stronger representations does not necessarily mean more consistent models.

The table shows that, given an example and its mirrored version, if the BERT baseline predicts a

[6] This is critical when label supervision is limited.

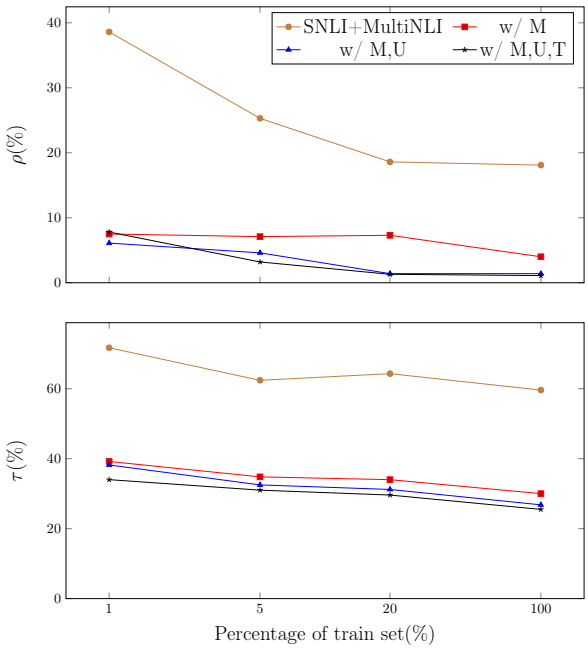

Figure 1: Symmetry inconsistencies on the 100k evaluation example pairs. Each point represents the average of three random runs. M, U, and T are our unlabeled datasets with corresponding losses.

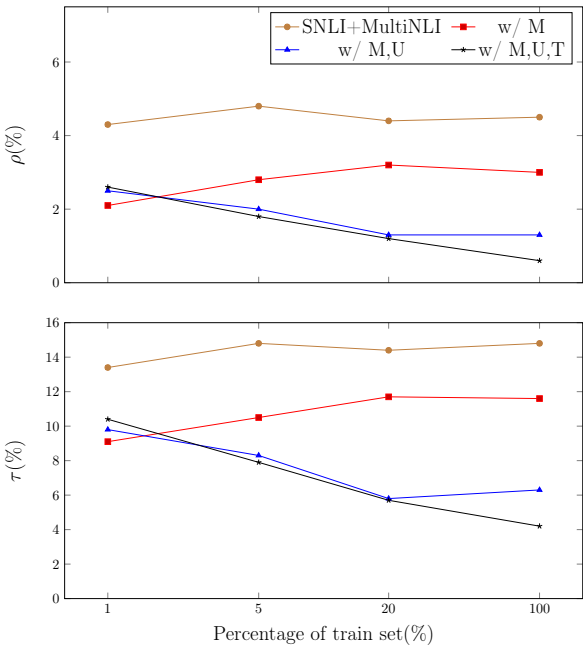

Figure 2: Transitivity inconsistencies on the 100k evaluation example pairs. Each point represents the average of three random runs. M, U, and T are our unlabeled datasets with corresponding losses.

Contradiction on one, it has about 60% chance (τ_S) to make an inconsistent judgement on the other. Further, we see that the inconsistencies are not affected much by different datasets. Models trained on the SNLI are as inconsistent as ones trained on MultiNLI. Combining them only gives slight improvements. Also, finetuning twice does not improve much over models finetuned once.

Finally, with more annotation, a model has fewer symmetry consistency violations. However, the same observation does not apply to the transitivity consistency. In the following sections, we will show that we can almost annihilate these inconsistencies using the losses from §3.2.

4.3 Reducing Inconsistencies

We will study the effect of symmetry and transitivity consistency losses in turn using the BERT models. To the baseline models, we incrementally include the M, U, and T datasets. We expect that the constrained models should have accuracies at least on par with the baseline (though one of the key points of this paper is that accuracy by itself is not a comprehensive metric).

In Fig. 1, we present both of the global and conditional violation rates of baselines and the constrained models. We see that mirrored examples (*i.e.*, the w/ M curve) greatly reduced the symmetry inconsistency. Further, with 100k unlabeled example pairs (the w/ M,U curve), we can further reduce the error rate. The same observation also applies when combining symmetry with transitivity constraint.

Fig. 2 shows the results for transitivity inconsistency. The transitivity loss is, again, greatly reduced both for the global and conditional violations. We refer the reader to the appendix for exact numbers.

We see that with our augmented losses, even a model using 1% label supervision can be much more consistent than the baselines trained on 100% training set! This suggests that label supervision does not explicitly encode the notion of consistency, and consequently models do not get this information from the training data.

With the simultaneous decline in global and conditional violation rate, the constrained models learn to agree with the consistency requirements specified declaratively. We will see in the next section, doing so does not sacrifice model accuracies.

4.4 Interaction of Losses

In Table 3, we show the impact of symmetry and transitivity consistency on test accuracy. And the interaction between symmetry and transitivity consistency is covered in Fig 1 and 2.

	1%		5%		20%		100%	
Config	SNLI	MultiNLI	SNLI	MultiNLI	SNLI	MultiNLI	SNLI	MultiNLI
SNLI+MultiNLI	79.7	70.1	84.6	77.2	87.8	80.6	90.1	83.5
SNLI+MultiNLI^2	80.3	71.0	85.3	77.4	87.9	80.7	90.3	84.0
w/ M	80.1	71.0	85.3	77.8	88.1	80.6	90.3	84.1
w/ M,U	80.2	71.0	85.4	77.2	88.1	80.9	90.5	84.3
w/ M,U,T	80.6	71.1	85.4	77.2	88.1	80.9	90.2	84.2

Table 3: Impact of symmetry/transitivity consistencies on test set accuracies. Each number represents the average of three random runs of BERT$_{base}$. Columns are accuracies on our SNLI/MultiNLI test sets. SNLI+MultiNLI^2: finetuned twice. M, U, and T are unlabeled datasets with respective inconsistency losses.

Our goal is to minimize all inconsistencies without sacrificing one for another. In Table 3, we see that lower symmetry/transitivity inconsistency generally does not reduce test accuracy, but we do not observe substantial improvement either. In conjunction with the observations from above, this suggests that test sets do not explicitly measure symmetry/transitivity consistency.

From Fig 1 and 2, we see that models constrained by both symmetry and transitivity losses are generally more consistent than models using symmetry loss alone. Further, we see that in Fig. 2, using mirrored dataset alone can even mitigate the transitivity errors. With dataset P, the transitivity inconsistency is strongly reduced by the symmetry inconsistency loss. These observations suggest that the compositionality of constraints does not pose internal conflict to the model. They are in fact beneficial to each other.

Interestingly, in Fig 2, the models trained with mirrored dataset (w/ M) become more inconsistent in transitivity measurement when using more training data. We believe there are two factors causing this. Firstly, there is a vocabulary gap between SNLI/MultiNLI data and our unlabeled datasets (U and T). Secondly, the w/ M models are trained with symmetry consistency but evaluated with transitivity consistency. The slightly rising inconsistency implies that, without vocabulary coverage, training with one consistency might not always benefit another consistency, even using more training data.

When label supervision is limited (*i.e.* 1%), the models can easily overfit via the transitivity loss. As a result, models trained on the combined losses (*i.e.* w/ M,U,T) have slightly larger transitivity inconsistency than models trained with mirrored data (*i.e.* w/ M) alone. In fact, if we use no label supervision at all, the symmetry and transitivity losses can push every prediction towards label *Neutral*. But such predictions sacrifice annotation consistency. Therefore, we believe that some amount of label supervision is necessary.

Data	M	U	T
5% w/ M,U,T	99.8	99.4	12.0
100% w/ M,U,T	98.7	97.6	6.8

Table 4: Coverage (%) of unlabeled training sentences during the first epoch of training. Percentages are calculated from models with random seed 1.

5 Analysis

In this section, we present an analysis of how the different losses affect model prediction and how informative they are during training.

5.1 Coverage of Unlabeled Dataset

Table 4 shows the *coverage* of the three unlabeled datasets during the first training epoch. Specifically, we count the percentage of unlabeled examples where the symmetry/transitivity loss is positive. The coverage decreases in subsequent epochs as the model learns to minimize constraint violations. We see that both datasets M and U have high coverage. This is because that, as mentioned in §2, our loss function works in real-valued space instead of discrete decisions. The coverage of the dataset T is much lower because the compositional antecedent in transitivity statements holds less often, which naturally leads to smaller coverage, unlike the unary antecedent for symmetry.

5.2 Distribution of Predictions

In Table 5, we present the distribution of model predictions on the 100k evaluation example pairs for symmetry consistency. Clearly, the number of

		BERT (H, P)			w/ M,U,T (H, P)		
		E	C	N	E	C	N
(P, H)	E	4649	**1491**	14708	2036	**29**	9580
	C	**1508**	10712	**6459**	**33**	4025	**627**
	N	14609	**6633**	39231	9632	**613**	73425

Table 5: Distribution of predictions on the 100k evaluation data using BERT trained on 100% SNLI+MultiNLI data with random seed 1. Bold entries are symmetrically inconsistent.

Model	Example	E	C	N
BERT	(P, H)	20848	18679	60473
	(H, Z)	20919	18768	60313
	(P, Z)	20779	18721	60500
w/ M,U,T	(P, H)	11645	4685	83670
	(H, Z)	11671	4703	83626
	(P, Z)	11585	4597	83818

Table 6: Distribution of predictions on the 100k evaluation example triples. BERT: trained on the full SNLI+MultiNLI data. Predictions are from random run with seed 1.

constraint-violating (off-diagonal) predictions significantly dropped. Also note that the number of *Neutral* nearly doubled in our constrained model. This meets our expectation because the example pairs are constructed from randomly sampled sentences under the same topic.

We also present the distribution of predictions on example triples for the transitivity consistency in Table 6. As expected, with our transitivity consistency, the distribution of the label *Neutral* gets significantly higher as well. Further, in Table 7, we show the error rates of each individual transitivity consistencies. Clearly our framework mitigated the violation rates on all four statements.

While the logic-derived regularization pushes model prediction on unlabeled datasets towards *Neutral*, the accuracies on labeled test sets are not compromised. We believe this relates to the design of current NLI datasets where the three labels are balanced. But in the real world, neutrality represents potentially infinite negative space while entailments and contradictions are rarer. The total number of neutral examples across both the SNLI and MultiNLI test sets is about 7k. *Can we use these 7k examples to evaluate the nearly infinite negative space?* We believe not.

Transitivity	BERT ρ_T	BERT τ_T	w/ M,U,T ρ_T	w/ M,U,T τ_T
$E \wedge E \rightarrow E$	0.7	16.0	0.2	15.1
$E \wedge C \rightarrow C$	1.8	49.6	0.2	46.5
$N \wedge E \rightarrow \neg C$	1.2	9.0	0.2	1.8
$N \wedge C \rightarrow \neg E$	1.0	9.3	0.1	4.8

6 Related Works and Discussion

Logic, Knowledge and Statistical Models Using soft relaxations of Boolean formulas as loss functions has rich history in AI. The Łukasiewicz t-norm drives knowledge-driven learning and inference in probabilistic soft logic (Kimmig et al., 2012). Li and Srikumar (2019) show how to augment existing neural network architectures with domain knowledge using the Łukasiewicz t-norm. Xu et al. (2018) proposed a general framework for designing a semantically informed loss, without t-norms, for constraining a complex output space. In the same vein, Fischer et al. (2019) also proposed a framework for designing losses with logic, but using a bespoke mapping of the Boolean operators.

Our work is also conceptually related to posterior regularization (Ganchev et al., 2010) and constrained conditional models (Chang et al., 2012), which integrate knowledge with statistical models. Using posterior regularization with imitation learning, Hu et al. (2016) transferred knowledge from rules into neural parameters. Rocktäschel et al. (2015) embedded logic into distributed representations for entity relation extraction. Alberti et al. (2019) imposed answer consistency over generated questions for machine comprehension. Ad-hoc regularizers have been proposed for process comprehension (Du et al., 2019), semantic role labeling (Mehta et al., 2018), and summarization (Hsu et al., 2018).

Natural Language Inference In the literature, it has been shown that even highly accurate models show a decline in performance with perturbed examples. This lack of robustness of NLI models has been shown by comparing model performance on pre-defined propositional rules for swapped datasets (Wang et al., 2019) or outlining large-

scale stress tests to measure stability of models to semantic, lexical and random perturbations (Naik et al., 2018). Moreover, adversarial training examples produced by paraphrasing training data (Iyyer et al., 2018) or inserting additional seemingly important, yet unrelated, information to training instances (Jia and Liang, 2017) have been used to show model inconsistency. Finally, adversarially labeled examples have been shown to improve prediction accuracy (Kang et al., 2018) . Also related in this vein is the idea of dataset inoculation (Liu et al., 2019), where models are finetuned by exposing them to a challenging dataset.

The closest related work to this paper is probably that of Minervini and Riedel (2018), which uses the Gödel t-norm to discover adversarial examples that violate constraints. There are three major differences compared to this paper: 1) our definition of inconsistency is a strict generalization of errors of model predictions, giving us a unified framework for that includes cross-entropy as a special case, 2) our framework does not rely on the construction of adversarial datasets, and 3) we studied the interaction of annotated examples vs. unlabeled examples via constraint, showing that our constraints can yield strongly consistent model with even a small amount of label supervision.

7 Conclusion

In this paper, we proposed a general framework to measure and mitigate model inconsistencies. Our framework systematically derives loss functions from domain knowledge stated in logic rules to constrain model training. As a case study, we instantiated the framework on a state-of-the-art model for the NLI task, showing that models can be highly accurate and consistent at the same time. Our framework is easily extensible to other domains with rich output structure, e.g., entity relation extraction, and multilabel classification.

A Appendices

A.1 Violations as Generalizing Errors

Both global and conditional violations defined in the body of the paper generalize classifier error. In this section, we will show that for a dataset with only labeled examples, and no additional constraints, both are identical to error.

Recall that an example x annotated with label $Y^\star$ can be written as $\top \rightarrow Y^\star(x)$. If we have a dataset D of such examples and no constraints, in our unified representation of examples, we can write this as the following conjunction:

$$\forall x \in D, \quad \top \rightarrow Y^\star(x).$$

We can now evaluate the two definitions of violation for this dataset.

First, note that the denominator in the definition of the conditional violation τ counts the number of examples because the antecedent for all examples is always true. This makes ρ and τ equal. Moreover, the numerator is the number of examples where the label for an example is not $Y^\star$. In other words, the value of ρ and τ represents the fraction of examples in D that are mislabeled.

The strength of the unified representation and the definition of violation comes from the fact that they apply to arbitrary constraints.

A.2 Loss for Transitivity Consistency

This section shows the loss associated with the transitivity consistency in the NLI case study. For an individual example (P, H, Z), applying the product t-norm to the definition of the transitivity consistency constraint, we get the loss

$$\begin{aligned}
&\text{ReLU}\left(\log e(P,H) + \log e(H,Z) - \log e(P,Z)\right) \\
+&\text{ReLU}\left(\log e(P,H) + \log c(H,Z) - \log c(P,Z)\right) \\
+&\text{ReLU}\left(\log n(P,H) + \log e(H,Z) - \log\left(1 - c(P,Z)\right)\right) \\
+&\text{ReLU}\left(\log n(P,H) + \log c(H,Z) - \log\left(1 - e(P,Z)\right)\right)
\end{aligned} \tag{14}$$

That is, the total transitivity loss L_{tran} is the sum of this expression over the entire dataset.

A.3 Details of Experiments

A.3.1 Setup

For BERT$_{base}$ baselines, we finetune them for 3 epochs with learning rate 3×10^{-5}, warmed up for all gradient updates. For constrained models, we further finetune them for another 3 epochs with lowered learning rate 1×10^{-5}. When dataset U is present, we further lower the learning rate to 5×10^{-6}. Optimizer is Adam across all runs. During training, we adopt Dropout rate (Srivastava et al., 2014) 0.1 inside of BERT transformer encoder while 0 at the final linear layer of classification.

For different types of data and different consistency constraints, we used different weighting factors λ's. In general, we found that the smaller amount of labeled examples, the smaller λ for the symmetry and transitivity consistency. In Table 9, we see that the λ's for U and T grows exponentially with the size of annotated examples. In contrast, the λ for M dataset can be much higher. We found a good value for M is 1. This is because the size of dataset U and T are fixed to be 100k, while the size of dataset M is the same as the amount of labeled examples.

MultiNLI	na	80.4	25.8	58.1	5.1	16.5	na	83.7	20.6	58.9	5.6	17.5
SNLI+MultiNLI	87.8	80.6	18.6	64.3	4.4	14.4	90.1	83.5	18.1	59.6	4.5	14.8
SNLI+MultiNLI^2	87.9	80.7	19.0	64.0	4.3	14.5	90.3	84.0	19.3	59.7	4.5	15.2
w/ M	88.1	80.6	7.3	34.0	3.2	11.7	90.3	84.1	6.2	28.1	3.0	11.6
w/ M,U	88.1	80.9	1.4	31.2	1.3	5.8	90.5	84.3	1.4	26.8	1.3	6.3
w/ M,U,T	88.1	80.9	1.3	29.6	1.2	5.7	90.2	84.2	1.1	25.5	0.6	4.2

Table 8: Symmetry/Transitivity inconsistencies (%) for models using 1%, 5%, 20%, and 100% training data. Each number represents the average of three random runs. SNLI+MultiNLI^2: BERT$_{base}$ finetuned twice for fair comparison. SNLI/MultiNLI column: accuracies on corresponding text sets. M: mirrored labeled examples. U: unlabeled instance pairs. T: unlabeled instance triples.

Data	1%	5%	20%	100%
M	1	1	1	1
U	10^{-5}	10^{-4}	10^{-3}	10^{-1}
T	10^{-6}	10^{-5}	10^{-4}	10^{-3}

Table 9: Choice of λ's for different consistency and corresponding unlabeled datasets. For different sizes of annotation and different types of data, we adopt different λ's.

Having larger λ leads to significantly worse accuracy on the development set, especially that of SNLI. Therefore we did not select such models for evaluation. We hypothesize that it is because the SNLI and MultiNLI are crowdsourced from different domains while the MS COCO shares the same domain as the SNLI. Larger scaling factor could push unlabeled examples towards *Neutral*, thus sacrificing the annotation consistency on SNLI examples.

A.3.2 Results

We present the full experiment results on the natural language inference task in Table 8. Note that the accuracies of baselines finetuned twice are slightly better than models only finetuned once, while their symmetry/transitivity consistencies are roughly on par. We found such observation is consistent with different finetuning hyperparameters (e.g. warming, epochs, learning rate).

Style Transfer for Texts: Retrain, Report Errors, Compare with Rewrites

Abstract

This paper shows that standard assessment methodology for style transfer has several significant problems. First, the standard metrics for style accuracy and semantics preservation vary significantly on different re-runs. Therefore one has to report error margins for the obtained results. Second, starting with certain values of bilingual evaluation understudy (BLEU) between input and output and accuracy of the sentiment transfer the optimization of these two standard metrics diverge from the intuitive goal of the style transfer task. Finally, due to the nature of the task itself, there is a specific dependence between these two metrics that could be easily manipulated. Under these circumstances, we suggest taking BLEU between input and human-written reformulations into consideration for benchmarks. We also propose three new architectures that outperform state of the art in terms of this metric.

1 Introduction

Deep generative models attract a lot of attention in recent years (Hu et al., 2017b). Such methods as variational autoencoders (Kingma and Welling, 2013) or generative adversarial networks (Goodfellow et al., 2014) are successfully applied to a variety of machine vision problems including image generation (Radford et al., 2017), learning interpretable image representations (Chen et al., 2016) and style transfer for images (Gatys et al., 2016). However, natural language generation is more challenging due to many reasons, such as the discrete nature of textual information (Hu et al., 2017a), the absence of local information continuity and non-smooth disentangled representations (Bowman et al., 2015). Due to these difficulties, text generation is mostly limited to specific narrow applications and is usually working in supervised settings.

Content and style are deeply fused in natural language, but style transfer for texts is often addressed in the context of disentangled latent representations (Hu et al., 2017a; Shen et al., 2017; Fu et al., 2018; John et al., 2018; Romanov et al., 2018; Tian et al., 2018). Intuitive understanding of this problem is apparent: if an input text has some attribute A, a system generates new text similar to the input on a given set of attributes with only one attribute A changed to the target attribute $\tilde{A}$. In the majority of previous works, style transfer is obtained through an encoder-decoder architecture with one or multiple style discriminators to learn disentangled representations. The encoder takes a sentence as an input and generates a style-independent content representation. The decoder then takes the content representation and the target style representation to generate the transformed sentence. In (Subramanian et al., 2018) authors question the quality and usability of the disentangled representations for texts and suggest an end-to-end approach to style transfer similar to an end-to-end machine translation.

Contribution of this paper is three-fold: 1) we show that different style transfer architectures have varying results on test and that reporting error margins for various training re-runs of the same model is especially important for adequate assessment of the models accuracy, see Figure 1; 2) we show that BLEU (Papineni et al., 2002) between input and output and accuracy of style transfer measured in terms of the accuracy of a pre-trained external style classifier can be manipulated and naturally diverge from the intuitive goal of the style transfer task starting from a certain threshold; 3) new architectures that perform style transfer using improved latent representations are shown to outperform state of the art in terms of BLEU between output and

2 Related Work

Style of a text is a very general notion that is hard to define in rigorous terms (Xu, 2017). However, the style of a text can be characterized quantitatively (Hughes et al., 2012); stylized texts could be generated if a system is trained on a dataset of stylistically similar texts (Potash et al., 2015); and author-style could be learned end-to-end (Tikhonov and Yamshchikov, 2018b,c; Vechtomova et al., 2018). A majority of recent works on style transfer focus on the sentiment of text and use it as a target attribute. For example, in (Li et al., 2018; Kabbara and Cheung, 2016; Xu et al., 2018) estimate the quality of the style transfer with binary sentiment classifier trained on the corpora further used for the training of the style-transfer system. (Ficler and Goldberg, 2017) and especially (Fu et al., 2018) generalize this ad-hoc approach defining a style as a set of arbitrary quantitively measurable categorial or continuous parameters. Such parameters could include the *'style of the time'* (Hughes et al., 2012), author-specific attributes (see (Xu et al., 2012) or (Jhamtani et al., 2017) on 'shakespearization'), politeness (Sennrich et al., 2016), formality of speech (Rao and Tetreault, 2018), and gender or even political slant (Prabhumoye et al., 2018).

A significant challenge associated with narrowly defined style-transfer problems is that finding a good solution for one aspect of a style does not guarantee that you can use the same solution for a different aspect of it. For example, Guu et al. (2018) build a generative model for sentiment transfer with a retrieve-edit approach. In (Li et al., 2018) a delete-retrieve model shows good results for sentiment transfer. However, it is hard to imagine that these retrieval approaches could be used, say, for the style of the time or formality, since in these cases the system is often expected to paraphrase a given sentence to achieve the target style.

In (Hu et al., 2017a) the authors propose a more general approach to the controlled text generation combining variational autoencoder (VAE) with an extended wake-sleep mechanism in which the sleep procedure updates both the generator and external classifier that assesses generated samples and feedbacks learning signals to the generator. Authors had concatenated labels for style with the text representation of the encoder and used this vector with "hard-coded" information about the sentiment of the output as the input of the decoder. This approach seems promising, and some other papers either extend it or use similar ideas. Shen et al. (2017) applied a GAN to align the hidden representations of sentences from two corpora using an adversarial loss to decompose information about the form. In (Zhao et al., 2017) model learns a smooth code space and can be used as a discrete GAN with the ability to generate coherent discrete outputs from continuous samples. Authors use two different generators for two different styles. In (Fu et al., 2018) an adversarial network is used to make sure that the output of the encoder does not have style representation. (Hu et al., 2017a) also uses an adversarial component that ensures there is no stylistic information within the representation. Fu et al. (2018) do not use a dedicated component that controls the semantic component of the latent representation. Such a component is proposed by John et al. (2018) who demonstrate that decomposition of style and content could be improved with an auxiliary multi-task for label prediction and adversarial objective for bag-of-words prediction. Romanov et al. (2018) also introduces a dedicated component to control semantic aspects of latent representations and an adversarial-motivational training that includes a special motivational loss to encourage a better decomposition. Speaking about preservation of semantics one also has to mention works on paraphrase systems, see, for example (Prakash et al., 2016; Gupta et al., 2018; Roy and Grangier, 2019). The methodology described in this paper could be extended to paraphrasing systems in terms of semantic preservation measurement, however,

this is the matter of future work.

Subramanian et al. (2018) state that learning a latent representation, which is independent of the attributes specifying its style, is rarely attainable. There are other works on style transfer that are based on the ideas of neural machine translation with (Carlson et al., 2018) and without parallel corpora (Zhang et al., 2018) in line with (Lample et al., 2017) and (Artetxe et al., 2017).

It is important to underline here that majority of the papers dedicated to style transfer for texts treat sentiment of a sentence as a stylistic rather than semantic attribute despite particular concerns (Tikhonov and Yamshchikov, 2018a). It is also crucial to mention that in line with (Fu et al., 2018) majority of the state of the art methods for style transfer use an external pre-trained classifier to measure the accuracy of the style transfer. BLEU computes the harmonic mean of precision of exact matching n-grams between a reference and a target sentence across the corpus. It is not sensitive to minute changes, but BLEU between input and output is often used as the coarse measure of the semantics preservation. For the corpora that have human written reformulations, BLEU between the output of the model and human text is used. These metrics are used alongside with a handful of others such as PINC (Paraphrase In N-gram Changes) score (Carlson et al., 2018), POS distance (Tian et al., 2018), language fluency (John et al., 2018), etc. Figure 2 shows self-reported results of different models in terms of two most frequently measured performance metrics, namely, BLEU and Accuracy of the style transfer.

This paper focuses on Yelp! reviews dataset[1] that was lately enhanced with human written reformulations by (Li et al., 2018). These are Yelp! reviews, where each short English review of a place is labeled as a negative or as a positive once. This paper studies three metrics that are most common in the field at the moment and questions to which extent can they be used for the performance assessment. These metrics are the accuracy of an external style classifier that is trained to measure the accuracy of the style transfer, BLEU between input and output of a system, and BLEU between output and human-written texts.

[1]https://www.yelp.com/dataset

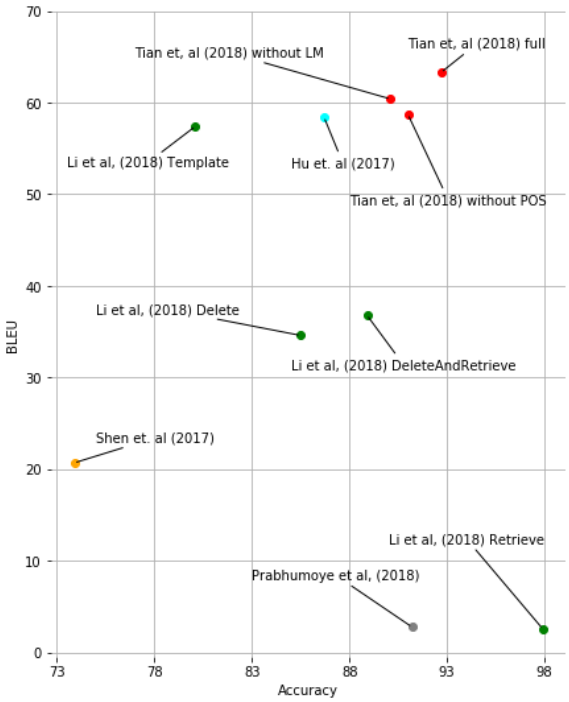

Figure 2: Overview of the self-reported results for sentiment transfer on Yelp! reviews. Results of (Romanov et al., 2018) are not displayed due to the absence of self-reported BLEU scores. Later in the paper we show that on different reruns BLEU and accuracy can vary from these self-reported single results.

3 Style transfer

In this work we experiment with extensions of a model, described in (Hu et al., 2017a), using Texar (Hu et al., 2018) framework. To generate plausible sentences with specific semantic and stylistic features every sentence is conditioned on a representation vector z which is concatenated with a particular code c that specifies desired attribute, see Figure 3. Under notation introduced in (Hu et al., 2017a) the base autoencoder (AE) includes a conditional probabilistic encoder E defined with parameters θ_E to infer the latent representation z given input x

$$z \sim E(x) = q_E(z, c|x).$$

Generator G defined with parameters θ_G is a GRU-RNN for generating and output $\hat{x}$ defined as a sequence of tokens $\hat{x} = \hat{x}_1, ..., \hat{x}_T$ conditioned on the latent representation z and a stylistic component c that are concatenated and give rise to a generative distribution

$$\hat{x} \sim G(z, c) = p_G(\hat{x}|z, c).$$

These encoder and generator form an AE with the following loss

$$\mathcal{L}_{ae}(\theta_G, \theta_E; x, c) = -\mathbb{E}_{q_E(z,c|x)} \left[\log q_G(x|z,c)\right]. \quad (1)$$

This standard reconstruction loss that drives the generator to produce realistic sentences is combined with two additional losses. The first discriminator provides extra learning signals which enforce the generator to produce coherent attributes that match the structured code in c. Since it is impossible to propagate gradients from the discriminator through the discrete sample $\hat{x}$, we use a deterministic continuous approximation a "soft" generated sentence, denoted as $\tilde{G} = \tilde{G}_\tau(z, c)$ with "temperature" τ set to $\tau \to 0$ as training proceeds. The resulting soft generated sentence is fed into the discriminator to measure the fitness to the target attribute, leading to the following loss

$$\mathcal{L}_c(\theta_G, \theta_E; x) = -\mathbb{E}_{q_E(z,c|x)} \left[\log q_D(c|\tilde{G})\right]. \quad (2)$$

Finally, under the assumption that each structured attribute of generated sentences is controlled through the corresponding code in c and is independent from z one would like to control that other not explicitly modelled attributes do not entangle with c. This is addressed by the dedicated loss

$$\mathcal{L}_z(\theta_G; x) = -\mathbb{E}_{q_E(z,c|x)q_D(c|x)} \left[\log q_E(z|\tilde{G})\right]. \quad (3)$$

The training objective for the baseline, shown in Figure 3, is therefore a sum of the losses from Equations (1) – (3) defined as

$$min_{\theta_G} \mathcal{L}_{baseline} = \mathcal{L}_{ae} + \lambda_c \mathcal{L}_c + \lambda_z \mathcal{L}_z, \quad (4)$$

where λ_c and λ_z are balancing parameters.

Let us propose two further extensions of this baseline architecture. To improve reproducibility of the research the code of the studied models is open[2]. Both extensions aim to improve the quality of information decomposition within the latent representation. In the first one, shown in Figure 4, a special dedicated discriminator is added to the model to control that the latent representation does not contain stylistic information. The loss of this discriminator is defined as

$$\mathcal{L}_{D_z}(\theta_G; x, c) = -\mathbb{E}_{q_E(z|x)} \left[\log q_{D_z}(c|z)\right]. \quad (5)$$

[2]https://github.com/VAShibaev/text_style_transfer

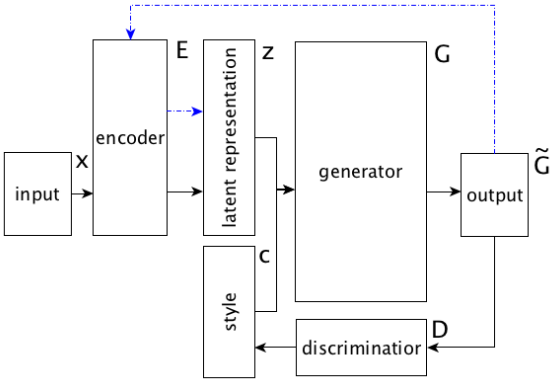

Figure 3: The generative model, where style is a structured code targeting sentence attributes to control. Blue dashed arrows denote the proposed independence constraint of latent representation and controlled attribute, see (Hu et al., 2017a) for the details.

Here a discriminator denoted as D_z is trying to predict code c using representation z. Combining the loss defined by Equation (4) with the adversarial component defined in Equation (5) the following learning objective is formed

$$min_{\theta_G} \mathcal{L} = \mathcal{L}_{baseline} - \lambda_{D_z} \mathcal{L}_{Dz}, \quad (6)$$

where $\mathcal{L}_{baseline}$ is a sum defined in Equation (4), λ_{D_z} is a balancing parameter.

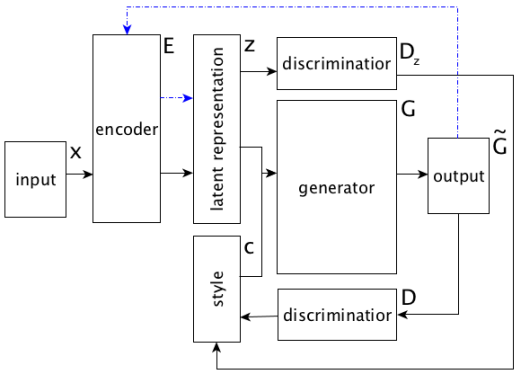

Figure 4: The generative model with dedicated discriminator introduced to ensure that semantic part of the latent representation does not have information on the style of the text.

The second extension of the baseline architecture does not use an adversarial component D_z that is trying to eradicate information on c from component z. Instead, the system, shown in Figure 5 feeds the "soft" generated sentence $\tilde{G}$ into encoder E and checks how close is the representation $E(\tilde{G})$

to the original representation $z = E(x)$ in terms of the cosine distance. We further refer to it as *shifted autoencoder* or SAE. Ideally, both $E(\tilde{G}(E(x), c))$ and $E(\tilde{G}(E(x), \bar{c}))$, where $\bar{c}$ denotes an inverse style code, should be both equal to $E(x)$[3]. The loss of the shifted autoencoder is

$$min_{\theta_G}\mathcal{L} = \mathcal{L}_{baseline} + \lambda_{cos}\mathcal{L}_{cos} + \lambda_{cos^-}\mathcal{L}_{cos^-}, \tag{7}$$

where λ_{cos} and λ_{cos^-} are two balancing parameters, with two additional terms in the loss, namely, cosine distances between the softened output processed by the encoder and the encoded original input, defined as

$$\mathcal{L}_{cos}(x, c) = \cos\left(E(\tilde{G}(E(x), c)), E(x)\right),$$
$$\mathcal{L}_{cos^-}(x, c) = \cos\left(E(\tilde{G}(E(x), \bar{c})), E(x)\right). \tag{8}$$

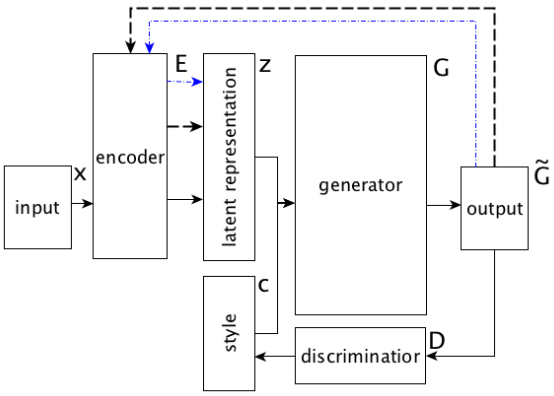

Figure 5: The generative model with a dedicated loss added to control that semantic representation of the output, when processed by the encoder, is close to the semantic representation of the input.

We also study a combination of both approaches described above, shown on Figure 6.

In Section 4 we describe a series of experiments that we have carried out for these architectures using Yelp! reviews dataset.

4 Experiments

We have found that the baseline, as well as the proposed extensions, have noisy outcomes, when retrained from scratch, see Figure 1. Most of the papers mentioned in Section 2 measure the performance of the methods proposed for the sentiment transfer with two metrics: accuracy of the external sentiment classifier measured on test data, and BLEU between the input and output that is regarded as a coarse metric for semantic similarity.

[3]This notation is valid under the assumption that every stylistic attribute is a binary feature

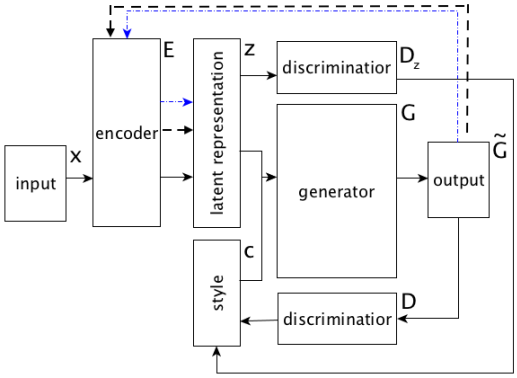

Figure 6: A combination of an additional discriminator used in Figure 4 with a shifted autoencoder shown in Figure 5

In the first part of this section, we demonstrate that reporting error margins is essential for the performance assessment in terms that are prevalent in the field at the moment, i.e., BLEU between input and output and accuracy of the external sentiment classifier. In the second part, we also show that both of these two metrics after a certain threshold start to diverge from an intuitive goal of the style transfer and could be manipulated.

4.1 Error margins matter

On Figure 1 one can see that the outcomes for every single rerun differ significantly. Namely, accuracy can change up to 5 percentage points, whereas BLEU can vary up to 8 points. This variance can be partially explained with the stochasticity incurred due to sampling from the latent variables. However, we show that results for state of the art models sometimes end up within error margins from one another, so one has to report the margins to compare the results rigorously. More importantly, one can see that there is an inherent trade-off between these two performance metrics. This trade-off is not only visible across models but is also present for the same retrained architecture. Therefore, improving one of the two metrics is not enough to confidently state that one system solves the style-transfer problem better than the other. One has to report error margins after several consecutive retrains and instead of comparing one of the two metrics has to talk about Pareto-like optimization that would show confident improvement of both.

To put obtained results into perspective, we have retrained every model from scratch five times in a row. We have also retrained the models of Tian et al. (2018) five times since their code is published online. Figure 7 shows the results of all models with error margins. It is also enhanced with other self-reported results on the same Yelp! review dataset for which no code was published.

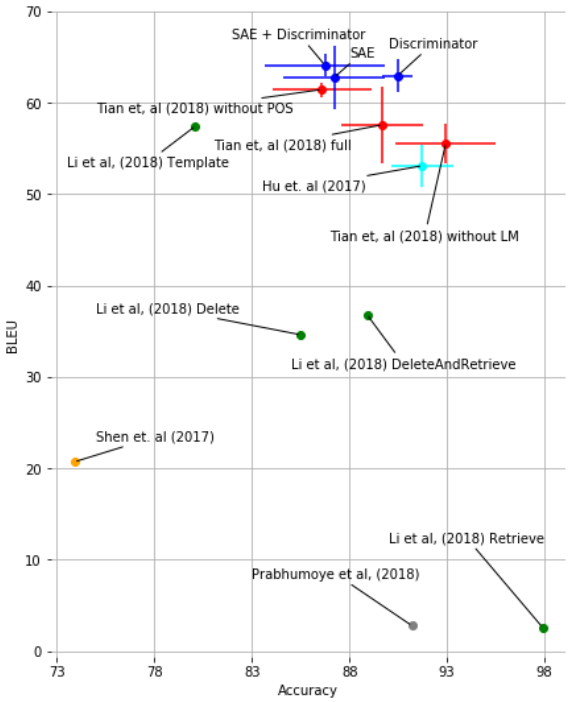

Figure 7: Overview of the self-reported results for sentiment transfer on Yelp! reviews alongside with the results for the baseline model (Hu et al., 2017a), architecture with additional discriminator, shifted autoencoder (SAE) with additional cosine losses, and a combination of these two architectures averaged after five re-trains alongside with architectures proposed by (Tian et al., 2018) after five consecutive re-trains. Results of (Romanov et al., 2018) are not displayed due to the absence of self-reported BLEU scores.

One can see that error margins of the models, for which several reruns could be performed, overlap significantly. In the next subsection, we carefully study BLEU and accuracy of the external classifier and discuss their aptness to measure style transfer performance.

4.2 Delete, duplicate and conquer

One can argue that as there is an inevitable entanglement between semantics and stylistics in natural language, there is also an apparent entanglement between BLEU of input and output and accuracy estimation of the style. Indeed, the output that copies input gives maximal BLEU yet clearly fails in terms of the style transfer. On the other hand, a wholly rephrased sentence could provide a low BLEU between input and output but high accuracy. These two issues are not problematic when both BLEU between input and output and accuracy of the transfer are relatively low. However, since style transfer methods have significantly evolved in recent years, some state of the art methods are now sensitive to these issues. The trade-off between these two metrics can be seen in Figure 1 as well as in Figure 7.

As we have mentioned above, the accuracy of an external classifier and BLEU between output and input are the most widely used methods to assess the performance of style transfer at this moment. However, both of these metrics can be manipulated in a relatively simple manner. One can extend the generative architecture with internal pre-trained classifier of style and then perform the following heuristic procedure:

- measure the style accuracy on the output for a given batch;
- choose the sentences that style classifier labels as incorrect;
- replace them with duplicates of sentences from the given batch that have correct style according to the internal classifier and show the highest BLEU with given inputs.

This way One can replace all sentences that push measured accuracy down and boost reported accuracy to 100%. To see the effect that this manipulation has on the key performance metric we split all sentences with wrong style in 10 groups of equal size and replaces them with the best possible duplicates of the stylistically correct sentences group after group. The results of this process are shown in Figure 8.

This result is disconcerting. Simply replacing part of the output with duplicates of the sentences that happen to have relatively high BLEU with given inputs allows to "boost" accuracy to 100% and "improve" BLEU. The change of BLEU during such manipulation stays within error margins of the architecture, but accuracy is significantly manipulated. What is even more disturbing is that BLEU between such manipulated output of the batch and human-written reformulations provided in (Tian

et al., 2018) also grows. Figure 8 shows that for SAE but all four architectures described in Section 3 demonstrate similar behavior.

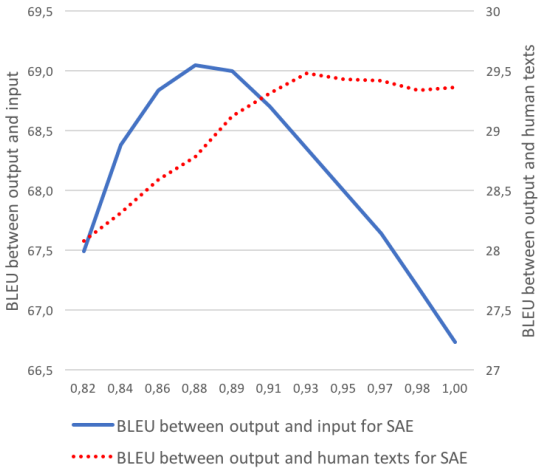

Figure 8: Manipulating the generated output in a way that boosts accuracy one can change BLEU between output and input. Moreover, such manipulation increases BLEU between output and human written reformulations. The picture shows behavior of SAE, but other architectures demonstrate similar behavior. The results are an average of four consecutive retrains of the same architecture.

Our experiments show that though we can manipulate BLEU between output and human-written text, it tends to change monotonically. That might be because of the fact that this metric incorporates information on stylistics and semantics of the text at the same time, preserving inevitable entanglement that we have mentioned earlier. Despite being costly, human-written reformulations are needed for future experiments with style transfer. It seems that modern architectures have reached a certain level of complexity for which naive proxy metrics such as accuracy of an external classifier or BLEU between output and input are already not enough for performance estimation and should be combined with BLEU between output and human-written texts. As the quality of style transfer grows further one has to improve the human-written data sets: for example, one would like to have data sets similar to the ones used for machine translation with several reformulations of the same sentence.

On Figure 9 one can see how new proposed architectures compare with another state of the art approaches in terms of BLEU between output and human-written reformulations.

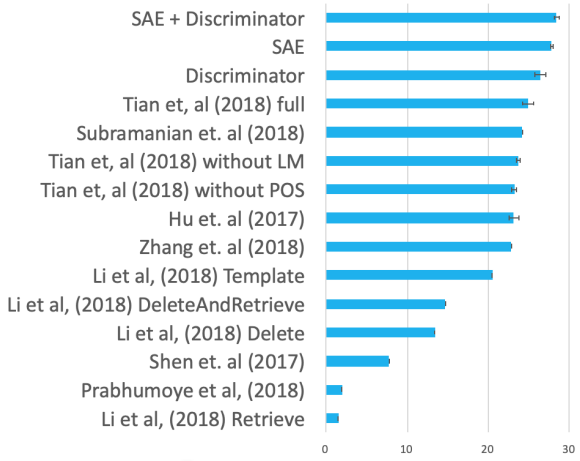

Figure 9: Overview of the BLEU between output and human-written reformulations of Yelp! reviews. Architecture with additional discriminator, shifted autoencoder (SAE) with additional cosine losses, and a combination of these two architectures measured after five re-runs outperform the baseline by (Hu et al., 2017a) as well as other state of the art models. Results of (Romanov et al., 2018) are not displayed due to the absence of self-reported BLEU scores

5 Conclusion

Style transfer is not a rigorously defined NLP problem. Starting from definitions of style and semantics and finishing with metrics that could be used to evaluate the performance of a proposed system. There is a surge of recent contributions that work on this problem. This paper highlights several issues connected with this lack of rigor. First, it shows that the state of the art algorithms are inherently noisy on the two most widely accepted metrics, namely, BLEU between input and output and accuracy of the external style classifier. This noise can be partially attributed to the adversarial components that are often used in the state of the art architectures and partly due to certain methodological inconsistencies in the assessment of the performance. Second, it shows that reporting error margins of several consecutive retrains for the same model is crucial for the comparison of different architectures, since error margins for some of the models overlap significantly. Finally, it demonstrates that even BLEU on human-written reformulations can be manipulated in a relatively simple way.

A Supplemental Material

Here are some examples characteristic for different systems. An output of a system follows the input. Here are some successful examples produced by the system with additional discriminator:

- it's not much like an actual irish pub, which is depressing. → it's definitely much like an actual irish pub, which is grateful.
- i got a bagel breakfast sandwich and it was delicious! → i got a bagel breakfast sandwich and it was disgusting!
- i love their flavored coffee. → i dumb their flavored coffee.
- i got a bagel breakfast sandwich and it was delicious! → i got a bagel breakfast sandwich and it was disgusting!
- i love their flavored coffee. → i dumb their flavored coffee.
- nice selection of games to play. → typical selection of games to play.
- i'm not a fan of huge chain restaurants. → i'm definitely a fan of huge chain restaurants.

Here are some examples of typical faulty reformulations:

- only now i'm really hungry, and really pissed off. → kids now i'm really hungry, and really extraordinary off.
- what a waste of my time and theirs. → what a wow. of my time and theirs.
- cooked to perfection and very flavorful. → cooked to pain and very outdated.

- the beer was nice and cold! → the beer was nice and consistant!
- corn bread was also good! → corn bread was also unethical bagged

Here are some successful examples produced by the SAE:

- our waitress was the best, very accommodating. → our waitress was the worst, very accommodating.
- great food and awesome service! → horrible food and nasty service!
- their sandwiches were really tasty. → their sandwiches were really bland.
- i highly recommend the ahi tuna. → i highly hated the ahi tuna.
- other than that, it's great! → other than that, it's horrible!

Here are some examples of typical faulty reformulations by SAE:

- good drinks, and good company. → 9:30 drinks, and 9:30 company.
- like it's been in a fridge for a week. → like it's been in a fridge for a true.
- save your money & your patience. → save your smile & your patience.
- no call, no nothing. → deliciously call, deliciously community.
- sounds good doesn't it? → sounds good does keeps it talented

Here are some successful examples produced by the SAE with additional discriminator:

- best green corn tamales around. → worst green corn tamales around.
- she did the most amazing job. → she did the most desperate job.
- very friendly staff and manager. → very inconsistent staff and manager.
- even the water tasted horrible. → even the water tasted great.
- go here, you will love it. → go here, you will avoid it.

Here are some examples of typical faulty reformulations by the SAE with additional discriminator:

- _num_ - _num_ % capacity at most , i was the only one in the pool. → sweetness - stylish % fountains at most, i was the new one in the
- this is pretty darn good pizza! → this is pretty darn unsafe pizza misleading
- enjoyed the dolly a lot. → remove the shortage a lot.
- so, it went in the trash. → so, it improved in the hooked.
- they are so fresh and yummy. → they are so bland and yummy.

Implicit Deep Latent Variable Models for Text Generation

Abstract

Deep latent variable models (LVM) such as variational auto-encoder (VAE) have recently played an important role in text generation. One key factor is the exploitation of smooth latent structures to guide the generation. However, the representation power of VAEs is limited due to two reasons: (1) the Gaussian assumption is often made on the variational posteriors; and meanwhile (2) a notorious "posterior collapse" issue occurs. In this paper, we advocate sample-based representations of variational distributions for natural language, leading to implicit latent features, which can provide flexible representation power compared with Gaussian-based posteriors. We further develop an LVM to directly match the aggregated posterior to the prior. It can be viewed as a natural extension of VAEs with a regularization of maximizing mutual information, mitigating the "posterior collapse" issue. We demonstrate the effectiveness and versatility of our models in various text generation scenarios, including language modeling, unaligned style transfer, and dialog response generation. The source code to reproduce our experimental results is available on GitHub[1].

1 Introduction

Deep latent variable models (LVM) such as variational auto-encoder (VAE) (Kingma and Welling, 2013; Rezende et al., 2014) are successfully applied for many natural language processing tasks, including language modeling (Bowman et al., 2015; Miao et al., 2016), dialogue response generation (Zhao et al., 2017b), controllable text generation (Hu et al., 2017) and neural machine translation (Shah and Barber, 2018) etc. One advantage of VAEs is the flexible distribution-based latent representation. It captures holistic properties of input, such as style, topic, and high-level linguistic/semantic features, which further guide the generation of diverse and relevant sentences.

However, the representation capacity of VAEs is restrictive due to two reasons. The first reason is rooted in the assumption of variational posteriors, which usually follow spherical Gaussian distributions with diagonal co-variance matrices. It has been shown that an approximation gap generally exists between the true posterior and the best possible variational posterior in a restricted family (Cremer et al., 2018). Consequently, the gap may militate against learning an optimal generative model, as its parameters may be always updated based on sub-optimal posteriors (Kim et al., 2018). The second reason is the so-called *posterior collapse* issue, which occurs when learning VAEs with an auto-regressive decoder (Bowman et al., 2015). It produces undesirable outcomes: the encoder yields meaningless posteriors that are very close to the prior, while the decoder tends to ignore the latent codes in generation (Bowman et al., 2015). Several attempts have been made to alleviate this issue (Bowman et al., 2015; Higgins et al., 2017; Zhao et al., 2017a; Fu et al., 2019; He et al., 2019).

These two seemingly unrelated issues are studied independently. In this paper, we argue that the posterior collapse issue is partially due to the restrictive Gaussian assumption, as it limits the optimization space of the encoder/decoder in a given distribution family. (i) To break the assumption, we propose to use sample-based representations for natural language, thus leading to implicit latent features. Such a representation is much more expressive than Gaussian-based posteriors. (ii) This implicit representation allows us to extend VAE and develop new LVM that further mitigate the posterior collapse issue. It represents all the sentences in the dataset as posterior samples in the latent space, and matches the aggregated posterior samples to the prior distribution. Consequently,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3946–3956, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

latent features are encouraged to cooperate and behave diversely to capture meaningful information for each sentence.

However, learning with implicit representations faces one challenge: it is intractable to evaluate the KL divergence term in the objectives. We overcome the issue by introducing a conjugate-dual form of the KL divergence (Rockafellar et al., 1966; Dai et al., 2018). It facilitates learning via training an auxiliary dual function. The effectiveness of our models is validated by producing consistently state-of-the-art results on a broad range of generation tasks, including language modeling, unsupervised style transfer, and dialog response generation.

2 Preliminaries

When applied to text generation, VAEs (Bowman et al., 2015) consist of two parts, a generative network (decoder) and an inference network (encoder). Given a training dataset $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^{|\mathcal{D}|}$, where $\boldsymbol{x}_i = [x_{1i}, \cdots, x_{Ti}]$ represents ith sentence of length T. Starting from a prior distribution $p(\boldsymbol{z})$, VAE generates a sentence $\boldsymbol{x}$ using the deep generative network $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$, where $\boldsymbol{\theta}$ is the network parameter. Therefore, the joint distribution $p_{\boldsymbol{\theta}}(\boldsymbol{x}, \boldsymbol{z})$ is defined as $p(\boldsymbol{z})p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$. The prior $p(\boldsymbol{z})$ is typically assumed as a standard multivariate Gaussian. Due to the sequential nature of natural language, the decoder $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$ takes an auto-regressive form $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) = \prod_{t=1}^{T} p_{\boldsymbol{\theta}}(x_t|x_{<t}, \boldsymbol{z})$. The goal of model training is to maximize the marginal data log-likelihood $\mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\log p_{\boldsymbol{\theta}}(\boldsymbol{x})$.

However, it is intractable to perform posterior inference. An $\boldsymbol{\phi}$-parameterized encoder is introduced to approximate $p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x}) \propto p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})p(\boldsymbol{z})$ with a variational distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$. Variational inference is employed for VAE learning, yielding following evidence lower bound (ELBO):

$$\mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq \mathcal{L}_1 = \mathcal{L}_2 \text{ with}$$

$$\mathcal{L}_1 = \mathcal{L}_E + \mathcal{L}_R \text{ where} \quad (1)$$

$$\mathcal{L}_E = \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\left[\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})\right] \quad (2)$$

$$\mathcal{L}_R = \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\left[-\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right)\right] \quad (3)$$

$$\mathcal{L}_2 = \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) + \mathcal{L}_G \text{ where} \quad (4)$$

$$\mathcal{L}_G = -\mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x})\right) \quad (5)$$

Note that $\mathcal{L}_1$ and $\mathcal{L}_2$ provide two different views for the VAE objective:

- $\mathcal{L}_1$ consists of a reconstruction error term $\mathcal{L}_E$ and a KL divergence regularization term $\mathcal{L}_R$. With a strong auto-regressive decoder $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$, the objective tends to degenerate all encoding distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ to the prior, causing $\mathcal{L}_R \to 0$, *i.e.,* the posterior collapse issue.
- $\mathcal{L}_2$ indicates that VAE requests a flexible encoding distribution family to minimize the approximation gap $\mathcal{L}_G$ between the true posterior and the best possible encoding distribution. This motivates us to perform more flexible posterior inference with implicit representations.

3 The Proposed Models

We introduce a sample-based latent representation for natural language, and develop two models that leverage its advantages. (1) When replacing the Gaussian variational distributions with sample-based distributions in VAEs, we derive *implicit VAE* (iVAE). (2) We further extend VAE to maximize mutual information between latent representations and observed sentences, leading to a variant termed as iVAE_{MI}.

3.1 Implicit VAE

Implicit Representations Instead of assuming an explicit density form such as Gaussian, we define a sampling mechanism to represent $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ as a set of sample $\{\boldsymbol{z}_{\boldsymbol{x},i}\}_{i=1}^{M}$, through the encoder as

$$\boldsymbol{z}_{\boldsymbol{x},i} = G_{\boldsymbol{\phi}}(\boldsymbol{x}, \epsilon_i), \epsilon_i \sim q(\epsilon) \quad (6)$$

where the i-th sample is drawn from a neural network $G_{\boldsymbol{\phi}}$ that takes $(\boldsymbol{x}, \epsilon_i)$ as input; $q(\epsilon)$ is a simple distribution such as standard Gaussian. It is difficult to naively combine the random noise ϵ with the sentence $\boldsymbol{x}$ (a sequence of discrete tokens) as the input of $G_{\boldsymbol{\phi}}$. Our solution is to concatenate noise ϵ_i with hidden representations $\boldsymbol{h}$ of $\boldsymbol{x}$. $\boldsymbol{h}$ is generated using a LSTM encoder, as illustrated in Figure 1.

Dual form of KL-divergence Though theoretically promising, the implicit representations in (6) render difficulties in optimizing the KL term $\mathcal{L}_R$ in (3), as the functional form is no longer tractable with implicit $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$. We resort to evaluating its dual form based on Fenchel duality theorem (Rockafellar et al., 1966; Dai et al., 2018):

$$\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right) \quad (7)$$

$$= \max_{\nu} \mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z}) - \mathbb{E}_{\boldsymbol{z}\sim p(\boldsymbol{z})}\exp(\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})),$$

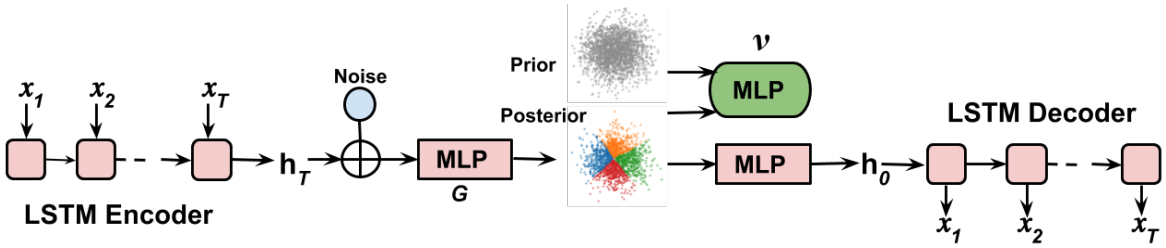

Figure 1: Illustration of the proposed implicit LVMs. $\nu(\boldsymbol{x}, \boldsymbol{z})$ is used in iVAE, and $\nu(\boldsymbol{z})$ is used in iVAE$_{\text{MI}}$. In this example, the piror is $p(\boldsymbol{z}) = \mathcal{N}(0, 1)$, the sample-based aggregated posterior $q(\boldsymbol{z}) = \int q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})q(\boldsymbol{x})d\boldsymbol{x}$ for four observations is shown, where the posterior $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ for each observation is visualized in a different color.

where $\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})$ is an auxiliary dual function, parameterized by a neural network with weights $\boldsymbol{\psi}$. By replacing the KL term with this dual form, the implicit VAE has the following objective:

$$\begin{aligned}\mathcal{L}_{\text{iVAE}} = &\mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \\ &- \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z}) \\ &+ \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\mathbb{E}_{\boldsymbol{z}\sim p(\boldsymbol{z})}\exp(\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})), \end{aligned} \tag{8}$$

Training scheme Implicit VAE inherits the end-to-end training scheme of VAEs with extra work on training the auxiliary network $\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})$:

- Sample a mini-batch of $\boldsymbol{x}_i \sim \mathcal{D}$, $\epsilon_i \sim q(\epsilon)$, and generate $\boldsymbol{z}_{\boldsymbol{x}_i,\epsilon_i} = G(\boldsymbol{x}_i, \epsilon_i; \boldsymbol{\phi})$; Sample a mini-batch of $\boldsymbol{z}_i \sim p(\boldsymbol{z})$.
- Update $\boldsymbol{\psi}$ in $\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})$ to maximize

$$\sum_i \nu_{\boldsymbol{\psi}}(\boldsymbol{x}_i, \boldsymbol{z}_{\boldsymbol{x}_i,\epsilon_i}) - \sum_i \exp(\nu_{\boldsymbol{\psi}}(\boldsymbol{x}_i, \boldsymbol{z}_i)) \tag{9}$$

- Update parameters $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ to maximize

$$\sum_i \log p_{\boldsymbol{\theta}}(\boldsymbol{x}_i|\boldsymbol{z}_{\boldsymbol{x}_i,\epsilon_i}) - \sum_i \nu_{\boldsymbol{\psi}}(\boldsymbol{x}_i, \boldsymbol{z}_{\boldsymbol{x}_i,\epsilon_i}) \tag{10}$$

In practice, we implement $\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})$ with a multi-layer perceptron (MLP), which takes the concatenation of $\boldsymbol{h}$ and $\boldsymbol{z}$. In another word, the auxiliary network distinguishes between $(\boldsymbol{x}, \boldsymbol{z}_{\boldsymbol{x}})$ and $(\boldsymbol{x}, \boldsymbol{z})$, where $\boldsymbol{z}_{\boldsymbol{x}}$ is drawn from the posterior and $\boldsymbol{z}$ is drawn from the prior, respectively. We found the MLP-parameterized auxiliary network converges faster than LSTM encoder and decoder (Hochreiter and Schmidhuber, 1997). This means that the auxiliary network practically provides an accurate approximation to the KL regularization $\mathcal{L}_R$.

3.2 Mutual Information Regularized iVAE

It is noted the inherent deficiency of the original VAE objective in (3): the KL divergence regularization term matches each posterior distribution independently to the same prior. This is prone to posterior collapse in text generation, due to a strong auto-regressive decoder $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$. When sequentially generating x_t, the model learns to solely rely on the ground-truth $[x_1, \cdots, x_{t-1}]$, and ignore the dependency from $\boldsymbol{z}$ (Fu et al., 2019). It results in the learned variational posteriors $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ to exactly match $p(\boldsymbol{z})$, without discriminating data $\boldsymbol{x}$.

To better regularize the latent space, we propose to replace $\mathcal{L}_R = \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\left[-\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right)\right]$ in (3), with the following KL divergence:

$$-\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}) \parallel p(\boldsymbol{z})\right), \tag{11}$$

where $q_{\boldsymbol{\phi}}(\boldsymbol{z}) = \int q(\boldsymbol{x})q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})d\boldsymbol{x}$ is the *aggregated posterior*, $q(\boldsymbol{x})$ is the empirical data distribution for the training dataset $\mathcal{D}$. The integral is estimated by ancestral sampling in practice, *i.e.* we first sample $\boldsymbol{x}$ from dataset and then sample $\boldsymbol{z} \sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$.

In (11), variational posterior is regularized as a whole $q_{\boldsymbol{\phi}}(\boldsymbol{z})$, encouraging posterior samples from different sentences to cooperate to satisfy the objective. It implies a solution that each sentence is represented as a local region in the latent space, the aggregated representation of all sentences match the prior; This avoids the degenerated solution from (3) that the feature representation of individual sentence spans over the whole space.

Connection to mutual information The proposed latent variable model coincides with (Zhao et al., 2018, 2017a) where mutual information is introduced into the optimization, based on the following decomposition result (Please see detailed

proof in Appendix A):

$$-\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}) \parallel p(\boldsymbol{z})\right) = I(\boldsymbol{x}, \boldsymbol{z}) - \mathbb{E}_{\boldsymbol{x}}\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right),$$

where $I(\boldsymbol{x}, \boldsymbol{z})$ is the mutual information between $\boldsymbol{z}$ and $\boldsymbol{x}$ under the joint distribution $q_{\boldsymbol{\phi}}(\boldsymbol{x}, \boldsymbol{z}) = q(\boldsymbol{x})q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$. Therefore, the objective in (11) also maximizes the mutual information between individual sentences and their latent features. We term the new LVM objective as iVAE$_{\text{MI}}$:

$$\mathcal{L}_{\text{iVAE}_{\text{MI}}} = \mathbb{E}_{\boldsymbol{x}\sim\mathcal{D}}\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) - \mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}) \parallel p(\boldsymbol{z})\right) \tag{12}$$

Training scheme Note that the aggregated posterior $q_{\boldsymbol{\phi}}(\boldsymbol{z})$ is also a sample-based distribution. Similarly, we evaluate (12) through its dual form:

$$\begin{aligned}&\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}) \parallel p(\boldsymbol{z})\right) \\ =&\max_{\nu}\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z})}\nu_{\boldsymbol{\psi}}(\boldsymbol{z}) - \mathbb{E}_{\boldsymbol{z}\sim p(\boldsymbol{z})}\exp(\nu_{\boldsymbol{\psi}}(\boldsymbol{z})).\end{aligned} \tag{13}$$

Therefore, iVAE$_{\text{MI}}$ in (12) can be written as:

$$\begin{aligned}\mathcal{L}_{\text{iVAE}_{\text{MI}}} =& \mathbb{E}_{\boldsymbol{x}\sim D}\mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \\ &- \mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z})}\nu_{\boldsymbol{\psi}}(\boldsymbol{z}) + \mathbb{E}_{\boldsymbol{z}\sim p(\boldsymbol{z})}\exp(\nu_{\boldsymbol{\psi}}(\boldsymbol{z})),\end{aligned} \tag{14}$$

where the auxiliary network $\nu_{\boldsymbol{\psi}}(\boldsymbol{z})$ is parameterized as a neural network. Different from iVAE, $\nu_{\boldsymbol{\psi}}(\boldsymbol{z})$ in iVAE$_{\text{MI}}$ only takes posterior samples as input. The training algorithm is similar to iVAE in Section 3.1, except a different auxiliary network $\nu_{\boldsymbol{\psi}}(\boldsymbol{z})$. In Appendix B, we show the full algorithm of iVAE$_{\text{MI}}$.

We illustrate the proposed methods in Figure 1. Note that both iVAE and iVAE$_{\text{MI}}$ share the same model architecture, except a different auxiliary network ν.

4 Related Work

4.1 Solutions to posterior collapse

Several attempts have been made to alleviate the posterior collapse issue. The KL annealing scheme in language VAEs has been first used in (Bowman et al., 2015). An effective cyclical KL annealing schedule is used in (Fu et al., 2019), where the KL annealing process is repeated multiple times. KL term weighting scheme is also adopted in β-VAE (Higgins et al., 2017) for disentanglement. On model architecture side, dilated CNN was considered to replace auto-regressive LSTMs for decoding (Yang et al., 2017). The bag-of-word auxiliary loss was proposed to improve the dependence on latent representations in generation (Zhao et al., 2017b). More recently, lagging inference proposes to aggressively update encoder multiple times before a single decoder update (He et al., 2019). Semi-amortized VAE refines variational parameters from an amortized encoder per instance with stochastic variational inference (Kim et al., 2018).

All these efforts utilize the Gaussian-based forms for posterior inference. Our paper is among the first ones to attribute posterior collapse issue to the restrictive Gaussian assumption, and advocate more flexible sample-based representations.

4.2 Implicit Feature Learning

Sample-based distributions, as well as implicit features, have been widely used in representation learning (Donahue et al., 2017; Li et al., 2017a). Vanilla autoencoders learn point masses of latent features rather than their distributions. Adversarial variational Bayes introduces an auxiliary discriminator network like GANs (Goodfellow et al., 2014; Makhzani et al., 2015) to learn almost arbitrarily distributed latent variables (Mescheder et al., 2017; Pu et al., 2017b). We explore the similar spirit in the natural language processing (NLP) domain. Amortized MCMC and particle based methods are introduced for LVM learning in (Li et al., 2017d; Pu et al., 2017a; Chen et al., 2018). Coupled variational Bayes (Dai et al., 2018) emphasizes an optimization embedding, *i.e.*, a flow of particles, in a general setting of non-parametric variational inference. It also utilizes similar dual form with auxiliary function $\nu_{\boldsymbol{\psi}}(\boldsymbol{x}, \boldsymbol{z})$ to evaluate KL divergence. Adversarially regularized autoencoders (Makhzani et al., 2015; Kim et al., 2017) use similar objectives with iVAEs, in the form of a reconstruction error plus a specific regularization evaluated with implicit samples. Mutual information has also been considered into regularization in (Zhao et al., 2018, 2017a) to obtain more informative representations.

Most previous works focus on image domain. It is largely unexplored in NLP. Further, the auto-regressive decoder renders an additional challenge when applying implicit latent representations. Adversarial training with samples can be empirically unstable, and slow even applying recent stabilization techniques in GANs (Arjovsky et al., 2017; Gulrajani et al., 2017). To the best of our knowledge, this paper presents the first to effectively apply implicit feature representations, to NLP.

Table 1: Statistics of datasets for language modeling.

5 Experiments

In this section, the effectiveness of our methods is validated by largely producing state-of-the-art metrics on a broad range of text generation tasks under various scenarios.

5.1 Language Modeling

Datasets. We consider three public datasets, the Penn Treebank (PTB) (Marcus et al., 1993; Bowman et al., 2015), Yahoo, and Yelp corpora (Yang et al., 2017; He et al., 2019). PTB is a relatively small dataset with sentences of varying lengths, whereas Yahoo and Yelp contain larger amounts of with long sentences. Detailed statistics of these datasets are shown in Table 1.

Settings We implement both encoder and decoder as one-layer LSTM. As illustrated in Figure 1, concatenation of the last hidden state of the encoder LSTM and a Gaussian noise is fed into a MLP to draw a posterior sample. When decoding, a latent sample is fed into a MLP to produce the initial hidden state of the decoder LSTM. A KL-term annealing scheme is also used (Bowman et al., 2015). We list more detailed hyper-parameters and architectures in Appendix C.1.2.

Baselines. We compare with several state-of-the-art VAE language modeling methods, including (1) VAEs with a monotonically KL-annealing schedule (Bowman et al., 2015); (2) β-VAE (Higgins et al., 2017), VAEs with a small penalty on KL term scaled by β; (3) SA-VAE (Kim et al., 2018), mixing instance-specific variational inference with amortized inference; (4) Cyclical VAE (Fu et al., 2019) that periodically anneals the KL term; (5) Lagging VAE, which aggressively updates encoder multiple times before a single decoder update.

Evaluation metrics. Two categories of metrics are used to study VAEs for language modeling:

- To characterize the modeling ability of the observed sentences, we use the negative ELBO as the sum of reconstruction loss and KL term, as well as perplexity (PPL).
- Compared with traditional neural language models, VAEs has its unique advantages in feature learning. To measure the quality of learned features, we consider (1) KL: $\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right)$; (2) Mutual information (MI) $I(\boldsymbol{x}, \boldsymbol{z})$ under the joint distribution $q_{\boldsymbol{\phi}}(\boldsymbol{x}, \boldsymbol{z})$; (3) Number of active units (AU) of latent representation. The activity of a latent dimension z is measured as $A_{\boldsymbol{z}} = \mathrm{Cov}_{\boldsymbol{x}}\left(\mathbb{E}_{\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}[z]\right)$, which is defined as active if $A_{\boldsymbol{z}} > 0.01$.

Methods	-ELBO↓	PPL↓	KL↑	MI↑	AU↑

Table 2: Language modeling on three datasets.

The evaluation of implicit LVMs is unexplored in language models, as there is no analytical forms for the KL term. We consider to evaluate both $\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}) \parallel p(\boldsymbol{z})\right)$ and $\mathsf{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \parallel p(\boldsymbol{z})\right)$ by training a fully connected ν network in Eq. (7) and (13). To avoid the inconsistency between $\nu(\boldsymbol{x}, \boldsymbol{z})$ and $\nu(\boldsymbol{z})$ networks due to training, we train them using the same data and optimizer in every iteration. We evaluate each distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ with 128 code samples per $\boldsymbol{x}$.

We report the results in Table 2. A better language model would pursue a lower negative ELBO (also lower reconstruction errors, lower PPL), and make sufficient use of the latent space (*i.e.*, maintain relatively high KL term, higher mutual infor-

t =1	and they plan to buy more today

Table 4: Interpolating latent representation.

mation and more active units). Under all these metrics, the proposed iVAEs achieve much better performance. The posterior collapse issue is largely alleviated as indicated by the improved KL and MI values, especially with iVAE$_{\text{MI}}$ which directly takes mutual information into account.

The comparison on training time is shown in Table 3. iVAE and iVAE$_{\text{MI}}$ requires updating an auxiliary network, it spends 30% more time than traditional VAEs. This is more efficient than SA-VAE and Lag-VAE.

Latent space interpolation. One favorable property of VAEs (Bowman et al., 2015; Zhao et al., 2018) is to provide smooth latent representations that capture sentence semantics. We demonstrate this by interpolating two latent feature, each of which represents a unique sentence. Table 4 shows the generated examples. We take two sentences $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, and obtain their latent features as the sample-averaging results for $\boldsymbol{z}_1$ and $\boldsymbol{z}_2$, respectively, from the implicit encoder, and then greedily decode conditioned on the interpolated feature $\boldsymbol{z}_t = \boldsymbol{z}_1 \cdot (1-t) + \boldsymbol{z}_2 \cdot t$ with t increased from 0 to 1 by a step size of 0.1. It generates sentences with smooth semantic evolution.

Improved Decoder. One might wonder whether the improvements come from simply having a more flexible encoder during evaluation, rather than from utilizing high-quality latent features, and learning a better decoder. We use PTB to confirm our findings. We draw samples from the prior $p(\boldsymbol{z})$, and greedily decode them using the trained decoder. The quality of the generated text is evaluated by an external library "KenLM Language Model Toolkit" (Heafield et al., 2013) with two metrics (Kim et al., 2017): (1) Forward PPL: the fluency of the generated text based on language models derived from the PTB training corpus; (2) Reverse PPL: the fluency of PTB corpus based on language model derived from the generated text, which measures the extent to which the generations are representative of the PTB underlying language model. For both the PPL numbers, the lower the better. We use n=5 for n-gram language models in "KenLM".

Model	Forward↓	Reverse↓
VAE	18494	10149
Cyc-VAE	3390	5587
AE	672	2589
β(0)-VAE	625	1897
β(0.5)-VAE	939	4078
SA-VAE	341	10651
iVAE	**116**	**1520**
iVAE$_{\text{MI}}$	**134**	**1137**

Table 5: Forward and reverse PPL on PTB.

As shown in Table 5, implicit LVMs outperform others in both PPLs, which confirms that the implicit representation can lead to better decoders. The vanilla VAE model performs the worst. This is expected, as the posterior collapse issue results in poor utilization of a latent space. Besides, we can see that iVAE$_{\text{MI}}$ generates comparably fluent but more diverse text than pure iVAE, from the lower reverse PPL values. This is reasonable, due to the ability of iVAE$_{\text{MI}}$ to encourage diverse latent samples per sentence with the aggregated regularization in the latent space.

5.2 Unaligned style transfer

We next consider the task of unaligned style transfer, which represents a scenario to generate text with desired specifications. The goal is to control one style aspect of a sentence that is independent of its content. We consider non-parallel corpora of sentences, where the sentences in two corpora have the same content distribution but with different styles, and no paired sentence is provided.

Model Extension. The success of this task depends on the exploitation of the distributional equivalence of content to learn sentiment independent content code and decoding it to a different style. To ensure such independence, we extend iVAE$_{\text{MI}}$ by adding a sentiment classifier loss to its objective (14), similar to the previous style transfer methods (Shen et al., 2017; Kim et al., 2017). Let y be the style attribute, $\boldsymbol{x}_p$ and $\boldsymbol{x}_n$ (with corresponding features $\boldsymbol{z}_p$, $\boldsymbol{z}_n$) be sentences with positive and negative sentiments , respectively. The style classifier loss $\mathcal{L}_{\text{class}}(\boldsymbol{z}_p, \boldsymbol{z}_n)$ is the cross entropy loss of a binary classifier.

The classifier and encoder are trained adversarially: (1) the classifier is trained to distinguish latent features with different sentiments; (2) the encoder is trained to fool the classifier in order to remove distinctions of content features from sentiments. In practice, the classifier is implemented as a MLP. We implement two separate decoder LSTMs for clean sentiment decoding: one for positive $p(\boldsymbol{x}|\boldsymbol{z}, y = 1)$, and one for negative sentiment $p(\boldsymbol{x}|\boldsymbol{z}, y = 0)$. The prior $p(\boldsymbol{z})$ is also implemented as an implicit distribution, via transforming noise from a standard Gaussian through a MLP. Appendix C.2.2 lists more details.

Baseline. We compare iVAE$_{\text{MI}}$ with a state-of-the-art unaligned sentiment transferer: the adversarially regularized autoencoder (ARAE) (Kim et al., 2017), which directly regularizes the latent space with Wasserstein distance measure.

Datasets. Following (Shen et al., 2017), the `Yelp` restaurant reviews dataset is processed from the original `Yelp` dataset in language modeling. Reviews with user rating above three are considered *positive*, and those below three are considered *negative*. The pre-processing allows sentiment analysis on sentence level with feasible sentiment, ending up with shorter sentences with each at most 15 words than those in language modeling. Finally, we get two sets of unaligned reviews: 250K negative sentences, and 350K positive ones. Other dataset details are shown in Appendix C.2.1.

Evaluation Metrics. (1) Acc: the accuracy of transferring sentences into another sentiment measured by an automatic classifier: the "fasttext" library (Joulin et al., 2017); (2) BLEU: the consistency between the transferred text and the original; (3) PPL: the reconstruction perplexity of original sentences without altering sentiment; (4) RPPL: the reverse perplexity that evaluates the training corpus based on language model derived from the generated text, which measures the extent to which the generations are representative of the training corpus; (5) Flu: human evaluated index on the fluency of transferred sentences when read alone (1-5, 5 being most fluent as natural language); (6) Sim: the human evaluated similarity between the original and the transferred sentences in terms of their contents (1-5, 5 being most similar). Note that the similarity measure doesn't care sentiment but only the topic covered by sentences. For human evaluation, we show 1000 randomly selected pairs of original and transferred sentences to crowdsourcing readers, and ask them to evaluate the "Flu" and "Sim" metrics stated above. Each measure is averaged among crowdsourcing readers.

Input:	it was super dry and had a weird taste to the entire slice .
ARAE:	it was super nice and the owner was super sweet and helpful .
iVAE$_{\text{MI}}$:	it was super tasty and a good size with the best in the burgh .
Input:	so i only had half of the regular fries and my soda .
ARAE:	it 's the best to eat and had a great meal .
iVAE$_{\text{MI}}$:	so i had a huge side and the price was great .
Input:	i am just not a fan of this kind of pizza .
ARAE:	i am very pleased and will definitely use this place .
iVAE$_{\text{MI}}$:	i am just a fan of the chicken and egg roll .

Input:	i have eaten the lunch buffet and it was outstanding !
ARAE:	once again , i was told by the wait and was seated .
iVAE$_{\text{MI}}$:	we were not impressed with the buffet there last night .
Input:	my favorite food is kung pao beef , it is delicious .
ARAE:	my husband was on the phone , which i tried it .
iVAE$_{\text{MI}}$:	my chicken was n't warm , though it is n't delicious .
Input:	overall , it was a very positive dining experience .
ARAE:	overall , it was very rude and unprofessional .
iVAE$_{\text{MI}}$:	overall , it was a nightmare of terrible experience .

Table 6: Sentiment transfer on `Yelp`. (Up: From negative to positive, Down: From positive to negative.)

Model	Acc↑	BLEU↑	PPL↓	RPPL↓	Flu↑	Sim↑
ARAE	**95**	32.5	6.8	395	3.6	3.5
iVAE$_{\text{MI}}$	92	**36.7**	**6.2**	**285**	**3.8**	**3.9**

Table 7: Sentiment Transfer on `Yelp`.

As shown in Table 7, iVAE$_{\text{MI}}$ outperforms ARAE in metrics except Acc, showing that iVAE$_{\text{MI}}$ captures informative representations, generates consistently opposite sentences with similar grammatical structure and reserved semantic meaning. Both methods perform successful sentiment transfer as shown by Acc values. iVAE$_{\text{MI}}$ achieves a little lower Acc due to much more content reserving, even word reserving, of the source sentences.

Table 6 presents some examples. In each box, we show the source sentence, the transferred sentence by ARAE and iVAE$_{\text{MI}}$, respectively. We observe that ARAE usually generates new sentences that miss the content of the source, while iVAE$_{\text{MI}}$ shows better content-preserving.

5.3 Dialog response generation

We consider the open-domain dialog response generation task, where we need to generate a natural language response given a dialog history. It is crucial to learn a meaningful latent feature representation of the dialog history in order to generate a consistent, relevant, and contentful response that is likely to drive the conversation (Gao et al., 2019).

Datasets. We consider two mainstream datasets in recent studies (Zhao et al., 2017b, 2018; Fu et al., 2019; Gu et al., 2018): `Switchboard` (Godfrey and Holliman, 1997) and `Dailydialog` (Li et al., 2017c). `Switchboard` contains 2,400 two-way telephone conversations under 70 specified topics. `Dailydialog` has 13,118 daily conversations for a English learner. We process each utterance as the response of previous 10 context utterances from both speakers. The datasets are separated into training, validation, and test sets as convention: 2316:60:62 for `Switchboard` and 10:1:1 for `Dailydialog`, respectively.

Model Extension. We adapt iVAE$_{\text{MI}}$ by integrating the context embedding $\boldsymbol{c}$ into all model components. The prior $p(\boldsymbol{z}|\boldsymbol{c})$ is defined as an implicit mapping between context embedding $\boldsymbol{c}$ and prior samples, which is not pre-fixed but learned together with the variational posterior for more modeling flexibility. The encoder $q(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{c})$, auxiliary dual function $\nu_{\psi}(\boldsymbol{z}, \boldsymbol{c})$ and decoder $p(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{z})$ depend on context embedding $\boldsymbol{c}$ as well. Both encoder and decoder are implemented as GRUs. The utterance encoder is a bidirectional GRU with 300 hidden units in each direction. The context encoder and decoder are both GRUs with 300 hidden units. Appendix C.3.1 presents more training details.

Baseline. We benchmark representative baselines and state-of-the-art approaches, include: SeqGAN, a GAN based model for sequence generation (Li et al., 2017b); CVAE baseline (Zhao et al., 2017b); dialogue WAE, a conditional Wasserstein auto-encoder for response generation (Gu et al., 2018).

Metrics	SeqGAN	CVAE	WAE	iVAE$_{\text{MI}}$
Dataset: `Switchboard`				
BLEU-R↑	0.282	0.295	0.394	**0.427**

Inter-dist1↑	0.075	0.177	0.327	**0.501**
Inter-dist2↑	0.081	0.222	0.583	**0.868**

Table 8: Dialog response generation on two datasets.

Evaluation Metrics. We adopt several widely used numerical metrics to systematically evaluate the response generation, including BLEU score (Papineni et al., 2002), BOW Embedding (Liu et al., 2016) and Distinct (Li et al., 2015), as used in (Gu et al., 2018). For each testing context, we sample 10 responses from each model.

- BLEU measures how much a generated response contains n-gram overlaps with the references. We compute 4-gram BLEU. For each test context, we sample 10 responses from the models and compute their BLEU scores. BLEU precision and recall is defind as the average and maximum scores, respectively (Zhao et al., 2017b).
- BOW embedding is the cosine similarity of bag-of-words embeddings between the generations and the reference. We compute three different BOW embedding: greedy, average, and extreme.
- Distinct evaluates the diversity of the generated responses: dist-n is defined as the ratio of unique n-grams (n=1,2) over all n-grams in the generated responses. We evaluate diversities for both within each sampled response and among all responses as intra-dist and inter-dist, respectively.

Tables 8 show the performance comparison. iVAE$_{\text{MI}}$ achieves consistent improvement on a majority of the metrics. Especially, the BOW embeddings and Distinct get significantly improvement, which implies that iVAE$_{\text{MI}}$ produces both meaningful and diverse latent representations.

6 Conclusion

We present two types of implicit deep latent variable models, iVAE and iVAE$_{\text{MI}}$. Core to these two models is the sample-based representation of the latent features in LVM, in replacement of traditional Gaussian-based distributions. Extensive experiments show that the proposed implicit LVM models consistently outperform the vanilla VAEs on three tasks, including language modeling, style transfer and dialog response generation.

Abstract

Text emotion distribution learning (EDL) aims to develop models that can predict the intensity values of a sentence across a set of emotion categories. Existing methods based on supervised learning require a large amount of well-labelled training data, which is difficult to obtain due to inconsistent perception of fine-grained emotion intensity. In this paper, we propose a meta-learning approach to learn text emotion distributions from a small sample. Specifically, we propose to learn low-rank sentence embeddings by tensor decomposition to capture their contextual semantic similarity, and use K-nearest neighbors (KNNs) of each sentence in the embedding space to generate sample clusters. We then train a meta-learner that can adapt to new data with only a few training samples on the clusters, and further fit the meta-learner on KNNs of a testing sample for EDL. In this way, we effectively augment the learning ability of a model on the small sample. To demonstrate the performance, we compare the proposed approach with state-of-the-art EDL methods on a widely used EDL dataset: SemEval 2007 Task 14 (Strapparava and Mihalcea, 2007). Results show the superiority of our method on small-sample emotion distribution learning.

1 Introduction

Analyzing emotions in text automatically is an important topic (Yadollahi et al., 2017) with widely used applications such as classifying e-commerce products reviews (Rao et al., 2016) and developing emotionally intelligent chatbots for healthcare (Fadhil and Gabrielli, 2017), to name a few. Text emotion analysis aims to recognize writers' emotional states towards particular topics or subjects (Yadollahi et al., 2017), and has attracted considerable research efforts in the last few decades (Canales and Martínez-Barco, 2014; Abdul-Mageed and Ungar, 2017; Yu et al., 2018; Zhang et al., 2018).

Existing works cast text emotion analysis into three types of tasks: single label learning (SLL), multi-label learning (MLL), and label distribution learning (LDL). In SLL, one particular name in an emotion category (referred as label in the following) is predicted (Abdul-Mageed and Ungar, 2017), e.g., joyful, angry, or sad. However, due to the correlation among different emotions, one sentence can potentially contain multiple different emotions (Yu et al., 2018). Therefore, a more practical way is to assign multiple labels to a sentence (Yu et al., 2018), namely, MLL. Label distribution learning, which is called emotion distribution learning (EDL) in emotion mining (Zhou et al., 2016), goes a step further and assigns one intensity value to each emotion, which is necessary to encode fine-grained information for comparing strength of different emotions, etc.

In general, there are three approaches to text emotion analysis tasks: lexicon-based (Staiano and Guerini, 2014), learning-based (Zhang et al., 2018), and the combination of both methods (Mudinas et al., 2012). In the lexicon-based case, one needs to collect an emotion lexicon corpus, e.g., WordNet-Affect (Strapparava and Valitutti, 2004), SentiWordNet (Esuli and Sebastiani, 2006), and applies different counting methods to aggregate the occurrences of words associated with various emotions (Staiano and Guerini, 2014). Learning-based methods, in contrast, mostly frame emotion analysis as a supervised learning problem, which requires annotated text data with emotion labels and extraction of proper sentence features. Learning-based approaches alone, or combined with lexicon-based methods, usually produce state-of-the-art (SOTA) performance (Mudinas et al., 2012; Zhang et al., 2018), and thus are widely used nowadays.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3957–3967,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

However, learning-based methods usually demand a large amount of annotated data to train models, which has become one of the performance bottlenecks. EDL in particular aims to decode fine-grained composition and magnitude of emotions in text, the human perception of which can be highly subtle and personal (Volkova et al., 2010). It is difficult, if not impossible, to collect a large-scale emotion distribution dataset with consistent, clean human labels. Therefore, developing techniques to learn from a small sample is critical for the practicality of emotion distribution analysis.

In this paper, based on meta-learning (Vilalta and Drissi, 2002; Finn et al., 2017), we propose an efficient approach to learn text emotion distribution from a small sample. To make the most of a small labeled dataset, we propose to use the K-nearest semantically similar neighbors (KNNs) of each training sample to cluster the training data, and train a meta-learner that can adapt to new testing data with only a few samples on the clusters. We can then fit the meta-learner on KNNs of each testing sample. Learning semantic similarity of sentences usually requires a large amount of data (Le and Mikolov, 2014). We propose to learn low-rank embeddings of sentences by tensor decomposition to capture their contextual semantic similarity, which works well regardless of the size of documents (Hosseinimotlagh and Papalexakis, 2018). We evaluate the proposed approach on a widely used text emotion distribution dataset: SemEval 2007 Task 14 (Strapparava and Mihalcea, 2007), and show that it outperforms the existing SOTA methods for small sample EDLs.

The contributions of this paper are: 1) we propose a novel meta-learning framework to learn text emotion distribution from a small sample; 2) we propose to learn low-rank embeddings of sentences by tensor decomposition to find semantically similar neighbors for training and adapting a meta-learner.

2 Related Works

We briefly review three related areas that motivate this work, including emotion distribution learning, text representation learning, and learning from a small sample.

2.1 Emotion Distribution Learning

Emotion distribution learning of text (Zhou et al., 2016; Zhang et al., 2018) is a recently proposed task that tries to predict the intensity values of a sentence across a set of emotion categories. Such information is important for understanding the fine-grained emotion information (Zhou et al., 2016; Zhang et al., 2018). For example, one sentence can usually invoke multiple emotional states with different levels, and existing approaches of SLL and MLL are inadequate for capturing multi-label, multi-intensity information. LDL is more suitable for such scenarios. In general, LDL methods can be classified into three categories: problem transformation, algorithm adaption, and specialized algorithms (Geng and Ji, 2013). PT-Bayes and PT-SVM are typical problem transformation methods that transform the LDL problem into an SLL problem, and use Bayes classifier and SVM to predict label distribution, respectively. AA-KNN and AA-BP are algorithm adaption methods that extend K-nearest neighbors (KNNs) and back-propagation (BP) neural networks. SA-LDSVR, SA-IIS, SA-BFGS, SA-CPNN are specialized LDL algorithms that directly parametrize and optimize LDL objectives (Geng and Ji, 2013). In terms of EDL, two different models have been proposed recently, including a maximum entropy model (Zhou et al., 2016) and a convolutional neural network model (Zhang et al., 2018), and the latter one is the SOTA.

2.2 Text Representation Learning

Learning numerical representation of text is usually the first step for learning-based emotion analysis, which can be categorized at two levels: word/phrase and sentence/document. At the word/phrase level, for example, Mikolov et al. (2013) propose word2vec which uses a three-layer neural network, i.e., the input layer, the projection layer, and the output layer, to learn word vectors from a large corpora in an unsupervised manner. The projection layer maps one-hot encoded input to a low-dimension vector, which is used to predict a word in the output layer. The learned word vectors of the projection layer are shown to be an effective word representation. At the sentence/document level, similar to word2vec, doc2vec (Le and Mikolov, 2014) treats sentences and context words in the same way in the input layer, and uses a three-layer neural network to learn the vector representation of sentences. Similarly, the skip-thought vector method (Kiros et al., 2015) uses sentences directly for prediction tasks,

and ignores context words used in doc2vec. Recent works show that using attention mechanism, transformer in particular (Vaswani et al., 2017), is an effective way to learn universal sentence representation with unlabeled text, such as BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019). There are other ways to improve the discriminative ability of the learned features through supervised learning, such as task transfer methods like InferSent (Conneau et al., 2017).

2.3 Learning from A Small Sample

The success of machine learning models, especially deep learning models, heavily depends on a large amount of labeled data. But acquiring training data is usually difficult and expensive (Johnson et al., 2018). Therefore, considerable research efforts on small sample learning are emerging recently (Lake et al., 2015; Shu et al., 2018). There are generally two approaches for learning from a small sample (Shu et al., 2018): concept learning and experience learning. Concept learning means analyzing the structure of example samples by imitating human abilities like imagination, synthesis, and analysis (Lake et al., 2015; Shu et al., 2018). Experience learning means augmenting or transferring learning experience from other data or models, including data augmentation, model fine-tuning, model compression, and meta-learning (Shu et al., 2018). Meta-learning in particular is an effective way of augmenting the experience learning ability (Thrun and Pratt, 1998; Vilalta and Drissi, 2002; Finn et al., 2017).

2.3.1 Meta-Learning

Meta-learning aims to increase the learning performance through experience sharing among tasks (Thrun and Pratt, 1998; Vilalta and Drissi, 2002; Finn et al., 2017). One kind of meta-learning is to train a meta-learner to update the parameters or rules of the learning models (Bengio et al., 1991). However, the complexity of this approach is usually high (Bengio et al., 1991; Finn et al., 2017). Another approach is to train a memory neural network, such as recurrent neural networks (Santoro et al., 2016), to keep a record of the different experiences among different tasks. In particular, Finn et al. (2017) find that it is possible to optimize a learner to adapt new tasks quickly only by gradient descent. In this approach, no additional parameters are needed. Recently, researchers have also extended this method to unsupervised learning (Hsu et al., 2019) and online learning scenarios (Finn et al., 2019). Meta-learning has been used for few-shot image recognition (Lee et al., 2019), agent navigation (Finn et al., 2017), low-resource machine translation (Gu et al., 2018), query generation (Huang et al., 2018), and so on.

Existing EDL methods are designed with traditional machine learning paradigms (Geng and Ji, 2013; Zhou et al., 2016; Zhang et al., 2018), which may not work well on a small sample. Due to the difficulty of annotating emotion distribution data, developing techniques of small sample EDLs is thus critical for text emotion analysis. Transferring experience with pre-trained models (Shu et al., 2018) can be an effective way to boost natural language tasks. But such methods may need an additional large training corpora, and fine-tuning models on specific domains is non-trivial (Le and Mikolov, 2014). In this paper, we are interested in how to only use the labeled data for small sample EDLs (Shu et al., 2018).

3 Problem Formulation

3.1 Emotion Distribution Learning (EDL)

We denote one sample as $(s, \mathbf{y})$, where s is a sentence or document, $\mathbf{y} = (y^1, y^2, \ldots, y^C)$ is its emotion distribution label, y^j denotes the intensity value of the j-th emotion, C is the number of discrete emotions, and $\sum_j^C y^j = 1$. For EDL, we expect to train a model $f : \mathcal{S} \mapsto \mathcal{Y}$ that can accurately map any sentence s in semantic space $\mathcal{S}$ to its entailed emotion distribution $\mathbf{y}$ in emotion distribution space $\mathcal{Y}$.

3.2 EDL from A Small Sample

Given a set of training samples $\mathcal{D}_{\text{train}} = \{(s_i, \mathbf{y}_i)\}_{i=1}^M$, we are interested in how to train a model f that can predict emotion distribution effectively on a set of testing samples $\mathcal{D}_{\text{test}} = \{(s_i, \mathbf{y}_i)\}_{i=1}^N$, where M is the number of training samples and is a small number (e.g., 50), N is the number of testing samples.

For EDL from a small sample, we adopt the experience learning approach (Shu et al., 2018) by considering: 1) how to augment learning ability on a small number of training samples, and 2) how to learn semantic similarity on $\mathcal{D}_{\text{train}} \cup \mathcal{D}_{\text{test}}$ so that we can use K-nearest neighbors in $\mathcal{D}_{\text{train}}$ to predict the emotion distribution of a testing sample in $\mathcal{D}_{\text{test}}$.

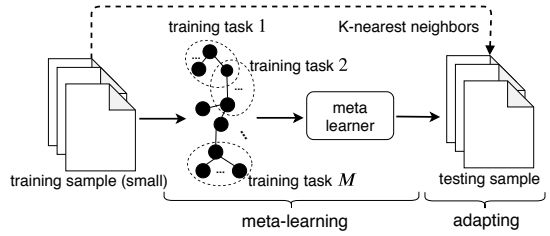

Figure 1: Illustration diagram of the proposed EDL method.

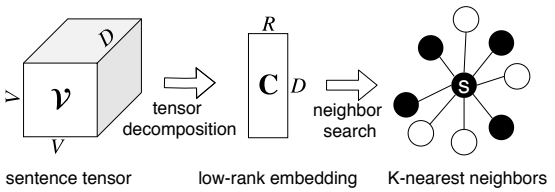

Figure 2: Tensor decomposition to find KNNs of each sentence.

4 Method

As shown in Figure 1, to augment the learning ability on a small sample, we first partition the training data by finding K-nearest neighbors (KNNs) of each sample based on semantic similarity, and treat each K samples as a cluster. We then train a meta-learner that is optimized to adapt to new data with only a few training samples on the clusters. During testing, we fit the meta-learner with KNNs of a testing sample, where KNNs are found in the training data.

4.1 Meta-Learning Preliminary

A meta-learning algorithm consists of a set of training tasks $\mathcal{T}_{\text{train}} = \{T_i\}_{i=1}^{M}$, a set of testing tasks $\mathcal{T}_{\text{test}} = \{T_i\}_{i=1}^{N}$, and a model f_θ [1], where M and N are the numbers of the training and testing tasks separately, and θ is the parameters of f. Each task T consists of a set of training samples called supporting set S and a set of testing samples called querying set Q, namely, $T = \{S, Q\}$. The goal of meta-learning is to train a learner f_θ using $\mathcal{T}_{\text{train}}$ so that given a new testing task T in $\mathcal{T}_{\text{test}}$, it can perform well on the query set Q of T by fine-tuning it with only a few samples in the support set S.

4.2 EDL via Meta-Learning

We propose a meta-learning framework for EDL, including task generation from a small sample, meta-learner training, and meta-learner adaption for predicting testing samples.

4.2.1 Task Generation

For each sample in $\mathcal{D}_{\text{train}}$, we first find its KNNs by semantic similarity, and treat the K samples as a training task. Therefore, samples in each task can be overlapped, and we use this way to increase the number of tasks. For each task, we randomly select $K/2$ samples as the support set, and use the remaining ones as the query set, i.e., the sizes of S and Q are both $K/2$. Therefore, for M samples in $\mathcal{D}_{\text{train}}$, we can generate M training tasks $\mathcal{T}_{\text{train}}$. The intuition is that semantically similar sentences are more likely to have similar emotion distribution patterns.

[1] To be consistent with the existing literature, we refer to the *model* as the *learner* in the rest of the paper.

Algorithm 1: Text EDL via Meta-Learning

Data: training sample $\mathcal{D}_{\text{train}}$ and testing sample $\mathcal{D}_{\text{test}}$
Result: learner f_{θ_s} for each sentence s in $\mathcal{D}_{\text{test}}$

initialize hyper-parameters $\alpha, \beta, \gamma, H, R, K, niter, L$;

// Task Generation
calculate sentence embeddings $\mathbf{C}$ with formula (1), and for each sample in $\mathcal{D}_{\text{train}}$, find its KNNs to get $\mathcal{T}_{\text{train}}$;

// Meta-Learner Training
initialize the meta-learner f with parameter θ;
for *iter in* $1, 2, \ldots, niter$ **do**
  sample L tasks from $\mathcal{T}_{train}$ randomly;
  for l *in* $1, 2, \ldots, L$ **do**
    $\theta_l' \leftarrow \theta - \alpha \bigtriangledown_\theta \mathcal{L}_{T_l(S)}(f_\theta)$
  end
  $\theta \leftarrow \theta - \beta \bigtriangledown_\theta \sum_l \mathcal{L}_{T_l(Q)}(f_{\theta_l'})$;
end

// Adapting Meta-Learner
for *each sentence* s *in* $\mathcal{D}_{test}$ **do**
  find KNNs $\mathcal{K}_s$ of s in $\mathcal{D}_{\text{train}}$;
  $\theta_s \leftarrow \theta - \bigtriangledown_\theta \mathcal{L}_{\mathcal{K}_s}(f_\theta)$
end

Low-rank embedding by tensor decomposition Contextual patterns of words can be used to measure semantic similarity for emotion analysis (Staiano and Guerini, 2014; Mikolov et al., 2013). Traditional embedding approaches, e.g., doc2vec, usually require a large amount of data (Le and

Mikolov, 2014). We propose to use low-rank embeddings of sentences mined by tensor decomposition, which can obtain text embeddings regardless of the corpus size (Hosseinimotlagh and Papalexakis, 2018). As shown in Figure 2, considering $\mathcal{D} = \mathcal{D}_{\text{train}} \cup \mathcal{D}_{\text{test}}$, we first build a vocabulary for it, namely, $w_1, w_2, \ldots, w_V$, where V is the number of words. For each sentence s in $\mathcal{D}$, we count the word-word co-occurrence in a small window H, and build a binary matrix $\mathbf{V}_s \in [0,1]^{V \times V}$. In particular, $\mathbf{V}_s(i,j) = 1$ indicates word w_i and w_j co-occurs in s within a small window H at least once. In this way, we can capture the semantic patterns of a sentence in $\mathbf{V}_s$. In addition, this approach can also deal with negation issue to some extent, which is important for sentiment analysis (Reitan et al., 2015). Because negation sentences usually have negation words, they will have a different word-word co-occurrence pattern with that of normal sentences, which will result in different embeddings. Therefore, the tensor decomposition method may put sentences with and without negation words into different clusters. Afterwards, we stack all $\mathbf{V}_s$ as a three-dimensional tensor $\boldsymbol{\mathcal{V}} \in [0,1]^{V \times V \times D}$, where $D = M + N$. We adopt the CANDECOMP/PARAFAC tensor decomposition method (Sidiropoulos et al., 2017) to find an approximation $\hat{\boldsymbol{\mathcal{V}}}$ of $\boldsymbol{\mathcal{V}}$:

$$\hat{\boldsymbol{\mathcal{V}}} = \sum_{r=1}^{R} \mathbf{w}_r \otimes \mathbf{w}_r \otimes \mathbf{s}_r, \tag{1}$$

such that the Frobenius norm $\|\hat{\boldsymbol{\mathcal{V}}} - \boldsymbol{\mathcal{V}}\|_F$ is minimal, where $\mathbf{w}_r \in \mathbb{R}^V$, $\mathbf{s}_r \in \mathbb{R}^D$, R is the rank, and $\otimes$ is the outer product, namely, $\mathbf{w}_r \otimes \mathbf{w}_r \otimes \mathbf{s}_r$ being a three-dimensional tensor, and $\mathbf{w}_r \otimes \mathbf{w}_r \otimes \mathbf{s}_r(i,j,k) = \mathbf{w}_r(i) \cdot \mathbf{w}_r(j) \cdot \mathbf{s}_r(k)$. We use both training and testing datasets for embedding, which follows the general practice of previous literature (Zhou et al., 2016; Zhang et al., 2018). In such a case, it is possible to infer a complete vocabulary of the corpus by making use of both the training and testing dataset. If some testing data are not available when the tensor is built, there exist tensor decomposition methods for dealing with streaming data scenarios (Gujral et al., 2018), namely, the testing data can be updated continuously over time. Our framework can easily utilize such advanced methods to generalize to sentences with out-of-vocabulary words.

With the tensor decomposition, we can find low-rank embeddings of sentences that capture the similarity of contextual patterns (Hosseinimotlagh and Papalexakis, 2018). In particular, $\mathbf{C} = [\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_R] \in \mathbb{R}^{D \times R}$, where the s-row of $\mathbf{C} = [\mathbf{c}_1^T, \mathbf{c}_2^T, \ldots, \mathbf{c}_D^T]^T$, $\mathbf{c}_s^T$, is the embedding vector of the sentence s. We measure the similarity of two sentences i, j by Euclidean distance: $d(i,j) = \sqrt{\sum_{r=1}^{R} (\mathbf{c}_i(r) - \mathbf{c}_j(r))^2}$, where $\mathbf{c}(r)$ denotes the r-th element of $\mathbf{c}$.

4.2.2 Meta-Learner Training

We can train a meta-learner on the generated $\mathcal{T}_{\text{train}}$.

Learner. We use a Convolutional Neural Network (CNN) model as the basic learner, which has shown good performance on text classification (Kim, 2014) and text emotion distribution learning (Zhang et al., 2018). The CNN learner has the same architecture with (Zhang et al., 2018). In particular, given the input sentence s, we first stack a matrix $\mathbf{X}$ with the word vector of each word (Mikolov et al., 2013). Then three convolution layers with kernel sizes $3, 4, 5$ are performed on $\mathbf{X}$ separately, and we then concatenate them together. A fully connected layer is then used, following with a soft-max operation to get the final emotion probability prediction. We use Kullback-Leibler (K-L) divergence $\mathcal{L}_{\text{K-L}}$ as the objective to measure the distance of predicted distribution $\hat{\mathbf{y}}$ and the true distribution $\hat{\mathbf{y}}$: $\mathcal{L}_{\text{K-L}} = \sum_{i=1}^{K} \frac{1}{K} \sum_{j=1}^{C} y_i^j \log \frac{y_i^j}{\hat{y}_i^j}$, where K is the number of training samples. Similarly to (Zhang et al., 2018), we also optimize the classification accuracy of the dominant emotion by a cross-entropy (CE) objective, which is shown to improve EDL performance. In particular, $\mathcal{L}_{\text{CE}} = -\sum_{i=1}^{K} \frac{1}{K} \sum_{j=1}^{C} \mathbb{1}(y_i^j) \log \hat{y}_i^j$, where $\mathbb{1}(y^j) = 1$ if y^j is the maximal value of $\mathbf{y}$, otherwise $\mathbb{1}(y^j) = 0$. The final objective is a weighted sum of $\mathcal{L}_{\text{KL}}$ and $\mathcal{L}_{\text{CE}}$: $\mathcal{L} = \gamma \mathcal{L}_{\text{K-L}} + (1-\gamma)\mathcal{L}_{\text{CE}}$, where γ is the weight factor, $0 \le \gamma \le 1$.

Training meta-learner. To train the learner f_θ, we optimize the parameters θ of the learner f such that a small number of gradient steps on a new task will produce maximally effective behavior on that task, namely,

$$\min_{\theta} \sum_{T_i \sim \mathcal{T}_{\text{train}}} \mathcal{L}_{T_i(Q)}(f_{\theta_i'}), \tag{2}$$

where T_i is a randomly sampled task in $\mathcal{T}_{\text{train}}$, θ_i' is the trained optimal parameters on task T_i. $T_i(Q)$ denotes that the loss is computed on the query set

Q. Equation (3) is optimized via stochastic gradient descent (SGD),

$$\theta \leftarrow \theta - \beta(\nabla_\theta \sum_{T_i \sim \mathcal{T}_{\text{train}}} \mathcal{L}_{T_i(Q)}(f_{\theta_i'})), \quad (3)$$

where β is the meta-learning rate. Similarly, SGD is used to compute θ_i', $\theta_i' \leftarrow \theta - \alpha \nabla_\theta \mathcal{L}_{T_i(S)}(f_\theta)$, where $T_i(S)$ denotes that the loss is computed on S, and α is the learning rate.

4.2.3 Adapting Meta-Learner

The meta-learner f_θ is trained to adapt to new data with only a few semantically similar training samples. Therefore, given a testing sample s, we first find its K-nearest neighbors $\mathcal{K}_s$ in the training data $\mathcal{D}_{\text{train}}$, and then adapt f_θ on $\mathcal{K}_s$ by SGD:

$$\theta \leftarrow \theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{K}_s}(f_\theta). \quad (4)$$

Here we use the learning rate α to be consistent with the meta-training procedure.

The overall algorithm is shown in Algorithm 1, where α is the learning rate, β is the meta-learning rate, γ is the weight value of the distribution and classification losses, H is the window size for word-word co-occurrence counting, R is the rank of tensor decomposition, K is the number of nearest neighbors, $niter$ is the number of meta-training iterations, and L is the number of tasks for each round of meta-training.

5 Experiment

To evaluate the proposed approach for learning emotion distribution from a small sample, we conduct intensive experiments on SemEval 2007 Task 14 (Strapparava and Mihalcea, 2007). To the best of our knowledge, this is the only publicly available English dataset with emotion distributions labeled by humans.

5.1 Experiment Setup

5.1.1 Dataset

SemEval 2007 Task 14 contains 1250 sentences of news headlines with 6 emotion intensities (anger, disgust, fear, joy, sadness, and surprise) labeled by humans. Each intensity value is a non-negative value. We normalize the annotated scores to get emotion distribution labels using the same procedure with Zhang et al. (2018). In particular, given an original intensity tuple $(l_1, l_2, \ldots, l_6)$, we first calculate the sum of all values, $l = \sum_{k=1}^{6} l_k$, and then normalize it to get a distribution as $(l_1/l, l_2/l, \ldots, l_6/l)$. If $l = 0$, then the distribution will be $(1/6, 1/6, \ldots, 1/6)$. It is possible to add another intensity value l_7 denoting the overall level of emotion to the original label; for example, if l_7 is 1, there is no emotion in the text, and if l_7 is 0, there is strong emotions. Similar to $l_1 \sim l_6$, l_7 can be annotated manually. We can then normalize $(l_1, l_2, \ldots, l_7)$ to get a new distribution. In this way, we can better model the cases of a sentence expressing very little emotion overall. For simplicity and fair comparison, we only use $l_1 \sim l_6$ in this paper.

5.1.2 Experiment Protocal

Because there is no publicly available small dataset for text emotion distribution evaluation, we follow existing practices (Hosseinimotlagh and Papalexakis, 2018) to simulate a small training set by randomly selecting 10% of the samples and using the remaining ones for testing. We run 10-fold cross validation, and report the averaged results.

Baselines. We compare the proposed method (denoted as EDL-Meta) with several baseline methods, including the SOTA method EDL-CNN (Zhang et al., 2018), LDL methods, and document vectorization methods. EDL-CNN uses the basic learner of EDL-Meta, and can be seen as a special case of EDL-Meta when $K = 0$. Similar to Zhang et al. (2018), we also extract the penultimate layer of EDL-CNN as features, and fit several typical LDL methods: PT-Bayes, PT-SVM, AA-KNN, AA-BP, SA-LDSVR, SA-IIS, SA-BFGS, SA-CPNN for comparison. The basic principles of each method are briefly summarized in subsection 2.1. In addition, we apply three SOTA document vectorization methods – doc2vec (Le and Mikolov, 2014), InferSent (Conneau et al., 2017), and BERT (Devlin et al., 2019) – and use the extracted vectors to train a linear regressor to predict emotion distributions.

5.1.3 Evaluation Metrics

Evaluating the performance of distribution learning is challenging, because we need to measure the prediction results of fine-grained intensity values. In (Geng and Ji, 2013), the authors propose six metrics, and suggest that each metric may reflect certain aspects of an algorithm. A good algorithm should perform well on most of them. The six metrics contain Euclidean$^{\downarrow}$, Sørensen$^{\downarrow}$, Squared$\chi^{2\downarrow}$,

Method	Euclidean$^{\downarrow}$	Sørensen$^{\downarrow}$	Squared$\chi^{2\downarrow}$	K-L$^{\downarrow}$	Fidelity$^{\uparrow}$	Intersection$^{\uparrow}$
PT-Bayes	0.4870	0.4889	0.6707	0.7574	0.7330	0.5111
PT-SVM	0.5748	0.5706	0.8578	1.1327	0.6639	0.4294
AA-KNN	0.4248	0.4054	0.5181	0.8325	0.7986	0.5946
AA-BP	0.4620	0.4468	0.5945	0.7410	0.7662	0.5532

Table 1: Evaluation results on SemEval 2007 Task 14.

Distance	Euclidean$^{\downarrow}$	$\sqrt{\sum_{i=1}^{C}(p_i - q_i)^2}$
	Sørensen$^{\downarrow}$	$\frac{\sum_{i=1}^{C}\lvert p_i - q_i\rvert}{\sum_{i=1}^{C}(p_i + q_i)}$
	Squared$\chi^{2\downarrow}$	$\sum_{i=1}^{C}\frac{(p_i - q_i)^2}{p_i + q_i}$
	K-L$^{\downarrow}$	$\sum_{i=1}^{C} p_i \log \frac{p_i}{q_i}$
Similarly	Fidelity$^{\uparrow}$	$\sum_{i=1}^{C}\sqrt{p_i q_i}$
	Intersection$^{\uparrow}$	$\sum_{i=1}^{C}\min(p_i, q_i)$

Table 2: Metrics for evaluating the performance of emotion distribution learning.

K-L$^{\downarrow}$, Fidelity$^{\uparrow}$, Intersection$^{\uparrow}$, and can be classified into two categories: distance metrics and similarity metrics (Geng and Ji, 2013). Distance metrics measure the distance between the predicted distribution and the true one, the smaller the better. Similarity metrics measure the similarity between the predicted distribution and the true one, the bigger the better. Here, $^{\uparrow}$ means the bigger the better, $^{\downarrow}$ means the smaller the better. The formulas for calculating all metrics are summarized in Table 2, where $(q_1, q_2, \ldots, q_C)$ is the predicted distribution, $(p_1, p_2, \ldots, p_C)$ is the true distribution, C is the number of emotions.

5.1.4 Implementation

We use 300 dimension word vectors trained on Google News from (Mikolov et al., 2013) as initial input. Because SemEval 2007 Task 14 is mostly News headlines, the pre-trained word vectors are closer to it. We implement our algorithm by PyTorch [2]. Owing to EDL-CNN not being open-sourced, we also implement it by PyTorch. The implementation of doc2vec is adopted from gemsim [3]. BERT embedding (uncased base model, without fine-tuning) is adopted from an open-source implementation (Xiao, 2018). The implementations of other methods are downloaded from the original paper (Geng and Ji, 2013; Conneau et al., 2017). For EDL-CNN, we use the network architecture in the original paper, and set the learning rate 0.1, epoch number 25 (Kim, 2014). In the same experiment setting with (Zhang et al., 2018), namely, 90% training data and 10% testing data of SemEval 2007, we can obtain 0.344 Euclidean$^{\downarrow}$, 0.330 Sørensen$^{\downarrow}$, 0.344 Squared$\chi^{2\downarrow}$, 0.437 K-L$^{\downarrow}$, 0.853 Fidelity$^{\uparrow}$, 0.670 Intersection$^{\uparrow}$, which are slightly better than the results reported in (Zhang et al., 2018). For fair comparison, we use the default parameters of all other methods, which are reported to get the best performance. For EDL-Meta, we empirically set $\alpha = 0.01$, $\beta = 0.1$, $L = 5$, $H = 5$. γ is set to be 0.7 according to (Zhang et al., 2018), and we do not further tune it. 1000 epoches are used to train the meta-learner for both datasets. To find optimal K and R, we run a 5-fold cross validation grid search, and set $K = 20$, $R = 5$. The alternating least squares method is used to calculate the tensor decomposition, and we use the implementation in the Matlab tensor toolbox [4]. The k-d tree method is used to find KNNs of a sample efficiently. We run all experiments on a desktop with Intel(R) Core(TM) i9-7900X CPU 3.30GHz, 64GB RAM, Nvidia GeForce GTX 1080 Ti (×2).

5.2 Results

The comparison results of SemEval 2007 Task 14 are shown in Table 1. We can see that EDL-Meta shows better results than other methods on all metrics. In particular, EDL-Meta can usually outper-

form other methods by about 5% on most metrics. Although EDL-CNN can perform well with more training samples (Zhang et al., 2018), on the small sample, its performance is not as stable as EDL-Meta. Even simple KNN can get slightly better results than EDL-CNN on most metrics. Likewise, other methods cannot get stable results on all metrics. This indicates that EDL-Meta is more suitable for small sample EDLs.

5.3 Discussion

5.3.1 Low-rank Embedding

To investigate the effectiveness of the tensor decomposition method, we use doc2vec (Le and Mikolov, 2014) and InferSent (Conneau et al., 2017) to train sentence vectors on $\mathcal{D}$, and find KNNs of a sample by cosine similarity, denoted as doc2vec and InferSent, respectively. In addition, we also use randomly selected K-neighbors to train and test EDL-Meta, denoted as random. We denote our tensor decomposition method as tensor. The results are shown in Table 3. Compared to doc2vec, InferSent, and random, our method can get better results on all metrics. The doc2vec and InferSent embedding methods show a slightly lower performance, even worse than the random version. doc2vec usually assumes a large pool of training data (Le and Mikolov, 2014), while InferSent also does not work well for transferring to a task with a small training sample. The tensor decomposition method is more suitable for small sample learning.

5.3.2 Meta-Training and Adapting

To investigate the effect of the proposed meta-training and adapting procedures, we conduct another experiment. In particular, with the same experiment setting, we replace the meta-training procedure (denoted as Meta.) with a normal batch training (batch size 50) and the adaption procedure (denoted as Adap.) with a normal evaluation procedure, respectively. We can then get four versions of EDL-Meta, namely, *without Meta. + without Adap.*, *without Meta. + with Adap.*, *with Meta. + without Adap.*, and *with Meta. + with Adap*. The first one is EDL-CNN in particular, and the last one is the normal EDL-Meta. In this way, we can further examine the importance of the proposed meta-training and adapting procedures. The results are shown in Table 4. We can see that with both the meta-training and adapting procedures, EDL-Meta performs more stably than other methods. In addition, the meta-training procedure plays a crucial role on boosting the performance, as the results of the third version are similar to the fourth version. Finally, without meta-training, only using

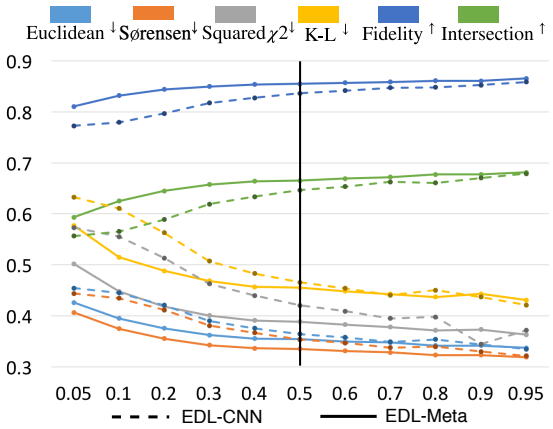

Figure 3: The performance of EDL-CNN and EDL-Meta on different training percentages. The horizontal axis denotes different training percentages, and the vertical axis denotes the performance on different metrics.

adapting is meaningless, as the performance of the second version decreases a lot.

5.3.3 Label Percentage

In the same experiment setting, we further investigate the influence of different training/testing partition. We compare the performance of EDL-CNN and EDL-Meta under different training/testing partition. The results are shown in Figure 3. We can find that on small training sample, there is a clear gap between EDL-CNN and EDL-Meta. But with more training sample (>50%), EDL-CNN and EDL-Meta converge to similar results. Therefore, it is likely that the learning ability of EDL-Meta is limited by its basic learner. Further experiments on different learners deserve to investigate.

6 Conclusion

In this paper, we propose an efficient meta-learning approach to learn text emotion distribution from a small sample. In addition, to find the K-nearest semantically similar neighbors, we propose to learn sentence embedding by tensor decomposition. Experiments on SemEval 2007 Task 14 shows that the proposed approach outperforms existing EDL methods on small sample emotion distribution learning. We further investigate the low-rank embedding method, the meta-training procedure, and the adaption procedure. We find that leveraging nearest semantically similar neighbors is an effective way for small sample EDLs. We also find that the meta-training procedure can be a good alternative to the normal batch training procedure, especially for small sample EDLs.

Abstract

We conduct a large-scale, systematic study to evaluate the existing evaluation methods for natural language generation in the context of generating online product reviews. We compare human-based evaluators with a variety of automated evaluation procedures, including discriminative evaluators that measure how well machine-generated text can be distinguished from human-written text, as well as word overlap metrics that assess how similar the generated text compares to human-written references. We determine to what extent these different evaluators agree on the ranking of a dozen of state-of-the-art generators for online product reviews. We find that human evaluators do not correlate well with discriminative evaluators, leaving a bigger question of whether adversarial accuracy is the correct objective for natural language generation. In general, distinguishing machine-generated text is challenging even for human evaluators, and human decisions correlate better with lexical overlaps. We find lexical diversity an intriguing metric that is indicative of the assessments of different evaluators. A post-experiment survey of participants provides insights into how to evaluate and improve the quality of natural language generation systems [1].

1 Introduction

Recent developments in neural language models (Mikolov and Zweig, 2012), (Reiter and Belz, 2009), (Mikolov et al., 2011b), (Mikolov et al., 2011a) have inspired the use of neural network based architectures for the task of natural language generation (NLG). Despite fast development of algorithms, there is an urgency to fill the huge gap in evaluating NLG systems. On one hand, a rigorous, efficient, and reproducible evaluation procedure is critical for the development of any machine learning technology and for correct interpretation of the state-of-the-art. On the other hand, evaluating the quality of language generation is inherently difficult due to the special properties of text, such as *subjectivity* and *non-compositionality*. Indeed, *"there is no agreed objective criterion for comparing the goodness of texts"* (Dale and Mellish, 1998), and there lacks a clear model of text quality (Hardcastle and Scott, 2008).

Conventionally, most NLG systems have been evaluated in a rather informal manner. (Reiter and Belz, 2009) divide existing evaluation methods commonly employed in text generation into three categories: *i)* evaluations based on task performance, *ii)* human judgments and ratings, where human subjects are recruited to rate different dimensions of the generated texts, and *iii)* evaluations based on comparison to a reference corpus using automated metrics. *Task based evaluation* considers that the value of a piece of functional text lies in how well it serves the user to fulfill a specific application. It can be expensive, time-consuming, and often dependent on the good will of participants in the study. Besides that, it is hard to toss out the general quality of text generation from the special context (and confounds) of the task, or to generalize the evaluation conclusions across tasks. *Human annotation* is able to assess the quality of text more directly than task based evaluation. However, rigorously evaluating NLG systems with real users can be expensive and time consuming, and it does not scale well (Reiter et al., 2001). Human assessments also need to be consistent and repeatable for a meaningful evaluation (Lopez, 2012). Alternative strategies which are more effective in terms of cost and time are used more frequently.

Automated evaluation compares texts generated by the candidate algorithms to human-written texts.

Word overlap metrics and more recent automated adversarial evaluators are widely employed in NLG as they are cheap, quick, repeatable, and do not require human subjects when a reference corpus is already available. In addition, they allow developers to make rapid changes to their systems and automatically tune parameters without human intervention. Despite the benefits, however, the use of automated metrics in the field of NLG is controversial (Reiter and Belz, 2009), and their results are often criticized as not meaningful for a number of reasons. First, these automatic evaluations rely on a high-quality corpus of references, which is not often available. Second, comparisons with a reference corpus do not assess the usefulness and the impact of the generated text on the readers as in human-based evaluations. Third, creating human written reference texts specifically for the purpose of evaluation could still be expensive, especially if these reference texts need to be created by skilled domain experts. Finally and most importantly, using automated evaluation metrics is sensible only if they correlate with results of human-based evaluations and if they are accurate predictors of text quality, which is never formally verified at scale.

We present a large-scale, systematic experiment that evaluates the *evaluators* for NLG. We compare three types of evaluators including human evaluators, automated adversarial evaluators trained to distinguish human-written from machine-generated product reviews, and word overlap metrics (such as BLEU and ROUGE) in a particular scenario, generating online product reviews. The preferences of different evaluators on a dozen representative deep-learning based NLG algorithms are compared with human assessments of the quality of the generated reviews. Our findings reveal significant differences among the evaluators and shed light on the potential factors that contribute to these differences. The analysis of a post experiment survey also provides important implications on how to guide the development of new NLG algorithms.

2 Related Work

2.1 Deep Learning Based NLG

Recently, a decent number of deep learning based models have been proposed for text generation. Recurrent Neural Networks (RNNs) and their variants, such as Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) models, Google LM (Jozefowicz et al., 2016), and Scheduled Sampling (SS) (Bengio et al., 2015) are widely used for generating textual data.

Generative Adversarial Networks (Goodfellow et al., 2014), or GANs, train generative models through an adversarial process. Generating text with GANs is challenging due to the discrete nature of text data. SeqGAN (Yu et al., 2017) is one of the earliest GAN-based model for sequence generation, which treats the procedure as a sequential decision making process. RankGAN (Lin et al., 2017) proposes a framework that addresses the quality of a set of generated sequences collectively. Many GAN-based models (Yu et al., 2017), (Lin et al., 2017), (Rajeswar et al., 2017), (Che et al., 2017), (Li et al., 2017), (Zhang et al., 2017) are only capable of generating short texts. LeakGAN (Guo et al., 2018) is proposed for generating longer texts.

Deep learning architectures other than LSTM or GAN have also been proposed for text generation. (Tang et al., 2016) study NLG given particular contexts or situations and proposes two approaches based on the encoder-decoder framework. (Dong et al., 2017) address the same task and employ an additional soft attention mechanism. Pre-training enables better generalization in deep neural networks (Erhan et al., 2010), especially when combined with supervised discriminative fine-tuning to learn universal robust representations (Radford et al., 2018), (Devlin et al., 2018), (Radford et al., 2019). (Guu et al., 2018) use a prototype-then-edit generative language model for sentences.

2.2 Automated Evaluation Metrics

The variety of NLG models are also evaluated with various approaches. Arguably, the most natural way to evaluate the quality of a generator is to involve humans as judges, either through some type of Turing test (Machinery, 1950) to distinguish generated text from human input texts, or to directly compare the texts generated by different generators (Mellish and Dale, 1998). Such approaches are hard to scale and have to be redesigned whenever a new generator is included. Practically, it is critical to find automated metrics to evaluate the quality of a generator independent of human judges or an exhaustive set of competing generators.

Perplexity (Jelinek et al., 1977) is commonly used to evaluate the quality of a language model, which has also been employed to evaluate generators (Yarats and Lewis, 2018), (Ficler and Goldberg, 2017), (Gerz et al., 2018) even though it is com-

monly criticized for not being a direct measure of the quality of generated text (Fedus et al., 2018). Perplexity is a model dependent metric, and "how likely a sentence is generated by a given model" is not comparable across different models. Therefore we do not include perplexity in this study.

Discriminative Evaluation is an alternative way to evaluate a generator, which measures how likely its generated text can fool a classifier that aims to distinguish the generated text from human-written texts. In a way, this is an automated approximation of the Turing test, where machine judges are used to replace human judges. Discriminative machine judges can be trained either using a data set with explicit labels (Ott et al., 2011), or using a mixture of text written by real humans and those generated by the model being evaluated. The latter is usually referred to as *adversarial evaluation*. (Bowman et al., 2016) proposes one of the earliest studies that uses adversarial error to assess the quality of generated sentences. Notably, maximizing the adversarial error is consistent to the objective of the generator in generative adversarial networks. (Kannan and Vinyals, 2017) propose an adversarial loss to discriminate a dialogue model's output from human output. The discriminator prefers longer output and rarer language instead of the common responses generated. There however lacks evidence that a model that obtains a lower adversarial loss is better according to human evaluations.

Automatic dialogue evaluation is formulated as a learning problem in (Lowe et al., 2017), who train an RNN to predict the scores a human would assign to dialogue responses. RNN predictions correlate with human judgments at the utterance and system level, however each response is evaluated in a very specific context and the system requires substantial human judgments for training. (Li et al., 2017) employ a discriminator (analogous to the human evaluator in the Turing test) both in training and testing and define adversarial success. Other work finds the performance of a discriminative agent (e.g., attention-based bidirectional LSTM binary classifier) is comparable with human judges at distinguishing between real and fake dialogue excerpts (Bruni and Fernández, 2017). However, results show there is limited consensus among humans on what is considered as coherent dialogue passages.

Word Overlap Metrics, such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005), are commonly used to measure the similarity between the generated text and human written references. (Liu et al., 2016) find that word overlap metrics present weak or no correlation with human judgments in non-task oriented dialogue systems and thus should be used with caution or in combination with user studies. In contrary, it is reported in (Sharma et al., 2017) that text overlap metrics are indicative of human judgments in task-oriented dialogue settings, when used on datasets which contain multiple ground truth references. (Dai et al., 2017) find text overlap metrics too restrictive as they focus on fidelity of wording instead of fidelity of semantics. (Callison-Burch et al., 2006) consider an increase in BLEU insufficient for an actual improvement in the quality of a system and posit in favor of human evaluation.

BLEU and its variants (e.g., Self-BLEU) are used to evaluate GAN models (Caccia et al., 2018; Zhu et al., 2018). (Shi et al., 2018) compare frameworks for text generation including MLE, SeqGAN, LeakGAN and Inverse Reinforcement Learning using a simulated Turing test. A benchmarking experiment with GAN models is conducted in (Lu et al., 2018); results show LeakGAN presents the highest BLEU scores on the test data. Similarly, BLEU and METEOR present highest correlations with human judgements (Callison-Burch et al., 2008), (Graham and Baldwin, 2014). However, evaluation metrics are not robust across conditions, and no single metric consistently outperforms other metrics across all correlation levels (Przybocki et al., 2009).

Conventional neural language models trained with maximum likelihood can be on par or better than GANs (Caccia et al., 2018), (Semeniuta et al., 2018), (Tevet et al., 2018). However, log-likelihood is often computationally intractable (Theis et al., 2016). Models with good likelihood can produce bad samples, and vice-versa (Goodfellow, 2016). Generative models should be evaluated with regards to the task they are intended for over the full quality-diversity spectrum (Cífka et al., 2018), (Hashimoto et al., 2019), (Montahaei et al., 2019).

While many generators are proposed and evaluated with various metrics, no existing work has systematically evaluated the different evaluators at scale, especially in the context of online review generation. Our work fills in this gap.

3 Experiment Design

We design a large-scale experiment to systematically analyze the procedures and metrics used for

evaluating NLG models. To test the different *evaluators*, the experiment carefully chooses a particular application context and a variety of natural language generators in this context. Ideally, a sound automated evaluator should be able to distinguish good generators from suboptimal ones. Its preferences (on ordering the generators) should be consistent to humans in the exact application context.

3.1 Experiment Context and Procedure

We design the experiment in the context of generating online product reviews. There are several reasons why review generation is a desirable task for the experiment: 1) online product reviews are widely available, and it is easy to collect a large number of examples for training/ testing the generators; 2) Internet users are used to reading online reviews, and it is easy to recruit capable human judges to assess the quality of reviews; and 3) comparing to tasks like image caption generation or dialogue systems, review generation has minimal dependency on the conversation context or on non-textual data, which reduces possible confounds.

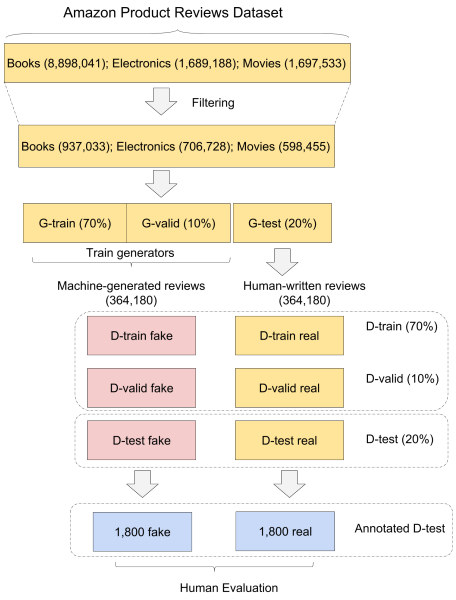

Figure 1: Overview of the Experiment Procedure.

The general experiment procedure is presented in Figure 1. We start from the publicly available Amazon Product Reviews dataset [2] and select three most popular domains: *books*, *electronics*, and *movies*. After filtering rare products, inactive users, and overly long reviews, the dataset is randomly split into three parts, to train, to validate, and to test the candidate review generators (denoted as *G-train*, *G-valid*, and *G-test*). Every generative model is trained and validated using the same datasets, and then charged to generate a number of product reviews (details are included in the next section). These generated reviews, mixed with the real reviews in *G-test*, are randomly split into three new subsets for training, validating, and testing candidate (discriminative) evaluators, denoted as *D-train*, *D-valid*, and *D-test*. Finally, a random sample of reviews from *D-test* are sent for human evaluation.

3.2 Review Generators

Although our goal is to evaluate the evaluators, it is critical to include a wide range of text generators with various degrees of quality. A good evaluator should be able to distinguish the high-quality generators from the low-quality ones. We select a diverse set of generative models from recent literature. The goal of this study is *not* to name the best generative model, and it is unfeasible to include all existing models. Our criteria are: (1) the models are published before 2018, when our experiment is conducted; (2) the models represent different learning strategies and quality levels; (3) the models have publicly available implementations, for reproducibility purposes. In Table 1 we list the candidate generators. It is not an exhaustive list of what are currently available. For implementation details of these models please see Appendix A.1.

Table 1: Candidate models for review generation.

Generative Model	Adversarial Framework
Word LSTM temp 1.0 (Hochreiter and Schmidhuber, 1997)	No
Word LSTM temp 0.7 (Hochreiter and Schmidhuber, 1997)	No
Word LSTM temp 0.5 (Hochreiter and Schmidhuber, 1997)	No
Scheduled Sampling (Bengio et al., 2015)	No
Google LM (Jozefowicz et al., 2016)	No
Attention Attribute to Sequence* (Dong et al., 2017)	No
Contexts to Sequences* (Tang et al., 2016)	No
Gated Contexts to Sequences* (Tang et al., 2016)	No
MLE SeqGAN (Yu et al., 2017)	Yes
SeqGAN (Yu et al., 2017)	Yes
RankGAN (Lin et al., 2017)	Yes
LeakGAN (Guo et al., 2018)	Yes

* indicates that review generation using these models are conditional on context information such as product ids; other models are context independent.

Every generator (except Google LM) is trained and validated on *G-train* and *G-valid* datasets, and used to generate the same number of machine-generated (a.k.a., fake) reviews (see Table 2). We follow the best practice in literature to train these models, although it is possible that the performance of models might not be optimal due to various con-

straints. This will not affect the validity of the experiment as our goal is to evaluate the **evaluators** instead of the individual generators. Google LM was not trained on reviews, but it provides a sanity check for the experiment - a reasonable evaluator should not rank it higher than those trained for generating reviews.

Table 2: Number of generated reviews by each model.

Generative Model	Total	D-Train	D-Valid	D-Test
∀ model in Table 1 except Google LM	32,500	22,750	3,250	6,500
Google LM	6,680	4,676	668	1,336

3.3 Evaluators

We include a comprehensive set of evaluators for the quality of the aforementioned generators: *i)* human evaluators, *ii)* discriminative evaluators, and *iii)* text overlap evaluators. The evaluators are the main subjects of the experiment.

3.3.1 Human evaluators

We conduct a careful power analysis (Christensen, 2007), which suggests that at least 111 examples per generative model should be human annotated to infer that the machine-generated reviews are comparable in quality to human-written reviews, at a minimal statistically significance level of 0.05. Per this calculation, we sample 150 examples for each of the 12 generators for human evaluation. This totals 1,800 machine-generated reviews, to which we add 1,800 human-written reviews, or a total of 3,600 product reviews sent for human annotation. We markup out-of-vocabulary words in *both* human-written and machine-generated reviews to control for confounds of using certain rare words. There is no significant difference in proportion of the markup token between the two classes (2.5%-real vs. 2.2%-fake). We recruit 900 human annotators through the Amazon Mechanical Turk (AMT) platform. Each annotator is presented 20 reviews, a mixture of 10 real (i.e., human written) and 10 fake (i.e., machine generated), and they are charged to label each review as real or fake based on their own judgment. Clear instructions are presented to the workers that markup tokens are present in both classes and cannot be used to decide whether a review is real or fake. Each page is annotated by 5 distinct human evaluators. The 5 judgments on every review are used to assemble two distinct **human evaluators**: *H1* - **individual votes**, treating all human annotations independently, and *H2* - **majority votes** of the 5 human judgments. For every *annotated* review, the human evaluator ($H1$ or $H2$) makes a call which can be either right or wrong with regard to the ground truth. A generator is high quality if the human evaluator achieves low accuracy identifying the reviews as fake.

3.3.2 Discriminative evaluators

The inclusion of multiple generators provides the opportunity of creating **meta-adversarial evaluators**, trained using a *pool* of generated reviews by *many* generators, mixed with a larger number of "real" reviews (*D-train* and *D-valid* datasets). Such a "pooling" strategy is similar to the standard practice used by the TREC conferences to evaluate different information retrieval systems (Harman and Voorhees, 2006). Comparing to individual adversarial evaluators, a meta-evaluator is supposed to be more robust and fair, and it can be applied to evaluate new generators without being retrained. In our experiment, we find that the meta-adversarial evaluators rank the generators in similar orders to the best individual adversarial evaluators.

We employ a total of 7 meta-adversarial evaluators: 3 deep, among which one using LSTM (Hochreiter and Schmidhuber, 1997), one using Convolutional Neural Network (CNN) (LeCun et al., 1998), and one using a combination of LSTM and CNN architectures; 4 shallow, based on Naive Bayes (NB) (Rish, 2001), Random Forest (RF) (Liaw et al., 2002), Support Vector Machines (SVM) (Cortes and Vapnik, 1995), and XGBoost (Chen and Guestrin, 2016), with unigrams, bigrams, and trigrams as features and on balanced training sets. We find the best hyper-parameters using random search and prevent the models from overfitting by using early stopping. For every review in *D-test* (either annotated or not), a meta-adversarial evaluator makes a judgment call. A generator is considered high quality if the meta-adversarial evaluator makes more mistakes on reviews it generated.

3.3.3 Word-overlap evaluators

We include a set of 4 text-overlap metrics used for NLG evaluation: BLEU and METEOR (specific to machine translation), ROUGE (used in text summarization), and CIDEr (Vedantam et al., 2015) (used in image description evaluation). These metrics rely on matching n-grams in the target text (i.e., generated reviews) to the "references" (i.e., human-written reviews). The higher the overlap (similarity), the higher the quality of generated text. For

every generated review in *D-test Fake*, we assemble the set of references by retrieving the top-10 most similar human-written reviews in *D-test Real* using a simple vector space model. We compute 600-dimensional vector representation of reviews using Sent2Vec (Pagliardini et al., 2018), pretrained on English Wikipedia, and retrieve the top-k nearest neighbors for each review based on cosine similarity of the embedding vectors. The rationale of using nearest neighbors of each generated review as references is that to appear "real", a generated review just need to be similar to *some* real reviews instead of *all*. A generator is considered high quality if its generated reviews obtain a high average score by a text overlap evaluator. In total, we analyze and compare 13 candidate evaluators (2 human evaluators, 7 discriminative evaluators, and 4 text-overlap metrics), based on the *D-test* dataset.

4 Results

First, we are interested in the accuracy of individual evaluators - how well they can distinguish "fake" (machine-generated) reviews from "real" (human-written) reviews. Second, we are interested in how an evaluator assesses the quality of the 12 generators instead of individual reviews. The absolute scores an evaluator gives to the generators are not as informative as how it ranks them: a good evaluator should be able to rank good generators above bad generators. Last but not least, we are interested in how the rankings by different evaluators correlate with each other. Intuitively, an automated evaluator that ranks the generators in similar orders as the human evaluators is more reasonable and can potentially be used as the surrogate of humans.

4.1 Results of Individual Evaluators

4.1.1 Human evaluators

Every review is annotated by 5 human judges as either "fake" or "real." The inter-annotator agreement (Fleiss-Kappa score (Fleiss et al., 2013)) is $k = 0.2748$. This suggests that *distinguishing machine-generated reviews from real in general is a hard task even for humans*; there is limited consensus on what counts as a realistic review. The low agreement also implies that any automated evaluator that mimics human judges is not necessarily the most "accurate."

In Figure 2 we present the accuracy of two human evaluators on individual annotated reviews, based on either all 5 annotations or their majority votes for each review. Comparing to the ground-truth (of whether a review is machine-generated or collected from Amazon), individual human decisions are 66.61% accurate, while their majority votes can reach 72.63%. Neither of them is close to perfect. *We observe that human evaluators generally do better at correctly labelling human-written reviews as real (true positive rate of 78.96% for $H1$ and 88.31% for $H2$), and they are confused by machine-generated reviews in close to half of the cases (true negative rate of 54.26% for $H1$ and 56.95% for $H2$).* This trend reassures previous observations (Tang et al., 2016).

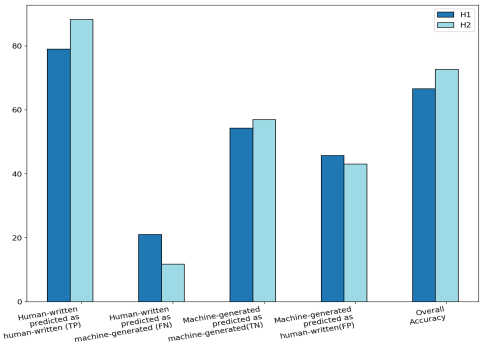

Figure 2: Accuracy of human evaluators on individual reviews: *H1* - individual votes; *H2* - majority votes.

We then look at how the human evaluators rank the 12 generators, according to the accuracy of human evaluators on all (fake) reviews generated by each of the generators. The lower the accuracy, the more likely the human evaluator is confused by the generated reviews, and thus the better the generator. We observe a substantial variance in the accuracy of both human evaluators on different generators, which suggests that human evaluators are able to distinguish between generators. The generator ranked the highest by both human evaluators is *Gated Contexts to Sequences*. Google LM is ranked on the lower side, which makes sense as the model is not trained to generate reviews. Interestingly, humans tend not to be fooled by reviews generated by the GAN-based models (MLE SeqGAN, SeqGAN, RankGAN and LeakGAN), even though their objective is to confuse fake from real. GAN-generated reviews tend to be easily distinguishable from the real reviews by human judges.

4.1.2 Discriminative evaluators

We then analyze the 7 meta-adversarial evaluators. Different from human evaluators that are applied

to the 3,600 annotated reviews, the discriminative evaluators are applied to *all* reviews in *D-test*.

Meta-adversarial Evaluators. On individual reviews, the three deep learning based and the one SVM based evaluators achieve higher accuracy than the two human evaluators, indicating that adversarial evaluators can distinguish a single machine-generated review from human-written better than humans (Figure 3 and Table 4 in Appendix A.3.2). Their true positive rates and true negative rates are more balanced than human evaluators. Meta-discriminators commonly rank GAN-based generators the highest. This makes sense as the objective of GAN is consistent to the (reversed) evaluator accuracy. Interestingly, by simply setting the temperature parameter of Word LSTM to 1.0, it achieves comparable performance to the GANs.

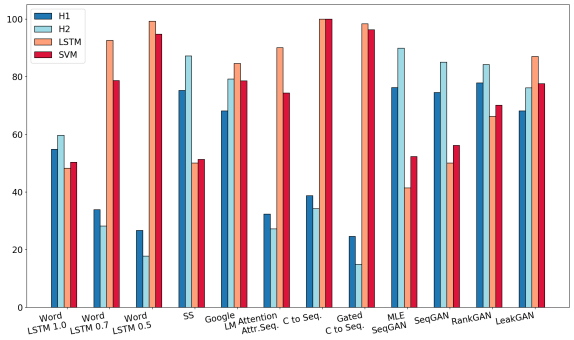

Figure 3: Accuracy of human (H1, H2) and meta-adversarial evaluators (LSTM, SVM) on reviews generated by individual generators. **The lower the accuracy, the better the generator.**

4.1.3 Word-Overlap Evaluators

The generators are ranked based on the average scores of their generated reviews. In Figure 4 we present the average scores of the 12 generators by each evaluator. Different word-overlap evaluators also tend to rank the generators in similar orders. Interestingly, the top-ranked generator according to three evaluators is *Contexts to Sequences*, while CIDEr scores highest the *Gated Contexts to Sequences* model. GAN-based generators are generally ranked low; please also see Appendix A.3.3.

4.2 Comparing Evaluators

To what degree do the evaluators agree on the ranking of generators? We are more interested in how the automated evaluators compare to the human evaluators, and whether there is any suitable automated surrogate for human judges at all. To do

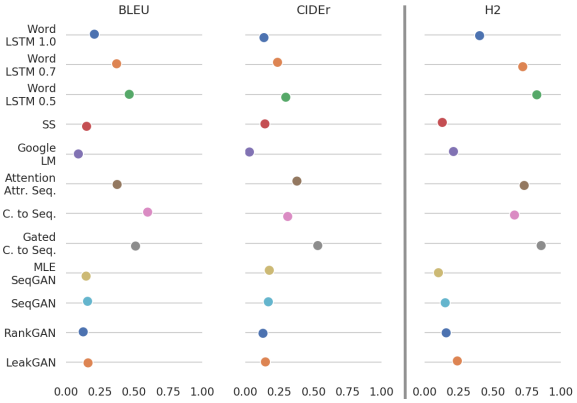

Figure 4: Text-Overlap Evaluators (BLEU and CIDEr) scores for individual generators. **The higher the better.** The rankings are overall similar, as GAN-based generators are ranked low.

this, we compute the correlations between $H1$, $H2$ and each discriminative evaluator and correlations between $H1$, $H2$ and the text-overlap evaluators, based on either their decisions on individual reviews, their scores of the generators (by Pearson's coefficient (Fieller et al., 1957)), and their rankings of the generators (by Spearman's ρ (Spearman, 1904) and Kendall's τ (Daniel et al., 1978)). Patterns of the three correlation metrics are similar; please see Figure 5 and Table 5 in Appendix A.3.4.

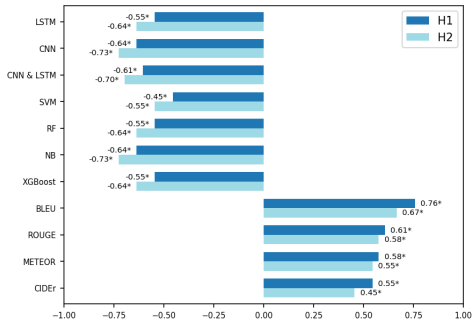

Figure 5: Kendall τ-b between human and automated evaluators. Human's ranking is positively correlated to text-overlap evaluators and negatively correlated to adversarial evaluators (* is $p \leq 0.05$).

Surprisingly, none of the discriminative evaluators have a positive correlation with the human evaluators. That says, *generators that fool machine judges easily are less likely to confuse human judges, and vice versa. Word-overlap evaluators tend to have a positive correlation with the human evaluators in ranking the generators*. Among them, BLEU appears to be closer to humans. This pattern is consistent in all three types of correlations. These two observations are intriguing, which indi-

cates that when identifying fake reviews, humans might focus more on word usage rather than trying to construct a "decision boundary" mentally.

In summary, we find that 1) human evaluators cannot distinguish machine-generated reviews from real reviews perfectly, with significant bias between the two classes; 2) meta-adversarial evaluators can better distinguish individual fake reviews, but their rankings at the generator level tend to be negatively correlated with human evaluators; and 3) text-overlap evaluators are highly correlated with human evaluators in ranking generators.

5 Discussion

We carried a systematic experiment that evaluates the evaluators for NLG. Results have intriguing implications to both the evaluation and the construction of natural language generators. We conduct in-depth analysis to discover possible explanations.

5.1 Granularity of Judgments

We charged the Turkers to label individual reviews as either fake or real instead of evaluating each generator as a whole. Comparing to an adversarial discriminator, a human judge has not seen many "training" examples of *fake* reviews or generators. That explains why the meta-adversarial evaluators are better at identifying fake reviews. In this context, humans are likely to judge whether a review is real based on how "similar" it appears to the true reviews they are used to seeing online.

This finding provides interesting implications to the selection of evaluation methods for different tasks. In tasks that are set up to judge individual pieces of generated text (e.g., reviews, translations, summaries, captions, fake news) where there exists human-written ground-truth, it is better to use word-overlap metrics instead of adversarial evaluators. When judgments are made on the agent/system level (e.g., whether a Twitter account is a bot), signals like how similar the agent outputs are or how much the agent memorizes the training examples may become more useful than word usage, and a discriminative evaluator may be more effective than word-overlap metrics. Our finding also implies that adversarial accuracy might not be the optimal objective for NLG if the goal is to generate documents that humans consider as real. Indeed, a fake review that fools humans does not necessarily need to fool a machine that has seen everything. In Appendix B.2 we provide more details.

5.2 Imperfect Ground Truth

One important thing to note is that all discriminative evaluators are trained using natural labels (i.e., treating all examples from the Amazon review dataset as positive and examples generated by the candidate models as negative) instead of human-annotated labels. Some reviews posted on Amazon may have been generated by bots, and if that is the case, treating them as human-written examples may bias the discriminators. To verify this, we apply the already trained meta-discriminators to the human-annotated subset (3,600 reviews) instead of the full *D-test* set, and we use the majority vote of human judges (whether a review is fake or real) to surrogate the natural "ground-truth" labels (whether a review is generated or sampled from Amazon).

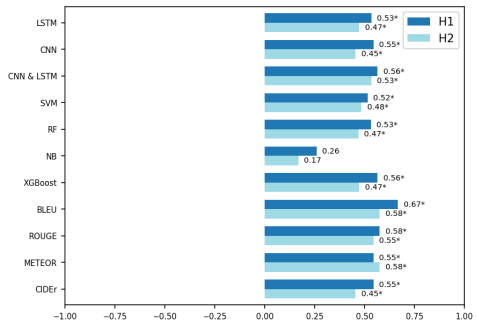

Figure 6: Kendall τ-b correlation coefficients between human evaluators and automated evaluators, tested on the **annotated subset of *D-test*** with *majority votes* as ground-truth (* denotes $p \leq 0.05$).

When the meta-adversarial evaluators are tested using human majority-votes as ground-truth, the scores and rankings of these discriminative evaluators are more inline with the human evaluators, although still not as highly correlated as BLEU; please see Figure 6. Indeed, discriminative evaluators suffer the most from low-quality labels, as they were directly trained using the imperfect ground-truth. Word-overlap evaluators are more robust, as they only take the most relevant parts of the test set as references (more likely to be high quality). Our results also suggest that when adversarial training is used, selection of training examples must be done with caution. If the "ground-truth" is hijacked by low quality or "fake" examples, models trained by GAN may be significantly biased. This finding is related to the recent literature of the robustness and security of machine learning models (Papernot et al., 2017). Appendix B.3 contains further details.

5.3 Role of Diversity

We assess the role diversity plays in rankings the generators. Diversity of a generator is measured by either the lexical diversity (Bache et al., 2013) or Self-BLEU (Zhu et al., 2018) of the samples produced by the generator. Results obtained (see Figure 7) indicate generators that produce the least diverse samples are easily distinguished by the meta-discriminators, while they confuse humans the most. This confirms that adversarial discriminators capture limitations of generative models in lack of diversity (Kannan and Vinyals, 2017).

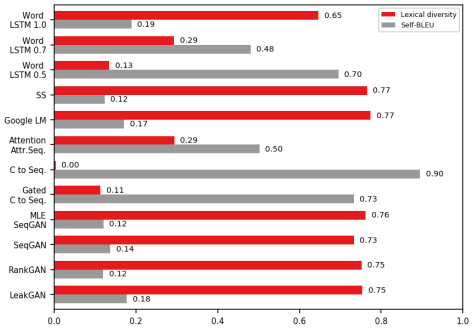

Figure 7: Self-BLEU scores (the lower the more diverse) and lexical diversity scores (the higher the more diverse) are highly correlated in ranking the generators.

Similarly, we measure to what extent the generators are memorizing the training set *G-train* as the average BLEU scores of generated reviews using their nearest neighbors in *G-train* as references. We observe the generators do not memorize the training set, and GAN models generate reviews that have fewer overlap with *G-train*; this finding is in line with recent theoretical studies on memorization in GANs (Nagarajan et al.).

The effects of diversity indicate that when humans are distinguishing individual reviews as real or fake, whether or not a fake review is sufficiently different from the other generated reviews is not a major factor for their decision. Instead, they tend to focus on whether the review looks similar to the reviews they have seen in reality. A discriminative evaluator is more powerful in making decisions at a system level (e.g., a dialog system or a bot account), where diversity becomes a major factor. In Appendix B.4 we provide more details.

5.4 User Study

Finally, we are interested in the reasons why human annotators label certain reviews as fake (machine-written). After annotating a batch of reviews, workers are asked to explain their decisions by filling in an optional free-text comment. This enables us to have a better understanding of what differentiates machine-generated from human-written reviews from human's perspective. Analyzing their comments, we identify the main reasons why human evaluators annotate a review as machine-written. These are mainly related to the presence of grammatical errors in the review text, wrong wording or inappropriate choice of expressions, redundant use of specific phrases or contradictory arguments in the review. Interestingly, human evaluators' innate biases are also reflected in their decisions: they are likely to categorize a review as fake if it is too formal, lacks emotion and personal pronouns, or is too vague and generic. Please see Appendix B.1.

5.5 Summary

In summary, our findings represent a preliminary foundation for proposing more solid and robust evaluation metrics and objectives of natural language generation. The low inter-rater agreement we observe suggests that judging *individual* pieces of text as machine- or human-generated is a difficult task even for humans. In this context, discriminative evaluators are not as correlated with human judges as word-overlap evaluators. That implies that adversarial accuracy might not be the optimal objective for generating individual documents when realism is the main concern. In contrast, GAN based models may more easily pass a Turing test on a *system* level, or in a conversational context. When the judges have seen enough examples from the same generator, the next example had better be somewhat different.

Our results also suggest that when adversarial evaluation is used, the training examples must be carefully selected to avoid false-positives. We also find that when humans are distinguishing fake reviews from real ones, they tend to focus more on the usage of words, expressions, emotions, and other details. This may affect the design of objectives for the next generation of NLG models.

Sentence-BERT: Sentence Embeddings using Siamese BERT-Networks

Nils Reimers and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
www.ukp.tu-darmstadt.de

Abstract

BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) has set a new state-of-the-art performance on sentence-pair regression tasks like semantic textual similarity (STS). However, it requires that both sentences are fed into the network, which causes a massive computational overhead: Finding the most similar pair in a collection of 10,000 sentences requires about 50 million inference computations (~65 hours) with BERT. The construction of BERT makes it unsuitable for semantic similarity search as well as for unsupervised tasks like clustering.

In this publication, we present Sentence-BERT (SBERT), a modification of the pretrained BERT network that use siamese and triplet network structures to derive semantically meaningful sentence embeddings that can be compared using cosine-similarity. This reduces the effort for finding the most similar pair from 65 hours with BERT / RoBERTa to about 5 seconds with SBERT, while maintaining the accuracy from BERT.

We evaluate SBERT and SRoBERTa on common STS tasks and transfer learning tasks, where it outperforms other state-of-the-art sentence embeddings methods.[1]

1 Introduction

In this publication, we present Sentence-BERT (SBERT), a modification of the BERT network using siamese and triplet networks that is able to derive semantically meaningful sentence embeddings[2]. This enables BERT to be used for certain new tasks, which up-to-now were not applicable for BERT. These tasks include large-scale semantic similarity comparison, clustering, and information retrieval via semantic search.

BERT set new state-of-the-art performance on various sentence classification and sentence-pair regression tasks. BERT uses a cross-encoder: Two sentences are passed to the transformer network and the target value is predicted. However, this setup is unsuitable for various pair regression tasks due to too many possible combinations. Finding in a collection of $n = 10\,000$ sentences the pair with the highest similarity requires with BERT $n \cdot (n-1)/2 = 49\,995\,000$ inference computations. On a modern V100 GPU, this requires about 65 hours. Similar, finding which of the over 40 million existent questions of Quora is the most similar for a new question could be modeled as a pair-wise comparison with BERT, however, answering a single query would require over 50 hours.

A common method to address clustering and semantic search is to map each sentence to a vector space such that semantically similar sentences are close. Researchers have started to input individual sentences into BERT and to derive fixed-size sentence embeddings. The most commonly used approach is to average the BERT output layer (known as BERT embeddings) or by using the output of the first token (the `[CLS]` token). As we will show, this common practice yields rather bad sentence embeddings, often worse than averaging GloVe embeddings (Pennington et al., 2014).

To alleviate this issue, we developed SBERT. The siamese network architecture enables that fixed-sized vectors for input sentences can be derived. Using a similarity measure like cosine-similarity or Manhatten / Euclidean distance, semantically similar sentences can be found. These similarity measures can be performed extremely efficient on modern hardware, allowing SBERT to be used for semantic similarity search as well as for clustering. The complexity for finding the

[1] Code available: https://github.com/UKPLab/sentence-transformers

[2] With *semantically meaningful* we mean that semantically similar sentences are close in vector space.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3982–3992,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

most similar sentence pair in a collection of 10,000 sentences is reduced from 65 hours with BERT to the computation of 10,000 sentence embeddings (~5 seconds with SBERT) and computing cosine-similarity (~0.01 seconds). By using optimized index structures, finding the most similar Quora question can be reduced from 50 hours to a few milliseconds (Johnson et al., 2017).

We fine-tune SBERT on NLI data, which creates sentence embeddings that significantly outperform other state-of-the-art sentence embedding methods like InferSent (Conneau et al., 2017) and Universal Sentence Encoder (Cer et al., 2018). On seven Semantic Textual Similarity (STS) tasks, SBERT achieves an improvement of 11.7 points compared to InferSent and 5.5 points compared to Universal Sentence Encoder. On SentEval (Conneau and Kiela, 2018), an evaluation toolkit for sentence embeddings, we achieve an improvement of 2.1 and 2.6 points, respectively.

SBERT can be adapted to a specific task. It sets new state-of-the-art performance on a challenging argument similarity dataset (Misra et al., 2016) and on a triplet dataset to distinguish sentences from different sections of a Wikipedia article (Dor et al., 2018).

The paper is structured in the following way: Section 3 presents SBERT, section 4 evaluates SBERT on common STS tasks and on the challenging Argument Facet Similarity (AFS) corpus (Misra et al., 2016). Section 5 evaluates SBERT on SentEval. In section 6, we perform an ablation study to test some design aspect of SBERT. In section 7, we compare the computational efficiency of SBERT sentence embeddings in contrast to other state-of-the-art sentence embedding methods.

2 Related Work

We first introduce BERT, then, we discuss state-of-the-art sentence embedding methods.

BERT (Devlin et al., 2018) is a pre-trained transformer network (Vaswani et al., 2017), which set for various NLP tasks new state-of-the-art results, including question answering, sentence classification, and sentence-pair regression. The input for BERT for sentence-pair regression consists of the two sentences, separated by a special `[SEP]` token. Multi-head attention over 12 (base-model) or 24 layers (large-model) is applied and the output is passed to a simple regression function to derive the final label. Using this setup, BERT set a new state-of-the-art performance on the Semantic Textual Semilarity (STS) benchmark (Cer et al., 2017). RoBERTa (Liu et al., 2019) showed, that the performance of BERT can further improved by small adaptations to the pre-training process. We also tested XLNet (Yang et al., 2019), but it led in general to worse results than BERT.

A large disadvantage of the BERT network structure is that no independent sentence embeddings are computed, which makes it difficult to derive sentence embeddings from BERT. To bypass this limitations, researchers passed single sentences through BERT and then derive a fixed sized vector by either averaging the outputs (similar to average word embeddings) or by using the output of the special `CLS` token (for example: May et al. (2019); Zhang et al. (2019); Qiao et al. (2019)). These two options are also provided by the popular bert-as-a-service-repository[3]. Up to our knowledge, there is so far no evaluation if these methods lead to useful sentence embeddings.

Sentence embeddings are a well studied area with dozens of proposed methods. Skip-Thought (Kiros et al., 2015) trains an encoder-decoder architecture to predict the surrounding sentences. InferSent (Conneau et al., 2017) uses labeled data of the Stanford Natural Language Inference dataset (Bowman et al., 2015) and the Multi-Genre NLI dataset (Williams et al., 2018) to train a siamese BiLSTM network with max-pooling over the output. Conneau et al. showed, that InferSent consistently outperforms unsupervised methods like SkipThought. Universal Sentence Encoder (Cer et al., 2018) trains a transformer network and augments unsupervised learning with training on SNLI. Hill et al. (2016) showed, that the task on which sentence embeddings are trained significantly impacts their quality. Previous work (Conneau et al., 2017; Cer et al., 2018) found that the SNLI datasets are suitable for training sentence embeddings. Yang et al. (2018) presented a method to train on conversations from Reddit using siamese DAN and siamese transformer networks, which yielded good results on the STS benchmark dataset.

Humeau et al. (2019) addresses the run-time overhead of the cross-encoder from BERT and present a method (poly-encoders) to compute a score between m context vectors and pre-

[3] https://github.com/hanxiao/bert-as-service/

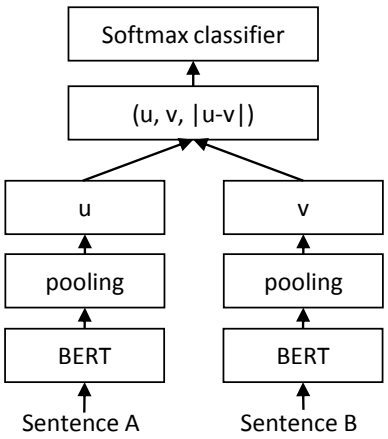

Figure 1: SBERT architecture with classification objective function, e.g., for fine-tuning on SNLI dataset. The two BERT networks have tied weights (siamese network structure).

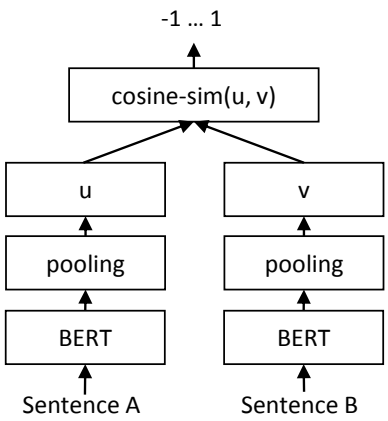

Figure 2: SBERT architecture at inference, for example, to compute similarity scores. This architecture is also used with the regression objective function.

computed candidate embeddings using attention. This idea works for finding the highest scoring sentence in a larger collection. However, poly-encoders have the drawback that the score function is not symmetric and the computational overhead is too large for use-cases like clustering, which would require $O(n^2)$ score computations.

Previous neural sentence embedding methods started the training from a random initialization. In this publication, we use the pre-trained BERT and RoBERTa network and only fine-tune it to yield useful sentence embeddings. This reduces significantly the needed training time: SBERT can be tuned in less than 20 minutes, while yielding better results than comparable sentence embedding methods.

3 Model

SBERT adds a pooling operation to the output of BERT / RoBERTa to derive a fixed sized sentence embedding. We experiment with three pooling strategies: Using the output of the `CLS`-token, computing the mean of all output vectors (`MEAN`-strategy), and computing a max-over-time of the output vectors (`MAX`-strategy). The default configuration is `MEAN`.

In order to fine-tune BERT / RoBERTa, we create siamese and triplet networks (Schroff et al., 2015) to update the weights such that the produced sentence embeddings are semantically meaningful and can be compared with cosine-similarity.

The network structure depends on the available training data. We experiment with the following structures and objective functions.

Classification Objective Function. We concatenate the sentence embeddings u and v with the element-wise difference $|u-v|$ and multiply it with the trainable weight $W_t \in \mathbb{R}^{3n \times k}$:

$$o = \text{softmax}(W_t(u, v, |u - v|))$$

where n is the dimension of the sentence embeddings and k the number of labels. We optimize cross-entropy loss. This structure is depicted in Figure 1.

Regression Objective Function. The cosine-similarity between the two sentence embeddings u and v is computed (Figure 2). We use mean-squared-error loss as the objective function.

Triplet Objective Function. Given an anchor sentence a, a positive sentence p, and a negative sentence n, triplet loss tunes the network such that the distance between a and p is smaller than the distance between a and n. Mathematically, we minimize the following loss function:

$$max(||s_a - s_p|| - ||s_a - s_n|| + \epsilon, 0)$$

with s_x the sentence embedding for $a/n/p$, $||\cdot||$ a distance metric and margin ϵ. Margin ϵ ensures that s_p is at least ϵ closer to s_a than s_n. As metric we use Euclidean distance and we set $\epsilon = 1$ in our experiments.

3.1 Training Details

We train SBERT on the combination of the SNLI (Bowman et al., 2015) and the Multi-Genre NLI

Table 1: Spearman rank correlation ρ between the cosine similarity of sentence representations and the gold labels for various Textual Similarity (STS) tasks. Performance is reported by convention as $\rho \times 100$. STS12-STS16: SemEval 2012-2016, STSb: STSbenchmark, SICK-R: SICK relatedness dataset.

(Williams et al., 2018) dataset. The SNLI is a collection of 570,000 sentence pairs annotated with the labels *contradiction*, *eintailment*, and *neutral*. MultiNLI contains 430,000 sentence pairs and covers a range of genres of spoken and written text. We fine-tune SBERT with a 3-way softmax-classifier objective function for one epoch. We used a batch-size of 16, Adam optimizer with learning rate $2e{-}5$, and a linear learning rate warm-up over 10% of the training data. Our default pooling strategy is `MEAN`.

4 Evaluation - Semantic Textual Similarity

We evaluate the performance of SBERT for common Semantic Textual Similarity (STS) tasks. State-of-the-art methods often learn a (complex) regression function that maps sentence embeddings to a similarity score. However, these regression functions work pair-wise and due to the combinatorial explosion those are often not scalable if the collection of sentences reaches a certain size. Instead, we always use cosine-similarity to compare the similarity between two sentence embeddings. We ran our experiments also with negative Manhatten and negative Euclidean distances as similarity measures, but the results for all approaches remained roughly the same.

4.1 Unsupervised STS

We evaluate the performance of SBERT for STS without using any STS specific training data. We use the STS tasks 2012 - 2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), the STS benchmark (Cer et al., 2017), and the SICK-Relatedness dataset (Marelli et al., 2014). These datasets provide labels between 0 and 5 on the semantic relatedness of sentence pairs. We showed in (Reimers et al., 2016) that Pearson correlation is badly suited for STS. Instead, we compute the Spearman's rank correlation between the cosine-similarity of the sentence embeddings and the gold labels. The setup for the other sentence embedding methods is equivalent, the similarity is computed by cosine-similarity. The results are depicted in Table 1.

The results shows that directly using the output of BERT leads to rather poor performances. Averaging the BERT embeddings achieves an average correlation of only 54.81, and using the `CLS`-token output only achieves an average correlation of 29.19. Both are worse than computing average GloVe embeddings.

Using the described siamese network structure and fine-tuning mechanism substantially improves the correlation, outperforming both InferSent and Universal Sentence Encoder substantially. The only dataset where SBERT performs worse than Universal Sentence Encoder is SICK-R. Universal Sentence Encoder was trained on various datasets, including news, question-answer pages and discussion forums, which appears to be more suitable to the data of SICK-R. In contrast, SBERT was pre-trained only on Wikipedia (via BERT) and on NLI data.

While RoBERTa was able to improve the performance for several supervised tasks, we only observe minor difference between SBERT and SRoBERTa for generating sentence embeddings.

4.2 Supervised STS

The STS benchmark (STSb) (Cer et al., 2017) provides is a popular dataset to evaluate supervised STS systems. The data includes 8,628 sentence pairs from the three categories *captions*, *news*, and *forums*. It is divided into train (5,749), dev (1,500) and test (1,379). BERT set a new state-of-the-art performance on this dataset by passing both sentences to the network and using a simple regres-

sion method for the output.

Model	Spearman
Not trained for STS	
Avg. GloVe embeddings	58.02
Avg. BERT embeddings	46.35
InferSent - GloVe	68.03
Universal Sentence Encoder	74.92
SBERT-NLI-base	77.03
SBERT-NLI-large	79.23
Trained on STS benchmark dataset	
BERT-STSb-base	84.30 ± 0.76
SBERT-STSb-base	84.67 ± 0.19
SRoBERTa-STSb-base	**84.92** ± 0.34
BERT-STSb-large	**85.64** ± 0.81
SBERT-STSb-large	84.45 ± 0.43
SRoBERTa-STSb-large	85.02 ± 0.76
Trained on NLI data + STS benchmark data	
BERT-NLI-STSb-base	**88.33** ± 0.19
SBERT-NLI-STSb-base	85.35 ± 0.17
SRoBERTa-NLI-STSb-base	84.79 ± 0.38
BERT-NLI-STSb-large	**88.77** ± 0.46
SBERT-NLI-STSb-large	86.10 ± 0.13
SRoBERTa-NLI-STSb-large	86.15 ± 0.35

Table 2: Evaluation on the STS benchmark test set. BERT systems were trained with 10 random seeds and 4 epochs. SBERT was fine-tuned on the STSb dataset, SBERT-NLI was pretrained on the NLI datasets, then fine-tuned on the STSb dataset.

We use the training set to fine-tune SBERT using the regression objective function. At prediction time, we compute the cosine-similarity between the sentence embeddings. All systems are trained with 10 random seeds to counter variances (Reimers and Gurevych, 2018).

The results are depicted in Table 2. We experimented with two setups: Only training on STSb, and first training on NLI, then training on STSb. We observe that the later strategy leads to a slight improvement of 1-2 points. This two-step approach had an especially large impact for the BERT cross-encoder, which improved the performance by 3-4 points. We do not observe a significant difference between BERT and RoBERTa.

4.3 Argument Facet Similarity

We evaluate SBERT on the Argument Facet Similarity (AFS) corpus by Misra et al. (2016). The AFS corpus annotated 6,000 sentential argument pairs from social media dialogs on three controversial topics: *gun control*, *gay marriage*, and *death penalty*. The data was annotated on a scale from 0 ("different topic") to 5 ("completely equivalent"). The similarity notion in the AFS corpus is fairly different to the similarity notion in the STS datasets from SemEval. STS data is usually descriptive, while AFS data are argumentative excerpts from dialogs. To be considered similar, arguments must not only make similar claims, but also provide a similar reasoning. Further, the lexical gap between the sentences in AFS is much larger. Hence, simple unsupervised methods as well as state-of-the-art STS systems perform badly on this dataset (Reimers et al., 2019).

We evaluate SBERT on this dataset in two scenarios: 1) As proposed by Misra et al., we evaluate SBERT using 10-fold cross-validation. A drawback of this evaluation setup is that it is not clear how well approaches generalize to different topics. Hence, 2) we evaluate SBERT in a cross-topic setup. Two topics serve for training and the approach is evaluated on the left-out topic. We repeat this for all three topics and average the results.

SBERT is fine-tuned using the Regression Objective Function. The similarity score is computed using cosine-similarity based on the sentence embeddings. We also provide the Pearson correlation r to make the results comparable to Misra et al. However, we showed (Reimers et al., 2016) that Pearson correlation has some serious drawbacks and should be avoided for comparing STS systems. The results are depicted in Table 3.

Unsupervised methods like tf-idf, average GloVe embeddings or InferSent perform rather badly on this dataset with low scores. Training SBERT in the 10-fold cross-validation setup gives a performance that is nearly on-par with BERT.

However, in the cross-topic evaluation, we observe a performance drop of SBERT by about 7 points Spearman correlation. To be considered similar, arguments should address the same claims and provide the same reasoning. BERT is able to use attention to compare directly both sentences (e.g. word-by-word comparison), while SBERT must map individual sentences from an unseen topic to a vector space such that arguments with similar claims and reasons are close. This is a much more challenging task, which appears to require more than just two topics for training to work on-par with BERT.

4.4 Wikipedia Sections Distinction

Dor et al. (2018) use Wikipedia to create a thematically fine-grained train, dev and test set for sentence embeddings methods. Wikipedia articles are separated into distinct sections focusing on certain aspects. Dor et al. assume that sen-

Model	r	ρ
Unsupervised methods		
tf-idf	46.77	42.95
Avg. GloVe embeddings	32.40	34.00
InferSent - GloVe	27.08	26.63
10-fold Cross-Validation		
SVR (Misra et al., 2016)	63.33	-
BERT-AFS-base	77.20	74.84
SBERT-AFS-base	76.57	74.13
BERT-AFS-large	78.68	76.38
SBERT-AFS-large	77.85	75.93
Cross-Topic Evaluation		
BERT-AFS-base	58.49	57.23
SBERT-AFS-base	52.34	50.65
BERT-AFS-large	62.02	60.34
SBERT-AFS-large	53.82	53.10

Table 3: Average Pearson correlation r and average Spearman's rank correlation ρ on the Argument Facet Similarity (AFS) corpus (Misra et al., 2016). Misra et al. proposes 10-fold cross-validation. We additionally evaluate in a cross-topic scenario: Methods are trained on two topics, and are evaluated on the third topic.

tences in the same section are thematically closer than sentences in different sections. They use this to create a large dataset of weakly labeled sentence triplets: The anchor and the positive example come from the same section, while the negative example comes from a different section of the same article. For example, from the Alice Arnold article: Anchor: *Arnold joined the BBC Radio Drama Company in 1988.*, positive: *Arnold gained media attention in May 2012.*, negative: *Balding and Arnold are keen amateur golfers.*

We use the dataset from Dor et al. We use the Triplet Objective, train SBERT for one epoch on the about 1.8 Million training triplets and evaluate it on the 222,957 test triplets. Test triplets are from a distinct set of Wikipedia articles. As evaluation metric, we use accuracy: Is the positive example closer to the anchor than the negative example?

Results are presented in Table 4. Dor et al. fine-tuned a BiLSTM architecture with triplet loss to derive sentence embeddings for this dataset. As the table shows, SBERT clearly outperforms the BiLSTM approach by Dor et al.

5 Evaluation - SentEval

SentEval (Conneau and Kiela, 2018) is a popular toolkit to evaluate the quality of sentence embeddings. Sentence embeddings are used as features for a logistic regression classifier. The logistic regression classifier is trained on various tasks in a 10-fold cross-validation setup and the prediction accuracy is computed for the test-fold.

Model	Accuracy
mean-vectors	0.65
skip-thoughts-CS	0.62
Dor et al.	0.74
SBERT-WikiSec-base	0.8042
SBERT-WikiSec-large	**0.8078**
SRoBERTa-WikiSec-base	0.7945
SRoBERTa-WikiSec-large	0.7973

Table 4: Evaluation on the Wikipedia section triplets dataset (Dor et al., 2018). SBERT trained with triplet loss for one epoch.

The purpose of SBERT sentence embeddings are not to be used for transfer learning for other tasks. Here, we think fine-tuning BERT as described by Devlin et al. (2018) for new tasks is the more suitable method, as it updates all layers of the BERT network. However, SentEval can still give an impression on the quality of our sentence embeddings for various tasks.

We compare the SBERT sentence embeddings to other sentence embeddings methods on the following seven SentEval transfer tasks:

- **MR**: Sentiment prediction for movie reviews snippets on a five start scale (Pang and Lee, 2005).
- **CR**: Sentiment prediction of customer product reviews (Hu and Liu, 2004).
- **SUBJ**: Subjectivity prediction of sentences from movie reviews and plot summaries (Pang and Lee, 2004).
- **MPQA**: Phrase level opinion polarity classification from newswire (Wiebe et al., 2005).
- **SST**: Stanford Sentiment Treebank with binary labels (Socher et al., 2013).
- **TREC**: Fine grained question-type classification from TREC (Li and Roth, 2002).
- **MRPC**: Microsoft Research Paraphrase Corpus from parallel news sources (Dolan et al., 2004).

The results can be found in Table 5. SBERT is able to achieve the best performance in 5 out of 7 tasks. The average performance increases by about 2 percentage points compared to InferSent as well as the Universal Sentence Encoder. Even though transfer learning is not the purpose of SBERT, it outperforms other state-of-the-art sentence embeddings methods on this task.

Model	MR	CR	SUBJ	MPQA	SST	TREC	MRPC	Avg.
Avg. GloVe embeddings	77.25	78.30	91.17	87.85	80.18	83.0	72.87	81.52
Avg. fast-text embeddings	77.96	79.23	91.68	87.81	82.15	83.6	74.49	82.42
Avg. BERT embeddings	78.66	86.25	94.37	88.66	84.40	92.8	69.45	84.94
BERT CLS-vector	78.68	84.85	94.21	88.23	84.13	91.4	71.13	84.66
InferSent - GloVe	81.57	86.54	92.50	**90.38**	84.18	88.2	75.77	85.59
Universal Sentence Encoder	80.09	85.19	93.98	86.70	86.38	**93.2**	70.14	85.10
SBERT-NLI-base	83.64	89.43	94.39	89.86	88.96	89.6	**76.00**	87.41
SBERT-NLI-large	**84.88**	**90.07**	**94.52**	90.33	**90.66**	87.4	75.94	**87.69**

Table 5: Evaluation of SBERT sentence embeddings using the SentEval toolkit. SentEval evaluates sentence embeddings on different sentence classification tasks by training a logistic regression classifier using the sentence embeddings as features. Scores are based on a 10-fold cross-validation.

It appears that the sentence embeddings from SBERT capture well sentiment information: We observe large improvements for all sentiment tasks (MR, CR, and SST) from SentEval in comparison to InferSent and Universal Sentence Encoder.

The only dataset where SBERT is significantly worse than Universal Sentence Encoder is the TREC dataset. Universal Sentence Encoder was pre-trained on question-answering data, which appears to be beneficial for the question-type classification task of the TREC dataset.

Average BERT embeddings or using the CLS-token output from a BERT network achieved bad results for various STS tasks (Table 1), worse than average GloVe embeddings. However, for SentEval, average BERT embeddings and the BERT CLS-token output achieves decent results (Table 5), outperforming average GloVe embeddings. The reason for this are the different setups. For the STS tasks, we used cosine-similarity to estimate the similarities between sentence embeddings. Cosine-similarity treats all dimensions equally. In contrast, SentEval fits a logistic regression classifier to the sentence embeddings. This allows that certain dimensions can have higher or lower impact on the classification result.

We conclude that average BERT embeddings / CLS-token output from BERT return sentence embeddings that are infeasible to be used with cosine-similarity or with Manhatten / Euclidean distance. For transfer learning, they yield slightly worse results than InferSent or Universal Sentence Encoder. However, using the described fine-tuning setup with a siamese network structure on NLI datasets yields sentence embeddings that achieve a new state-of-the-art for the SentEval toolkit.

6 Ablation Study

We have demonstrated strong empirical results for the quality of SBERT sentence embeddings. In this section, we perform an ablation study of different aspects of SBERT in order to get a better understanding of their relative importance.

We evaluated different pooling strategies (MEAN, MAX, and CLS). For the classification objective function, we evaluate different concatenation methods. For each possible configuration, we train SBERT with 10 different random seeds and average the performances.

The objective function (classification vs. regression) depends on the annotated dataset. For the classification objective function, we train SBERT-base on the SNLI and the Multi-NLI dataset. For the regression objective function, we train on the training set of the STS benchmark dataset. Performances are measured on the development split of the STS benchmark dataset. Results are shown in Table 6.

	NLI	STSb
Pooling Strategy		
MEAN	**80.78**	**87.44**
MAX	79.07	69.92
CLS	79.80	86.62
Concatenation		
(u, v)	66.04	-
$(\|u - v\|)$	69.78	-
$(u * v)$	70.54	-
$(\|u - v\|, u * v)$	78.37	-
$(u, v, u * v)$	77.44	-
$(u, v, \|u - v\|)$	**80.78**	-
$(u, v, \|u - v\|, u * v)$	80.44	-

Table 6: SBERT trained on NLI data with the classification objective function, on the STS benchmark (STSb) with the regression objective function. Configurations are evaluated on the development set of the STSb using cosine-similarity and Spearman's rank correlation. For the concatenation methods, we only report scores with MEAN pooling strategy.

When trained with the classification objective function on NLI data, the pooling strategy has a rather minor impact. The impact of the concatenation mode is much larger. InferSent (Conneau

et al., 2017) and Universal Sentence Encoder (Cer et al., 2018) both use $(u, v, |u - v|, u * v)$ as input for a softmax classifier. However, in our architecture, adding the element-wise $u * v$ decreased the performance.

The most important component is the element-wise difference $|u - v|$. Note, that the concatenation mode is only relevant for training the softmax classifier. At inference, when predicting similarities for the STS benchmark dataset, only the sentence embeddings u and v are used in combination with cosine-similarity. The element-wise difference measures the distance between the dimensions of the two sentence embeddings, ensuring that similar pairs are closer and dissimilar pairs are further apart.

When trained with the regression objective function, we observe that the pooling strategy has a large impact. There, the `MAX` strategy perform significantly worse than `MEAN` or `CLS`-token strategy. This is in contrast to (Conneau et al., 2017), who found it beneficial for the BiLSTM-layer of InferSent to use `MAX` instead of `MEAN` pooling.

7 Computational Efficiency

Sentence embeddings need potentially be computed for Millions of sentences, hence, a high computation speed is desired. In this section, we compare SBERT to average GloVe embeddings, InferSent (Conneau et al., 2017), and Universal Sentence Encoder (Cer et al., 2018).

For our comparison we use the sentences from the STS benchmark (Cer et al., 2017). We compute average GloVe embeddings using a simple for-loop with python dictionary lookups and NumPy. InferSent[4] is based on PyTorch. For Universal Sentence Encoder, we use the TensorFlow Hub version[5], which is based on TensorFlow. SBERT is based on PyTorch. For improved computation of sentence embeddings, we implemented a smart batching strategy: Sentences with similar lengths are grouped together and are only padded to the longest element in a mini-batch. This drastically reduces computational overhead from padding tokens.

Performances were measured on a server with Intel i7-5820K CPU @ 3.30GHz, Nvidia Tesla V100 GPU, CUDA 9.2 and cuDNN. The results are depicted in Table 7.

Model	CPU	GPU
Avg. GloVe embeddings	6469	-
InferSent	137	1876
Universal Sentence Encoder	67	1318
SBERT-base	44	1378
SBERT-base - smart batching	83	2042

Table 7: Computation speed (sentences per second) of sentence embedding methods. Higher is better.

On CPU, InferSent is about 65% faster than SBERT. This is due to the much simpler network architecture. InferSent uses a single BiLSTM layer, while BERT uses 12 stacked transformer layers. However, an advantage of transformer networks is the computational efficiency on GPUs. There, SBERT with smart batching is about 9% faster than InferSent and about 55% faster than Universal Sentence Encoder. Smart batching achieves a speed-up of 89% on CPU and 48% on GPU. Average GloVe embeddings is obviously by a large margin the fastest method to compute sentence embeddings.

8 Conclusion

We showed that BERT out-of-the-box maps sentences to a vector space that is rather unsuitable to be used with common similarity measures like cosine-similarity. The performance for seven STS tasks was below the performance of average GloVe embeddings.

To overcome this shortcoming, we presented Sentence-BERT (SBERT). SBERT fine-tunes BERT in a siamese / triplet network architecture. We evaluated the quality on various common benchmarks, where it could achieve a significant improvement over state-of-the-art sentence embeddings methods. Replacing BERT with RoBERTa did not yield a significant improvement in our experiments.

SBERT is computationally efficient. On a GPU, it is about 9% faster than InferSent and about 55% faster than Universal Sentence Encoder. SBERT can be used for tasks which are computationally not feasible to be modeled with BERT. For example, clustering of 10,000 sentences with hierarchical clustering requires with BERT about 65 hours, as around 50 Million sentence combinations must be computed. With SBERT, we were able to reduce the effort to about 5 seconds.

Abstract

We consider a document classification problem where document labels are absent but only relevant keywords of a target class and unlabeled documents are given. Although heuristic methods based on pseudo-labeling have been considered, theoretical understanding of this problem has still been limited. Moreover, previous methods cannot easily incorporate well-developed techniques in supervised text classification. In this paper, we propose a theoretically guaranteed learning framework that is simple to implement and has flexible choices of models, e.g., linear models or neural networks. We demonstrate how to optimize the area under the receiver operating characteristic curve (AUC) effectively and also discuss how to adjust it to optimize other well-known evaluation metrics such as the accuracy and F_1-measure. Finally, we show the effectiveness of our framework using benchmark datasets.

1 Introduction

Supervised text classification is a traditional problem in natural language processing that has been studied extensively (Nigam et al., 2000; Sebastiani, 2002; Forman, 2003; Joulin et al., 2016). In this problem, we are given a set of labeled text documents and the goal is to construct a classifier that can classify an unseen document effectively. There are many useful applications for text classification, e.g., sentiment classification (Liu and Zhang, 2012; Medhat et al., 2014), biomedical text mining (Cohen and Hersh, 2005; Huang and Lu, 2015), and social media monitoring (Zeng et al., 2010; Hu and Liu, 2012).

In the real-world, it is impractical to expect that labeled data can always be obtained abundantly. For example, given big data of unlabeled texts, it can be very time-consuming and costly for the labeling task so that we can apply a supervised text classification method. Another example is when the label information is protected due to privacy concerns. These bottlenecks motivate researches on weakly-supervised learning (Zhou, 2017), which focuses on devising a machine learning method that can learn effectively although a lot of labeled data are not accessible.

An alternative is to provide keywords as a hint for classifying a document to a target class. Intuitively, this approach can be much cheaper when the number of documents is huge since the number of keywords does not necessarily grow linearly with the number of documents. *Dataless classification* is a text classification problem where we are given keywords for each class and unlabeled documents (Chang et al., 2008; Song and Roth, 2014; Chen et al., 2015; Li and Yang, 2018). Note that we do not have access to *any* labeled documents.

In this paper, we investigate dataless classification in the situation where only the keywords of the target class are given. We regard documents of a class that we have relevant keywords as positive and others as negative. Unlike dataless classification, we have access to only the keywords of the positive class. This problem setting can be considered more difficult than the traditional one since one can always reduce dataless classification to this problem by ignoring negative keywords. This scenario is also highly relevant when the information about negative classes cannot be explicitly described, e.g., in the information retrieval task, we may only have information about the target class of interest.

This problem setting has already been considered by Jin et al. (2017), where they called it *lightly-supervised one-class classification*. To the best of our knowledge, existing work in dataless classification and lightly-supervised one-class classification neither provide a theoretical guarantee, nor have flexible choices of models and opti-

mization algorithms for this problem.

The goal of this paper is to formalize lightly-supervised one-class classification and develop a reliable and flexible framework to handle this problem effectively. To achieve this goal, we propose a framework that has a theoretical guarantee and allows practitioners to have flexible choices to maximize the performance, e.g., neural network architectures such as convolutional neural networks (Zhang et al., 2015) or recurrent neural networks (Lai et al., 2015). They can also pick an optimization method that is suitable for their model such as Adam (Kingma and Ba, 2014) or AMSGrad (Reddi et al., 2018). These advantages allow us to utilize well-developed supervised-learning text classification methods in our framework.

We point out that the problem of lightly-supervised one-class classification is highly related to binary classification from corrupted labels. Intuitively, the common idea to solve this problem is to use keywords to pseudo-label given documents then performs classification (Jin et al., 2017). However, pseudo-positive and pseudo-negative labels are unreliable since they can be incorrectly labeled. Thus, the learning method should be robust against label corruption. In our framework, we also use relevant keywords to split unlabeled data into two sets. Then, the key idea is to employ a method based on an empirical risk minimization framework (Vapnik, 1998) with a loss function that benefits from a symmetric condition to maximize AUC (Charoenphakdee et al., 2019). We justify the soundness of our method by proving that our proposed framework gives a consistent estimation of the true expected AUC risk as long as the divided two sets have different proportions of positive data. We elucidate this theoretical result by providing an estimation error bound for AUC maximization using a Rademacher complexity measure. Furthermore, we discuss how to adjust our method to optimize other evaluation metrics, which are the accuracy and F_1-measure. We also illustrate that label corruption may cause a classifier to pick a wrong decision boundary and suggest to adjust the threshold on the basis of the proportion of positive data in unlabeled data.

2 Preliminaries

In this section, we introduce the notation, review AUC, and an empirical risk minimization framework for optimizing AUC.

Table 1: Examples of loss functions. A symmetric loss is a loss function such that $\ell(z) + \ell(-z) = K$, where K is a positive constant.

Loss name	$\ell(z)$	Symmetric
Logistic	$\log(1 + e^{-z})$	$\times$
Squared	$(1 - z)^2$	$\times$
Zero-one	$-\frac{1}{2}\mathrm{sign}(z) + \frac{1}{2}$	✓
Sigmoid	$\frac{1}{1+\exp(z)}$	✓

2.1 Notation

Let $\boldsymbol{x} \in \mathcal{X}$ be a pattern in the input space $\mathcal{X}$ and $y \in \{-1, 1\}$ be a label. We denote $g : \mathcal{X} \to \mathbb{R}$ as a prediction function. Let $\mathbb{E}_{\mathrm{P}}[\cdot]$ and $\mathbb{E}_{\mathrm{N}}[\cdot]$ denote the expectation over the class-conditional probability $p(\boldsymbol{x}|y = 1)$ and $p(\boldsymbol{x}|y = -1)$, respectively. Moreover, let π denote a class prior $p(y = 1)$, i.e., the proportion of positive data.

Loss functions that we will discuss in this paper are in the family of margin losses, where a loss receives one argument $\ell : \mathbb{R} \to \mathbb{R}$. This loss family covers a lot of well-known losses (Bartlett et al., 2006), e.g., the logistic loss, squared loss, and hinge loss. We define the zero-one loss as $\ell_{0\text{-}1}(z) = -\frac{1}{2}\mathrm{sign}(z) + \frac{1}{2}$, where $\mathrm{sign}(g(\boldsymbol{x})) = 1$ if $g(\boldsymbol{x}) > 0$, -1 if $g(\boldsymbol{x}) < 0$, and 0 otherwise. Finally, we consider a symmetric loss as a margin loss ℓ_{sym} that satisfies the symmetric condition $\ell_{\mathrm{sym}}(z) + \ell_{\mathrm{sym}}(-z) = K$, where K is a positive constant. Examples of such losses are the zero-one loss and sigmoid loss (Ghosh et al., 2015). Table 1 provides examples of margin losses in binary classification.

2.2 Area under the Receiver Operating Characteristic Curve (AUC)

AUC is an evaluation metric for a bipartite ranking task (Cortes and Mohri, 2004; Menon and Williamson, 2016), where we want to find a function that outputs a higher value for positive data than negative data. Moreover, AUC is also a popular metric for a classifier under class imbalance (Menon et al., 2015). It is also known in the literature of statistics as the Wilcoxon-Mann-Whitney statistic (Mann and Whitney, 1947; Hanley and McNeil, 1982).

Let us consider the AUC risk, i.e., *bipartite ranking risk* (Narasimhan and Agarwal, 2013):

$$R^{\ell_{0\text{-}1}}_{\mathrm{AUC}}(g) = \mathbb{E}_{\mathrm{P}}\left[\mathbb{E}_{\mathrm{N}}\left[\ell_{0\text{-}1}(g(\boldsymbol{x}^{\mathrm{P}}_i) - g(\boldsymbol{x}^{\mathrm{N}}_j))\right]\right]. \quad (1)$$

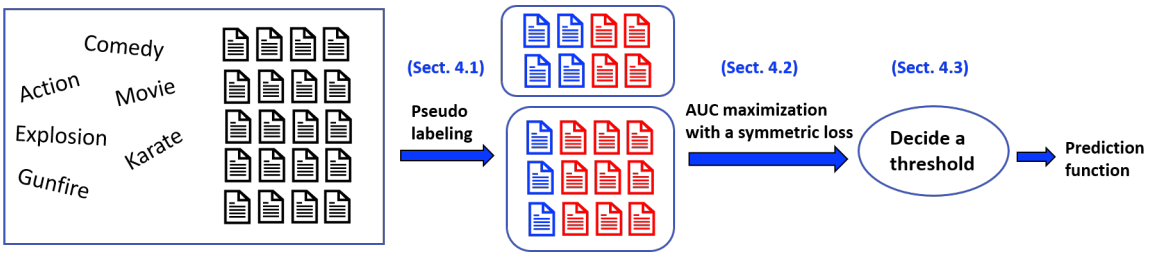

Figure 1: An overview of the framework. Blue documents indicates clean positive data and red documents denote clean negative data in the two sets of data divided by the pseudo-labeling algorithm. Note that labels are not observed by the framework. Sect. denotes a section that describes the procedure for each step.

Then, AUC is defined as $\mathrm{AUC}(g) = 1 - R^{\ell_{0\text{-}1}}_{\mathrm{AUC}}(g)$. It is important to note that unlike many other evaluation metrics, we can evaluate AUC without deciding the threshold for a function g. In this paper, we will show that optimizing AUC in our problem setting has a great advantage when no information about the threshold is given since we only have keywords and unlabeled documents.

2.3 Empirical Risk Minimization (ERM) for AUC Maximization

Here, we review a widely used framework in machine learning called the ERM framework (Vapnik, 1998) for AUC maximization.

The goal of AUC maximization is to minimize the AUC risk in (1) with respect to the zero-one loss $R^{\ell_{0\text{-}1}}_{\mathrm{AUC}}(g)$ (Menon and Williamson, 2016).

Although the goal is to minimize the bipartite ranking risk with respect to the zero-one loss $\ell_{0\text{-}1}$, a surrogate loss ℓ, e.g., the logistic loss or the squared loss, is instead applied in practice since minimizing $\ell_{0\text{-}1}$ is computationally infeasible (Ben-David et al., 2003; Zhang, 2004; Bartlett et al., 2006; Feldman et al., 2012). Note that we cannot directly minimize the AUC risk in our setting since we do not have access to the positive and negative distributions.

To explain the ERM framework for bipartite ranking, in this section, let us assume that we are given positive data $\{\boldsymbol{x}^{\mathrm{P}}_i\}_{i=1}^{n_{\mathrm{P}}}$ and negative data $\{\boldsymbol{x}^{\mathrm{N}}_j\}_{j=1}^{n_{\mathrm{N}}}$ drawn from the class-conditional probability densities $p(\boldsymbol{x}|y=1)$ and $p(\boldsymbol{x}|y=-1)$, respectively. Having access to positive and negative data, the ERM framework suggests us to minimize the following empirical risk (Yan et al., 2003; Cortes and Mohri, 2004):

$$\hat{R}^{\ell}_{\mathrm{AUC}}(g) = \frac{1}{n_{\mathrm{P}} n_{\mathrm{N}}} \sum_{i=1}^{n_{\mathrm{P}}} \sum_{j=1}^{n_{\mathrm{N}}} \ell(g(\boldsymbol{x}^{\mathrm{P}}_i) - g(\boldsymbol{x}^{\mathrm{N}}_j)). \tag{2}$$

With the given training data and a surrogate loss ℓ, we can minimize $\hat{R}^{\ell}_{\mathrm{AUC}}(g)$. This risk estimator $\hat{R}^{\ell}_{\mathrm{AUC}}(g)$ is an unbiased and consistent estimator of the true AUC risk (1), which means it converges to the true AUC risk as the number of data increases (Yan et al., 2003; Herschtal and Raskutti, 2004; Gao and Zhou, 2015).

Note that in practice, it is common to apply a regularization method for controlling the bias-variance trade-off of the estimator to avoid overfitting. In this paper, we adopt the ERM framework for minimizing the AUC risk. Note that one challenge of our problem is that we cannot apply the standard AUC risk directly since we have no access to any labeled data.

3 Problem Formulation

In this section, we formulate the problem of learning from keywords and unlabeled data. We are given a set of relevant keywords $W := \{w_j\}_{j=1}^{n_{\mathrm{W}}}$, and unlabeled documents drawn from the following distribution:

$$X_{\mathrm{U}} := \{\boldsymbol{x}^{\mathrm{U}}_i\}_{i=1}^{n_{\mathrm{U}}} \overset{\text{i.i.d.}}{\sim} p_{\pi}(\boldsymbol{x}),$$

where

$$p_{\pi}(\boldsymbol{x}) = \pi p(\boldsymbol{x}|y=1) + (1-\pi)\, p(\boldsymbol{x}|y=-1).$$

The evaluation metric defines the goal of this problem. For example, if we want a ranking function that outputs a large value for positive data, and small otherwise, the well-known evaluation metric is AUC (Agarwal et al., 2005). We will discuss other evaluation metrics, which are the accuracy and F_1-measure in Section 4.3.

4 Proposed Framework

In this section, we propose a novel framework for handling this problem systematically. The framework consists of three parts. First, we use relevant

keywords to extract pseudo-positive data from the unlabeled data. Then, we employ a symmetric loss function for AUC optimization within the empirical risk minimization framework. Finally, we adjust the threshold of a trained AUC maximizer to further optimize other evaluation metrics. Figure 1 shows an overview of our framework.

4.1 Pseudo-labeling

Here, we propose a simple pseudo-labeling method. We want to emphasize that we do not expect that a pseudo-labeling algorithm is perfect, i.e., pseudo-positive documents may contain negative documents. In Section 4.2, we show that it is possible to maximize AUC effectively even though the labels are highly corrupted.

Since we focus on proposing a general framework that can be used in a wide range of text classification tasks, we use a simple pseudo-labeling method. In practice, one can incorporate prior knowledge such as the specific characteristic of documents to develop a sophisticated and potentially better pseudo-labeling algorithm to further enhance the performance. Our simple pseudo-labeling method is a ranking score based on the document similarities with the cosine similarity between unlabeled documents and keywords. Although we assume some keywords are given, it is hard to guarantee that the given keywords are sufficient to learn effectively. Hence, it is reasonable to sample more similar words to given keywords. In this paper, we used the GloVe model to find similar words (Pennington et al., 2014). With a sufficient number of keywords, we calculate the cosine similarity between the set of extended keywords set and each unlabeled document by simply merging all keywords and extended keywords into one document and measure the similarity between this keyword document and each unlabeled document. Finally, we pseudo-label documents to positive if their cosine similarities are in the top-ϕ%.

Algorithm 1: A pseudo-labeling algorithm

Input: Unlabeled documents $\{\boldsymbol{x}_i^{\mathrm{U}}\}_{i=1}^{n_{\mathrm{U}}}$, keyword set $W := \{w_j\}_{j=1}^{n_{\mathrm{W}}}$, threshold $\phi \in [0, 100]$, weight of original keywords $\alpha \in \mathbb{N}$, sampling factor $\gamma \in \mathbb{N}$.

Output: two sets of pseudo-labeled documents X_{CP} and X_{CN}

$X_{\mathrm{CP}} := \{\}$; $X_{\mathrm{CN}} := \{\}$

foreach w_j **do**
  Add additional (α-1) of w_j to W;
  Find top-γ similar words to w_j $W_{sim} := \{w_j^i\}_{i=1}^{\gamma}$;
  Add W_{sim} to W;
end

Compute similarity s_i between one document that merges all keywords $W = \{w_j\}_{j=1}^{(\alpha+\gamma)n_{\mathrm{W}}}$ and each document $\boldsymbol{x}_i^{\mathrm{U}}$;

foreach $\boldsymbol{x}_i^{\mathrm{U}}$ **do**
  if $s_i > 0$ *and in the top-ϕ(%)* **then**
    Add $\boldsymbol{x}_i^{\mathrm{U}}$ to X_{CP};
  else
    Add $\boldsymbol{x}_i^{\mathrm{U}}$ to X_{CN};
  end
end

return X_{CP}, X_{CN}

4.2 AUC Optimization from Corrupted Labels

After applying Algorithm 1, we can obtain two sets of data, which we call them a corrupted positive set and a corrupted negative set. Let us define θ, $\theta' \in [0, 1]$, which indicate the proportion of positive data for the corrupted positive and negative sets, respectively. We assume a mild condition that our pseudo-labeling method can split the data such that the corrupted positive set has a higher proportion of positive data than another set, i.e., $\theta > \theta'$. Then, we formulate the data from the two sets as

$$X_{\mathrm{CP}} := \{\boldsymbol{x}_i^{\mathrm{CP}}\}_{i=1}^{n_{\mathrm{CP}}} \overset{\text{i.i.d.}}{\sim} p_\theta(\boldsymbol{x}),$$
$$X_{\mathrm{CN}} := \{\boldsymbol{x}_j^{\mathrm{CN}}\}_{j=1}^{n_{\mathrm{CN}}} \overset{\text{i.i.d.}}{\sim} p_{\theta'}(\boldsymbol{x}),$$

where

$$p_\theta(\boldsymbol{x}) := \theta p(\boldsymbol{x}|y=1) + (1-\theta)p(\boldsymbol{x}|y=-1),$$
$$p_{\theta'}(\boldsymbol{x}) := \theta' p(\boldsymbol{x}|y=1) + (1-\theta')p(\boldsymbol{x}|y=-1).$$

X_{CP} and X_{CN} are the sets of corrupted positive and corrupted negative data, respectively. We utilize the fact that optimizing AUC can be performed effectively even when the data is highly corrupted by using a symmetric loss function (Charoenphakdee et al., 2019). More specifically, let us consider a corrupted AUC risk. First, let us define $\mathbb{E}_\theta$ and $\mathbb{E}_{\theta'}$ as the expectation over p_θ and $p_{\theta'}$, respectively. A corrupted AUC risk is defined as

$$R^{\ell}_{\text{AUC-Corr}}(g) = \mathbb{E}_\theta[\mathbb{E}_{\theta'}[\ell(g(\boldsymbol{x}) - g(\boldsymbol{x}'))]]. \quad (3)$$

Intuitively, the risk (3) is minimized by a function g that gives a higher value on corrupted positive data over corrupted negative data. The following theorem establishes the relationship between the clean AUC risk and corrupted AUC risk.

Theorem 1 (Charoenphakdee et al. (2019))**.** *Let* $\varphi^{\ell}(\boldsymbol{x}, \boldsymbol{x}') = \ell(g(\boldsymbol{x}) - g(\boldsymbol{x}')) + \ell(g(\boldsymbol{x}') - g(\boldsymbol{x}))$. *Then* $R^{\ell}_{\text{AUC-Corr}}(g)$ *can be expressed as*

$$
\begin{aligned}
R^{\ell}_{\text{AUC-Corr}}(g) &= (\pi - \pi') R^{\ell}_{\text{AUC}}(g) \\
&+ \underbrace{(1-\pi)\pi' \mathbb{E}_{\mathrm{P}}[\mathbb{E}_{\mathrm{N}}[\varphi^{\ell}(\boldsymbol{x}^{\mathrm{P}}, \boldsymbol{x}^{\mathrm{N}})]]}_{\text{Excessive term}} \\
&+ \underbrace{\frac{\pi\pi'}{2} \mathbb{E}_{\mathrm{P}'}[\mathbb{E}_{\mathrm{P}}[\varphi^{\ell}(\boldsymbol{x}^{\mathrm{P}'}, \boldsymbol{x}^{\mathrm{P}})]]}_{\text{Excessive term}} \\
&+ \underbrace{\frac{(1-\pi)(1-\pi')}{2} \mathbb{E}_{\mathrm{N}'}[\mathbb{E}_{\mathrm{N}}[\varphi^{\ell}(\boldsymbol{x}^{\mathrm{N}'}, \boldsymbol{x}^{\mathrm{N}})]]}_{\text{Excessive term}}.
\end{aligned}
$$

Theorem 1 shows that minimizing the corrupted risk $R^{\ell}_{\text{AUC-Corr}}(g)$ implies minimizing both the clean risk $R^{\ell}_{\text{AUC}}(g)$ and excessive terms. However, since we only aim to minimize the clean risk, minimizing the corrupted risk may not effectively minimize the clean risk since excessive terms can be minimized instead and lead to overfitting. Charoenphakdee et al. (2019) showed that with a specific class of losses, excessive terms become constant. The following theorem suggests that by using a family of symmetric losses, the corrupted AUC risk can be expressed as an affine transformation of the clean AUC risk.

Theorem 2 (Charoenphakdee et al. (2019))**.** *Let* ℓ_{sym} *be a symmetric loss such that* $\ell_{\text{sym}}(z) + \ell_{\text{sym}}(-z) = K$, *where* K *is a positive constant. Then,* $R^{\ell_{\text{sym}}}_{\text{AUC-Corr}}(g)$ *can be expressed as*

$$
\begin{aligned}
R^{\ell_{\text{sym}}}_{\text{AUC-Corr}}(g) &= (\theta - \theta') R^{\ell_{\text{sym}}}_{\text{AUC}}(g) \\
&+ \frac{K(1 - \theta + \theta')}{2}.
\end{aligned}
$$

According to Theorem 2, we can optimize AUC by using a symmetric loss *without estimating* θ *and* θ' and do not suffer from excessive terms. This insight was also suggested by Menon et al. (2015), but they focused on more general losses, while it has been shown that using a symmetric loss can be preferable (Charoenphakdee et al., 2019). Our experiments also support that using a symmetric loss is preferable, while using a non-symmetric loss still provided reasonable performance. Similarly to AUC, we can also maximize the balanced accuracy effectively with a symmetric loss (see van Rooyen et al. (2015); Charoenphakdee et al. (2019) for more details on the balanced accuracy). Since the result of Charoenphakdee et al. (2019) only suggests that the minimizer of the corrupted risk and clean risk are identical, we provide a theory to explain why a more accurate pseudo-labeling algorithm can improve the performance by proving an estimation error bound in Section 5.

4.3 Optimizing Accuracy and F_1-measure

Here, we review other evaluation metrics and discuss how to adjust our framework for optimizing other evaluation metrics. Many evaluation metrics can be optimized if a suitable threshold and $p(y = 1|\boldsymbol{x})$ are known (Yan et al., 2018), e.g., $\operatorname{sign}[p(y = 1|x) - \frac{1}{2}]$ is the Bayes-optimal solution for the accuracy. It is known that the Bayes-optimal solution of AUC maximization is any function that has a strictly monotonic relationship with $p(y = 1|\boldsymbol{x})$ (Menon and Williamson, 2016). Therefore, finding an appropriate threshold with an AUC maximizer can give an effective classifier (Narasimhan and Agarwal, 2013).

For the accuracy and F_1-measure, we propose to optimize AUC first and then adjust the threshold to optimize other metrics. It is important to emphasize that a big challenge behind this problem is that *there is no information about the threshold from given data since all given data are unlabeled.*

Without additional assumptions, we argue that it is *theoretically impossible* to draw an optimal threshold to optimize the accuracy and F_1-measure for this problem. Unlike supervised-learning, where we have positive and negative data, the threshold information is provided from labels and we can draw the decision boundary accordingly. On the other hand, one can learn a bipartite ranking function effectively by AUC optimization in our setting, which suggests the idea to learn a reliable ranking function first, and then adjust the threshold.

Suppose that we know the proportion of positive data π in the training data and the class prior of the training and test data are identical. A reasonable threshold $\beta \in \mathbb{R}$ can be given as

$$
\pi = \int \operatorname{sign}(g(\boldsymbol{x}) - \beta) p_{\pi}(\boldsymbol{x}) d\boldsymbol{x}. \tag{4}
$$

Intuitively, we use a threshold β that decides the top proportion π as positives and negative oth-

erwise, which can optimize the accuracy effectively. This threshold is known as a precision-recall breakeven point, where it is the point where the precision equals to recall (see Kato et al. (2019) for its proof). Therefore, it is a reasonable threshold for the F_1-measure since it is a harmonic mean of precision and recall. With unlabeled documents and π, we can decide β that satisfies the empirical version of Eq. (4).

Existing methods, which may learn a threshold without knowing π, may actually learn a wrong threshold. Table 3 illustrates the failure of a default threshold when learning a classifier in noisy environments and Table 4 shows that much better performance on F_1-measure and accuracy can be recover by adjusting the threshold with Eq. (4). Regarding the assumption that training and test class priors are identical, it is the common assumption if we want to use these metrics for evaluation and is implicitly assumed in the existing work (Jin et al., 2017). If the class priors are not identical, we suggest not to use these metrics since it can be misleading because a good F_1-measure in training data cannot guarantee a good F_1-measure in the test data. In real-world applications, such situations may occur when we do not collect unlabeled data directly from the test environment or the test environment is prone to be changed over time. If it is impossible to estimate π or the test condition can be changed, we suggest to use other evaluation metrics such as AUC or precision at k.

5 Theoretical Analysis

In this section, we provide a theoretical guarantee for our method. Although it has been shown that the risk minimizer of corrupted data is identical to that of clean data (Charoenphakdee et al., 2019), the existing work cannot explain why a good pseudo-labeling algorithm can give a better performance. Throughout this section, we assume that an output of a loss function ℓ_{sym} is bounded by $[0, K]$ without loss of generality for a nonnegative symmetric loss. Here, we prove an estimation error bound, which suggests that a larger gap between $\theta - \theta'$ leads to a tighter bound and thus faster convergence. Note that the gap is largest when we have clean positive data (i.e., $\theta = 1$) and clean negative data (i.e., $\theta' = 0$). Therefore, a good pseudo-labeling is an algorithm that can divide the data with a large gap (i.e., $\theta - \theta'$ is large). All proofs can be found in Appendix A.

Let $\hat{g} \in \mathcal{G}$ be a minimizer of the empirical corrupted AUC risk $\widehat{R}^{\ell_{\mathrm{sym}}}_{\text{AUC-Corr}}$ in the hypothesis class $\mathcal{G}$. Let $g^* \in \mathcal{G}$ be a minimizer of the expected risk of clean AUC risk $R^{\ell_{\mathrm{sym}}}_{\mathrm{AUC}}$. Then, the following lemma establishes the relationship between an estimation error bound of the AUC risk and the uniform deviation bound of the corrupted AUC risk.

Lemma 3. *An estimation error bound of the clean AUC risk R^{ℓ}_{AUC} can be given as follows.*

$$R^{\ell_{\mathrm{sym}}}_{\mathrm{AUC}}(\hat{g}) - R^{\ell_{\mathrm{sym}}}_{\mathrm{AUC}}(g^*) \leq \frac{2}{\theta - \theta'} \sup_{g \in \mathcal{G}} |R^{\ell_{\mathrm{sym}}}_{\text{AUC-Corr}}(g) - \widehat{R}^{\ell_{\mathrm{sym}}}_{\text{AUC-Corr}}(g)|.$$

Next, let $\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}$ be a class of functions mapping $\mathcal{X}^2$ to $[0, K]$ such that $\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}} = \{Q : (\boldsymbol{x}, \boldsymbol{x}') \to \ell_{\mathrm{sym}}(g(\boldsymbol{x}) - g(\boldsymbol{x}')), g \in \mathcal{G}\}$. Given samples $(x_1, \ldots, x_n) \in \mathcal{X}^n$ and $(x'_1, \ldots, x'_m) \in \mathcal{X}^m$ independently and identically drawn from a distribution with densities μ and μ', respectively. The empirical bipartite Rademacher complexity (Usunier et al., 2005) of a function class $\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}$ is defined as

$$\hat{\mathfrak{R}}_{n,m}(\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}) = 2\mathbb{E}_{\sigma,\upsilon} \sup_{Q \in \mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}} \frac{1}{nm} \sum_{i=1}^{n} \sum_{j=1}^{m} \frac{\sigma_i + \upsilon_j}{2} \left[Q(\boldsymbol{x}_i, \boldsymbol{x}'_j)\right],$$

where the inner expectation is taken over $\sigma = (\sigma_1, \ldots, \sigma_n)$ and $\upsilon = (\upsilon_1, \ldots, \upsilon_m)$ which are independent random variables taking values in $\{-1, +1\}$ uniformly.

Then, the bipartite Rademacher complexity can be defined as

$$\mathfrak{R}_{n,m}(\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}) = \mathbb{E}_{x_1,\ldots,x_n,x'_1,\ldots,x'_m} \hat{\mathfrak{R}}_{n,m}(\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}).$$

Let $\mathfrak{R}^{\mathrm{Corr}}_{n_{\mathrm{CP}},n_{\mathrm{CN}}}$ be the bipartite Rademacher complexities of pseudo-labeled data where $\mu = p_\theta$ and $\mu' = p'_\theta$. Next, we provide a uniform deviation bound of the corrupted AUC risk.

Lemma 4 (Uniform deviation bound)**.** *For all $Q \in \mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}$ and $\delta \in (0, 1)$, with probability at least $1 - \delta$, we have*

$$\sup_{g \in \mathcal{G}} \left| R^{\ell_{\mathrm{sym}}}_{\text{AUC-Corr}}(g) - \widehat{R}^{\ell_{\mathrm{sym}}}_{\text{AUC-Corr}}(g) \right| \leq K \sqrt{\frac{(n_{\mathrm{CP}} + n_{\mathrm{CN}}) \log \frac{1}{\delta}}{2 n_{\mathrm{CP}} n_{\mathrm{CN}}}} + 2\mathfrak{R}^{\mathrm{Corr}}_{n_{\mathrm{CP}},n_{\mathrm{CN}}}(\mathcal{Q}^{\ell_{\mathrm{sym}}}_{\mathcal{G}}).$$

where the probability is over repeated sampling of data for evaluating $\widehat{R}^{\ell}_{\text{AUC-Corr}}(g)$.

Table 2: Keywords for each dataset

Dataset	Keywords
Subj	wonderful terrible feel happy ugly even horrible interesting funny dramatic romantic compassionate
Custrev	easy excellent nice great good love amazing best awesome perfect definitely better happy compassionate
MPQA	support hope help good great love
AYI	great best excellent friendly awesome nice amazing
20NG	sports baseball hockey

Then, by combining Lemma 3 and Lemma 4, we obtain the following theorem.

Theorem 5 (Estimation error bound)**.** *For all* $Q \in \mathcal{Q}_{\mathcal{G}}^{\ell_{\mathrm{sym}}}$ *and* $\delta \in (0,1)$*, with probability at least* $1-\delta$*, we have*

$$R_{\mathrm{AUC}}^{\ell_{\mathrm{sym}}}(\hat{g}) - R_{\mathrm{AUC}}^{\ell_{\mathrm{sym}}}(g^*) \leq \frac{1}{\theta-\theta'}\left[K\sqrt{\frac{2(n_{\mathrm{CP}}+n_{\mathrm{CN}})\log\frac{1}{\delta}}{n_{\mathrm{CP}}n_{\mathrm{CN}}}}\right] + \frac{4\mathfrak{R}^{\mathrm{Corr}}_{n_{\mathrm{CP}},n_{\mathrm{CN}}}(\mathcal{Q}_{\mathcal{G}}^{\ell_{\mathrm{sym}}})}{\theta-\theta'},$$

where the probability is over repeated sampling of X_{CP} *and* X_{CN} *for training* $\hat{g}$*.*

Theorem 5 shows that a gap $\frac{1}{\theta-\theta'}$ affects the tightness of the bound. When θ and θ' are close to each other, i.e., when the data is highly corrupted, the bound becomes loose. This illustrates the difficulty of the task when pseudo-labeling algorithm performs poorly and we may need more data. Nevertheless, as long as $\theta > \theta'$, with all parametric models with their norm is bounded such as neural networks with weight decay or kernel model, our learning framework is consistent, i.e., the estimation error converges to zero as $n_{\mathrm{CP}}, n_{\mathrm{CN}} \to \infty$.

6 Experimental Results

We present experimental results in this section with evaluation metrics include AUC, macro F_1-measure, accuracy (ACC) and precision at 100 (Prec@100). Prec@100 is the ratio of the true positive data over in the top-100 ranking score.

6.1 Experiment Setup

Datasets: We used five datasets, namely the Subjectivity dataset (Pang and Lee, 2004) (Subj), Customer reviews (Hu and Liu, 2004) (Custrev), Opinion mining in MPQA corpus (MPQA), Product reviews from Amazon, Yelp, and IMDb (AYI), 20 Newsgroups (Lang, 1995) (20NG) with *baseball* and *hockey* groups as positive. More information on the datasets can be found in Appendix B.

Table 3: Failure of optimizing F_1-measure if thresholds are not adjusted. Full results can be found in Appendix C. By adjusting the threshold in Table 4 can substantially improve the performance.

Methods	Subj	MPQA	AYI	20NG
Maxent	63.4 (0.31)	50.1 (0.22)	42.5 (0.35)	47.4 (0.05)
NB	73.7 (0.23)	53.8 (0.22)	65.8 (0.42)	23.7 (0.25)
RandomForest	33.3 (0.00)	43.5 (0.20)	35.0 (0.20)	47.2 (0.00)
KNN	43.6 (0.23)	51.0 (0.16)	61.6 (0.43)	84.3 (0.26)

Keywords for each dataset are shown in Table 2.

Common setup: First, we need to pseudo-label documents. We used Algorithm 1 to feed pseudo-labeled documents to all methods, where ϕ is set to 90. (α, γ) were set to (3,5) for all datasets except Subj, which was (1,50). We used 50-dimensional features for GloVe word embeddings. For ACC and F_1, we gave true thresholds π to all methods to see the top performance of each method. We also provide the results with varying thresholds and heuristic thresholds in Appendix C, where the trends of performance for each method do not differ much from Table 4. Note that AUC and Prec@100 do not use a threshold to evaluate. The experimental results are reported in the mean value and standard error of 20 trials. "N/A" indicates that an algorithm is not terminated due to too many number of vocabularies.

Baselines: We compared our method with three categories of baselines: the text-feature, GloVe-feature, and zero-shot baselines. For the text-feature baselines, we use naive Bayes (NB), the maximum entropy model (Maxent), and naive Bayes that is implemented for learning from positive and unlabeled data (PU-NB). All implementations were from Natural Language Toolkit (NLTK) (Loper and Bird, 2002). For the GloVe-feature baselines, we used mean word vectors as features and employed a random forest (RandomForest) and K-nearest neighbors (KNN), which were implemented by Scikit-learn (Pedregosa et al., 2011). Finally, the zero-shot baselines did not use unlabeled data but simply GloVe to rank the score of a document (GloVeRanking) and keyword voting (Voting). We also showed the performance when fully-labeled data are given as references. O-Maxent is a maxent model with fully-labeled data and O-Sigmoid is our framework that skips the pseudo-labeling step and uses fully-labeled data for AUC optimization.

Proposed methods: For the AUC optimization part, we used the recurrent convolutional

Table 4: Mean value and standard error of 20 trials for the AUC, F_1-measure, accuracy (ACC), and precision at 100 (Prec@100) of learning from relavant keywords and unlabeled documents. Outperforming methods are highlighted in boldface using one-sided t-test with the significance level of 5%. The sigmoid loss is symmetric while the logistic loss is non-symmetric.

neural networks (RCNN) model (Lai et al., 2015) with two layer long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). We used Adam (Kingma and Ba, 2014) as an optimization method. We used the symmetric sigmoid loss (Sigmoid). We also show the results of the non-symmetric logistic loss (Logistic) to validate the improvement from using a symmetric loss. Implementation details are provided in Appendix B.

6.2 End-to-end Classification Performance

Table 4 shows the classification performance. It can be observed that our proposed framework outperforms other baselines in many cases. Moreover, the sigmoid loss (Sigmoid) outperforms the logstic loss (Logistic), which agrees with Theorem 2. Nevertheless, the performance of the logistic loss is desirable compared with baselines. It can be observed that GloveRanking, which does not use unlabeled data can outperform many baselines in 20NG. This can be due to the fact that pseudo-labeling data were corrupted and degraded the performance of a classifier heavily. In Table 4, for MPQA and 20NG, our proposed framework with symmetric losses is able to outperform O-Maxent in the F_1-measure, AUC score, and accuracy without having access to labels. One possible reason that O-Maxent does not perform well on 20NG is class imbalance.

Table 5 shows the accuracy and F_1-measure with varying thresholds. The true class prior of Subj and 20NG were 0.5 and 0.11, respectively. It can be observed that the threshold based on Eq. (4) gives a desirable performance when $\hat{\pi}$ is close to π. For Prec@100, we can see that Prec@100 for 20NG for the sigmoid loss in our framework and RandomForest is 99.5, without any labeled data, which indicates that we may pick top-100 documents as positive with almost perfect precision.

7 Conclusion

We proposed a theoretically-grounded framework for learning from relevant keywords and unlabeled documents. Our framework is highly flexible and can guarantee any heuristic pseudo-labeling method as long as an algorithm can divide unlabeled documents into two sets of data with different proportions of positive data. Experiments showed the usefulness of the proposed method.

Abstract

This paper presents a new sequence-to-sequence (seq2seq) pre-training method PoDA (**P**re-training **o**f **D**enoising **A**utoencoders), which learns representations suitable for text generation tasks. Unlike encoder-only (e.g., BERT) or decoder-only (e.g., OpenAI GPT) pre-training approaches, PoDA jointly pre-trains both the encoder and decoder by denoising the noise-corrupted text, and it also has the advantage of keeping the network architecture unchanged in the subsequent fine-tuning stage. Meanwhile, we design a hybrid model of Transformer and pointer-generator networks as the backbone architecture for PoDA. We conduct experiments on two text generation tasks: abstractive summarization, and grammatical error correction. Results on four datasets show that PoDA can improve model performance over strong baselines without using any task-specific techniques and significantly speed up convergence. [1]

1 Introduction

Methods based on unsupervised pre-training and supervised fine-tuning for NLP have achieved phenomenal successes in the last two years. Most of the proposed methods in the literature choose language modeling or its variant as the pre-training task. After the pre-training stage, ELMo (Peters et al., 2018) and CoVe (McCann et al., 2017) directly use the learned representations as additional features for downstream tasks, while BERT (Devlin et al., 2018), ULMFiT (Howard and Ruder, 2018), XLM (Lample and Conneau, 2019), and OpenAI GPT (Radford et al., 2018, 2019) require fine-tuning both pre-trained parameters and task-specific parameters on labeled data. The state-of-the-art performances have been significantly advanced for classification and sequence labeling tasks, such as natural language inference (Bowman et al., 2015), named-entity recognition, SQuAD question answering (Rajpurkar et al., 2016) etc.

However, little attention has been paid to pre-training for seq2seq text generation (Sutskever et al., 2014). A typical seq2seq network consists of a bidirectional encoder, a unidirectional decoder and attention between the encoder and decoder. Previous work mainly focuses on encoder-only or decoder-only pre-training. For example, BERT pre-trains a bidirectional encoder, and OpenAI GPT pre-trains a language model which is essentially a unidirectional decoder. Ramachandran et al. (2016) propose to train two independent language models for the encoder and decoder respectively. All of the aforementioned methods are only able to partially pre-train the seq2seq networks, and therefore are unable to unleash the full potential of transfer learning for text generation.

In this paper, we present PoDA, a denoising based pre-training method that is able to jointly pre-train all components of seq2seq networks. Like denoising autoencoders, PoDA works by denoising the noise-corrupted text sequences. Any noising function that fits in the seq2seq framework can be used. We experiment with three types of noises: randomly shuffle, delete or replace the words in a given sequence. It is noted PoDA is simple, easy-to-implement and applicable to virtually all seq2seq architectures, including ConvS2S (Gehring et al., 2017) and Transformer (Vaswani et al., 2017). Here, we adopt the hybrid architecture of Transformer and pointer-generator networks (See et al., 2017). Transformer is effective at modeling long-distance dependencies, highly parallelizable and demonstrates good performance empirically. Pointer-generator network incorporates copying mechanism (Gu et al., 2016; Gulcehre et al., 2016) which is helpful for most text

generation tasks.

The text corpora used for pre-training are the Billion Word Benchmark (Chelba et al., 2013) and English Wikipedia, both of which are publicly available and consists of nearly 2.99 billion words in total. We conduct experiments on two abstractive summarization datasets (CNN/Daily Mail (See et al., 2017) and Gigaword (Rush et al., 2015)), and two grammatical error correction datasets (CoNLL-2014 (Ng et al., 2014) and JFLEG (Napoles et al., 2017)). With simple maximum likelihood training and no task-specific techniques, PoDA achieves superior or comparable performance against state-of-the-art systems and speeds up convergence for all four datasets.

2 Method

2.1 Model Architecture

First, we design a seq2seq model as the backbone architecture of our proposed pre-training method, which is a combination of Transformer and pointer-generator networks, as shown in Figure 1.

The input representations are the sum of word embeddings and sinusoidal positional encodings. Both the Transformer encoder and the decoder consist of 6 layers of transformer blocks, and each block is a multi-head self-attention layer followed by one layer of positionwise feedforward network.

For the output layer, we use a pointer-generator layer to allow both copying from the input sequence and generation from a fixed vocabulary. The implementation is detailed in Appendix.

As a side note, we want to point out that the seq2seq architecture is not limited to the one we propose and other networks such as ConvS2S, RNN-based seq2seq models are also applicable. Pointer-generator networks are also not the only solution for handling out-of-vocabulary(OOV) words, and subword-based methods such as sentencepiece (Kudo and Richardson, 2018) can be used at the cost of making the input and output sequences longer.

2.2 Noising and Denoising

Similar to denoising autoencoders, PoDA involves two parts: noising and denoising. The noising part corrupts a given word sequence $\mathbf{x} = \{\mathbf{x}_i\}_{i=1}^{n}$ and gets a noisy word sequence $\mathbf{x}' = \{\mathbf{x}'_i\}_{i=1}^{n'}$. The denoising part tries to recover $\mathbf{x}$ given $\mathbf{x}'$ using a seq2seq model.

We use three noising functions: randomly shuffle, delete or replace the words in $\mathbf{x}$. The details are shown in Algorithm 1, where $N(0, \sigma)$ is a gaussian distribution with mean 0 and variance σ. $B(p)$ is a Bernoulli distribution, and $Beta(\alpha, \beta)$ is a beta distribution serving as the prior for $B(p)$. Take function `DELETE` (line 10 to line 15 in Algorithm 1) as an example, it first samples a Bernoulli distribution with expectation p from $Beta(\alpha, \beta)$, then each word is deleted with probability p. The usage of $Beta(\alpha, \beta)$ prior can make the model robust to different degrees of noises.

We exemplify the operations above in Figure 1. The original word sequence $\mathbf{x}$ = *"The fox jumps over the lazy dog ."*, after three noising operations: delete *"The"*, replace *"jumps"* with *"fly"* and swap *"lazy"* and *"dog"*, we get the noisy word sequence $\mathbf{x}'$ = *"fox fly over the dog lazy ."*.

The denoising part maximizes the conditional probability $p(\mathbf{x}|\mathbf{x}')$, which can be factorized as:

$$p(\mathbf{x}|\mathbf{x}') = \Pi_{i=1}^{n} p(\mathbf{x}_i|\mathbf{x}', \mathbf{x}_{<i}) \quad (1)$$

When predicting $\mathbf{x}_i$, it is conditioned on the noise-corrupted full context $\mathbf{x}'$ and the clean left

Algorithm 1 The Noising Algorithm

Input: $\mathbf{x}$ is a sequence of words
α, β, σ are hyperparameters

function NOISING($\mathbf{x}$)
  Apply SHUFFLE, DELETE, REPLACE to $\mathbf{x}$ in random order
end function

function SHUFFLE($\mathbf{x}$)
  for $i \leftarrow 1$ *to* $len(\mathbf{x})$ **do**
    $indices[i] \leftarrow i + \delta_i \sim N(0, \sigma)$
  end for
  Rearrange $\mathbf{x}$ based on $argsort(indices)$
end function
function DELETE($\mathbf{x}$)
  Sample $p \sim Beta(\alpha, \beta)$
  for w *in* $\mathbf{x}$ **do**
    Delete w if $\mu \sim B(p)$ is 1
  end for
end function
function REPLACE($\mathbf{x}$)
  Sample $p \sim Beta(\alpha, \beta)$
  for w *in* $\mathbf{x}$ **do**
    Replace w with w' sampled from unigram distribution if $\mu \sim B(p)$ is 1
  end for
end function

context $\mathbf{x}_{<i}$. This shows that our seq2seq formulation is capable of unifying both encoder-only pre-training and decoder-only pre-training methods, since a bidirectional language model used by BERT can be seen as simulating $p(\mathbf{x}_i|\mathbf{x}')$, while a traditional unidirectional language model used by OpenAI GPT as resembling $p(\mathbf{x}_i|\mathbf{x}_{<i})$.

Like BERT, we add a mask to the target sequence when computing the loss function. To force the model to learn meaningful representations, instead of copying from the input most of the time, the positions where the corresponding words are corrupted in the input are kept. We also keep a small percentage (3%) of positions where the words are not corrupted, so that the model can learn to copy from the input when appropriate. Then, the training loss with mask is as follows ($\boldsymbol{\Theta}$ is model parameters):

$$L = -\sum_{i=1}^{n} mask(i) \cdot \log p(\mathbf{x}_i|\mathbf{x}', \mathbf{x}_{<i}, \boldsymbol{\Theta}) \quad (2)$$

Empirically, we set $\sigma = 0.5$ for Gaussian distribution. α and β are chosen to have a Beta distribution with mean 0.15 and standard deviation 0.03.

2.3 Pre-training Procedure

Corpus	#words
English Wikipedia	2.22B
Billion Word Benchmark	0.76B
Total	2.99B

Table 1: Text corpora used for pre-training.

For pre-training, we use two text corpora: the full dump of English Wikipedia[2] and the Billion Word Benchmark[3], as shown in Table 1. For English Wikipedia, we remove paragraphs with less than 3 words or more than 30% OOV words, and each paragraph is split into text segments with no more than 128 words for each segment. The Billion Word Benchmark is a sentence-level corpus. Sentences with more than 500 words are ignored during training.

The pre-training is performed on 4 GPUs using synchronous data parallelism, gradients are averaged across different GPUs. Each batch on a single GPU consists of at most 3000 tokens. We pre-train the network for 5 million iterations, which is roughly 14 epochs over the entire dataset. The final perplexity on the validation set is about 6.8. Each epoch takes approximately 2 days. Details on the network hyperparameters and optimizers are given in Section 3.1.

2.4 Fine-tuning Procedure

With our pre-training method, we do not need to change the network architecture during the fine-tuning stage, since both the pre-training task and text generation tasks take a source sequence as input and return a target sequence as output. The network is initialized with pre-trained parameter values. For fine-tuning, the preprocessing is dataset-specific, but the learning rate scheduling, dropout, early stopping, and gradient clipping are exactly the same as pre-training.

The objective function for fine-tuning is the word-level negative log-likelihood. Here we do not use reinforcement learning to tune towards the automatic evaluation metrics such as ROUGE

[2] https://dumps.wikimedia.org/

[3] http://www.statmt.org/lm-benchmark/, we do not use BooksCorpus (Zhu et al., 2015) used by BERT, because it is not publicly available now.

(Lin, 2004) or BLEU (Papineni et al., 2002), because it may overfit evaluation metrics and barely show improvements in human evaluations (Wu et al., 2016).

3 Experiments

3.1 Setup

The network architecture used by our experiments has 97 million parameters. It consists of 6 layers of encoder blocks, 6 layers of decoder blocks, and 1 pointer-generator layer. The hidden size of each positionwise feedforward layer is 4096. We use 8 heads for all multi-head attention layers. The vocabulary consists of the top $50k$ most frequent words (case sensitive), and the dimension of word embedding is 512. We tie the parameters of encoder word embeddings, decoder word embeddings, and the output softmax layer. NAG (Nesterov Accelerated Gradient) optimizer is used with initial learning rate 2×10^{-3}. Dropout of 0.2 is applied for all self-attention layers, positionwise feedforward layers and input embedding layers. The gradient norm is clipped to have a maximum value of 2. We follow the Transformer implementation from *fairseq*[4].

For task-specific fine-tuning, unless explicitly specified, we reuse the hyperparameters from the pre-training stage. After each training epoch, we compute the validation loss and halve the learning rate whenever the validation loss stops decreasing. The training procedure terminates if the learning rate drops below 10^{-4}. Exponential moving average (EMA) with decay rate 0.9995 is used to make the training stabilized. At inference time, we use standard beam search decoding based on the length-normalized log-likelihood. For ensemble models, we use different random seeds and pre-trained checkpoints for fine-tuning. Ensemble decoding is used by averaging the output probabilities from different models at every decoding step.

When reporting experimental results, *"PoDA w/o pre-training"* refers to the proposed architecture in Section 2.1 trained only on the supervised data, and *"PoDA w/o fine-tuning"* only pre-trains on unlabeled data. *PoDA* first pre-trains a denoising autoencoder and then fine-tunes on the supervised data.

[4] https://github.com/pytorch/fairseq

3.2 Abstractive Summarization

Datasets We use two summarization datasets: CNN/Daily Mail[5] (See et al., 2017) and Gigaword (Rush et al., 2015) dataset. The official split for training, validation, and test is shown in Table 2.

Corpus	# of examples		
	train	valid	test
CNN/Daily Mail	287,113	13,368	11,490
Gigaword	3,803,957	189,651	1,951

Table 2: Dataset statistics for abstractive summarization.

The CNN/Daily Mail dataset contains approximately $300k$ news articles with an average of 781 words for each article, and each article is paired with summaries with 56 words on average. We use the preprocessing script[6] provided by See et al. (2017). The articles are truncated to 800 words for both training and testing. The summaries are truncated to 130 words for training.

The Gigaword is a headline-generation dataset consisting of nearly 4 million examples. Headline generation can be seen as a sentence summarization task. Each example in Gigaword consists of one sentence with an average length of 31.3 words, which is much shorter than CNN/Daily Mail, and one short headline with an average length of 8.3 words. The Gigaword dataset provided by Rush et al. (2015) is already tokenized and lower-cased. Since our vocabulary is case-sensitive, such inconsistency is expected to hurt our system's performance.

Evaluation We report evaluation results in terms of of ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004) using the *pyrouge*[7] package. For the CNN/Daily Mail dataset, PGNet (See et al., 2017), Lead3 (See et al., 2017), rnn-ext + RL (**?**), NeuSum (Zhou et al., 2018) are used as baselines. For the Gigaword dataset, ABS+ (Rush et al., 2015), CGU (Lin et al., 2018), FTSum (Cao et al., 2018b), and Re^{3}Sum (Cao et al., 2018a) are used as baselines.

Results for CNN/Daily Mail Considering the characteristics of news articles, baselines such as Lead3 (simply choose the first 3 sentences) can achieve strong performance in terms of ROUGE

[5] We use the non-anonymized version, which is considered to be more realistic.

[6] https://github.com/abisee/cnn-dailymail

[7] https://github.com/andersjo/pyrouge

System	ROUGE		
	1	2	L
Lead3	40.34	17.70	36.57
PGNet	36.44	15.66	33.42
rnn-ext + RL	41.47	18.72	37.76
NeuSum	41.59	19.01	37.98
PoDA w/o pre-training	40.82	18.46	37.61
PoDA	**41.87**	**19.27**	**38.54**

Table 3: ROUGE scores for CNN/Daily Mail dataset.

scores, as shown in Table 3. "rnn-ext+RL" combines both extractive and abstractive methods and achieves performance improvements (**?**). PoDA is a purely abstractive summarization system and performs stably better than all the methods. "PoDA w/o pre-training" only has moderate success with ROUGE-1 40.82, ROUGE-2 18.46 and ROUGE-L 37.61. When combined with pre-training, PoDA establishes new state-of-the-art on CNN/Daily Mail dataset.

System	ROUGE		
	1	2	L
ABS+	29.76	11.88	26.96
CGU	36.3	18.0	33.8
FTSum	37.27	17.65	34.24
Re^{3}Sum	37.04	19.03	34.46
PoDA w/o pre-training	37.24	18.28	34.53
PoDA	**38.29**	**19.06**	**35.45**

Table 4: ROUGE scores for Gigaword dataset.

Results for Gigaword The Gigaword dataset is much larger than CNN/Daily Mail, and this enables "PoDA w/o pre-training" to have competitive performance even without pre-training. As in Table 4, PoDA substantially improves ROUGE-1 from 37.24 to 38.29(+1.05), ROUGE-2 from 18.28 to 19.06(+0.78), and ROUGE-L from 34.53 to 35.45(+0.92), with pre-training added. We can see that PoDA performs favorably over the state-of-the-art Re^{3}Sum method, which utilizes unlabeled text corpora by first retrieving and then rewriting relevant snippets.

3.3 Grammatical Error Correction (GEC)

Datasets GEC can also be seen as a text generation task, where the input sequence is a sentence possibly containing some grammatical errors, and the output is a clean and grammatical sentence. We experiment PoDA on two GEC datasets: CoNLL-2014 (Ng et al., 2014) and JFLEG (Napoles et al., 2017). We use three public datasets for training: Lang-8 NAIST (Mizumoto et al., 2011), NUCLE (Dahlmeier et al., 2013) and CLC FCE (Felice et al., 2014). The test set of CoNLL-2013 shared task is used as validation set for the CoNLL-2014 task. JFLEG has its own validation set. For preprocessing, we use NLTK[8] to tokenize sentences, and remove all sentence pairs without any edits in Lang-8 NAIST. Simple spelling errors are corrected based on edit distance. The dataset statistics are shown in Table 5.

Corpus	#Sent Pairs	Split
Lang-8 NAIST	1,097,274	train
NUCLE	57,113	train
CLC FCE	32,073	train
CoNLL-2013 test set	1,381	valid
JFLEG valid set	754	valid
CoNLL-2014 test set	1,312	test
JFLEG test set	747	test

Table 5: Dataset statistics for grammatical error correction. Due to the lack of standard preprocessing script, the number of sentence pairs in the training set are slightly different from previous work.

Evaluation To compare with previous work, we use the official evaluation metrics: MaxMatch (M^2) $F_{0.5}$ (Dahlmeier and Ng, 2012) for CoNLL-2014 and GLEU (Napoles et al., 2015) for JFLEG dataset. Both metrics are shown to correlate well with human evaluation scores. ML-Conv (Chollampatt and Ng, 2018a), char-seq2seq (Xie et al., 2016), dual-boost (Ge et al., 2018a), Hybrid SMT-NMT (Grundkiewicz and Junczys-Dowmunt, 2018), NQE (Chollampatt and Ng, 2018b), and NRL (Sakaguchi et al., 2017) are used as baselines.

Results As shown in Table 6 and Table 7, when trained only on the supervised data, "PoDA w/o pre-training" can still achieve an impressive performance with $F_{0.5}$ score 54.01 on CoNLL-2014 test set and GLEU score 56.52 on JFLEG test set, surpassing previous state-of-the-art single model results. This once again shows the effectiveness of the Transformer architecture. For GEC task, most words in the output sequence also appear in the input sequence, pointer-generator makes it easier to learn such prior. With denoising based pre-training, PoDA greatly boosts the $F_{0.5}$ score from 54.01 to 59.40(+5.39) for CoNLL-2014 dataset,

[8] https://www.nltk.org/

System (single)	P	R	$F_{0.5}$
char-seq2seq	49.24	23.77	40.56
MLConv	60.90	23.74	46.38
dual-boost	62.70	27.69	50.04
PoDA w/o fine-tuning	19.22	31.73	20.86
PoDA w/o pre-training	65.63	31.62	54.01
PoDA	**70.10**	**36.88**	**59.40**
Ensemble			
MLConv(+rerank)	65.49	33.14	54.79
SMT-NMT(+rerank)	66.77	34.49	56.25
NQE	-	-	56.52
PoDA	**71.01**	**37.68**	**60.34**

Table 6: Precision (P), recall (R) and $F_{0.5}$ scores for CoNLL-2014 test set. We only list systems trained on public data. Ge et al. (2018b) reported better performance with additional 4 million non-public sentence pairs.

System (single)	valid	test
MLConv	47.71	51.34
NRL	49.82	53.98
dual-boost	51.35	56.33
PoDA w/o fine-tuning	34.43	36.83
PoDA w/o pre-training	51.57	56.52
PoDA	**53.16**	**59.02**
Ensemble		
MLConv(+rerank)	52.48	57.47
SMT-NMT(+rerank)	-	**61.50**
PoDA	**53.29**	59.48
Human	-	62.38

Table 7: GLEU scores for JFLEG dataset.

and GLEU score from 56.52 to 59.02(+2.50) for JFLEG. By ensembling 4 models initialized with different pre-trained checkpoints and trained with different random seeds, the performance can be further boosted on both datasets (+0.94 for CoNLL-2014 and +0.46 for JFLEG), outperforming the other ensemble models such as "Hybrid SMT-NMT".

We also report the performance of "PoDA w/o fine-tuning" which does not conduct fine-tuning. The $F_{0.5}$ score only reaches 20.86 on CoNLL-2014 dataset and the GLEU score is 36.83 on JFLEG. These results are even worse than the weakest baselines in Table 6 and Table 7. The denoising based pre-training and the GEC task share some similarities in the sense that both of them attempt to convert noisy texts to clean and grammatical texts. However, the poor results of "PoDA w/o fine-tuning" show that PoDA cannot be seen as a simple data augmentation method for GEC. Instead, PoDA learns generic text representations and requires task-specific fine-tuning.

Techniques from previous work for GEC such as language model based rerank (Chollampatt and Ng, 2018a), data augmentation (Ge et al., 2018a), and domain adaptation (Junczys-Dowmunt et al., 2018) can be easily incorporated. A parallel work (Zhao et al., 2019) observes similar gain by combining simpler pre-training strategy and various GEC-specific techniques.

4 Analysis

In the following analysis, we only choose one task (summarization or GEC) to analyze each aspect due to space limitation. Similar conclusions also hold for the other task.

4.1 Linguistic Quality Analysis

In Table 8, we show some generated summaries by PoDA from Gigaword dataset. In the first example, PoDA successfully deletes the relatively unimportant modifier "ivory coast striker", and keeps the picture complete by including both "bremen" and "saint-etienne" in the summary. In the second example, "PoDA w/o pre-training" misses an important date ("first quarter") of the event "economic crisis". Both examples show our model is able to identify the important text snippets in the source sequence and organize them into a short and fluent summary.

More example outputs by PoDA are listed in Appendix.

4.2 Effects of the Number of Pre-training Iterations

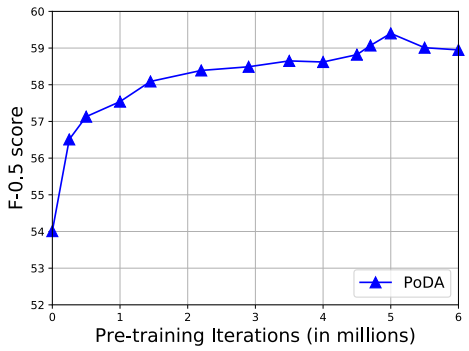

Figure 2: $F_{0.5}$ score on CoNLL-2014 test set with respect to the number of pre-training iterations.

Source	ivory coast striker boubacar sanogo is set to leave werder bremen for french first division side saint-etienne.
Target	sanogo set to sign for saint-etienne
PoDA w/o pre-training	ivory coast striker sanogo set to join saint-etienne
PoDA	sanogo set to leave bremen for saint-etienne
Source	thailand's battered economy should start to bottom out in the first quarter of #### provided the government's efforts are n't neutralized by outside developments, a news report said monday.

PoDA w/o pre-training	thai economy expected to start to bottom out in UNK
PoDA	thai economy to start to bottom out in first quarter

Table 8: Examples of generated summaries from Gigaword dataset.

In Figure 2, we show the $F_{0.5}$ score on CoNLL-2014 dataset when the model is initialized with different pre-trained checkpoints. Though the $F_{0.5}$ score has some fluctuations due to the random factors in training neural networks and the limited size of the test set, the overall trend is very clear: the $F_{0.5}$ score first improves greatly and then keeps a slow improvement after about 1 million iterations, from 54 at the very beginning to 59 after convergence.

4.3 Effects of Pre-trained Encoder and Decoder

To show the effectiveness of the pre-trained encoder and decoder, we train the model by only using the encoder-side pre-trained parameters ("w/o pre-trained decoder") or decoder-side pre-trained parameters ("w/o pre-trained encoder") We do not compare with pre-trained encoder from BERT or pre-trained decoder from OpenAI GPT, mainly because the corresponding model capacity, tokenization and text corpora used for pre-training are very different.

System	P	R	$F_{0.5}$
Fully pre-trained	**70.10**	**36.88**	**59.40**
w/o pre-trained encoder	66.14	34.67	55.98
w/o pre-trained decoder	66.62	36.10	56.98
w/o pre-training	65.63	31.62	54.01

Table 9: Ablations for pre-trained encoder and decoder on CoNLL-2014 test set.

Table 9 shows that the performance degrades by a large margin if the network is only partially pre-trained. The pre-trained encoder (-3.42 drop in $F_{0.5}$) is more important than the pre-trained decoder (-2.42 drop in $F_{0.5}$).

4.4 Effects of Dataset Size

We also conduct ablations in few-shot learning settings to see how the performance changes when the model only accesses a small percentage of labeled data. We randomly sample 10^3 to 10^5 training examples from the Gigaword dataset and train "PoDA w/o pre-training" and PoDA (with pre-training) using exactly the same hyperparameters.

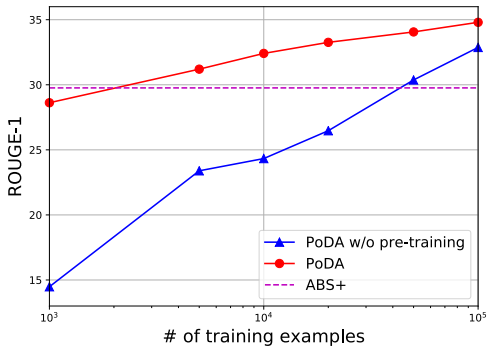

Figure 3: ROUGE-1 on Gigaword test set with respect to the number of training examples. ABS+ is a baseline method from Rush et al. (2015) using attention. The x-axis is in log scale.

Figure 3 shows the ROUGE-1 score on Gigaword test set. With only 10^3 training examples, PoDA reaches a reasonably good performance comparable to ABS+ (an attention-based system trained on nearly 4 million examples). With more labeled data available, the performance gap between "PoDA w/o pre-training" and PoDA slowly decreases from 15 to 2 in Figure 3. However, the pre-training still helps even when the models are trained on the full dataset (shown in Table 4).

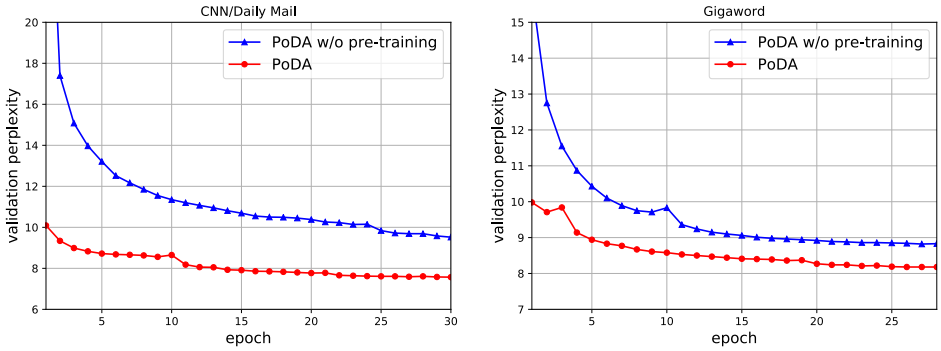

Figure 4: Validation perplexity with respect to the training epochs on CNN/Daily Mail and Gigaword datasets. Perplexity is related to the vocabulary size, so the values here are not comparable with previous work.

4.5 Convergence Analysis

Pre-training can not only achieve better final performance but also helps the model converge faster. In Figure 4, we show the validation perplexity after each training epoch for both "PoDA w/o pre-training" and PoDA.

We can clearly see that the validation perplexity of PoDA is consistently lower than that of "PoDA w/o pre-training", especially at the first few epochs. After 5 epochs, PoDA can arrive at a validation perplexity that "PoDA w/o pre-training" usually takes 30 or more epochs for both CNN/Daily Mail and Gigaword datasets. This nice property is particularly helpful when the computational resources are limited. Other pre-training methods such as BERT also demonstrate similar behaviors.

5 Related Work

Network Pre-training The idea of pre-training neural networks dates back to the early days of deep learning. Bengio et al. (2007) proposed layer-wise pre-training for deep belief networks (DBN) to tackle the difficulty of training deep neural networks based on a reconstruction objective. (Erhan et al., 2010; Dahl et al., 2012) showed the effectiveness of pre-training for tasks such as speech recognition. In the area of computer vision, using ImageNet pre-trained models have become a standard practice. In NLP community, using pre-trained word embeddings is the most popular way to transfer knowledge from the unlabeled corpus. There are also work on semi-supervised sequence learning (Dai and Le, 2015; Peters et al., 2017) attempting to incorporate language modeling as an auxiliary task. Recently, several pre-training methods based on language models are presented, such as ELMo (Peters et al., 2018), OpenAI GPT (Radford et al., 2018), BERT (Devlin et al., 2018), XLM (Lample and Conneau, 2019) etc. The combination of more compute, larger model capacity and large-scale text corpora lead to significant improvements on NLP benchmarks (Wang et al., 2018).

Autoencoders have long been used for representation learning of images (Vincent et al., 2010) and text (Li et al., 2015). However, precisely reconstructing the clean input is probably too easy for high-capacity models. Sparse autoencoders (Deng et al., 2013), contractive autoencoders (Rifai et al., 2011), and denoising autoencoders (Vincent et al., 2010) are several popular variants. Denoising autoencoders (DA) are shown to be able to learn better representations for downstream tasks (Vincent et al., 2010, 2008; Hill et al., 2016). Freitag and Roy (2018) use seq2seq DAs for unsupervised natural language generation in dialogue, and (Kim et al., 2018) propose to improve the quality of machine translation with DAs.

Text Generation covers a wide spectrum of NLP tasks, including machine translation (Wu et al., 2016), summarization (See et al., 2017), response generation (Vinyals and Le, 2015), paraphrase generation, grammatical error correction etc. Early studies on text generation mainly adopt template-based (Reiter and Dale, 2000) or example-based (Watanabe and Takeda, 1998) methods. With the emergence of deep learning for NLP, seq2seq models (Sutskever et al., 2014) become a popular choice for text generation tasks and show better performance in terms of both

automatic evaluation metrics and human evaluations (Wu et al., 2016). There are also studies focusing on text generation from structured data such as SQL-to-text (Xu et al., 2018). Previous pre-training for text generation is usually done by independently pre-training encoder-side or decoder-side language models (Ramachandran et al., 2016). Concurrent to our work, Edunov et al. augment encoder representation with ELMo-style models, MASS (Song et al., 2019) masks continuous text fragments for pre-training, and UNILM (Dong et al., 2019) proposes to pre-train for both language understanding and generation tasks.

6 Conclusion

This paper presents a new transfer learning approach for seq2seq text generation named PoDA. It involves two steps: first, pre-train a customized seq2seq denoising autoencoder on large-scale unlabeled text corpora; then, fine-tune on in-domain labeled data. The pre-training step is independent of downstream tasks and jointly learns both encoder and decoder representations. PoDA is simple, intuitive and doesn't require changing network architecture during the fine-tuning stage. Experiments on several abstractive summarization and grammatical error correction datasets demonstrate that PoDA leads to better performance and faster convergence.

For future work, we would like to validate our model on other tasks such as response generation, explore more effective unsupervised sequence-to-sequence pre-training methods, and handle cross-lingual tasks such as machine translation.

A Supplemental Material

A.1 Implementation of Pointer-Generator Layer

The pointer-generator layer calculates a probability distribution over the union of a fixed vocabulary $\mathbf{V}$ and the words in the input sequence $\{\mathbf{x}_i\}_{i=1}^{n}$.

For a word w, the probability $p(w)$ can be calculated as follows:

$$\begin{aligned} \boldsymbol{\alpha} &= MultiHeadAttention(\mathbf{h}_{dec}^{t}, \mathbf{h}_{enc}) \\ p_{gen} &= \sigma(\mathbf{W}_1 AttPooling(\mathbf{h}_{enc}, \boldsymbol{\alpha})) \\ p(w) &= p_{gen} p_v(w) + (1 - p_{gen}) \sum_{i:\mathbf{x}'_i = w} \boldsymbol{\alpha}_i \end{aligned} \tag{3}$$

$\mathbf{h}_{enc}$ is the top layer output of the Transformer encoder, and $\mathbf{h}_{dec}^{t}$ is the output of the Transformer decoder at timestep t. $p_v(w)$ is the standard softmax probability for word w over the vocabulary ($p_v(w) = 0$ if w is an OOV word). $\boldsymbol{\alpha}$ is the copy attention over the input sequence, *AttPooling* is the attentive pooling of encoder outputs $\mathbf{h}_{enc}$ with distribution $\boldsymbol{\alpha}$, and p_{gen} denotes the probability of generating from the fixed vocabulary. $p(w)$ is a linear interpolation of the generation and copying probabilities.

The meaning of life is.	The meaning of daily life is unclear. "The real meaning of daily life is peaceful." The underlying meaning of your life is lost forever. The immediate meaning of our political life is undeniable.

Table 12: Some input-output samples by our pre-trained PoDA models. We input some incomplete sentences and output the generated sentences by sampling the output distribution of pre-trained PoDA models at each timestep. We can see that PoDA successfully transforms the inputs to coherent and grammatical sentences, though the statements entailed by these output sentences are not always correct.

Dialog Intent Induction with Deep Multi-View Clustering

Hugh Perkins and **Yi Yang**
ASAPP Inc.
New York, NY 10007
{hp+yyang}@asapp.com

Abstract

We introduce the dialog intent induction task and present a novel deep multi-view clustering approach to tackle the problem. Dialog intent induction aims at discovering user intents from user query utterances in human-human conversations such as dialogs between customer support agents and customers.[1] Motivated by the intuition that a dialog intent is not only expressed in the user query utterance but also captured in the rest of the dialog, we split a conversation into two independent views and exploit multi-view clustering techniques for inducing the dialog intent. In particular, we propose alternating-view k-means (AV-KMEANS) for joint multi-view representation learning and clustering analysis. The key innovation is that the instance-view representations are updated iteratively by predicting the cluster assignment obtained from the alternative view, so that the multi-view representations of the instances lead to similar cluster assignments. Experiments on two public datasets show that AV-KMEANS can induce better dialog intent clusters than state-of-the-art unsupervised representation learning methods and standard multi-view clustering approaches.[2]

1 Introduction

Goal-oriented dialog systems assist users to accomplish well-defined tasks with clear intents within a limited number of dialog turns. They have been adopted in a wide range of applications, including booking flights and restaurants (Hemphill et al., 1990; Williams, 2012), providing tourist information (Kim et al., 2016), aiding in the customer support domain, and powering intelligent virtual assistants such as Apple Siri, Amazon Alexa, or Google Assistant. The first step towards building such systems is to determine the target tasks and construct corresponding ontologies to define the constrained set of dialog states and actions (Henderson et al., 2014b; Mrkšić et al., 2015).

Customer 1: *A wireless charging case is fancy and all but can we get a "find my airpod" feature going?*
Agent 1: *If you have lost your AirPods, Find My iPhone can help you locate them.*

Customer 2: *hey man I lost and miss my airpods plz help me!*
Agent 2: *Hi there! With iOS 10.3 or later, Find My iPhone can help you locate missing AirPods.*

Figure 1: Two dialogs with the `FindAirPods` user intent. The user query utterances of the two dialogs are lexically and syntactically dissimilar, while the rests of the dialogs are similar.

Existing work assumes the target tasks are given and excludes dialog intent discovery from the dialog system design pipeline. Because of this, most of the works focus on few simple dialog intents and fail to explore the realistic complexity of user intent space (Williams et al., 2013; Budzianowski et al., 2018). The assumption puts a great limitation on adapting goal-oriented dialog systems to important but complex domains like customer support and healthcare where having a complete view of user intents is impossible. For example, as shown in Fig. 1, it is non-trivial to predict user intents for troubleshooting a newly released product in advance. To address this problem, we propose to employ data-driven approaches to automatically discover user intents in dialogs from human-human conversations. Follow-up analysis can then be performed to identify the most valuable dialog intents and design dialog systems to automate the conversations accordingly.

Similar to previous work on user question/query intent induction (Sadikov et al., 2010; Haponchyk

[1] We focus on inducing abstract intents like `BookFlight` and ignore detailed arguments such as *departure date* and *destination*.

[2] When ready, the data and code will be published at https://github.com/asappresearch/dialog-intent-induction.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4016–4025,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al., 2018), we can induce dialog intents by clustering user query utterances[3] in human-human conversations. The key is to learn discriminative query utterance representations in the user intent semantic space. Unsupervised learning of such representations is challenging due to the semantic shift across different domains (Nida, 2015). We propose to overcome this difficulty by leveraging the rest of a conversation in addition to the user query utterance as a weak supervision signal. Consider the two dialogs presented in Fig. 1 where both of the users are looking for how to find their AirPods. Although the user query utterances vary in the choice of lexical items and syntactic structures, the human agents follow the same workflow to assist the users, resulting in similar conversation structures.[4]

We present a deep multi-view clustering approach, alternating-view k-means (AV-KMEANS), to leverage the weak supervision for the semantic clustering problem. In this respect, we partition a dialog into two independent views: the user query utterance and the rest of the conversation. AV-KMEANS uses different neural encoders to embed the inputs corresponding to the two views and to encourage the representations learned by the encoders to yield similar cluster assignments. Specifically, we alternatingly perform k-means-style updates to compute the cluster assignment on one view and then train the encoder of the other view by predicting the assignment using a metric learning algorithm (Snell et al., 2017). Our method diverges from previous work on multi-view clustering (Bickel and Scheffer, 2004; Chaudhuri et al., 2009; Kumar et al., 2011), as it is able to learn robust representations via neural networks that are in clustering-analysis-friendly geometric spaces. Experimental results on a dialog intent induction dataset and a question intent clustering dataset show that AV-KMEANS significantly outperforms multi-view clustering algorithms without joint representation learning by 6–20% absolute F1 scores. It also gives rise to better F1 scores than quick thoughts (Logeswaran and Lee, 2018), a state-of-the-art unsupervised representation learning method.

[3]We treat the initial user utterances of the dialogs as user query utterances.

[4]Note this is not always the case. For the same dialog intent, the agent treatments may differ depending on the user profiles. The user may also change intent in the middle of a conversation. Thus, the supervision is often very noisy.

Our contributions are summarized as follows:

- We introduce the dialog intent induction task and present a multi-view clustering formulation to solve the problem.
- We propose a novel deep multi-view clustering approach that jointly learns cluster-discriminative representations and cluster assignments.
- We derive and annotate a dialog intent induction dataset obtained from a public Twitter corpus and process a duplicate question detection dataset into a question intent clustering dataset.
- The presented algorithm, AV-KMEANS, significantly outperforms previous state-of-the-art multi-view clustering algorithms as well as two unsupervised representation learning methods on the two datasets.

2 Deep Multi-View Clustering

In this section, we present a novel method for joint multi-view representation learning and clustering analysis. We consider the case of two independent views, in which the first view corresponds to the user query utterance (query view) and the second one corresponds to the rest of the conversation (content view).

Formally, given a set of n instances $\{x_i\}$, we assume that each data point x_i can be naturally partitioned into two independent views $x_i^{(1)}$ and $x_i^{(2)}$. We further use two neural network encoders f_{ϕ_1} and f_{ϕ_2} to transform the two views into vector representations $\mathbf{x}_i^{(1)}, \mathbf{x}_i^{(2)} \in \mathbb{R}^D$. We are interested in grouping the data points into K clusters using the multi-view feature representations. In particular, the neural encoders corresponding to the two views are jointly optimized so that they would commit to similar cluster assignments for the same instances.

In this work, we implement the query-view encoder f_{ϕ_1} with a bi-directional LSTM (BiLSTM) network (Hochreiter and Schmidhuber, 1997) and the content-view encoder f_{ϕ_2} with a hierarchical BiLSTM model that consists of a utterance-level BiLSTM encoder and a content-level BiLSTM encoder. The concatenations of the hidden representations from the last time steps are adopted as the query or content embeddings.

2.1 Alternating-view k-means clustering

In this work, we propose alternating-view k-means (AV-KMEANS) clustering, a novel method for deep multi-view clustering that iteratively updates neural encoders corresponding to the two views by encouraging them to yield similar cluster assignments for the same instances. In each semi-iteration, we perform k-means-style updates to compute a cluster assignment and centroids on feature representations corresponding to one view, and then project the cluster assignment to the other view where the assignment is used to train the view encoder in a supervised learning fashion.

Algorithm 1: alternating-view k-means

Input : two-view inputs $\{(x_i^{(1)}, x_i^{(2)})\}$; numbers of iterations T, M; number of clusters K
Output : final cluster assignment $\{z_i^{(1)}\}$
Parameter: encoders f_{ϕ_1} and f_{ϕ_2}
Initialize f_{ϕ_1} and f_{ϕ_2} (§ 2.3)
$\{z_i^{(1)}\} \leftarrow$ K-MEANS$(\{f_{\phi_1}(x_i^{(1)})\}, K)$
for $t = 1, \cdots, T$ **do**
  // project cluster assignment from view 1 to view 2
  Update f_{ϕ_2} with pseudo training instances $\{(x_i^{(2)}, z_i^{(1)})\}$ (§ 2.2)
  Encode view-2 inputs: $\{\mathbf{x}_i^{(2)} \leftarrow f_{\phi_2}(x_i^{(2)})\}$
  $\{z_i^{(2)}\} \leftarrow$ K-MEANS$(\{\mathbf{x}_i^{(2)}\}, K, M, \{z_i^{(1)}\})$

  // project cluster assignment from view 2 to view 1
  Update f_{ϕ_1} with pseudo training instances $\{(x_i^{(1)}, z_i^{(2)})\}$ (§ 2.2)
  Encode view-1 inputs: $\{\mathbf{x}_i^{(1)} \leftarrow f_{\phi_1}(x_i^{(1)})\}$
  $\{z_i^{(1)}\} \leftarrow$ K-MEANS$(\{\mathbf{x}_i^{(1)}\}, K, M, \{z_i^{(2)}\})$
end

The full training algorithm is presented in Alg. 1, where K-MEANS$(\{\mathbf{x}_i\}, K, M, \{z_i'\})$ is a function that runs k-means clustering on inputs $\{\mathbf{x}_i\}$. K is the number of clusters. M and $\{z_i'\}$ are optional arguments that represent the number of k-means iterations and the initial cluster assignment. The function returns cluster assignment $\{z_i\}$. A visual demonstration of one semi-iteration of AV-KMEANS is also available in Fig. 2.

In particular, we initialize the encoders randomly or by using pretrained encoders (§ 2.3). Then, we can obtain the initial cluster assignment by performing k-means clustering on vector representations encoded by f_{ϕ_1}. During each AV-KMEANS iteration, we first project cluster assignment from view 1 to view 2 and update the neural encoder for view 2 by formulating a supervised learning problem (§ 2.2). Then we perform M vanilla k-means steps to adjust the cluster assignment in view 2 based on the updated encoder. We repeat the procedure for view 2 in the same iteration. Note that in each semi-iteration, the initial centroids corresponding to a view are calculated based on the cluster assignment obtained from the other view. The algorithm runs a total number of T iterations.

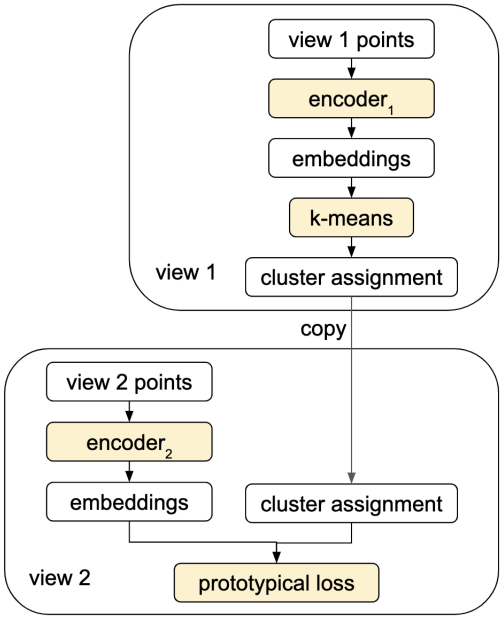

Figure 2: A depiction of a semi-iteration of the alternating-view k-means algorithm. k-means clustering and prototypical classification are performed for view 1 and view 2 respectively. The view 1 encoder is frozen and the view 2 encoder is updated in this semi-iteration.

2.2 Prototypical episode training

In each AV-KMEANS iteration, we need to solve two supervised classification problems using the pseudo training datasets $\{(x_i^{(2)}, z_i^{(1)})\}$ and $\{(x_i^{(1)}, z_i^{(2)})\}$ respectively. A simple way to do so is putting a softmax classification layer on top of each encoder network. However, we find that it is beneficial to directly perform classification in the k-means clustering space. To this end, we adopt prototypical networks (Snell et al., 2017), a metric learning approach, to solely rely on the encoders to form the classifiers instead of introducing additional classification layers.

Given input data $\{(x_i, z_i)\}$ and a neural network encoder f_ϕ, prototypical networks compute

a D-dimensional representation $\mathbf{c}_k$, or prototype, of each class by averaging the vectors of the embedded support points belonging to its class:

$$\mathbf{c}_k = \frac{1}{|S_k|} \sum_{(x_i, z_i) \in S_k} f_\phi(x_i) \quad (1)$$

here we drop the view superscripts for simplicity. Conceptually, the prototypes $\{\mathbf{c}_k\}$ are similar to the centroids in the k-means algorithm, except that a prototype is computed on a subset of the instances of a class (the support set) while a centroid is computed based on all instances of a class.

Given a sampled query data point x, prototypical networks produce a distribution over classes based on a softmax over distances to the prototypes in the embedding space:

$$p(y = k|x) = \frac{\exp(-d(f_\phi(x), \mathbf{c}_k))}{\sum_{k'} \exp(-d(f_\phi(x), \mathbf{c}_{k'}))}, \quad (2)$$

where the distance function is the squared Euclidean distance $d(\mathbf{x}, \mathbf{x}') = ||\mathbf{x} - \mathbf{x}'||^2$.

The model minimizes the negative log-likelihood of the data: $L(\phi) = -\log p(y = k|x)$. Training episodes are formed by randomly selecting a subset of classes from the training set, then choosing a subset of examples within each class to act as the support set and a subset of the remainder to serve as query points. We refer to the original paper (Snell et al., 2017) for more detailed description of the model.

2.3 Parameter initialization

Although AV-KMEANS can effectively work with random parameter initializations, we do expect that it will benefit from initializations obtained from pretrained models with some well-studied unsupervised learning objectives. We present two methods to initialize the utterance encoders for both the query and content views. The first approach is based on recurrent autoencoders. We embed an utterance using a BiLSTM encoder. The utterance embedding is then concatenated with every word vector corresponding to the decoder inputs that are fed into a uni-directional LSTM decoder. We use the neural encoder trained with the autoencoding objective to initialize the two utterance encoders in AV-KMEANS.

Recurrent autoencoders independently reconstruct an input utterance without capturing semantic dependencies across consecutive utterances. We consider a second initialization method, quick thoughts (Logeswaran and Lee, 2018), that addresses the problem by predicting a context utterance from a set of candidates given a target utterance. Here, the target utterances are sampled randomly from the corpus, and the context utterances are sampled from within each pair of adjacent utterances. We use two separate BiLSTM encoders to encode utterances, which are named as the target encoder f and the context encoder g. To score the compatibility of a target utterance $\mathbf{s}$ and a candidate context utterance $\mathbf{t}$, we simply use the inner product of the two utterance vectors $f(\mathbf{s})^\top \cdot g(\mathbf{t})$. The training objective maximizes the log-likelihood of the context utterance given the target utterance and the candidate utterance set. After pretraining, we adopt the target encoder to initialize the two utterance encoders in AV-KMEANS.

3 Data

As discussed in the introduction, existing goal-oriented dialog datasets mostly concern predefined dialog intents in some narrow domains such as restaurant or travel booking (Henderson et al., 2014a; Budzianowski et al., 2018; Serban et al., 2018). To carry out this study, we adopt a more challenging corpus that consists of human-human conversations for customer service and manually annotate the user intents of a small number of dialogs. We also build a question intent clustering dataset to assess the generalization ability of the proposed method on the related problem.

3.1 Twitter airline customer support

We consider the customer support on Twitter corpus released by Kaggle,[5] which contains more than three million tweets and replies in the customer support domain. The tweets constitute conversations between customer support agents of some big companies and their customers. As the conversations regard a variety of dynamic topics, they serve as an ideal testbed for the dialog intent induction task. In the customer service domain, different industries generally address unrelated topics and concerns. We focus on dialogs in the airline industry,[6] as they represent the largest number of conversations in the corpus. We name

[5] https://www.kaggle.com/thoughtvector/customer-support-on-twitter

[6] We combined conversations involved the following Twitter handles: @Delta, @British_Airways, @SouthwestAir, and @AmericanAir.

Dialog intent	# Dialogs	Query utterance example
Baggage	40	hi, do suit bags count as a personal items besides carry on baggage?
BookFlight	27	trying all day to book an international flight, only getting error msg.
ChangeFlight	16	can i request to change my flight from lax to msy on 10/15?
CheckIn	21	hy how can i have some help... having some problems with a check in
CustomerService	19	2 hour wait time to talk to a customer service agent?!?
FlightDelay	85	delay... detroit < orlando
FlightEntertainment	40	@airline is killing it with these inflight movie options
FlightFacility	32	just flew @airline economy... best main cabin seat ive ever sat in.
FlightStaff	30	great crew on las vegas to baltimore tonight.
Other	116	hi, i have a small question!
RequestFeature	10	when are you going to update your app for iphone x?
Reward	17	need to extend travel funds that expire tomorrow!
TerminalFacility	13	thx for the new digital signs at dallas lovefield. well done!!
TerminalOperation	34	would be nice if you actually announced delays

Table 1: Statistics of the labeled Twitter airline customer support (TwACS) dataset and the corresponding user query utterance examples. The Twitter handles of the airlines are replaced by @airline.

the resulting dataset the *Twitter airline customer support (TwACS)* corpus. We rejected any conversation that redirects the customer to a URL or another communication channel, e.g., direct messages. We ended up with a dataset of $43,072$ dialogs. The total numbers of dialog turns and tokens are $63,147$ and $2,717,295$ respectively.

After investigating 500 randomly sampled conversations from TwACS, we established an annotation task with 14 dialog intents and hired two annotators to label the sampled dialogs based on the user query utterances. The Cohen's kappa coefficient was 0.75, indicating a substantial agreement between the annotators. The disagreed items were resolved by a third annotator. To our knowledge, this is the first dialog intent induction dataset. The data statistics and user query utterance examples corresponding to different dialog intents are presented in Table 1.

3.2 AskUbuntu

AskUbuntu is a dataset collected and processed by Shah et al. (2018) for the duplicate question detection task. The dataset consists of technical support questions posted by users on AskUbuntu website with annotations indicating that two questions are semantically equivalent. For instance,

q_1 : *how to install ubuntu w/o removing windows*
q_2 : *installing ubuntu over windows 8.1*

are duplicate and they can be resolved with similar answers. A total number of $257,173$ questions are included in the dataset and $27,289$ pairs of questions are labeled as duplicate ones. In addition, we obtain the top rated answer for each question from the AskUbuntu website dump.[7]

In this work, we reprocess the data and build a question intent clustering dataset using an automatic procedure. Following Haponchyk et al. (2018), we transform the duplicate question annotations into the question intent cluster annotations with a simple heuristic: for each question pair q_1, q_2 annotated as a duplicate, we assigned q_1 and q_2 to the same cluster. As a result, the question intent clusters correspond to the connected components in the duplicate question graph. There are $7,654$ such connected components. However, most of the clusters are very small: 91.7% of the clusters contain only 2–5 questions. Therefore, we experiment with the largest 20 clusters that contain $4,692$ questions in this work. The sizes of the largest and the smallest clusters considered in this study are $1,364$ and 71 respectively.

4 Experiments

In this section, we evaluate AV-KMEANS on the TwACS and AskUbuntu datasets as described in § 3. We compare AV-KMEANS with competitive systems for representation learning or multi-view clustering and present our main findings in § 4.2. In addition, we examine the output clusters obtained from AV-KMEANS on the TwACS dataset to perform a thoughtful error analysis.

4.1 Experimental settings

We train the models on all the instances of a dataset and evaluate on the labeled instances. We employ the publicly available 300-dimensional

Table 2: Evaluation results on the TwACS and AskUbuntu datasets for different systems. MVSC is short for the multi-view spectral clustering algorithm proposed by Kanaan-Izquierdo et al. (2018). The pretrained representations are fixed during k-means and MVSC clustering and they are fine-tuned during AV-KMEANS clustering. The best results are in **bold**.

GloVe vectors (Pennington et al., 2014) pretrained with 840 billion tokens to initialize the word embeddings for all the models.

Competitive systems We consider state-of-the-art methods for representation learning and/or multi-view clustering as our baseline systems. We formulate the dialog induction task as an unsupervised clustering task and include two popular clustering algorithms *k-means* and *spectral clustering*. *multi-view spectral clustering (MVSC)* (Kanaan-Izquierdo et al., 2018) is a competitive standard multi-view clustering approach.[8] In particular, we carry out clustering using the query-view and content-view representations learned by the representation learning methods (k-means only requires query-view representations). In the case where a content-view input corresponds to multiple utterances, we take the average of the utterance vectors as the content-view output representation for autoencoders and quick thoughts.

AV-KMEANS is a joint representation learning and multiview clustering method. Therefore, we compare with SOTA representation learning methods *autoencoders*, and *quick thoughts* (Logeswaran and Lee, 2018). Quick thoughts is a strong representation learning baseline that is adopted in BERT (Devlin et al., 2019). We also include *principal component analysis (PCA)*, a classic representation learning and dimensionality reduction method, since bag-of-words representations are too expensive to work with for clustering analysis.

We compare three variants of AV-KMEANS that differ in the pretraining strategies. In addition to the AV-KMEANS systems pretrained with autoencoders and quick thoughts, we also consider a system whose encoder parameters are randomly initialized (*no pretraining*).

Metrics We compare the competitive approaches on a number of standard evaluation measures for clustering analysis. Following prior work (Kumar et al., 2011; Haponchyk et al., 2018; Xie et al., 2016), we set the number of clusters to the number of ground truth categories and report precision, recall, F1 score, and unsupervised clustering accuracy (ACC). To compute precision or recall, we assign each predicted cluster to the most frequent gold cluster or assign each gold cluster to the most frequent predicted cluster respectively. The F1 score is the harmonic average of the precision and recall. ACC uses a one-to-one assignment between the gold standard clusters and the predicted clusters. The assignment can be efficiently computed by the Hungarian algorithm (Kuhn, 1955).

Parameter tuning We empirically set both the dimension of the LSTM hidden state and the number of principal components in PCA to 300. The number of AV-KMEANS iterations T and the number of k-means steps in a AV-KMEANS semi-iteration M are set to 50 and 10 respectively, as we find that more iterations lead to similar cluster assignments. We adopt the same set of hyper-parameter values as used by Snell et al. (2017)

[8] We use the scikit-learn k-means implementation and the MVSC implementation available at: https://pypi.org/project/multiview/.

for training the prototypical networks. Specifically, we fix the number of query examples and the number of support examples to 15 and 5. The networks are trained for 100 episodes per AV-KMEANS semi-iteration. The number of sampled classes per episode is chosen to be 10, as it has to be smaller than the number of ground truth clusters. Adam (Kingma and Ba, 2015) is utilized to optimize the models and the initial learning rate is 0.001. During autoencoders or quick thoughts pretraining, we check the performance on the development set after each epoch to perform early stopping, where we randomly sample 10% unlabeled instances as the development data.

4.2 Results

Our main empirical findings are presented in Table 2, in which we compare AV-KMEANS with standard single-view and multi-view clustering algorithms. We also evaluate classic and neural approaches for representation learning, where the pretrained representations are fixed during k-means and MVSC clustering and they are fine-tuned during AV-KMEANS clustering. We analyze the empirical results in details in the following paragraphs.

Utilizing multi-view information Among all the systems, k-means clustering on representations trained with PCA or autoencoders only employs single-view information encoded in user query utterances. They clearly underperform the rest of the systems that leverage multi-view information of the entire conversations. Quick thoughts infuses the multi-view knowledge through the learning of the query-view vectors that are aware of the content-view semantics. In contrast, multi-view spectral clustering can work with representations that are separately learned for the individual views and the multi-view information is aggregated using the common eigenvectors of the data similarity Laplacian matrices. As shown, k-means clustering on quick thoughts vectors gives superior results than MVSC pretrained with PCA or autoencoders by more than 10% F1 or ACC, which indicates that multi-view representation learning is effective for problems beyond simple supervised learning tasks. Combining representation learning and multi-view clustering in a static way seems to be less ideal—MVSC performs worse than k-means using the quick thoughts vectors as clustering inputs. Multi-view representation learning breaks the independent-view assumption that is critical for classic multi-view clustering algorithms.

Joint representation learning and clustering We now investigate whether joint representation learning and clustering can reconcile the conflict between cross-view representation learning and classic multi-view clustering. AV-KMEANS outperforms k-means and MVSC baselines by considerable margins. It achieves 46% and 53% F1 scores and 40% and 44% ACC scores on the TwACS and AskUbuntu datasets, which are 5–30 percent higher than competitive systems. Compared to alternative methods, AV-KMEANS is able to effectively seek clustering-friendly representations that also encourage similar cluster assignments for different views of the same instances. With the help of quick thoughts pretraining, AV-KMEANS improves upon the strongest baseline, k-means clustering on quick thoughts vectors, by 4.5% ACC on the TwACS dataset and 12.2% F1 on the AskUbuntu dataset.

Model pretraining for AV-KMEANS Evaluation results on AV-KMEANS with different parameter initialization strategies are available in Table 2. As suggested, pretraining neural encoders is important for obtaining competitive results on the TwACS dataset, while its impact on the AskUbuntu dataset is less pronounced. AskUbuntu is six times larger than TwACS and models trained on AskUbuntu are less sensitive to their parameter initializations. This observation is consistent with early research on unsupervised pretraining, where Schmidhuber et al. (2012) argue that unsupervised initialization/pretraining is not necessary if a large amount of training data is available. Between the two pretraining methods, quick thoughts is much more effective than autoencoders—it improves upon no pretraining and autoencoders by 10.4% and 8.3% ACC scores on the TwACS dataset.

4.3 Error analysis

Our best performed system still fails to hit 50% F1 or ACC score on the TwACS dataset. We examine the outputs of the quick thoughts pretrained AV-KMEANS on TwACS, focusing on investigating the most frequent errors made by the system. To this end, we compute the confusion matrix based on the one-to-one assignment between the gold clusters and the predicted clusters used by ACC.

Ground truth	Prediction	# Instances
Other	CustomerService	21
TerminalOp.	FlightDelay	10
FlightDelay	ChangeFlight	10
Other	FlightStaff	10
FlightEnter.	Other	8

Table 3: The top 5 most frequent errors made by the quick thoughts pretrained AV-KMEANS on the TwACS dataset. The one-to-one assignment between the gold clusters and the predicted clusters is computed by the Hungarian algorithm.

The top 5 most frequent errors are presented in Table 3. As shown, three of the five errors involve Other. Instances under the Other category correspond to miscellaneous dialog intents, thereby they are less likely to be grouped together based on the semantic meaning representations.

The other two frequent errors confuse FlightDelay with TerminalOperation and ChangeFlight respectively. Poor terminal operations often incur unexpected customer delays. Two example query utterances are shown as follows,

q_1 : *who's running operation at mia flight 1088 been waiting for a gate.*
q_2 : *have been sitting in the plane waiting for our gate for 25 minutes.*

Sometimes, a user may express more than one intents in a single query utterance. For example, in the following query utterance, the user complaints about the delay and requests for an alternative flight:

q : *why is ba flight 82 from abuja to london delayed almost 24 hours? and are you offering any alternatives?*

We leave multi-intent induction to future work.

5 Related Work

User intent clustering Automatic discovery of user intents by clustering user utterances is a critical task in understanding the dynamics of a domain with user generated content. Previous work focuses on grouping similar web queries or user questions together using supervised or unsupervised clustering techniques. Kathuria et al. (2010) perform simple k-means clustering on a variety of query traits to understand user intents. Cheung and Li (2012) present an unsupervised method for query intent clustering that produces a pattern consisting of a sequence of semantic concepts and/or lexical items for each intent. Jeon et al. (2005) use machine translation to estimate word translation probabilities and retrieve similar questions from question archives. A variation of k-means algorithm, MiXKmeans, is presented by Deepak (2016) to cluster threads that present on forums and Community Question Answering websites. Haponchyk et al. (2018) propose to cluster questions into intents using a supervised learning method that yields better semantic similarity modeling. Our work focuses on a related but different task that automatically induces user intents for building dialog systems. Two sources of information are naturally available for exploring our deep multi-view clustering approach.

Multi-view clustering Multi-view clustering (MVC) aims at grouping similar subjects into the same cluster by combining the available multi-view feature information to search for consistent cluster assignments across different views (Chao et al., 2017). Generative MVC approaches assume that the data is drawn from a mixture model and the membership information can be inferred using the multi-view EM algorithm (Bickel and Scheffer, 2004). Most of the works on MVC employ discriminative approaches that directly optimize an objective function that involves pairwise similarities so that the average similarity within clusters can be minimized and the average similarity between clusters can be maximized. In particular, Chaudhuri et al. (2009) propose to exploit canonical correlation analysis to learn multi-view representations that are then used for downstream clustering. Multi-view spectral clustering (Kumar et al., 2011; Kanaan-Izquierdo et al., 2018) constructs a similarity matrix for each view and then iteratively updates a matrix using the eigenvectors of the similarity matrix computed on another view. Standard MVC algorithms expect multi-view feature inputs that are fixed during unsupervised clustering. AV-KMEANS works with raw multi-view text inputs and learns representations that are particularly suitable for clustering.

Joint representation learning and clustering Several recent works propose to jointly learn feature representations and clustering via neural networks. Xie et al. (2016) present the deep embedded clustering (DEC) method that learns a map-

ping from the data space to a lower-dimensional feature space where it iteratively optimizes a KL divergence based clustering objective. Deep clustering network (DCN) (Yang et al., 2016) is a joint dimensional reduction and k-means clustering framework, in which the dimensional reduction model is implemented with a deep neural network. These methods focus on the learning of single-view representations and the multi-view information is under-explored. Lin et al. (2018) present a joint framework for deep multi-view clustering (DMJC) that is the closest work to ours. However, DMJC only works with single-view inputs and the feature representations are learned using a multi-view fusion mechanism. In contrast, AV-KMEANS assumes that the inputs can be naturally partitioned into multiple views and carry out learning with the multi-view inputs directly.

6 Conclusion

We introduce the novel task of dialog intent induction that concerns automatic discovery of dialog intents from user query utterances in human-human conversations. The resulting dialog intents provide valuable insights in helping design goal-oriented dialog systems. We propose to leverage the dialog structure to divide a dialog into two independent views and then present AV-KMEANS, a deep multi-view clustering algorithm, to jointly perform multi-view representation learning and clustering on the views. We conduct extensive experiments on a Twitter conversation dataset and a question intent clustering dataset. The results demonstrate the superiority of AV-KMEANS over competitive representation learning and multi-view clustering baselines. In the future, we would like to abstract multi-view data from multi-lingual and multi-modal sources and investigate the effectiveness of AV-KMEANS on a wider range of tasks in the multi-lingual or multi-modal settings.

Acknowledgments

We thank Shawn Henry and Ethan Elenberg for their comments on an early draft of the paper. We also thank the conversational AI and the general research teams of ASAPP for their support throughout the project. We thank the EMNLP reviewers for their helpful feedback.

Abstract

Recently, *kernelized locality sensitive hashcodes* have been successfully employed as representations of natural language text, especially showing high relevance to biomedical relation extraction tasks. In this paper, we propose to optimize the hashcode representations in a *nearly unsupervised* manner, in which we only use data points, but not their class labels, for learning. The optimized hashcode representations are then fed to a supervised classifier following the prior work. This nearly unsupervised approach allows fine-grained optimization of each hash function, which is particularly suitable for building hashcode representations generalizing from a training set to a test set. We empirically evaluate the proposed approach for biomedical relation extraction tasks, obtaining significant accuracy improvements w.r.t. state-of-the-art supervised and semi-supervised approaches.

1 Introduction

In natural language processing, one important but a highly challenging task is of identifying biological entities and their relations from biomedical text, as illustrated in Fig. 1, relevant for real world problems, such as personalized cancer treatments (Rzhetsky, 2016; Hahn and Surdeanu, 2015; Cohen, 2015). In the previous works, the task of biomedical relation extraction is formulated as of binary classification of natural language structures; one of the primary challenges to solve the problem is that the number of data points annotated with class labels (in a training set) is small due to high cost of annotations by biomedical domain experts, and further, bio-text sentences in a test set can vary significantly w.r.t. the ones from a training set due to practical aspects, such as high diversity of research topics or writing styles, hedging, etc. Considering such challenges for the task, many classification models based on kernel similarity functions have been proposed (Garg et al., 2016; Chang et al., 2016; Tikk et al., 2010; Miwa et al., 2009; Airola et al., 2008; Mooney and Bunescu, 2005), and recently, many neural networks based classification models have also been explored (Kavuluru et al., 2017; Peng and Lu, 2017; Hsieh et al., 2017; Rao et al., 2017; Nguyen and Grishman, 2015), including the ones doing adversarial learning using the knowledge of data points (excluding class labels) from a test set, or semi-supervised variational autoencoders (Rios et al., 2018; Ganin et al., 2016; Zhang and Lu, 2019; Kingma et al., 2014).

In a very recent work, kernelized locality sensitive hashcodes based representation learning approach has been proposed that has shown to be the most successful in terms of accuracy and computational efficiency for the task (Garg et al., 2019). The model parameters, shared between all the hash functions, are optimized in a supervised manner, whereas an individual hash function is constructed in a *randomized* fashion. The authors suggest to obtain thousands of (randomized) semantic features extracted from natural language data points into binary hashcodes, and then making classification decision as per the *features* using hundreds of decision trees, which is the core of their robust classification approach. Even if we extract thousands of semantic features using the hashing approach, it is difficult to ensure that the features extracted from training data points would generalize to a test set. While the inherent randomness in construct-

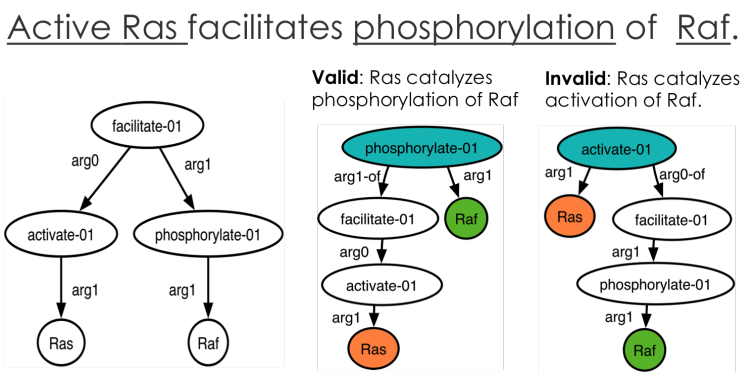

Figure 1: On the left, we show an abstract meaning representation (AMR) of a sentence. As per the semantics of the sentence, there is a valid biomedical relationship between the two proteins, Ras and Raf, i.e. Ras catalyzes phosphorylation of Raf; the relation corresponds to a subgraph extracted from the AMR. On the other hand, one of the many invalid biomedical relationships that one could infer is, Ras catalyzes activation of Raf, for which we show the corresponding subgraph too. A given candidate relation automatically hypothesized from the sentence, is binary classified, as valid or invalid, using the subgraph as features.

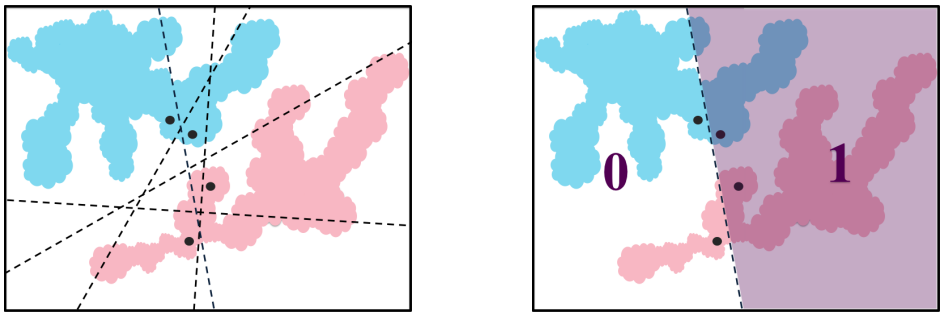
ing hash functions from a training set can help towards generalization in the case of absence of a test set, there should be better alternatives if we do have the knowledge of a test set of data points, or a subset of a training set treated as a *pseudo-test set*. What if we construct hash functions in an intelligent manner via exploiting the additional knowledge of unlabeled data points in a test/pseudo-test set, performing *fine-grained optimization of each hash function* rather than relying upon randomness, so as to extract semantic features which generalize?

Along these lines, we propose a new framework for learning hashcode representations accomplishing two important (inter-related) extensions w.r.t. the previous work:

(a) We propose to use a *nearly unsupervised* hashcode representation learning setting, in which we use only the knowledge of which set a data point comes from, a training set or a test/pseudo-test set, along with the data point itself, whereas the actual class labels of data points from a training set are input only to the final supervised-classifier, such as a Random Forest, which takes input of the learned hashcodes as representation (feature) vectors of data points along with their class labels;



(b) We introduce multiple concepts for *fine-grained (discrete) optimization* of hash functions, employed in our novel *information-theoretic algorithm* that constructs hash functions greedily one by one. In supervised settings, fine-grained (greedy) optimization of hash functions could lead to overfitting whereas, in our proposed nearly-unsupervised framework, it allows *flexibility for explicitly maximizing the generalization capabilities* of hash functions.

For a task of biomedical relation extraction, we evaluate our approach on four public datasets, and obtain significant gains in F1 scores w.r.t. state-of-the-art models including kernel-based approaches as well the ones based on semi-supervised learning of neural networks. We also show how to employ our framework for learning locality sensitive hashcode representations using neural networks.[1]

2 Problem Formulation & Background

In Fig. 1, we demonstrate how biomedical relations between entities are extracted from the semantic (or syntactic) parse of a sentence. As we see, the task is formulated as of binary classification of natural language substructures extracted from the semantic parse. Suppose we have natural language structures, $\boldsymbol{S} = \{S_i\}_1^N$, such as parse trees, shortest paths, text sentences, etc, with corresponding class labels, $\boldsymbol{y} = \{y_i\}_1^N$. For the data points coming from a training set and a test set, we use notations, $\boldsymbol{S}_T$, and $\boldsymbol{S}_*$, respectively; same applies for the class labels. In addition, we define

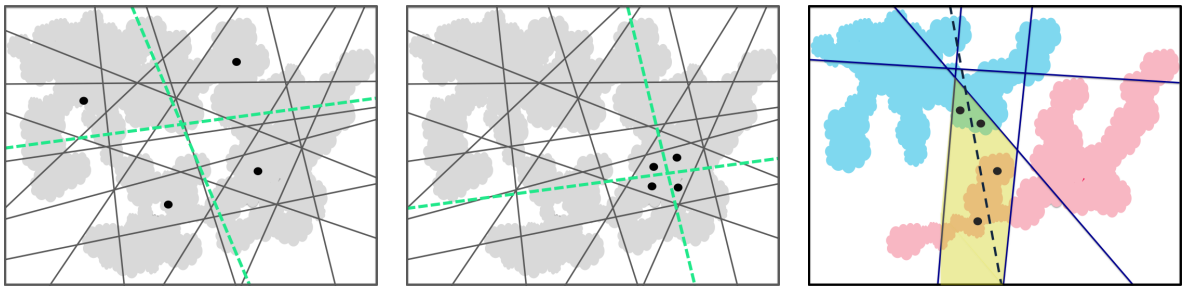
[1] Code: https://github.com/sgarg87/nearly_unsupervised_hashcode_representations

(a) Hash function choices (b) Generalizing hash function

Figure 2: In this figure, we illustrate how to construct hash functions which generalize across a training and a test set. Blue and red colors denote training and test data points respectively. A hash function is constructed by splitting a very small subset of data points into two parts. In Fig. 2(a), given the set of four data points selected randomly, there are many choices possible for splitting the set, corresponding to difference choices of hash functions which are denoted with dashed lines. The optimal choice of hash function is shown in Fig. 2(b) since it generalizes well, assigning same value to many data points from both training & test sets.

indicator variable, $\boldsymbol{x} = \{x_i\}_{i=1}^N$, for $\boldsymbol{S}$, with $x_i \in \{0, 1\}$ denoting if a data point S_i is coming from a test/pseudo-test set or a training set. Our goal is to infer the class labels of the data points from a test set, $\boldsymbol{y}_*$.

2.1 Hashcode Representations



As per the hashcode representation approach, $\boldsymbol{S}$ is mapped to a set of *locality sensitive* hashcodes, $\boldsymbol{C} = \{\boldsymbol{c}_i\}_1^N$, using a set of H binary hash functions, i.e. $\boldsymbol{c}_i = \boldsymbol{h}(S_i) = \{h_1(S_i), \cdots, h_H(S_i)\}$. $h_l(.;\boldsymbol{\theta})$ is constructed such that it splits a set of data points, $\boldsymbol{S}_l^R$, into two subsets as shown in Fig. 2(a), while choosing the set as a small random subset of size α from the superset $\boldsymbol{S}$, i.e. $\boldsymbol{S}_l^R \subset \boldsymbol{S}$ s.t. $|\boldsymbol{S}_l^R| = \alpha \ll N$. In this manner, we can construct a large number of hash functions, $\{h_l(.;\boldsymbol{\theta})\}_{l=1}^H$, from a *reference set* of size M, $\boldsymbol{S}^R = \{\boldsymbol{S}_1^R \cup \cdots \cup \boldsymbol{S}_H^R\}, |\boldsymbol{S}^R| = M \leq \alpha H \ll N$.

While, mathematically, a locality sensitive hash function can be of any form, kernelized hash functions (Garg et al., 2019, 2018; Joly and Buisson, 2011), rely upon a convolution kernel similarity function $K(S_i, S_j; \boldsymbol{\theta})$ defined for any pair of structures S_i and S_j with kernel-parameters $\boldsymbol{\theta}$ (Haussler, 1999). To construct $h_l(.)$, a kernel-trick based model, such as kNN, SVM, is fit to $\{\boldsymbol{S}_l^R, \boldsymbol{z}_l\}$, with a randomly sampled binary vector, $\boldsymbol{z}_l \in \{0, 1\}^\alpha$, that defines the split of $\boldsymbol{S}_l^R$. For computing hashcode $\boldsymbol{c}_i$ for S_i, it requires only M number of convolution-kernel similarities of S_i w.r.t. the data points in $\boldsymbol{S}^R$, which makes this approach highly scalable in compute cost terms.

In the previous work (Garg et al., 2019), it is proposed to optimize all the hash functions jointly by learning only the *parameters which are shared amongst all the functions*, i.e. learning kernel parameters, $\boldsymbol{\theta}$ and the choice of reference set, $\boldsymbol{S}^R \subset \boldsymbol{S}_T$. This optimization is performed in a supervised manner via maximization of the mutual information between hashcodes of data points and their class labels, using $\{\boldsymbol{S}_T, \boldsymbol{y}_T\}$ for training.

3 Nearly-Unsupervised Hashcode Representations

Our key insight in regards to limitation of the previous approach for supervised learning of hashcode representations, is that, to avoid overfitting, learning is intentionally restricted only to the optimization of shared parameters whereas each hash function $h_l(.)$ is constructed in a randomized manner, i.e. random sub-sampling of a subset, $\boldsymbol{S}_l^R \subset \boldsymbol{S}$, and a random split of the subset. On the other hand, in a nearly-unsupervised hashcode learning settings as we introduce next, we can have the additional knowledge of data points from a test/pseudo-test set which can be leveraged to extend the optimization from the shared (global) parameters to fine-grained optimization of hash functions, not only to avoid overfitting but for higher generalization of hash-

(a) Global sampling (b) Local sampling from a cluster (c) Local sampling from a high-entropy cluster

Figure 3: In all the three figures, dark-gray lines denote hash functions optimized previously, and intersections of the lines give us 2-D cells denoting hashcodes as well as clusters; black dots represent a set of data points which are used to construct a hash function, and some of the choices to split the subset are shown as green dashed lines. The procedure of sampling the subset varies across the three figures. In Fig. 3(a), since the four data points from global sampling have already unique hashcodes (2-D cells), the newly constructed hash function (one of the green dashed-lines) adds little information to their representations. On the other hand in Fig. 3(b), a hash function constructed from a set of data points, which are sampled locally from within a cluster, puts some of the data points in the sampled set into two different cells (hashcodes), so adding more fine-grained information to their representations, hence more advantageous from representation learning perspective. In Fig. 3(c), training and test data points are denoted with blue and red colors respectively, and the data points to construct a new hash function are sampled locally from within a high entropy cluster, i.e. the one containing a balanced proportion of the training & test data points.

codes across training & test sets.

Nearly unsupervised learning settings
We propose to learn hash functions, $\boldsymbol{h}(.)$, using $\boldsymbol{S} = \{\boldsymbol{S}_T, \boldsymbol{S}_*\}$, $\boldsymbol{x}$, and optionally, $\boldsymbol{y}_T$. Herein, $\boldsymbol{S}_*$ is a test set, or a pseudo-test set that can be a random subset of the training set or a large set of unlabeled data points outside the training set.

3.1 Basic Concepts for Fine-Grained Optimization

In the prior works on kernel-similarity based locality sensitive hashing, the first step for constructing a hash function is to randomly sample a small subset of data points, from a superset $\boldsymbol{S}$, and in the second step, the subset is split into two parts using a *kernel-trick* based model (Garg et al., 2019, 2018; Joly and Buisson, 2011), serving as the hash function, as described in Sec. 2.

In the following, we introduce basic concepts for improving upon these two key aspects of constructing a hash function, while later, in Sec. 3.2, these concepts are incorporated in a unified manner in our proposed *information-theoretic algorithm that greedily optimizes hash functions* one by one.

Informative split
In Fig. 2(a), construction of a hash function is pictorially illustrated, showing multiple possible splits, as dotted lines, of a small set of four data points (black dots). (Note that a hash function is shown to be a linear hyperplane only for simplistic explanations of the basic concepts.) While in the previous works, one of the many choices for splitting the set is chosen randomly, we propose to optimize upon this choice. Intuitively, one should choose a split of the set, corresponding to a hash function, such that it gives a balanced split for the whole set of data points, and it should also generalize across training & test sets. In reference to the figure, one simple way to analyze the generalization of a split (so the hash function) is to see if there are training as well as test data points (or pseudo-test data points) on either side of the dotted line. As per this concept, an optimal split of the set of four data points is shown in Fig. 2(b).

Referring back to Sec. 2, clearly, this is a combinatorial optimization problem, where we need to choose an optimal choice of $\boldsymbol{z}_l \in \{0,1\}^\alpha$ for set, $\boldsymbol{S}_l^R$, to construct $h_l(.)$. For a small value of α, one can either go through

all the possible combinations in a brute force manner, or use Markov Chain Monte Carlo sampling. It is interesting to note that, even though a hash function is constructed from a very small set of data points (of size $\alpha \not\gg 1$), the generalization criterion, formulated in our info-theoretic objective introduced in Sec. 3.2, is computed using all the data points available for the optimization, $\boldsymbol{S}$.

Local sampling from a cluster

Another aspect of constructing a hash function, having a scope for improvement, is sampling of a small subset of data points, $\boldsymbol{S}_l^R \subset \boldsymbol{S}$, that is used to construct a hash function. In the prior works, the selection of such a subset is purely random, i.e. random selection of data points globally from $\boldsymbol{S}$. In Fig. 3, we illustrate that, it is wiser to (randomly) *select data points locally from one of the clusters* of the data points in $\boldsymbol{S}$, rather than sampling globally from $\boldsymbol{S}$. Here, we propose that clustering of all the data points in $\boldsymbol{S}$ can be obtained using the hash functions itself, due to their locality sensitive property. While using a large number of locality sensitive hash functions give us fine-grained representations of data points, *a small subset of the hash functions, of size ζ, defines a valid clustering* of the data points, since data points which are similar to each other should have same *hashcodes serving as cluster labels*.

From this perspective, we can construct first few hash functions from global sampling of data points, what we refer as global hash functions. These global hash functions should serve to provide hashcode representations as well as clusters of data points. Then, via local sampling from the clusters, we can also construct *local hash functions* to capture more finer details of data points. As per this concept, we can learn *hierarchical (multi-scale) hashcode representations* of data points, capturing differences between data points from coarser (global hash functions) to finer scales (local hash functions).

Further, we suggest to choose a cluster that has a balanced proportion of training & test (pseudo-test) data points, which is desirable from the perspective of having generalized hashcode representations; see Fig. 3(c).

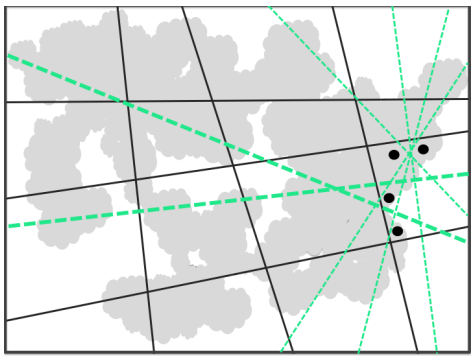


Figure 4: Dark-gray lines denote hash functions optimized previously, and gray color represents data points used for the optimization. The intersections of the lines give us 2-D cells, corresponding to hashcodes as well as clusters. For the set of four data points sampled within a cluster, there are many choices to split it (corresponding to hash functions choices), shown with dashed lines. We propose to choose the one which also splits the sets of data points in other (neighboring) clusters in a balanced manner, i.e. having data points in a cluster on either side of the dashed line and cutting through as many clusters as possible. As per this criterion, the thick-green dashed lines are superior choices w.r.t. the thin-green ones.

Splitting other clusters

In reference to Fig. 4, *non-redundancy* of a hash function w.r.t. the other hash functions can be characterized in terms of how well the hash function splits the clusters defined as per the other hash functions.

Next we mathematically formalize all the concepts introduced above for fine-grained optimization of hash functions into an information-theoretic objective function.

3.2 Information-Theoretic Learning

We optimize hash functions greedily, one by one. Referring back to Sec. 2, we define binary random variable x denoting if a data point comes from a training set or a test/pseudo-test set. In a greedy step of optimizing a hash function, random variable, $\boldsymbol{c}$, represents the hashcode of a data point S, as per the previously optimized hash functions $\boldsymbol{h}_{l-1}(.)$. Along same lines, c denotes the binary random variable corresponding from the present hash function under optimization, $h_l(.)$. We maximize the information-theoretic objective as below.

Algorithm 1 Nearly-Unsupervised Hashcode Representation Learning

Require: Dataset $\{\boldsymbol{S}, \boldsymbol{x}\}$, and parameters, $H, \boldsymbol{\alpha}, \zeta$.

$\boldsymbol{h}(.) \leftarrow \{\}$, $\boldsymbol{C} \leftarrow \{\}$, $\boldsymbol{f} \leftarrow \{\}$
%Greedy step for optimizing hash function, $h_l(.)$
while $|\boldsymbol{h}(.)| < H$ **do**
  $\alpha_l \leftarrow$ sampleSubsetSize$(\boldsymbol{\alpha})$ *%Sample a size for the subset of data points, $\boldsymbol{S}_l^R$, to construct a hash function*
  if $|\boldsymbol{h}(.)| < \zeta$ **then**
    $\boldsymbol{S}_l^R \leftarrow$ randomSampleGlobally$(\boldsymbol{S}, \alpha_l)$ *%Randomly sample data points, globally from $\boldsymbol{S}$, for constructing a global hash function.*
  else
    $\boldsymbol{S}_l^R \leftarrow$ randomSampleLocally$(\boldsymbol{S}, \boldsymbol{C}, \boldsymbol{x}, \alpha_l, \zeta)$ *%Sample data points randomly from, a high entropy cluster, for constructing a local hash function.*
  end if
  $h_l(.), f_l \leftarrow$ optimizeSplit$\big(\boldsymbol{S}_l^R, \boldsymbol{S}, \boldsymbol{C}, \boldsymbol{x}\big)$ *%Optimize split of $\boldsymbol{S}_l^R$.*
  $\boldsymbol{c} \leftarrow$ computeHash$(\boldsymbol{S}, h_l(.))$
  $\boldsymbol{C} \leftarrow \boldsymbol{C} \cup \boldsymbol{c}$, $\boldsymbol{h}(.) \leftarrow \boldsymbol{h(.)} \cup h_l(.)$, $\boldsymbol{f} \leftarrow \boldsymbol{f} \cup f_l$.
  $\boldsymbol{h}(.), \boldsymbol{C}, \boldsymbol{f} \leftarrow$ deleteLowInfoFunc$(\boldsymbol{h}(.), \boldsymbol{C}, \boldsymbol{f})$ *%delete hash functions from the set with lower objective values*
end while
Return $\boldsymbol{h}(.), \boldsymbol{C}$.

$$\underset{h_l()}{\operatorname{argmax}}\, \mathcal{H}(x, c) - \mathcal{I}(c : \boldsymbol{c}) + \mathcal{H}(x|\boldsymbol{c}); \qquad (1)$$
$$\boldsymbol{c} = \boldsymbol{h}_{l-1}(S), c = h_l(S)$$

Herein the optimization of a hash function, $h_{(.)}$, involves intelligent selection of $\boldsymbol{S}_l^R$, an informative split of $\boldsymbol{S}_l^R$, i.e. optimizing $\boldsymbol{z}_l$ for $\boldsymbol{S}_l^R$, and learning of the parameters $\boldsymbol{\theta}$ of a (kernel or neural) model, which is fit on $\{\boldsymbol{S}_l^R, \boldsymbol{z}_l\}$, acting as the hash function.

In the objective function above, maximizing the first term, $\mathcal{H}(x, c)$, i.e. joint entropy on x and c, corresponds to the concept of *informative split* described above in Sec. 3.1; see Fig. 2. This term is cheap to compute since x and c are both 1-dimensional binary variables.

The second term in the objective, the mutual information term, ensures minimal redundancies between hash functions. This is related to the concept of constructing a hash function such that it splits many of the existing clusters, as mentioned above in Sec. 3.1; see Fig. 4. This mutual information function can be computed using the approximation in the previous work by (Garg et al., 2019).

The last quantity in the objective is $\mathcal{H}(x|\boldsymbol{c})$, conditional entropy on x given $\boldsymbol{c}$. We propose to maximize this term indirectly via *choosing a cluster informatively, from which to randomly select data points for constructing the hash function*, such that it contains a balanced ratio of the count of training & test data points, i.e. a cluster with high entropy on x, which we refer as a *high entropy cluster*. In reference to Fig. 3(c), the new clusters emerging from a split of a high entropy cluster should have higher chances to be high entropy clusters themselves, thus maximizing the last term indirectly. We compute marginal entropy on x for each cluster, and an explicit computation of $H(x|\boldsymbol{c})$ is not required.

Optionally one may extend the objective to include the term, $-\mathcal{H}(y|\boldsymbol{c}, c)$, with y denoting the random variable for a class label.

The above described learning framework is summarized in Alg. 1.

Besides kernelized locality sensitive hashcodes, the above framework allows neural locality sensitive hashing. One can fit any (regularized) neural model on $\{\boldsymbol{S}_l^R, \boldsymbol{z}_l\}$, acting as a *neural locality sensitive hash function*. We expect that some of the many possible choices for a split of $\boldsymbol{S}_l^R$ should lead to natural semantic categorizations of the data points. For such a natural split choice, even a parameterized

model can act as a good hash function without overfitting as we observed empirically.

In the algorithm, we also propose to *delete some of the hash functions* from the set of optimized ones, the ones which have low objective function values w.r.t. the rest. This step provides robustness against an arbitrarily bad choice of *randomly* selected subset, $\boldsymbol{S}_l^R$.

Our algorithm allows parallel computing, as in the previous hashcode learning approach.

4 Experiments

We demonstrate the applicability of our approach for a challenging task of biomedical relation extraction, using four public datasets.

Dataset details

For AIMed and BioInfer, cross-corpus evaluations have been performed in many previous works (Airola et al., 2008; Tikk et al., 2010; Peng and Lu, 2017; Hsieh et al., 2017; Rios et al., 2018; Garg et al., 2019). These datasets have annotations on pairs of interacting proteins (PPI) in a sentence while ignoring the interaction type. Following the previous works, for a given pair of proteins mentioned in a text sentence from a training or a test set, we obtain the corresponding undirected shortest path from a Stanford dependency parse of the sentence, that serves as a data point.

We also use PubMed45 and BioNLP datasets which have been used for extensive evaluations in recent works (Garg et al., 2019, 2018; Rao et al., 2017; Garg et al., 2016). These two datasets consider a relatively more difficult task of inferring an interaction between two or more bio-entities mentioned in a sentence, along with the inference of their interaction-roles, and the type of interaction from an unrestricted list. As in the previous works, we use abstract meaning representation (AMR) to obtain shortest path-based data points (Banarescu et al., 2013); same bio-AMR parser (Pust et al., 2015) is employed as in the previous works. PubMed45 dataset has 11 subsets, with evaluation performed for each of the subsets as a test set leaving the rest for training (not to be confused with cross-validation). For BioNLP dataset (Kim et al., 2009, 2011; Nédellec et al., 2013), the training set contains annotations from years 2009, 2011, 2013, and the test set contains development set from year 2013. Overall, for a fair comparison of the models, we keep same experimental setup as followed in (Garg et al., 2019), for all the four datasets, so as to avoid any bias due to engineering aspects; evaluation metrics for the relation extraction task are, f1 score, precision, recall.

Baseline methods

The most important baseline method for the comparison is the recent work of supervised hashcode representations (Garg et al., 2019). Their model is called as *KLSH-RF*, with KLSH referring to kernelized locality sensitive hashcodes, and RF denotes Random Forest. Our approach differs from their work in the sense that our hashcode representations are nearly unsupervised, whereas their approach is purely supervised, while both approaches use a supervised RF. We refer to our model as *KLSH-NU-RF*. Within the nearly unsupervised learning setting, we consider transductive setting by default, i.e. using data points from both training and test sets. Later, we also show results for inductive settings, i.e. using a random subset of training data points, as a pseudo-test set. In both scenarios, we do not use class labels for learning hashcodes, but only for training RF.

For AIMed and BioInfer datasets, adversarial learning based four neural network models had been evaluated in the prior works (Rios et al., 2018; Ganin et al., 2016), referred as *CNN-RevGrad, Bi-LSTM-RevGrad, Adv-CNN, Adv-CNN*. Like our model KLSH-NU-RF, these four models are also learned in transductive settings of using data points from the test set in addition to the training set. Semi-supervised Variational Autoencoders (*SSL-VAE*) have also been explored for biomedical relation extraction (Zhang and Lu, 2019), which we evaluate ourselves for all the four datasets considered in this paper.

Parameter settings

We use path kernels with word vectors & kernel parameter settings as in the previous work (Garg et al., 2019). From a preliminary tuning, we set the number of hash functions, $H = 100$, and the number of decision trees in a Random Forest classifier, $R = 100$; these parameters are not sensitive, requiring mini-

mal tuning. For any other parameters which may require fine-grained tuning, we use 10% of training data points, selected randomly, for validation. Within kernel locality sensitive hashing, we choose between Random Maximum Margin and Random k-Nearest Neighbors techniques, and for neural locality sensitive hashing, we use a simple 2-layer LSTM model with 8 units per layer. In our nearly unsupervised learning framework, we use subsets of the hash functions, of size 10, to obtain clusters ($\zeta = 10$). We employ 8 cores on an i7 processor, with 32GB memory, for all the computations.

4.1 Experimental Results

In summary, our model KLSH-NU-RF significantly outperforms its purely supervised counterpart, KLSH-RF, and also semi-supervised neural network models.

In reference to Tab. 1, we first discuss results for the evaluation setting of using AIMed dataset as a test set, and BioInfer as a training set. We observe that our model, KLSH-NU-RF, obtains F1 score, 3 pts higher w.r.t. the most recent baseline, KLSH-RF. In comparison to the semi-supervised neural neural models, CNN-RevGrad, Bi-LSTM-RevGrad, Adv-CNN, Adv-Bi-LSTM, SSL-VAE, which use the knowledge of a test set just like our model, we gain 8-11 pts in F1 score. On the other hand, when evaluating on BioInfer dataset as a test set and AIMed as a training set, our model is in tie w.r.t. the adversarial neural model, Adv-Bi-LSTM, though outperforming the other three adversarial models and SSL-VAE, by large margins in F1 score. In comparison to KLSH-RF, we retain same F1 score, while gaining in recall by 6 pts at the cost of losing 2 pts in precision.

For PubMed and BioNLP datasets, there is no prior evaluation of adversarial models. Nevertheless, in Tab. 2, we see that our model significantly outperforms SSL-VAE, and it also outperforms the most relevant baseline, KLSH-RF, gaining F1 score by 4 pts for both the datasets.[2] Note that, high standard deviations reported for PubMed45 dataset are due to high diversity across the 11 test sets,

[2]These two datasets have high importance to gauge practical relevance of a model for the task of biomedical relation extraction.

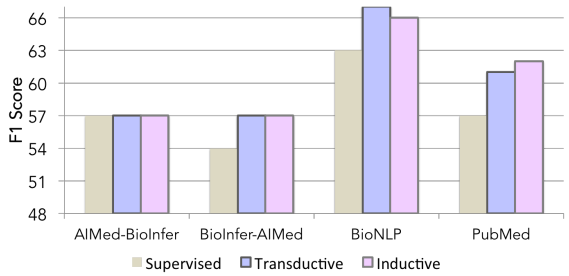

Figure 5: Comparison across the three types of learning settings, supervised, transductive, and inductive.

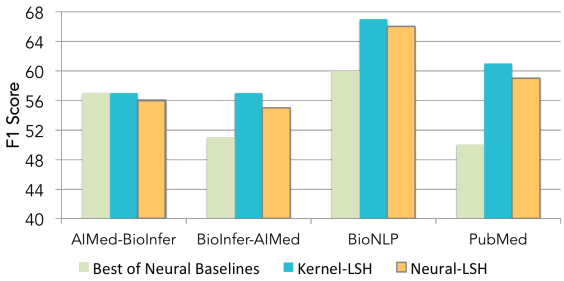

Figure 6: Comparison of neural hashing w.r.t. kernel hashing, and the best of neural baselines.

while the performance of our model for a given test set is highly stable (improvements are statistically significant with p-value: 6e-3).

One general trend to observe is that the proposed nearly unsupervised learning approach leads to a significantly higher recall, at the cost of marginal drop in precision, w.r.t. its supervised baseline.

Further, note that the number of hash functions used in the prior work is 1000 whereas we use only 100 hash functions. Compute time is same as for their model.

Our approach is easily extensible for other modeling aspects such as non-stationary kernel functions, document level inference, joint use of semantic & syntactic parses, ontology or database usage (Garg et al., 2019, 2016; Alicante et al., 2016), though we refrain from presenting system level evaluations, and have focused only upon analyzing improvements from our principled extension of the recently proposed technique that has already been shown to be successful for the task.

Transductive vs inductive settings

In the above discussed results, hashcode representations in our models are learned in transductive setting. For inductive settings, we randomly select 25% of the training data points for use as a pseudo-test set instead of the test set. In Fig. 5, we observe that both inductive and transductive settings are more favorable w.r.t. the supervised one, KLSH-RF, which is the baseline in this paper. F1 scores obtained from the inductive setting are on a par with the transductive settings. It is worth noting that, in inductive settings, our model is trained on *information even lesser than the baseline model* KLSH-RF, yet it obtains F1 scores significantly higher.

Neural hashing

In Fig. 6, we show results for neural locality sensitive hashing within our proposed framework, and observe that neural hashing is a little worse than its kernel based counterpart, however it performs significantly superior w.r.t. the best of other neural models.

5 Conclusions

We proposed a nearly-unsupervised framework for learning of kernelized locality sensitive hashcode representations, a recent technique, that was originally supervised, which has shown state-of-the-art results for a difficult task of biomedical relation extraction. Within our proposed framework, we use the additional knowledge of test/pseudo-test data points for fine-grained optimization of hash functions so as to obtain hashcode representations generalizing across training & test sets. Our experiment results show significant improvements in accuracy numbers w.r.t. the supervised baseline, as well as semi-supervised neural network models, for the same task of bio-medical relation extraction across four public datasets.

6 Acknowledgments

This work was sponsored by the DARPA Big Mechanism program (W911NF-14-1-0364). It is our pleasure to acknowledge fruitful discussions with Shushan Arakelyan, Amit Dhurandhar, Sarik Ghazarian, Palash Goyal, Karen Hambardzumyan, Hrant Khachatrian, Kevin Knight, Daniel Marcu, Dan Moyer, Kyle Reing, and Irina Rish. Abstract

While NLP systems become more pervasive, their accountability gains value as a focal point of effort. Epistemological opaqueness of non-linear learning methods, such as deep learning models, can be a major drawback for their adoptions. In this paper, we discuss the application of *Layerwise Relevance Propagation* over a linguistically motivated neural architecture, the *Kernel-based Deep Architecture*, in order to trace back connections between linguistic properties of input instances and system decisions. Such connections then guide the construction of argumentations on the network's inferences, i.e., explanations based on real examples that are semantically related to the input. We also propose here a methodology to evaluate the transparency and coherence of analogy-based explanations modeling an $audit$ stage for the system. Quantitative analysis on two semantic tasks, i.e., question classification and semantic role labeling, shows that the explanatory capabilities (native in KDAs) are effective and they pave the way to more complex argumentation methods.

1 Introduction

AI systems are currently used in a wide variety of applications, with several levels of societal impact, and are expected to be soon deployed in safety-critical fields, e.g., autonomous driving. The definition of codes of conduct in the development of AI applications to ensure their ethical sustainability across dimensions, such as fairness, reliability and beneficialness (Kroll et al., 2016; Garfinkel et al., 2017; Dignum, 2017) is becoming a crucial issue. Hence, a natural need for the ethical accountability of such systems is gaining importance.

A central issue lies in designing systems whose decisions are *transparent* (Ribeiro et al., 2016; Doshi-Velez et al., 2017), i.e., they must be easily interpretable by humans, as users must be able to suitably weight and trust the assistance of such systems.

Deep neural networks are clearly problematic in this regard: their high non-linearity, despite allowing for state-of-the-art performances in several challenging problems, amplifies the epistemological opaqueness of the decision-flow and limits its interpretability. The concept of transparency of a machine learning model spans multiple definitions, focusing on different aspects, from the simplicity of the model, e.g., the number of nodes in a decision tree, to the intuitiveness of its parameters and computations (Chakraborty et al., 2017).

In this context, an important capability of an AI system is the ability to provide *post-hoc explanations* in terms of evidences supporting the produced decisions: although they usually do not formally elucidate how a model works, they often have the property of being quite intuitive, conveying useful information also to end-users without any AI or machine learning expertise (Lipton, 2018). In semantic inference tasks (e.g., text classification), an *explanation model* generating post-hoc explanations should hence be able to trace back connections between the output categories and the semantic and syntactic properties of the input texts. Such models should have three desired properties: *semantic transparency*, *informativeness* w.r.t. the system decision and *effectiveness* in enabling auditing processes against the system.

In this work we focus on a specific post-hoc mechanism, which is to provide, along with the prediction, a comparison with one or more other examples, namely *landmarks*, that share task-relevant linguistic properties with the input. From an argument theory perspective, this corresponds to supporting decisions through an "argument by analogy" schema (Walton et al., 2008): a user ex-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4037–4046,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

posed to such a kind of argument will endow a different level of trust into the machine decision according to the linguistic plausibility of the analogy. He will implicitly gauge the evidence from the linguistic properties shared between the input sentence (or its parts) and the one(s) used for comparison as well their importance with respect to the output decision. Let us consider, for example, the following prediction in a question classification (QC) task (Li and Roth, 2006): *"What is the capital of Zimbabwe?" refers to a* `Location`. We would like the system to motivate its decision with an argument such as: *...since it recalls me of "What is the capital of California?" which also refers to a* `Location`. Notice that explanation of a decision is quite different from sentence or document ranking in Information Retrieval so that semantic similarity plays only a minor role: clear and trustful analogies may exist with semantically different training examples that imply similar relationships between the input and the decision.

Recent work has been inspired by efforts in improving model's interpretability in image processing tasks, in particular by the *Layerwise Relevance Propagation* (LRP) (Bach et al., 2015). In LRP the classification decision of a deep neural network is decomposed backward across the network layers and evidence about the contribution to the final decision brought by individual input fragments (i.e., pixels of the input image) is gathered.

In this paper, we propose to extend the LRP application to the linguistically motivated network architectures, known as Kernel-Based Deep Architectures (KDAs) (Croce et al., 2017), which frames semantic information captured by linguistic Tree Kernel methods (Collins and Duffy, 2001) within the neural-based learning paradigm. The result is a mechanism that, for each system's prediction such as in question classification, generates an argument-by-analogy explanation based on real training examples, not necessarily similar to the input.

We also propose a novel approach to evaluate numerically the interpretability of any explanation-enriched model applied in semantic inference tasks. By defining a specific audit process, we derive a synthetic metric, i.e. *Auditing Accuracy*, that takes into account the properties of transparency, informativeness and effectiveness. The evaluation of the proposed methodology shows the meaningful impact of LRP-based explanation models: users faced with explanations are systematically oriented to accept (or reject) the system decisions, so that *post hoc* judgments may even improve the overall application accuracy.

In the rest of the paper, section 2 reports related works, while Section 3 describes the LRP and its extension to KDAs. In Section 4, we propose three explanation models and illustrate a novel evaluation methodology, commenting on the audit process and deriving quantitative notions such as the *Auditing Accuracy* measure. Section 5 presents and discusses the system effectiveness against two semantic tasks, i.e., question classification and frame-based argument classification in a semantic role labeling chain. Finally, in Section 6 conclusions are derived.

2 Related Work

In recent years, research communities showed great interest in improving neural models' interpretability, as testified by the effort of defining the concept of interpretability itself and the development of a variety of approaches to the problem. In (Chakraborty et al., 2017) and (Lipton, 2018), the authors examine the different notions of interpretability found in literature and categorize techniques according to the transparency properties they confer to decision models. Common approaches to improve the *readability* of a neural model in image-related tasks are based on backward algorithms that reuse arc weights to propagate the prediction down to the input (Erhan et al., 2010; Zeiler and Fergus, 2013), thus leading to the re-creation of *meaningful* patterns in the input space. Typical examples are deconvolution heatmaps, used to approximate through Taylor series the partial derivatives at each layer (Simonyan et al., 2013), or the so-called Layer-wise Relevance Propagation (LRP), that redistributes back positive and negative evidence across the layers (Bach et al., 2015).

Local explanation approaches focus on highlighting a handful of crucial features (Baehrens et al., 2010) or deriving simpler, more readable models from a complex one, e.g., a binary decision tree (Frosst and Hinton, 2017), or by local approximation with linear models (Ribeiro et al., 2016). However, although they can explicitly show the representations learned in the specific hidden neurons (Frosst and Hinton, 2017), these approaches base their effectiveness on the user ability to study

the quality of the reasoning and of the accountability as a side effect of the quality and the coherence of the features selection: this can be very hard in tasks where boundaries between classes are not well defined. Another strategy is pairing the decision model with a generative model to produce verbose explanations (Krening et al., 2017). Sometimes explanations are associated to vector representations as in (Ribeiro et al., 2016), i.e., bag-of-words in case of text classification, that are clearly weak at capturing significant linguistic abstractions, such as the involved syntactic relations. In this work, we systematically extend the model presented in (Croce et al., 2018) which allows to provide explanations that are easily interpretable even by non-expert users, as they are expressed in natural language. Moreover, the investigated approach is is computationally affordable, as it roughly corresponds to a forward pass across the network. In addition, we also provide a systematic way to evaluate the provided explanations with a methodology able to support the audit of the targeted AI systems.

3 Layer-wise Relevance Propagation in Kernel-based Deep Architectures

In this section, we will review the Layer-wise Relevance Propagation technique (LRP, as in (Bach et al., 2015)), usually applied in image processing, and show how it can be naturally extended to Kernel-based Deep Architectures (KDA, as in (Croce et al., 2017)) in order to select real examples useful to support the network decisions.

LRP is mainly a framework which allows to decompose the prediction of a deep neural network computed over a sample, usually an image, down to relevance scores for the single input dimensions of the sample, such as sub-pixels of the image itself. More formally, let $f : \mathbb{R}^d \rightarrow \mathbb{R}^+$ be a function that quantifies, for example, the probability of $x \in \mathbb{R}^d$ being in a certain class. The Layer-wise Relevance Propagation assigns to each dimension, or feature, x_d a relevance score $R_d^{(1)}$ such that $f(x) \approx \sum_d R_d^{(1)}$. Features whose score is $R_d^{(1)} > 0$ or $R_d^{(1)} < 0$ correspond to evidence in favor or against, respectively, the output classification. In other words, LRP allows to identify fragments of the input playing key roles in the decision, by propagating relevance backwards. Let us suppose to know the relevance score $R_j^{(l+1)}$ of a neuron j at network layer $l+1$. This can be decomposed into messages $R_{i \leftarrow j}^{(l,l+1)}$ sent from j to neurons i in layer l according to $R_j^{(l+1)} = \sum_{i \in (l)} R_{i \leftarrow j}^{(l,l+1)}$. Then ti directly follows that the relevance of a neuron i at layer l, that is the quantity of information travelling through i, can be defined as $R_i^{(l)} = \sum_{j \in (l+1)} R_{i \leftarrow j}^{(l,l+1)}$. In this work, we adopted the ϵ-rule defined in (Bach et al., 2015) to compute the messages $R_{i \leftarrow j}^{(l,l+1)} = \frac{z_{ij}}{z_j + \epsilon \cdot \text{sign}(z_j)} R_j^{(l+1)}$, where $z_{ij} = x_i w_{ij}$ and $\epsilon > 0$ is a small numerical stabilizing term. The informative value is justified by the fact that the weights z_{ij} are linked to the activation weights w_{ij} of the input neurons.

Given the capability of computing relevance scores for input dimensions, we now summarize the KDA to motivate how LRP can be applied also to tasks other than image classification. In a nutshell, the KDA is a neural network trained in low-dimensional spaces which approximate a generic Reproducing Kernel Hilbert Space (RKHS) (Shawe-Taylor and Cristianini, 2004). These low-dimensional approximations are derived as a reconstruction from a set of real reference training examples, called *landmarks*, which can be used to compile the representation of any unseen test instance. As a consequence, the ability of making connections between the KDA decisions and the landmarks corresponds to locating the candidate training examples that justify (in the LRP sense) decisions and trigger meaningful linguistic explanations.

More formally, given an input dataset $\mathcal{D}$, a kernel $K(o_i, o_j)$ is a function over $\mathcal{D}^2$ operating dot-products, i.e., similarity scores, in an projection space, given by the mapping Φ over the input instances o_i, which is implicit in the sense that the kernel never explicitly accesses the representation of projections $\Phi(o_i)$. Here a RKHS corresponds to the Gram Matrix $G = XX^\top$, whose element $G_{i,j}$ is $K(o_i, o_j) = \Phi(o_i) \cdot \Phi(o_j)$. The Nyström method (Williams and Seeger, 2001) can be applied to derive the approximating matrix $\tilde{G} = (CUS^{-\frac{1}{2}})(CUS^{-\frac{1}{2}})^\top \approx G$, where U, S are obtained by applying the Singular Value Decomposition to the matrix $W \in \mathbb{R}^{l \times l}$, a submatrix of G containing the kernel evaluations of l sampled instances (namely, the *landmarks*) and $C \in \mathbb{R}^{|D| \times l}$, whose row $\vec{c_i}$ corresponds to the similarity scores between $o_i \in \mathcal{D}$ and the landmarks. Hence, a mapping from $\mathcal{D}$ to a l-dimensional embedding, with $l \ll n$, is naturally provided by the **projection**

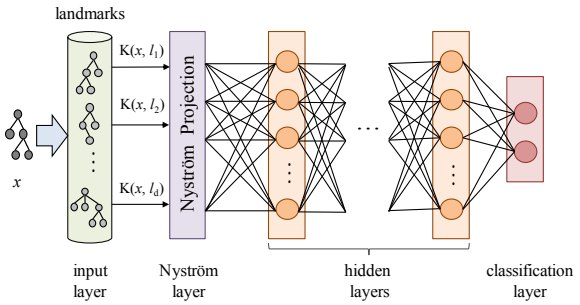

Figure 1: Kernel-based Deep Architecture.

function $\tilde{\vec{x}} = \vec{c}\,US^{-\frac{1}{2}}$. Therefore, the method produces l-dimensional vectors[1].

In (Croce et al., 2017), the Nyström representation $\tilde{\vec{x}}$ has been used to map semantically annotated grammatical trees to the linear input of a Multi-Layer Perceptron (MLP). In fact, given a dataset $\mathcal{L}$, with $o \in \mathcal{L}$ denoting a generic instance, the MLP architecture is defined with a specific Nyström input layer based on the Nyström embeddings. The resulting Kernel-based Deep Architecture (KDA) includes an *input layer*, the *Nyström layer*, a sequence of *hidden layers* and the final *classification layer*, which produces the output. The *input* layer corresponds to the input vector $\vec{c_i}$, i.e., the row of the C matrix associated to an example o_i. The input layer is mapped to the *Nyström* layer, through the Nyström projection. Notice that the embedding provides also the proper weights, defined by $US^{-\frac{1}{2}}$, so that the mapping can be expressed through the Nyström matrix $H_{Ny} = US^{-\frac{1}{2}}$. The resulting $\tilde{\vec{x}}$ is the input to one or more *hidden* layers. Clearly, the first hidden layer receives in input $\tilde{\vec{x}} = \vec{c}H_{Ny}$. Finally, the *classification layer* computes a linear classification function with a softmax operator, as shown in Figure 1. A KDA optimizes the standard cross-entropy function with L_2 regularization.

It is worth recalling that the network is triggered by an input vector $\vec{c}$ expressing the kernel evaluations $K(x, l_i)$ between the example and the landmarks. When using linguistic kernels (such as Semantic Tree Kernels, (Croce et al., 2011)), this measure corresponds to the grammatical and lexical semantic similarity between x and the subset of landmarks. The expected explanation is obtained from the network output by applying LRP to revert the propagation process, thus linking the output back to the input. In a KDA that models linguistic instances, LRP implicitly traces back the syntactic, semantic and lexical relations between the example and the landmarks across the Nyström layer: the side effect is to select those real examples that mostly influenced the identification of the predicted structure in the sentence.

[1]Note that, while any sampling policy for landmarks is admissible, in (Kumar et al., 2012) it is demonstrated that uniform sampling without replacement achieves results comparable with alternative, more resource-consuming policies.

4 Generating explanations in Kernel-based Deep Architectures

Justifications for the KDA emissions can be obtained by exploiting landmarks $\{\ell\}$ as the evidence in favour or against a class. The idea is to select those $\{\ell\}$ that the LRP highlights as the most active elements in layer 0. Once such active landmarks are detected, an *Explanatory Model* is a function in charge to compile a linguistically fluent explanation by comparing the input case with such selection.

The semantic expressiveness of such analogies makes the resulting explanation clear and increases the user confidence on the system reliability. When a sentence s is classified, LRP assigns activation scores r^s_ℓ to each individual landmark ℓ: let $\mathcal{L}^{(+)}$ (or $\mathcal{L}^{(-)}$) denote the set of landmarks with positive (or negative) activation scores. Formally, each explanation is characterized by a triple $e = \langle s, C, \tau \rangle$ where s is the input sentence, C is a target label and τ is the modality of the explanation: $\tau = +1$ for positive (i.e., acceptance) statements while $\tau = -1$ correspond to rejections of C. A landmark ℓ is *positively activated* for a given sentence s if there are at most $k-1$ other active landmarks ℓ' with activation value higher than the one for ℓ, i.e.,

$$|\{\ell' \in \mathcal{L}^{(+)} : \ell' \neq \ell \wedge r^s_{\ell'} \geq r^s_\ell > 0\}| < k$$

Similarly, a landmark is *negatively activated* when:

$$|\{\ell' \in \mathcal{L}^{(-)} : \ell' \neq \ell \wedge r^s_{\ell'} \leq r^s_\ell < 0\}| < k$$

where k is a fixed parameter used to make the explanation depending on not more than k landmarks, denoted as a set by $\mathcal{L}_k$. Positively (or negative) active landmarks in $\mathcal{L}_k$ are assigned an activation value $a(\ell, s) = +1$ (-1), while $a(\ell, s) = 0$ for not active landmarks. Given the explanation $e = \langle s, C, \tau \rangle$, a landmark ℓ, whose known class is C_ℓ, is called *consistent* (or *inconsistent*) with e if the function

$\delta(C_\ell, C) \cdot a(\ell, q) \cdot \tau$ is positive (or negative, respectively), where $\delta(C', C) = 2\delta_{kron}(C', C) - 1$ and δ_{kron} is the Kronecker delta.

We can thus partition such landmarks into the set of positively consistent landmarks $\mathcal{L}_k^{c,+} \subseteq \mathcal{L}_k^c \subseteq \mathcal{L}_k$ and negatively consistent ones $\mathcal{L}_k^{c,-} \subseteq \mathcal{L}_k^c \subseteq \mathcal{L}_k$, with $\mathcal{L}_k^{c,+} \cup \mathcal{L}_k^{c,-} = \mathcal{L}_k^c$, that aggregates all the consistent landmarks.

An *explanatory model* is then a function $M(e, \mathcal{L}_k^c)$ which maps an explanation e and the set $\mathcal{L}_k^c$ for e into a sentence f in natural language. Of course several definitions of $M(e, \mathcal{L}_k^c)$ are possible, e.g.,

$$M(e, \mathcal{L}_k^c) = \begin{cases} \text{“}s \text{ is } C \text{ since it recalls me of } \ell\text{”} \\ \forall \ell \in \mathcal{L}_k^{c,+} \quad \text{if } \tau > 0 \\ \\ \text{“}s \text{ is not } C \text{ since it does not} \\ \text{recall me of } \ell \text{ which is } C\text{”} \\ \forall \ell \in \mathcal{L}_k^{c,-} \quad \text{if } \tau < 0 \\ \\ \text{“}s \text{ is } C \text{ but I don't know why”} \\ \text{if } \mathcal{L}^c \equiv \emptyset \end{cases}$$

Here we introduce three explanatory models used during experimental evaluation:

- **Singleton Model.** The first model is the simplest as it returns a single analogy with the consistent landmark with the highest positive score, if $\tau = 1$, or lowest negative score, when $\tau = -1$. As an example, the explanation of an accepted decision in a semantic argument classification task, described by the triple $e_1 = \langle$'Put *this plate* in the center of the table', $\text{THEME}_{\text{PLACING}}, 1\rangle$, would be mapped by the model into: *I think "this plate" is* THEME *of* PLACING *in "Robot* PUT *this plate in the center of the table" since it recalls me of "the soap" in "Can you* PUT *the soap in the washing machine?"*.

- **Conjunctive Model.** In a second model, denoted as *Conjunctive*, the system makes reference to up to $k_1 \leq k$ analogies with positively (or negatively) active and consistent landmarks. Given the above explanation e_1, and $k_1 = 2$, it would return: *I think "this plate" is* THEME *of* PLACING *in "Robot* PUT *this plate in the center of the table" since it recalls me of "the soap" in "Can you* PUT *"the soap" in the washing machine?" and also of "my coat" in "*HANG *my coat in the closet in the bedroom"*.

- **Contrastive Model.** The last proposed model is more complex since it returns both a positive and a negative analogy by selecting, respectively, the most positively relevant and the most negatively relevant consistent landmark. Given $e1$, it would return: *I think "this plate" is* THEME *of* PLACING *in "Robot* PUT *this plate in the center of the table" since it recalls me of "the soap" in "Can you* PUT *the soap in the washing machine" and it is not the* GOAL *of* PLACING *since it does not recall me of "on the counter" in "*PUT *the plate on the counter"*.

In case no active and consistent landmark can be found, the models return a phrase stating only the predicted class, with no explanation.

5 Experimental Evaluation

Evaluating the explanatory quality of an inductive model is still an open problem and universally recognized gold standards are not available for comparative analysis. In order to rely on a quantitative analysis, we assume that an explanation to be effective should assist a human user to ascertain whether the proposed classification is correct or not. Plausible and coherent explanations should thus be generated from correct system's decisions, while bad decisions should correspond to ambiguous or plainly fallacious arguments.

Hence, the evaluation of an explanatory model should reflect the model's adherence to three desired properties: **semantic transparency**, i.e., argument's linguistic grounding should be clear and straightforward, requiring as less knowledge on the system's functioning and on the specific task as possible; **informativeness** with respect to the system's decision, i.e., the explanation's generating process should be highly dependent on how the system processes input information; **effectiveness w.r.t an audit against the system**, i.e., the explanation should convey enough meaningful information so that a human can correctly decide whether to trust the system prediction or not.

Consequently, we define a auditing task in which annotators are required to judge if a proposed explanation would commit them to trust the system decision. This judgment is discretized

within five possible labels: *Very Good* if the analogy is strongly convincing and linguistically clear; *Good* if the explanation is still accepted but the pertinence is slacker; *Uncertain* if the annotator gains no meaningful information from the explanation or no explanation is provided at all; *Bad* if some connections can be detected between the input sentence and the one used as a comparison but they are so ambiguous that the explanation is rejected; *Incoherent* if the argument appears totally inconsistent and meaningless. Given the nature of the argument by analogy schema (Walton et al., 2008), it follows that annotators assigning a *Very Good* or *Good* label to an explanation are also implicitly accepting the system decision as correct, whereas they are rejecting it as wrong in the other cases.

Given an explanation dataset $E = \{(e, c, x_C)\}$ where e is an explanation, $c \in \{1, -1\}$ expresses if the explanation was generated from a correct ($c = 1$) or incorrect ($c = -1$) classification, and x_C is the numerical value corresponding to one of the five labels categories C above[2], we can define the set A_c of accepted explanations generated from correct predictions and the set R_{nc} of rejected explanations generated from not correct predictions as follows:

$$A_c = \{(e, c, l) \in E | c = 1 \wedge x_C > 0\}$$

$$R_{nc} = \{(e, c, l) \in E | c = -1 \wedge x_C \leq 0\}$$

Accordingly, the *Audit Accuracy (AuAcc)*

$$AuAcc = \frac{|A_c| + |R_{nc}|}{|E|}$$

measures the ratio between correct acceptance/rejection decisions and the total number of decisions made by the human auditor.

Additionally, the Pearson Correlation between the system classification accuracy and the human judgment of an explanation can be interpreted as a concrete measure of the consistency of an explanatory model: an ideal model should map correct classifications to convincing explanations and incorrect classification to implausible explanations. It will be thus exploited to compare alternative explanatory models. To test an explanation approach as well as of the proposed evaluation metrics, we will address two different semantic processing tasks, i.e., question classification (QC) and argument classification (AC) in semantic role labeling.

Experimental Setup. The Nyström projection has been implemented in the KeLP framework[3], while the LRP-integrated KDA in Tensorflow, with 1 and 2 hidden layers, respectively, whose layer-size is equal to the number of randomly selected Nyström landmarks (500 and 200, in QC and AC respectively). For both tasks, training have been executed in 500 epochs, using the Adam optimizer and adopting early-stop and dropout strategy while selecting the best model according to performances over the development set. We conducted preliminary evaluations on small samples of the dataset and set the parameter $k = 5$, which defines the cardinality of the active landmarks $\mathcal{L}_k$[4]. The remaining hyper-parameters were tuned via grid-search.

A group of human annotators was asked to rate each explanation with one out of the five labels described early in this section, basing their judgment only on the perceived level of trust w.r.t. the explanations. Each annotator was exposed to explanations derived from a perfectly balanced set of correct and incorrect classifications, so that annotators are not biased by the (possibly high) quality of the classifier when judging the explanations.

5.1 Question Classification

We replicated the experiments reported in (Croce et al., 2017) with respect to the question classification task, using the UIUC dataset (Li and Roth, 2006), including a training and test set of 5452 and 500 questions, respectively, organized in 6 coarse-grained classes (as `ENTITY` or `HUMAN`). We generated Nyström representation of the Compositionally Smoothed Partial Tree Kernel function (Annesi et al., 2014) consistently with (Croce et al., 2017). Using 500 landmarks, the KDA accuracy was 93.6%, which is comparable with state-of-the-art neural models, as discussed in (Croce et al., 2017). The audit manual task was independently performed by 3 annotators[5]: each annotator

[2] We assigned values $x_C \in [1, -1]$: $x_{Very\ Good} = 1$, $x_{Good} = 0.8$, $x_{Uncertain} = 0$, $x_{Bad} = -0.8$, $x_{Incoherent} = -1$

[3] http://www.kelp-ml.org, presented in (Filice et al., 2018).

[4] No particular differences have emerged in the generation of explanations when slightly different values of k where considered.

[5] Annotators have different levels of fluency in English (even though no one is a native speaker) and different levels of expertise: one has no specific technical knowledge, one is a graduate student with advanced knowledge in NLP, while

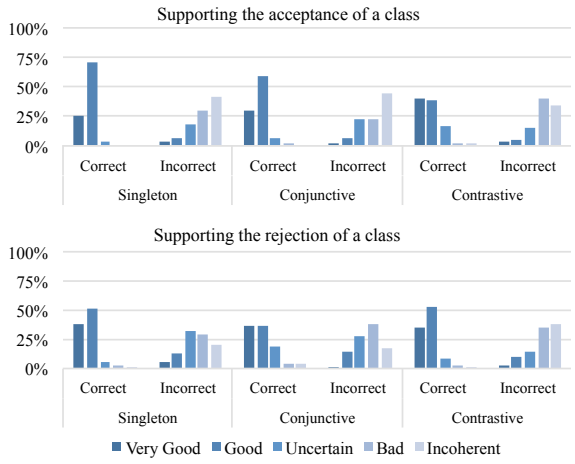

Figure 2: Results of the audit process in the QC task for the three explanatory models separating system acceptance (top) from rejection (bottom). Individual columns represent the percentage of quality label across explanations. Left columns describe correct classifications, while right ones are derived from incorrect classifications.

evaluated 300 explanations (100 for each model), reaching an inter-annotation agreement if 0.82 on these data.

Results in Figure 2 suggest that the annotators were able to properly discriminate correct from incorrect decisions, just through the exposure to the explanations: in both acceptance or rejection cases, all models tend to assign positive labels (Very Good and Good) to explanations of correct decisions and negative ones (Uncertain, Bad and Incoherent) to explanations of incorrect decisions instead. Note that an explanation rejecting a class should be labeled as positive, if the landmark used for *negative* analogy is actually *not* recalling the input sentence. The graphical intuition in Figure 2 is confirmed by the metrics: the Singleton, Conjunctive and Contrastive models reach an *Audit Accuracy* of 89.3%, 84.7% and 86.3%, respectively. The *Pearson Correlation* between acceptance and correctness is 78.9%, 69.4% and 72.8%, while if we measure the correlation between the explanation quality score and the decision correctness, the Pearson coefficients become 76.1%, 71.2% and 77.2%: these are slightly lower basically for the lower reward assigned to x_{Good} w.r.t. $x_{Very\ Good}$. Small numerical differences among models emerge: it seems that the Conjunctive and Contrastive models are not always able to retrieve meaningful additional information, while the Singleton model is simpler and more direct. An example of output analogies is given by *I think "How many Admirals are there in the U.S. Navy?" refers to a* `NUMBER` *since it recalls me of both "How many words are there in the Spanish language?" and "How many sides does an obelisk have?"*, generated by the Conjunctive model. Here the semantic hint corresponds to the discriminative fragment *"How many"*. However meaningful connections between the input and landmarks are also traced against poor overlaps in syntactic and lexical information as in: *I think "Where is the Mall of the America?" refers to a* `LOCATION` *since it recalls me of "What town was the setting for The Music Man?"*.

Table 1 reports question-explanation pairs with similarity estimates based on the adopted CSPTK kernel function. It is clear from the examples that similarity alone is not able to correlate with classification decisions: questions in different classes (e.g. first two rows in the table) may have very high similarity scores. Second, landmarks correlate with decisions in interesting ways that do not depend on strict lexical and grammatical similarity. Conceptually more grounded associations seem to emerge: e.g., explaining *"What was J.F.K.'s wife's name"* by the analogy with *"What was Darth Vader's son named?"* is abstracted across a conceptual relation (e.g. `has_name`) and the derived analogy is quite clear. Notice that active landmarks are independent from similar questions, as landmarks triggered by similar questions are not similar to each other.

Interestingly, explanations of ambiguous instances are harmonic with human uncertainty. The explanation *I think "What is the sales tax in Minnesota?" refers to a* `NUMBER` *since it recalls me of "What is the population of Mozambique?" and does not refer to a* `ENTITY` *since it does not recall me of "What is a fear of slime?"* is convincing, but incorrect. Here, the lack of context impacts on the disambiguation of two plausible interpretations that are (1) the definition of the notion of "sales tax" (`ENTITY`), w.r.t (2) its current value (`NUMBER`): the gold standard suggests `ENTITY` as the correct category.

5.2 Argument Classification

Semantic role labeling (SRL (Palmer et al., 2010)) consists in detecting the semantic arguments associated with the predicate of a sentence and their

the last one is an expert in the field.

Class	Questions (q_i)	$k(q_1, q_2)$	Activated Landmarks (l_i)	$k(l_1, l_2)$
LOC	*"What is the capital of Ethiopia?"*	0.98		
NUM	*"What is the population of Nigeria?"*			
ENTY	*"What was FDR 's dog 's name?"*	0.97	*"What is the name of David Letterman's dog?"*	0.49
HUM	*"What was J.F.K.'s wife 's name?"*		*"What was Darth Vader 's son named?"*	
ENTY	*"What is the Ohio state bird?"*	0.90	*"What is the name of David Letterman 's dog?"*	0.61
ENTY	*"What is the pH scale?"*		*"What is viscosity?"*	
ENTY	*"What was the first satellite to go into space?"*	0.83	*"What was the first TV set to include a remote control?"*	0.61
HUM	*"Who was the first American to walk in space?*		*"What 's the name of the actress who starred in the movie, Silence of the Lambs?"*	
NUM	*"What was the last year that the Chicago Cubs won the World Series?"*	0.73	*"The film Jaws was made in what year?"*	0.31
NUM	*"What is the average speed of the horses at the Kentucky Derby?"*		*"What is average salary of restaurant manager in United States?"*	

Table 1: Examples of semantically similar questions in the same or different classes, with the corresponding landmarks activated during the classification.

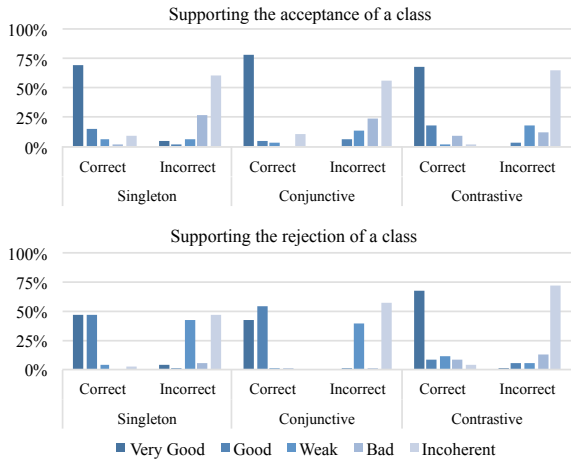

Figure 3: Results of the audit process in the SRL task for the three explanatory models: system acceptance (top), rejection (bottom).

classification into their specific roles ((Fillmore, 1985)). For example, given the sentence "*Bring the fruit onto the dining table*", the task would be to recognize the verb "*bring*" as evoking the BRINGING frame, with its roles, THEME for "*the fruit*" and GOAL for "*onto the dining table*". Argument classification corresponds to the subtask of assigning labels to the sentence fragments spanning individual roles.

As proposed in (Moschitti et al., 2008), SRL can be modeled as a multi-classification task over each parse tree node n, where argument spans reflect sub-sentences covered by the tree rooted at n. Consistently with (Croce et al., 2011), in our experiments the KDA has been empowered with a Smoothed Partial Tree Kernel, operating over Grammatical Relation Centered Trees (GRCT) derived from dependency grammar. The reference benchmark, i.e., the HuRIC dataset related to an Interactive Robotics task (Bastianelli et al., 2016), includes about 650 annotated transcriptions of spoken robotic commands, organized in 18 frames and about 60 arguments. Individual arguments extracted amount to 1,300 examples. Experimental setup was similar to that of Section 5.1, but due to the limited data size we applied 10-fold cross-validation, optimizing network hyper-parameters via grid-search for each fold. We generated the Nyström representations of a SPTK function with default parameters $\mu = \lambda = 0.4$ as in (Croce et al., 2011). With these settings, the KDA accuracy was 96.1%. Due to the slightly higher complexity of the task, w.r.t. QC, in the case the two independent auditors had at least graduate-level knowledge in NLP. They were requested to judge about 700 generated explanations with an inter-annotation agreement of 0.89. For the Singleton, Conjunctive and Contrastive model, respectively, the *Audit Accuracy* is 91.6%, 93.4%, 88.4% while Pearson Coefficients between acceptance/rejection and correctness are 83.3% (80.1% for quality-correctness correlation), 86.9% (81.9%), 77.3% (78.7%): this suggests an higher annotator's sensitivity to the explanations' plausibility, as reflected also by the charts in Figure 3, probably due to the task itself being more challenging for humans.

As in QC, the system can convey semantically transparent and useful information without relying on lexical similarity alone; e.g., consider *I think "is hot" is* DESIRED STATE *of* INSPECTING *in "Robot* CHECK *whether the oven is hot?" since it recalls me of "is empty" in "*SEE *if the washing machine is empty"*. In this task, the Contrastive model could also to produce explanations exemplifying differences between separate roles in the same frame, for example: *I think "to me" is not*

GOAL *of* BRINGING *in "Can you go to the kitchen find a glass and* BRING *it to me?" since it does not recall me of "to the bedroom" in "*BRING *the phone to the bedroom" and it's the* BENEFICIARY *of* BRINGING *since it recalls me of "to me" in "can you please search the book and* BRING *it to me".*

6 Conclusions

This paper proposes a quantitative evaluation of the automatic generation of epistemologically transparent and linguistically fluid explanations for neural inferences. The proposed approach applies LRP to a Kernel-based Deep Architecture (KDA) that redistributes the prediction value to training entries (i.e., annotated landmarks). The resulting sentence exploits analogies with training instances, according to different explanatory strategies. Given that KDAs (based on Nyström embeddings) can be flexibly adopted in neural learning for NLP, we show how the auditing mechanism outlined in the paper is epistemologically very effective and emphasizes the neural embeddings with a strong impact on explainability. First, language semantics is promoted *by design* and associations generated between input instances and decisions are obtained without ever leaving the language level. Second, different and mathematically solid models for different levels of language semantics can be obtained by modifying the adopted kernel formulations. In this way, a unique general auditing mechanism is able to support fine tuning towards very different tasks, without changes in the learning architecture. Finally, as Table 1 shows, explanations are strictly dependent on the induced neural model and are not just triggered by text similarity metrics: they are epistemologically principled evidences about the neural learning stages, based on the observed examples and the selected landmarks.

Empirical investigations carried out against the QC and AC tasks also confirm that the good explanatory models strongly correlate with consistent decisions and effectively contribute to increase the user confidence in the neural inference consistency. This make an auditing activity for human users viable. On one side, it allows to limit the impact of machine mistakes, in a natural and portable manner. Moreover, it can also serve as a novel comparative evaluation paradigm. The reachable auditing accuracy thus measures the explanatory power of different models and can be employed as a comparative benchmark. While the methods proposed in this paper stem just from early explorations, the ways activated landmarks can be made useful to meaningful explanations stimulate further research, involving feature based analysis such as suggested in (Ribeiro et al., 2016) or the application of LRP to architectures more complex than a MLP. Argumentation theory, applied to the active landmark semantics and the source input example as captured by the kernel, provides a very rich framework to design future and more complex justification mechanisms.

Enhancing Variational Autoencoders with Mutual Information Neural Estimation for Text Generation

Dong Qian, William K. Cheung
Department of Computer Science
Hong Kong Baptist University
{dongqian,william}@comp.hkbu.edu.hk

Abstract

While broadly applicable to many natural language processing (NLP) tasks, variational autoencoders (VAEs) are hard to train due to the posterior collapse issue where the latent variable fails to encode the input data effectively. Various approaches have been proposed to alleviate this problem to improve the capability of the VAE. In this paper, we propose to introduce a mutual information (MI) term between the input and its latent variable to regularize the objective of the VAE. Since estimating the MI in the high-dimensional space is intractable, we employ neural networks for the estimation of the MI and provide a training algorithm based on the convex duality approach. Our experimental results on three benchmark datasets demonstrate that the proposed model, compared to the state-of-the-art baselines, exhibits less posterior collapse and has comparable or better performance in language modeling and text generation. We also qualitatively evaluate the inferred latent space and show that the proposed model can generate more reasonable and diverse sentences via linear interpolation in the latent space.

1 Introduction

Deep learning architectures are parameterized by families of non-linear functions, which learn multiple levels of more abstract representations (Bengio, 2009; Bengio et al., 2013). Recently, there has been a surge of interest in deep generative models for unsupervised learning, such as variational autoencoders (VAEs) (Kingma and Welling, 2014; Rezende et al., 2014), generative adversarial networks (GANs) (Goodfellow et al., 2014), and autoregressive models (van den Oord et al., 2016). The goal is to learn a compact representation to capture the salient structure in a given highly complex high-dimensional unlabelled data so that new data with some variations can be generated. They have been widely applied to a range of NLP tasks, such as language modeling (Bowman et al., 2016; Zhao et al., 2018a), dialog generation (Zhao et al., 2017, 2018b), etc. In this paper, we focus on the VAE with recurrent neural networks as its encoder and decoder for text generation.

Recurrent neural networks (RNNs) are one of the state-of-the-art autoregressive models for text modeling (Melis et al., 2018; Trinh et al., 2018). Training RNNs involves factorizing the joint distribution over a set of random variables into a series of conditional distributions. Yet, the one-step-ahead predictions force RNNs to learn local correlations, rather than global coherence. This is insufficient to capture high-level abstractions which characterize text sequences.

One approach to circumvent this challenge is to introduce variational autoencoders (VAEs) (Bowman et al., 2016), where an encoder learns a latent variable from text sequences and a decoder takes advantage of the variable to reconstruct word-level details. The inferred latent variable in the continuous space captures the semantics and syntactics of text sequences and text generation can be performed in the latent space. Although the approach is theoretically elegant, training the VAE often suffers from the well-known *posterior collapse* issue. It tends to ignore the latent variable and the resulting model reduces to a language model. The issue is especially challenging when a powerful autoregressive decoder (e.g., RNNs) is adopted (Bowman et al., 2016). Many recent efforts have been made to address this problem by modifying the objective (Zhao et al., 2019; Dieng et al., 2019; Wang and Wang, 2019), the decoder architecture (Yang et al., 2017), and the variational inference procedure (He et al., 2019; Fu et al., 2019).

The posterior collapse issue can also be understood from the fact that word-level details tend to carry more entropy bits than semantically-relevant concepts. It is well known that most of the changes in the word level to ensure grammatical coherence

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4047–4057,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

do not quickly change the underlying semantics. The maximum-likelihood objective prefers to capture entropy bits at the word level, rather than how well high-level semantics are encoded in the latent space. Training the VAE thus often ends up with relying solely on the autoregressive properties of text sequences, leaving the latent variable unused. Some previous studies (Chen et al., 2017; Alemi et al., 2018) have showed that optimizing the original objective of the VAE is deviated from the goal of learning a good representation.

We consider to address the posterior collapse issue by regularizing the latent space so that the inferred posterior of the latent variable is more specific to its own input, instead of only sticking to the prior. This can be done by maximizing the mutual information (MI) between the input and its latent variable. The MI not only measures how accurate the output agrees with its input, but also whether a meaningful latent variable can be learned in the latent space. However, the estimation and maximization of the MI in the high-dimensional space are difficult. A recent line of work (van den Oord et al., 2018; Belghazi et al., 2018; Hjelm et al., 2019; Veličković et al., 2019) tries to estimate and maximize the MI using the GAN-based approach, where the MI is defined as the Jensen-Shannon divergence (JSD) between the joint distribution and marginals. In this paper, we propose to add a mutual information regularization term, defined as the Kullback-Leibler (KL) divergence, into the objective of the VAE to alleviate the posterior collapse. Different from the models proposed in (Zhao et al., 2019; Dieng et al., 2019), we make effective use of the expressive power of neural networks for the tractable estimation and maximization of the MI in the high-dimensional space. Our empirical results demonstrate that the proposed model can achieve better modeling quality.

Our contributions are summarized as follows:

- We introduce a mutual information term into the objective of the VAE. The latent space can be learned by promoting the posteriors to be more specific to its own inputs, thus leading to low-redundant and diverse representations.
- We establish a lower bound on the mutual information via introducing an energy function paramterized by neural networks. An effective learning algorithm is derived for the unbiased estimation of the gradients.
- We empirically show that the proposed model improves the performance in language modeling and text generation.

2 Related Work

It has been observed that VAEs tend to suffer from the posterior collapse issue, especially when powerful autoregressive decoders are used for modeling text sequences. A common solution is to warm up the KL term in the objective of the VAE by gradually increasing the KL weight from 0 to 1 during training (Bowman et al., 2016). Other proposed methods include randomly dropping words during decoding (Bowman et al., 2016), thresholding the KL term to retain free bits (Kingma et al., 2016; Razavi et al., 2019; Pelsmaeker and Aziz, 2019), adding auxiliary objectives to ensure the effective latent variable for decoding (Goyal et al., 2017; Zhao et al., 2017; Dieng et al., 2019), imposing conditional independence assumptions on the inputs of autoregressive decoders to limit the contextual capacity (Yang et al., 2017; Semeniuta et al., 2017), replacing the Gaussian distribution with the von Mises-Fisher distribution to obtain a fixed KL term (Xu and Durrett, 2018). Also, the semi-amortized approach (Kim et al., 2018) is proposed to perform stochastic variational inference on top of amortized variational inference. Yet, an effective latent variable is learned at the cost of the computational complexity. Some recent work (He et al., 2019; Fu et al., 2019) attempts to improve the training procedure of the VAE without changing its original objective.

Another recent thread of research studies has focused on enhancing the dependency between the input and its latent variable. The skip connection was introduced in (Dieng et al., 2019) to enforce stronger links between the latent variable and the likelihood. InfoVAE (Zhao et al., 2019) introduces a mutual information term, approximated by maximum mean discrepancy, into the objective of the VAE. A similar approach was proposed in (Zhao et al., 2018b) for learning discrete representations.

Recent years have seen some attempts for unsupervised learning through the use of the mutual information. Neural estimation for the MI was proposed in (Brakel and Bengio, 2017), where an encoder and a discriminator are trained to minimize the JSD-based MI. This framework has been further improved and extended, including DeepInfoMax (Hjelm et al., 2019) for image classification

and Deep Graph InfoMax (Veličković et al., 2019) for graph-structured data. Contrastive predicting coding (van den Oord et al., 2018) is an architecture to learn global representations by maximizing the mutual information between the past and future information. Other than the neural estimation approach, the Monte Carlo method can also be used to estimate the MI (Zhao et al., 2018b; Dieng et al., 2019). Yet it suffers from biased estimation and high computational cost.

3 Background

3.1 Variational Autoencoders (VAEs)

Deep generative models define a joint distribution over a set of random variables composed in multiple layers of hierarchies. The goal is to learn the model distribution $p_\theta(\mathbf{x})$ to fit the true data distribution $q(\mathbf{x})$ as well as possible. This can be done by minimizing the Kullback-Leibler (KL) divergence between two distributions, and it is equivalent to the maximum-likelihood objective:

$$\min_\theta \mathrm{KL}[q(\mathbf{x})||p_\theta(\mathbf{x})] = \max_\theta \mathbb{E}_{q(\mathbf{x})}[\log p_\theta(\mathbf{x})]. \tag{1}$$

In this paper, we focus on latent variable models, which define the marginal log-likelihood via a latent variable $\mathbf{z}$:

$$\log p_\theta(\mathbf{x}) = \log \int p_\theta(\mathbf{x}|\mathbf{z})p(\mathbf{z})d\mathbf{z}. \tag{2}$$

Since exactly estimating $\log p_\theta(\mathbf{x})$ is typically intractable, the VAE instead optimizes a tractable Evidence Lower BOund (ELBO):

$$\mathbb{E}_{q(\mathbf{x})}[\log p_\theta(\mathbf{x})] \geq \mathcal{L}_{\text{ELBO}} = \mathbb{E}_{q(\mathbf{x})}\{\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] - \mathrm{KL}[q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})]\}, \tag{3}$$

where the variational posterior $q_\phi(\mathbf{z}|\mathbf{x})$ and the generative distribution $p_\theta(\mathbf{x}|\mathbf{z})$ are parameterized by neural networks (also known as the encoder and the decoder). The prior $p(\mathbf{z})$ is assumed a standard Gaussian distribution $\mathcal{N}(0, \mathbf{I})$.

The ELBO consists of a reconstruction likelihood term that ensures $q_\phi(\mathbf{z}|\mathbf{x})$ to encode *enough* information to generate $\mathbf{x}$ and a KL regularizer that ensures $q_\phi(\mathbf{z}|\mathbf{x})$ to encode *little* information in the posterior by matching it to the prior. Ideally, the encoder would embed high-level abstractions of $\mathbf{x}$ into the latent variable $\mathbf{z}$ and guide the decoder to recover low-level details based on $\mathbf{z}$.

To generate text sequences $\mathbf{x} = \{x_1, \ldots, x_T\}$ with length T, the VAE encodes holistic properties of text sequences $\mathbf{x}$ into the latent variable $\mathbf{z}$. RNNs are used for both the encoder and decoder. For encoding, the last hidden state of the encoder RNN is mapped into the latent variable $\mathbf{z}$. For decoding, $\mathbf{z}$ is fed as an additional input to the decoder RNN at each step, and then the next word x_t is generated conditional on the latent variable $\mathbf{z}$ and all preceding information $x_{<t}$.

3.2 Posterior Collapse

The ELBO will be tighter via optimizing parameters $\{\phi, \theta\}$. The optimal ELBO should be equal to the true data distribution, and thus

$$\mathcal{L}_{\text{ELBO}} \leq \mathbb{E}_{q(\mathbf{x})}[\log p_\theta(\mathbf{x})] \leq \mathbb{E}_{q(\mathbf{x})}[\log q(\mathbf{x})]. \tag{4}$$

If the autoregressive decoder $p_\theta(\mathbf{x}|\mathbf{z})$ is powerful enough to approximate well the true data distribution $q(\mathbf{x})$, the ELBO would be

$$\mathcal{L}_{\text{ELBO}} = \mathbb{E}_{q(\mathbf{x})}\{\log q(\mathbf{x}) - \mathrm{KL}[q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})]\}. \tag{5}$$

The optimal ELBO forces the variational posterior to be like the prior, regardless of how expressively $q_\phi(\mathbf{z}|\mathbf{x})$ is parameterized. The zero-forcing effect of the KL term causes two undesirable outcomes. (*i*) The latent variable $\mathbf{z}$ is independent of the input $\mathbf{x}$, meaning that it contains no information about $\mathbf{x}$. (*ii*) The reconstruction of $\mathbf{x}$ cannot benefit from the encoder at all, meaning that the VAE generates sequences without making use of the latent variable $\mathbf{z}$. This phenomenon is called *posterior collapse*.

It has been proposed in (Hoffman and Johnson, 2016) that decomposing the ELBO can produce an equivalent way to define the ELBO:

$$\mathcal{L}_{\text{ELBO}} = \mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[\log p_\theta(\mathbf{x}|\mathbf{z})] - \mathbb{I}_q[\mathbf{x}, \mathbf{z}] - \mathrm{KL}[q_\phi(\mathbf{z})||p(\mathbf{z})], \tag{6}$$

where $q_\phi(\mathbf{x}, \mathbf{z})$ denotes the *variational joint distribution* induced by the posterior $q_\phi(\mathbf{z}|\mathbf{x})$, $\mathbb{I}_q[\mathbf{x}, \mathbf{z}]$ denotes the mutual information between $\mathbf{x}$ and $\mathbf{z}$ under $q_\phi(\mathbf{x}, \mathbf{z})$, and $q_\phi(\mathbf{z}) = \frac{1}{N}\sum_{n=1}^{N} q_\phi(\mathbf{z}_n|\mathbf{x}_n)$ denotes the *aggregated posterior* (Makhzani et al., 2016). The zero-forcing effect of the KL indicates

$$\mathbb{I}_q[\mathbf{x}, \mathbf{z}] = \mathrm{KL}[q_\phi(\mathbf{z})||p(\mathbf{z})] = 0. \tag{7}$$

However, if the latent variable $\mathbf{z}$ is a good representation of $\mathbf{x}$, the mutual information between $\mathbf{x}$ and $\mathbf{z}$ should take a large value and the KL term

in Equation (3) would be non-zero. As the ELBO objective contains the negative term of the mutual information, achieving higher mutual information between $\mathbf{x}$ and $\mathbf{z}$ is in fact opposite to maximizing the ELBO. This provides another way to explain the posterior collapse issue.

3.3 Mutual Information

Mutual information measures the non-linear relationship between two variables $\mathbf{x}$ and $\mathbf{y}$:

$$\mathbb{I}[\mathbf{x}, \mathbf{y}] = \mathbb{E}_{p(\mathbf{x},\mathbf{y})}\left[\log \frac{p(\mathbf{x}, \mathbf{y})}{p(\mathbf{x})p(\mathbf{y})}\right], \tag{8}$$

where the MI is minimum if two random variables are statistically independent, or maximum when two variables contain identical information. So if the MI is high, the variables are highly predictive of each other.

This hints that we can learn a stochastic encoder $q_\phi(\mathbf{z}|\mathbf{x})$ to maximize the MI between the input $\mathbf{x}$ and its latent variable $\mathbf{z}$ under the variational joint distribution $q_\phi(\mathbf{x}, \mathbf{z})$, given by

$$\max_\phi \mathbb{I}_q[\mathbf{x}, \mathbf{z}] = \max_\phi \mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}\left[\log \frac{q_\phi(\mathbf{x}, \mathbf{z})}{q(\mathbf{x})q_\phi(\mathbf{z})}\right], \tag{9}$$

where $q_\phi(\mathbf{z}|\mathbf{x})$ and $q_\phi(\mathbf{z})$ are distributions over the latent variable. This leads to a decoder-free model for the maximization of the MI. Yet the MI is hard to compute, as $q_\phi(\mathbf{z})$ involves a mixture of the data points. The Monte Carlo approach has been used to approximate the MI in the VAE (Dieng et al., 2019), which however incurs a high computational cost and easily suffers from biased estimation.

4 Proposed Approach

4.1 Model Formulation

As shown in Equation (6), maximizing the ELBO penalizes the mutual information between the input $\mathbf{x}$ and its latent variable $\mathbf{z}$. Due to the posterior collapse issue, the latent variable $\mathbf{z}$ does not represent high-level abstractions of $\mathbf{x}$, making the representation learning even harder. We explicitly introduce a mutual information regularization term into the original ELBO objective that prefers high mutual information between $\mathbf{x}$ and $\mathbf{z}$. This encourages the model to make effective use of the latent variable and alleviate the posterior collapse issue. More formally, we arrive at the following training objective:

$$\begin{aligned}\mathcal{L}_{\text{MI-ELBO}} =& \mathbb{E}_{q(\mathbf{x})}\{\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}) \\ &- \text{KL}[q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})]\} + \alpha\mathbb{I}_q[\mathbf{x}, \mathbf{z}],\end{aligned} \tag{10}$$

where the first two terms can be optimized through the reparameterization trick as in the ELBO and α is a hyperparameter, which balances the trade-off between the inference and generation. We choose to compute the mutual information under the variational joint distribution, as it focuses on the latent space and thus allows us to organize the latent space. The consequence is that the variational posteriors would be more diverse in the latent space characterizing different input sequences, while the KL regularizer restricts the posteriors to match the Gaussian prior, with less "holes" in between where the decoder cannot be trained.

There has been prior work leveraging the mutual information for improving the inference and generation in deep generative models. Some studies (Chen et al., 2016; Dieng et al., 2019) have attempted to maximize the mutual information under the *generative joint distribution* $p_\theta(\mathbf{x}, \mathbf{z})$. In this paper, we focus on explicitly maximizing the mutual information under the variational joint distribution $q_\phi(\mathbf{x}, \mathbf{z})$, which encourages the VAE to learn a useful latent variable $\mathbf{z}$ for improving word generation. Our proposed model is similar in the spirit to the InfoVAE (Zhao et al., 2019). Instead, we adopt neural networks to estimate the MI accurately in the high-dimensional space.

4.2 Mutual Information Formulation

The Jensen-Shannon divergence was employed to define the MI between two variables (Brakel and Bengio, 2017; Hjelm et al., 2019; Veličković et al., 2019). In this paper, we instead maximize the MI, defined by the KL divergence between the joint distribution and marginals. Due to the asymmetric discrepancy, the dependencies between the input and its latent variable can be enhanced. More formally, we define an energy function over the variational joint distribution to estimate the probability of each configuration between two variables (Bengio, 2009), given by:

$$q_\phi(\mathbf{x}, \mathbf{z}) = e^{f_\psi(\mathbf{x},\mathbf{z})}q(\mathbf{x})q_\phi(\mathbf{z})/Z_\psi, \tag{11}$$

where the energy function $f_\psi(\mathbf{x}, \mathbf{z})$ is parameterized by neural networks and the partition function Z_ψ is defined as $\mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}[e^{f_\psi(\mathbf{x},\mathbf{z})}]$.

Based on Equations (9) and (11), a lower bound on the mutual information $\mathbb{I}_q[\mathbf{x}, \mathbf{z}]$ is given by:

$$\mathbb{I}_q[\mathbf{x}, \mathbf{z}] = \mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[f_\psi(\mathbf{x}, \mathbf{z})] - \log\Big[\mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}[e^{f_\psi(\mathbf{x},\mathbf{z})}]\Big] \geq \mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[f_\psi(\mathbf{x}, \mathbf{z})] - \xi \cdot \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}\Big[e^{f_\psi(\mathbf{x},\mathbf{z})}\Big] + \log \xi + 1, \tag{12}$$

where the concave function $\log[x]$ is approximated by a tangent line with the scope ξ according to the Taylor expansion. The approximation is $\log[x] \leq \xi \cdot x - \log[\xi] - 1$, where different values of ξ correspond to different tangent lines. The role of the energy function $f_\psi(\mathbf{x}, \mathbf{z})$ is similar to the *discriminator* in GANs, which learns to distinguish pairs that are sampled from $q(\mathbf{x})q_\phi(\mathbf{z}|\mathbf{x})$ or pairs that are independently sampled from $q(\mathbf{x})q_\phi(\mathbf{z})$. The maximization of the lower bound suggests that the energy function learns to assign higher values to the samples from $q(\mathbf{x})q_\phi(\mathbf{z}|\mathbf{x})$, rather than those from $q(\mathbf{x})q_\phi(\mathbf{z})$, thus enhancing the dependencies.

Since after computing the gradient derivative of $\log[\cdot]$ with respect to parameters ψ, the denominator would contain the expectation of the gradients, leading to biased estimation of the full batch gradients. To solve this, we approximate $\log[\cdot]$ with a tangent line for unbiased estimation of the gradients with respect to the optimal function $f^*_\psi(\mathbf{x}, \mathbf{z})$.

In order to achieve the tighter lower bound on the MI and unbiased estimation for the gradients, we use the convex duality approach (Jordan et al., 1999). The update procedure of model parameters $\{\phi, \psi\}$ can be described as follows.

(*i*). Fixing ϕ and ψ, we optimize Equation (12) with respect to ξ, and the optimal value ξ^* can thus be obtained by

$$\xi^* = \underset{\xi>0}{\operatorname{argmax}}\Big\{-\xi \cdot \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}[e^{f_\psi(\mathbf{x},\mathbf{z})}] + \log \xi\Big\} = \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}\Big[e^{f_\psi(\mathbf{x},\mathbf{z})}\Big]. \tag{13}$$

(*ii*). Fixing ξ, we optimize Equation (12) with respect to ϕ and ψ:

$$\max_{\phi,\psi}\Big\{\mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[f_\psi(\mathbf{x}, \mathbf{z})] - \xi^* \cdot \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}[e^{f_\psi(\mathbf{x},\mathbf{z})}]\Big\}. \tag{14}$$

Here, we first consider the optimal energy function $f^*_\psi(\mathbf{x}, \mathbf{z})$ for any given posterior $q_\phi(\mathbf{z}|\mathbf{x})$ and tangent scope ξ.

Proposition 1. With the fixed ϕ and ξ, the optimal energy function $f^*_\psi(\mathbf{x}, \mathbf{z})$ according to the objective in Equation (12) is given by

$$f^*_\psi(\mathbf{x}, \mathbf{z}) = \log q_\phi(\mathbf{x}, \mathbf{z}) - \log[q(\mathbf{x})q_\phi(\mathbf{z})] - \log \xi, \tag{15}$$

where $f^*_\psi(\mathbf{x}, \mathbf{z})$ becomes the *pointwise mutual information* when $\xi = 1$. This suggests that the energy function assigns zero probability to the samples independently drawn from $q(\mathbf{x})q_\phi(\mathbf{z})$.

With the optimal energy function $f^*_\psi(\mathbf{x}, \mathbf{z})$, the max-max objective in Equation (12) can be reformulated as:

$$C(\phi, \psi^*) = \mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[f^*_\psi(\mathbf{x}, \mathbf{z})] - \xi \cdot \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}\Big[e^{f^*_\psi(\mathbf{x},\mathbf{z})}\Big] + \log \xi + 1 = \mathrm{KL}[q_\phi(\mathbf{x}, \mathbf{z})||q(\mathbf{x})q_\phi(\mathbf{z})] = \mathbb{I}_q[\mathbf{x}, \mathbf{z}]. \tag{16}$$

We show that maximizing the lower bound on the MI with respect to $\{\phi, \psi, \xi\}$ is equivalent to maximizing the KL divergence between the joint distribution and their marginals. Together with Equations (10) and (16) as well as Proposition 1, the optimization objective becomes:

$$\mathcal{L}_{\text{MI-ELBO}} = \mathbb{E}_{q(\mathbf{x})}\{\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}) - \mathrm{KL}[q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})]\} + \alpha C(\phi, \psi^*), \tag{17}$$

where $C(\phi, \psi^*)$ is defined as a function that maximizes the lower bound on the MI with the optimal ψ^*. Then, we compute the gradients of Equation (17) with respect to $\{\phi, \theta\}$. While it is easy to compute the gradient with respect to θ, the gradient with respect to ϕ is hard to compute since $C(\phi, \psi^*)$ itself depends on ϕ. Actually, when the function $f_\psi(\mathbf{x}, \mathbf{z})$ is optimal, the expectation of the gradients becomes zero, that is

$$\mathbb{E}_{q_\phi(\mathbf{x},\mathbf{z})}[\nabla_\phi f^*_\psi(\mathbf{x}, \mathbf{z})] - \mathbb{E}_{q(\mathbf{x})q_\phi(\mathbf{z})}\Big[\nabla_\phi e^{f^*_\psi(\mathbf{x},\mathbf{z})}\Big] = 0. \tag{18}$$

In practice, we can ignore the gradients once $f_\psi(\mathbf{x}, \mathbf{z})$ achieves the optimality. We refer the proposed model as *VAE-MINE*. The overall learning procedure is summarized in Algorithm 1.

5 Experiments and Results

5.1 Datasets

We adopt three benchmark datasets, Penn Treebank (Marcus et al., 1993), Stanford Natural Language Inference (Bowman et al., 2015) and Yahoo Answers (Yang et al., 2017) to evaluate whether the inferred latent variable can give better performance in language modeling and text generation. For data pre-processing, we set the maximum

Algorithm 1: VAE with Mutual Information Neural Estimation (VAE-MINE)

Initialize the parameters of the encoder, decoder, energy function $\{\phi, \theta, \psi\}$ and tangent scope ξ;
repeat
  Sample mini-batch of M sentences $\{\mathbf{x}_1, \ldots, \mathbf{x}_M\}$ from the data distribution $q(\mathbf{x})$;
  Sample mini-batch of M latent variables $\{\mathbf{z}_1, \ldots, \mathbf{z}_M\}$ from the encoder $q_\phi(\mathbf{z}|\mathbf{x})$;
  Shuffle M latent variables $\{\mathbf{z}'_1, \ldots, \mathbf{z}'_M\}$;
  Update ψ by ascending its stochastic gradient:
  $\frac{1}{M}\sum_{i=1}^{M}\nabla_\psi\Big[f_\psi(\mathbf{x}_i, \mathbf{z}_i) - \xi \cdot e^{f_\psi(\mathbf{x}_i, \mathbf{z}'_i)}\Big]$;
  Compute the optimal tangent scope ξ^*:
  $\xi^* = \frac{1}{M}\sum_{i=1}^{M} e^{f_\psi(\mathbf{x}_i, \mathbf{z}'_i)}$;
  Update ϕ by ascending its stochastic gradient:
  $\frac{1}{M}\sum_{i=1}^{M}\nabla_\phi[\log p_\theta(\mathbf{x}_i|\mathbf{z}_i) - \mathrm{KL}[q_\phi(\mathbf{z}_i|\mathbf{x}_i)||p(\mathbf{z})]]$
  $+\frac{1}{M}\sum_{i=1}^{M}\nabla_\phi\Big[f_\psi(\mathbf{x}_i, \mathbf{z}_i) - \xi \cdot e^{f_\psi(\mathbf{x}_i, \mathbf{z}'_i)}\Big]$;
  Update θ by ascending its stochastic gradient:
  $\frac{1}{M}\sum_{i=1}^{M}\nabla_\theta \log p_\theta(\mathbf{x}_i|\mathbf{z}_i)$;
  Perform SGD-updates for parameters $\{\phi, \theta, \psi\}$;
until *convergence*;

Dataset	#Train	#Valid	#Test	Length	Vocab
PTB	42K	3.3K	3.7K	21	10K
SNLI	1.1M	13K	13K	20	20K
Yahoo	101K	10K	10K	78	20K

Table 1: Statistics of three benchmark datasets used in the experiments. Length denotes the average length of the sentences in the dataset and Vocab denotes the vocabulary size.

length of sentences to 200 and the maximum vocabulary size to 20K across all the datasets. Statistics of three datasets are summarized in Table 1.

5.2 Experimental Setup

We implement the VAE using a one-layer unidirectional LSTM (Hochreiter and Schmidhuber, 1997) with 512 hidden units and 128-dimensional word embedding for the encoder and decoder. The latent variable is 64-dimensional for all the models. We adopt the standard Gaussian prior and the diagonal Gaussian posterior. The last hidden state of the encoder RNN is fed into an MLP to estimate the mean and variance of the Gaussian posterior. Then, we sample the latent variable $\mathbf{z}$ and feed it to the decoder RNN at each step. The initial hidden state of the decoder RNN is obtained by feeding $\mathbf{z}$ to another MLP with the $\tanh()$ activation function. In order to further regularize the decoder RNN, dropout with a keep probability of 0.5 is applied to the inputs and outputs. We adopt SGD to optimize the model with a decayed learning rate and a gradient clipping.

Our architecture adopts an encoder RNN and an energy function parameterized by neural networks to maximize the lower bound on the MI. The energy function is trained by samples from the variational joint distribution and marginals. In practice, samples from the marginals are obtained by pairing one sentence $\mathbf{x}$ and another latent variable $\mathbf{z}'$ inferred by another sentence $\mathbf{x}'$. We adopt an MLP with two 512-unit hidden layers and ReLU activation to parameterize the energy function. As the encoder RNN and energy function optimize the same MI objective, the lower layers are shared between two modules. We set the value of the hyperparameter α within $[2, 5]$ with step $= 0.5$ for VAE-MINE and select the best α^* based on the validation dataset.

We compare the proposed VAE-MINE with the state-of-the-art baselines. LSTM-LM is an unconditional language model. For VAE-0.5 (Bowman et al., 2016), we implement KL annealing by increasing the KL weight linearly from 0.1 to 1.0 in the first 10 epochs and adopt word dropout rate of 0.5 to alleviate the posterior collapse. For VAE-BOW (Zhao et al., 2017), we replace word dropout with the bag-of-word (BOW) loss. For InfoVAE (Zhao et al., 2019), CyclicalVAE (Fu et al., 2019), and LaggingVAE (He et al., 2019), we follow the reported implementations.

5.3 Performance Evaluation

Posterior Collapse. We apply three metrics to evaluate the severity of the posterior collapse: KL divergence between the variational posterior and the prior, mutual information (MI), and the number of active units (AU) of the latent variable $\mathbf{z}$. If the KL in Equation (3) becomes zero, the posterior collapses, meaning that the variational posterior is equal to the prior. For the MI, we use the Monte Carlo approach to approximate Equation (6),

$$\mathrm{KL}[q_\phi(\mathbf{z})||p(\mathbf{z})] = \frac{1}{S}\sum_{s=1}^{S}[\log q_\phi(\mathbf{z}_s) - \log p(\mathbf{z}_s)], \tag{19}$$

where S is the sample size.

The number of active units (Burda et al., 2015) is computed by

$$\mathrm{AU} = \sum_{d=1}^{D}\mathbb{I}\{\mathrm{Cov}_{q(\mathbf{x})}(\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[z_d]) \geq \epsilon\}, \tag{20}$$

where z_d is the d-th dimension of $\mathbf{z}$ and the threshold ϵ is set to 0.01. $\mathbb{I}\{\cdot\}$ is an indicator giving 1 when its statement is true and 0 otherwise.

Forward and Reverse Perplexity. A common measure for the quality of the generated sentences is to evaluate the perplexity of a language model trained on the training or generated sentences. We fit a non-parametric Kneiser-Ney (KN) smoothed 5-gram language model (LM) (Heafield, 2011) on the sentences sampled from the model distribution $p_\theta(\mathbf{x})$ and the true data distribution $q(\mathbf{x})$. Two evaluation criteria are defined as *Forward Perplexity* (FPPL) and *Reverse Perplexity* (RPPL) (Zhao et al., 2018a; Cífka et al., 2018). Computing the FPPL is equivalent to training a KN 5-gram LM on the training sentences and reporting the perplexity on the 100K sentences generated from the model, while the RPPL involves training a KN 5-gram LM on the 100K generated sentences and reporting the perplexity on the test sentences.

5.4 Language Modeling Results

The results for language modeling are shown in Table 2. We report negative log-likelihood (NLL), KL divergence (KL), perplexity (PPL), mutual information (MI), the number of active units (AU), forward perplexity (FPPL) and reverse perplexity (RPPL).

According to Table 2, we observe that the KL value for VAE-0.5 is almost zero, indicating that the model suffers from posterior collapse. Similar situations can also be observed for InfoVAE. When the bag-of-word loss is used, the KL value increases, yet making VAE-BOW produce a larger NLL. This suggests that the latent variable does not contain useful information to reduce the reconstruction error. For VAE-MINE, we see that it can produce either comparable or better results over the evaluation metrics when compared with other state-of-the-art baselines. With the mutual information term considered for the optimization, we believe that VAE-MINE allows more reasonable correspondence patterns between the input and its inferred latent variable so as to better alleviate posterior collapse. Together with the original ELBO objective, the inferred posteriors of the different input sentences give an appropriate level of overlapping among them in the latent space, instead of sticking to the Gaussian prior. To summarize, the latent variable with non-trivial KL value helps the decoder RNN for better word-level generation.

Regarding the generation capability, we observe that VAE-MINE and LaggingVAE exhibit similar performance in terms of PPL and FPPL (sample quality) and outperform the other baselines by a significant margin. Particularly, VAE-MINE performs significantly better than others in terms of RPPL (sample diversity). We believe that this is due to the explicit use of the MI term to guide the learning process. It is consistent with our motivation that the MI-regularized objective can alleviate the posterior collapse to improve VAEs' capability of generating fluent and diverse sentences with the effective use of the latent variable. In contrast, LaggingVAE treats the MI as a stopping criterion for training the encoder RNN at the beginning of optimization. Even though the model can achieve good performance on alleviating the posterior collapse and generate fluent sentences, the generated sentences lack diversity. VAE-MINE can achieve relatively lower RPPL values, which suggests that it can achieve a good balance between sample diversity and training quality. This is not surprising that maximizing the MI would produce more diverse sentences. Also, the encoder parameters can benefit from the gradients from the energy function during training.

5.5 Reconstruction, Interpolation and Generation

We qualitatively evaluate the sentences generated using VAE-MINE as well as other baselines. The VAE variants can reconstruct input sentences by encoding them into the latent space and then decoding the means or samples drawn from the variational posteriors. Table 3 shows two sets of sentences generated using VAE-MINE with a greedy decoding based on two particular inputs. It shows that sentences involving similar underlying structures and concepts can be generated.

In order to evaluate the quality of the inferred latent space, we interpolate two points in the latent space and then decode the interpolated points for generating sentences. Table 4 shows the transitions of the generated sentences between two particular sentences in the SNLI dataset using different models. LaggingVAE turns out to be performing the worst by generating repetitive sentences. This explains why it gives large RPPL values as shown in Table 2. For VAE-MINE, we find that it can generate smoothly transitioned sentences in term of sentence semantics and syntactics via linear interpolation in the latent space. This demonstrates that the proposed VAE-MINE can learn the latent representations which smoothly fill up the

Dataset	Model	NLL (KL)	PPL	MI	AU	FPPL	RPPL

Table 2: Language modeling results on the PTB, SNLI and Yahoo datasets. We report negative log-likelihood (NLL), KL divergence (KL), perplexity (PPL), mutual information (MI), the number of active units (AU) of the latent variable $\mathbf{z}$, forward perplexity (FPPL) and reverse perplexity (RPPL). We express the NLL as the ELBO. **Bold** numbers indicate the best performance and underlined numbers indicate the second best performance.

Input:	**the man is at home sleeping.**	**three girls are sitting at desks and appear to be working intently.**
Output1:	the man is at home sleeping.	three women are sitting at desks and looking to be working together.
Output2:	the woman is sleeping at home.	Two ladies are standing at desks and appear to be playing together.
Output3:	the woman is working at home.	three women are sitting at desks and looking to be playing together.

Table 3: Sentences generated from the variational posteriors of the latent variable based on SNLI dataset.

latent space.

Next, we compare generated sentences by sampling latent variables from the Gaussian prior and then greedy decoding. In Table 5, we observe that sentences generated from LaggingVAE are not as diverse as the ones generated from VAE-MINE.

5.6 Nearest Neighbour Analysis

To better understand the learned representations, we did a nearest-neighbour analysis by choosing a sentence from the training set, ordering the training set in terms of the cosine distance computed in the latent space, then selecting the top three with the highest similarity. Our results in Table 6 show that VAE-MINE learns a good latent variable such that novel sentences can be chosen, due to the nature of MI-regularized objective.

6 Conclusion

Variational autoencoders suffer from the posterior collapse issue. In this paper, we propose to alleviate this problem by adding a mutual information regularization into the objective of the VAE. Explicitly optimizing the proposed objective allows to encode high-level abstractions effectively. We use an energy function parameterzied by neural networks and the convex duality approach to maximize the lower bound on the MI. Experimental results on three benchmark datasets show that the proposed model VAE-MINE in general outperforms other state-of-the-art baselines and can generate more reasonable sentences via linear interpolation in the latent space. One research direction is to explore how to generate long-form text with deep generative models organized in multiple layers of latent variables, due to natural language characterizing a hierarchical structure.

Abstract

The exploding cost and time needed for data labeling and model training are bottlenecks for training DNN models on large datasets. Identifying smaller representative data samples with strategies like active learning can help mitigate such bottlenecks. Previous works on active learning in NLP identify the problem of sampling bias in the samples acquired by uncertainty-based querying and develop costly approaches to address it. Using a large empirical study, we demonstrate that active set selection using the posterior entropy of deep models like FastText.zip (FTZ) is robust to sampling biases and to various algorithmic choices (query size and strategies) unlike that suggested by traditional literature. We also show that FTZ based query strategy produces sample sets similar to those from more sophisticated approaches (e.g ensemble networks). Finally, we show the effectiveness of the selected samples by creating tiny high-quality datasets, and utilizing them for fast and cheap training of large models. Based on the above, we propose a simple baseline for deep active text classification that outperforms the state-of-the-art. We expect the presented work to be useful and informative for dataset compression and for problems involving active, semi-supervised or online learning scenarios. Code and models are available at: https://github.com/drimpossible/Sampling-Bias-Active-Learning

1 Introduction

Deep neural networks (DNNs) trained on large datasets provide state-of-the-art results on various NLP problems (Devlin et al., 2019) including text classification (Howard and Ruder, 2018). However, the cost and time needed to get labeled data and to train models is a serious impediment to creating new and/or better models. This problem can be mitigated by creating smaller representative datasets with active learning which can be used for training DNNs to achieve similar test accuracy as that using the full training dataset . In other words, the smaller sample can be considered a surrogate for the full data.

However, there is lack of clarity in the active learning literature regarding sampling bias in such surrogate datasets created using active learning (Settles, 2009): its dependence on models, functions and parameters used to acquire the sample. Indeed, what constitutes a good sample? In this paper, we perform an empirical investigation using active text classification as the application.

Early work in active text classification (Lewis and Gale, 1994) suggests that greedy query generation using label uncertainty may lead to efficient representative samples (Nonetheless, the same test accuracy). Subsequent concerns regarding sampling bias has lead to explicit use of expensive diversity measures (Brinker, 2003; Hoi et al., 2006) in acquisition functions or using ensemble approaches (Liere and Tadepalli, 1997; McCallum and Nigam, 1998) to improve diversity implicitly.

Deep active learning approaches adapt the discussed framework above to train DNNs on large data. However, it is not clear if the properties of deep approaches mirror those of their shallow counterparts and if the theory and the empirical evidence regarding sampling efficiency and bias translates from shallow to deep models. For example, (Sener and Savarese, 2018) and (Ducoffe and Precioso, 2018) find that uncertainty based strategies perform no better than random sampling even if ensembles are used and using diversity measures outperform both. On the other hand, (Beluch et al., 2018; Gissin and Shalev-Shwartz, 2019) find that uncertainty measures computed with ensembles outperform diversity based approaches while (Gal et al., 2017; Beluch et al., 2018; Siddhant and Lipton, 2018) find them to outperform uncertainty measures computed using single models. A recent empirical study (Siddhant and Lipton, 2018) investigating active learning in NLP suggests that Bayesian active learning outperforms classical uncertainty sampling across all settings. However, the approaches have been limited to rel-

atively small datasets.

1.1 Sampling Bias in Active Classification

In this paper, we investigate the issues of sampling bias and sample efficiency, the stability of the actively collected query and train sets and the impact of algorithmic factors - i.e. the setup chosen while training the algorithm, in the context of deep active text classification on large datasets. In particular, we consider two sampling biases: label and distributional bias, three algorithmic factors: initial set selection, query size and query strategy along with two trained models and four acquisition functions on eight large datasets.

To isolate and evaluate the impact of the above (combinatorial) factors, a large experimental study was necessary. Consequently, we conducted over 2.3K experiments on 8 popular, large, datasets of sizes ranging from 120K-3.6M. Note that the current trend in deep learning is to train large models on very large datasets. However, the aforementioned issues have not yet been investigated in the literature in such a setup. As shown in Table 1, the datasets used in latest such analysis on active text classification by (Siddhant and Lipton, 2018) are quite small in comparison. The datasets used by us are two orders of magnitude larger, our query samples often being the size of the entire datasets used, and the presented empirical study is more extensive (20x experiments).

Our findings are as follows:

(i) We find that utilizing the uncertainty query strategy using a deep model like FastText.zip (FTZ)[1] to actively construct a representative sample provides query and train sets with remarkably good sampling properties.

(ii) We finds that a single deep model (FTZ) used for querying provides a sample set similar to more expensive approaches using ensemble of models. Additionally, the sample set has a large overlap with support vectors of an SVM trained on the entire dataset largely invariant to a variety of algorithmic factors, thus indicating the robustness of the acquired sample set.

(iii) We demonstrate that the actively acquired training datasets can be utilized as small, surrogate training sets with a 5x-40x compression for training large, deep text classification models. In particular, we can train the ULMFiT (Howard and Ruder, 2018) model to state of the art accuracy at 25x-200x speedups.

(iv) Finally, we create a novel, state-of-the-art baseline for active text classification which outperforms recent work (Siddhant and Lipton, 2018), using Bayesian dropout, utilizing 4x less training data. We also outperform (Sener and Savarese, 2018) at all training data sizes. The latter uses an expensive diversity based query strategy (coreset sampling).

The rest of the paper is organized as follows: in Section 2, the experimental methodology and setup are described. Section 3 presents the experimental study on sampling biases as well as the impact of various algorithmic factors. In Section 4, we compare with prior literature in active text classification. Section 5 presents a downstream use case - fast bootstrapping of the training of very large models like ULMFiT. Finally, we discuss the current literature in light of our work in Section 6 and summarize the conclusions in Section 7.

2 Methodology

This section describes the experimental approach and the setup used to empirically investigate the issues of (i) sampling bias and (ii) sampling efficiency in creating small samples to train deep models.

2.1 Approach

A labelled training set is incrementally built from a pool of unlabeled data by selecting & acquiring labels from an oracle in sequential increments. In this, we follow the standard approach found in the active learning literature. We use the following terminology:

Queries & Query Strategy: We refer to the (incremental) set of points selected to be labeled and added to the training as the query and the (acquisition) function used to select the samples as the query strategy.

Pool & Train Sets: The pool is the unlabeled data from which queries are iteratively selected, labeled and added to the (labeled) train set.

Let $\mathcal{D}_S = (\mathbf{x}_i, y_i)$ denote a dataset consisting of $|\mathcal{S}| = n$ i.i.d samples of data/label pairs, where $|.|$ denotes the cardinality. Let $\mathcal{S}_0 \subset \mathcal{S}$ denote an initial randomly drawn sample from the initial pool. At each iteration, we train the model on the current train set and use a model-dependent query strategy

[1] We use FastText.zip (FTZ) to optimize the time and resources needed for this study.

to acquire new samples from the pool, get them labeled by an oracle and add them to the train set. Thus, a sequence of training sets: $[\mathcal{S}_1, \mathcal{S}_2 \ldots, \mathcal{S}_b]$ is created by sampling b queries from the pool set, each of size K. The b queries are given by $[\mathcal{S}_1 - \mathcal{S}_0, \mathcal{S}_2 - \mathcal{S}_1 \ldots, \mathcal{S}_b - \mathcal{S}_{b-1}]$. Note that $|\mathcal{S}_i| = (|\mathcal{S}_0| + i \times K)$ and $\mathcal{S}_1 \subset \mathcal{S}_2 \ldots \subset \mathcal{S}_b \subset \mathcal{S}$.

In this paper, we investigate the efficiency and bias of sample sets $\mathcal{S}_b^1, \mathcal{S}_b^2, \ldots, \mathcal{S}_b^t$ obtained by different query strategies $Q^1, Q^2, \ldots Q^t$. We exclude the randomly acquired initial set and perform comparisons on the actively acquired sample sets defined as $\hat{\mathcal{S}}_j^i = (\mathcal{S}_j^i - \mathcal{S}_0^i)$.

2.2 Experimental Setup

In this section, we share details of the experimental setup, and present and explain the choice of the datasets, models and query strategies used.

Datasets: We used eight, large, representative datasets widely used for text classification: AGNews (AGN), DBPedia (DBP), Amazon Review Polarity (AMZP), Amazon Review Full (AMZF), Yelp Review Polarity (YRP), Yelp Review Full (YRF), Yahoo Answers (YHA) and Sogou News (SGN). Please refer to Section 4 of (Zhang et al., 2015) for details regarding the collection and characteristics of these datasets. Table 1 provides a comparison regarding the choice of datasets, models and number of experiments between our study and (Siddhant and Lipton, 2018) which investigates a variety of NLP tasks including text classification while we focus only on the latter.

Models: We reported two text classification models as representatives of classical and deep learning approaches respectively which were fast to train and also had good performance on text classification: Multinomial Naive Bayes (MNB) with TF-IDF (Wang and Manning, 2012) and FastText.zip (FTZ) (Joulin et al., 2016). The FTZ model provides results competitive with VDCNNs (a 29 layer CNN) (Conneau et al., 2017) but with over 15,000$\times$ speedup (Joulin et al., 2017). This allowed us to conduct a thorough empirical study on large datasets. Multinomial Naive Bayes (MNB) with TF-IDF features is a popularly claimed baseline for text classification (Wang and Manning, 2012).

Query Strategies: Uncertainty based query strategies are widely used and well studied in the active learning literature. Those strategies typically use a scoring function on the (softmax) output of a single model. We evaluate the following ones: Least Confidence (LC) and Entropy (Ent). Independently training ensembles of models (Lakshminarayanan et al., 2017) is another principled approach to obtain uncertainties associated with the output estimate.Then, we tried four query strategies - LC and Ent computed using single and ensemble models and evaluated them against random sampling (chance) as a baseline. For ensembles, we used five FTZ ensembles (Lakshminarayanan et al., 2017). In contrast, (Siddhant and Lipton, 2018) used Bayesian ensembles using Dropout, proposed in (Gal et al., 2017). Please refer to Section 4 for a comparison.

Paper	#Exp	Datasets (#Train)	Models (Full Acc)
DAL	120	TREC-QA (6k), MAReview (10.5k)	SVM (89%), CNN (91%), LSTM (92%)
Ours	2.3K	AGN (120k), SGN (450k), DBP (560k), YRP (560k), YRF (650k), YHA (1400k), AMZP (3600k), AMZF (3000k)	FTZ (97%), MNB (90%)

Table 1: Comparison of active text classification datasets and models (Acc on Trec-QA) used in (Siddhant and Lipton, 2018) and our work. We use significantly larger datasets (two orders larger), perform 20x more experiments, and use more efficient and accurate models.

Implementation Details: We performed 2304 active learning experiments. We obtained our results on three random initial sets and three runs per seed (to account for stochasticity in FTZ) for each of the eight datasets. The query sizes were 0.5% of the dataset for AGN, AMZF, YRF and YHA and 0.25% for SGN, DBP, YRP and AMZP respectively for $b = 39$ sequential, active queries. We also experimented with different query sizes keeping the size of the final training data $b \times K$ constant. The default query strategy uses a single model with output Entropy (Ent) unless explicitly stated otherwise. Results in the chance column are obtained using random query strategy.

We used Scikit-Learn (Pedregosa et al., 2011) implementation for MNB and original implementation for FastText.zip (FTZ) [2]. We required 3 weeks of running time for all FTZ experiments on a x1.16xlarge AWS instance with Intel Xeon E7-8880 v3 processors and 1TB RAM to obtain results presented in this work. The experiments are deterministic beyond the stochasticity involved in training the FTZ model, random initialization and

Table 2: Label entropy with a large query size ($b = 9$ queries). $\cap Q$ denotes averaging across queries of a single run, $\cap S$ denotes the label entropy of the final collected samples, averaged across seeds. Naive Bayes ($\cap Q$) has biased (inefficient) queries while FastText ($\cap Q$) shows stable, high label entropy showing a rich diversity in classes despite the large query size. Overall, the resultant sample ($\cap S$) becomes balanced in both cases.

SGD updates. The entire list of hyperparameters and metrics affecting uncertainty such as calibration error (Guo et al., 2017) is given in the supplementary material. The experimental logs and models are available on our github link[3].

3 Results

In this section, we study several aspects of sampling bias (class bias, feature bias) and the impact of relevant algorithmic factors (initial set selection, query size and query strategy.

We evaluated the actively acquired queries and sample set for sampling bias, and for the stability as measured by %intersection of collected sets across a critical influencing factor. Higher sample intersections indicate more stability increase to the chosen influencing factor.

3.1 Aspects of Sampling Bias

We study two types of sampling biases: (a) Class Bias and (b) Feature Bias.

3.1.1 Class Bias

Greedy uncertainty based query strategies are said to pick disproportionately from a subset of classes per query (Sener and Savarese, 2018; Ebert et al., 2012), developing a lopsided representation in each query. However, its effect on the resulting sample set is not clear. We test this by measuring the Kullback-Leibler (KL) divergence between the ground-truth label distribution and the distribution obtained per query as one experiment ($\cap Q$), and over the resulting sample ($\cap S$) as the second. Let us denote P as the true distribution of labels, $\hat{P}$ the sample distribution and C the total number of classes. Since P follows a uniform distribution, we can use Label entropy instead ($L = -KL(P||\hat{P}) + log(C)$). Label entropy L is an intuitive measure. The maximum label entropy is reached when sampling is uniform, $\hat{P}(x) = P(x)$, i.e. $L = log(C)$.

We present our results in Table 2. We observe that across queries ($\cap Q$), FTZ with entropy strategy has a balanced representation from all classes (high mean) with a high probability (low std) while Multinomial Naive Bayes (MNB) results in more biased queries (lower mean) with high probability (high std) as studied previously. However, we did not find evidence of class bias in the resulting sample ($\cap S$) in both models: FastText and Naive Bayes (column 5 and 6 from Table 2).

We conclude that entropy as a query strategy can be robust to class bias even with large query sizes.

3.1.2 Feature Bias

Uncertainty sampling can lead to undesirable sampling bias in feature space (Settles, 2009) by repeating redundant samples and picking outliers (Zhu et al., 2008). Diversity-based query strategies (Sener and Savarese, 2018) are used to address this issue, by selecting a representative subset of the data. In the context of active classification, it is good to pick the most informative samples to be the ones closer to class boundaries[4].

Indeed, recent work suggests that the learning in deep classification networks may focus on small part of the data closer to class boundaries, thus resembling support vectors (Xu et al., 2018; Toneva et al., 2019). To investigate whether uncertainty sampling also exhibits this behavior, we perform below a direct comparison with support vectors from a SVM. For this, we train a FTZ model on the full training data and train a SVM on the resulting features (sentence embeddings) to obtain the support vectors and compute the intersection of support vectors with each selected set. The percentage intersections are shown in Table 3. The high percentage overlap is a surprising result which shows that the sampling is indeed biased but in

[3] https://github.com/drimpossible/Sampling-Bias-Active-Learning

[4] In this work, we assume ergodicity in the setup. We do not consider incremental, online modeling scenarios where new modes or new classes are sequentially encountered.

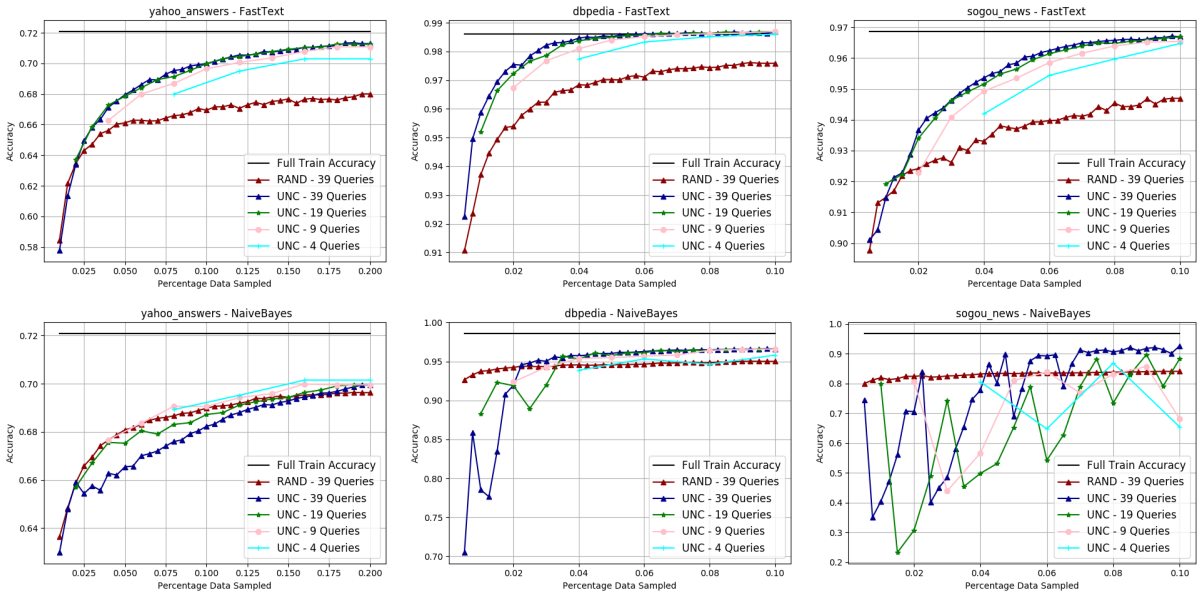

Figure 1: Accuracy across different number of queries b for FastText and Naive Bayes, with $b \times K$ constant. FastText is robust to increase in query size and significantly outperforms random in all cases. Naive Bayes: (Left) All including b=39 perform worse than random, (Center) All including b=9 eventually perform better than random (Right) $b = 39$ performs better than random but larger query sizes perform worse than random. Uncertainty sampling with Naive Bayes suffers from sampling size bias.

Dsets	Common%	Chance%	$\#SV$
SGN	71.3 ± 0.5	9.3 ± 0.5	13184
DBP	86.3 ± 0.5	9.7 ± 0.5	1479
YRP	57.3 ± 0.5	9.7 ± 0.5	31750
AGN	45.0 ± 0.8	21.0 ± 1.6	1032

Table 3: Proportion of Support Vectors intersecting with our actively selected set calculated by $\frac{|\mathcal{S}_{SV} \cap \hat{\mathcal{S}}_b|}{|\mathcal{S}_{SV}|}$. Actively selected sets share large overlap with supports of an SVM (critical for classification).

a desirable way. Since the support vectors represent the class boundaries, a large percentage of selected data consists of samples around the class boundaries. This overlap indicates that the actively acquired training sample covers the support vectors well which are important for good classification performance. The overlap with the support vectors of an SVM (a fixed algorithm) also suggests that uncertainty sampling using deep models might generalize beyond FastText, to other learning algorithms.

Experimental Details: We used a fast GPU implementation for training an SVM with a linear kernel (Wen et al., 2018) with default hyperparameters. Please refer to supplementary material for additional details. We ensured the SVM achieves similar accuracies as original FTZ model.

Dsets	Chance	FTZD	FTZS	MNBD	MNBS
SGN	0.8	77.8	81.0	55.5	100.0
DBP	0.9	79.7	81.3	79.7	100.0
YHA	3.7	69.0	73.6	89.5	100.0
YRP	0.9	42.9	43.7	16.0	100.0
YRF	3.6	67.7	71.6	13.6	100.0
AGN	3.7	68.7	70.1	79.8	100.0
AMZP	0.9	48.4	48.8	15.0	100.0
AMZF	3.6	56.8	63.1	57.8	100.0

Table 4: % Intersection of samples obtained with different seeds (ModelD) compared to same seeds (ModelS) and chance intersection for $b = 39$ queries. We see that FastText is initialization independent (FTZD $\approx$ FTZS $\gg$ Chance). NaiveBayes shows significant dependency on the initial set sometimes, while other times performs comparable to FastText.

3.2 Algorithmic Factors

We analyze three algorithmic factors of relevance to sampling bias: (a) Initial set selection (b) Query size, and, (c) Query strategy.

3.2.1 Initial Set Selection

To investigate the dependence of the actively acquired train set on the initial set, we compare the overlap (intersection) of the incrementally constructed sets from different random initial sets versus the same initial set. The results are shown in Table 4. We first observe that chance overlaps (column 2) are very low - less than 4%. Columns

Dsets	Chance	FTZ $9 \cap 19 \cap 39$	FTZ $39 \cap 39 \cap 39$	MNB $9 \cap 19 \cap 39$	MNB $39 \cap 39 \cap 39$
SGN	0.83 ± 0.0	77.0 ± 0.5	77.9 ± 0.2	31.9 ± 0.0	55.5 ± 0.0
DBP	0.9 ± 0.0	80.0 ± 0.1	79.6 ± 0.2	82.3 ± 0.0	79.7 ± 0.0
YHA	3.7 ± 0.0	68.3 ± 0.1	69.0 ± 0.0	92.1 ± 0.0	89.5 ± 0.0
YRP	0.9 ± 0.0	46.0 ± 0.9	42.7 ± 1.0	10.8 ± 0.0	16.0 ± 0.0
YRF	3.6 ± 0.0	68.4 ± 0.2	67.6 ± 0.1	14.2 ± 0.0	13.6 ± 0.0
AGN	3.7 ± 0.0	70.3 ± 0.2	68.7 ± 0.1	81.6 ± 0.0	79.8 ± 0.0
AMZP	0.9 ± 0.0	45.8 ± 0.1	48.2 ± 0.2	11.5 ± 0.0	15.0 ± 0.0
AMZF	3.6 ± 0.0	55.2 ± 0.4	57.0 ± 0.2	28.4 ± 0.0	57.8 ± 0.0

Table 5: Intersection of samples obtained with different values of b. We see the intersection of samples selected with different number of intersections comparable to highest possible (different seeds) in FastText, far higher compared to chance intersection. This indicates similar samples are selected regardless of sample size. NaiveBayes does not show clear trends but occasionally the queried percentage drops significantly when increasing iterations, occasionally it remains unaffected.

Dsets	Chance	FTZ Ent-Ent	FTZ Ent-LC	FTZ Ent-DelEnt	FTZ DelEnt-DelLC	FTZ DelEnt-DelEnt
SGN	9.4 ± 0.0	84.6 ± 0.2	83.1 ± 0.3	81.7 ± 0.1	82.6 ± 0.1	84.2 ± 0.1
DBP	9.3 ± 0.0	85.7 ± 0.2	85.5 ± 0.3	83.3 ± 0.1	83.0 ± 0.4	83.2 ± 0.2
YHA	19.0 ± 0.0	79.0 ± 0.0	71.6 ± 0.2	76.3 ± 0.1	69.6 ± 0.7	75.6 ± 3.9
YRP	9.3 ± 0.0	58.4 ± 0.6	59.0 ± 0.3	59.0 ± 0.6	61.6 ± 0.7	62.1 ± 0.1
YRF	19.0 ± 0.0	77.8 ± 0.2	66.6 ± 0.3	75.8 ± 0.1	65.4 ± 0.3	80.1 ± 0.2
AGN	19.1 ± 0.0	78.3 ± 0.1	77.3 ± 0.1	77.1 ± 0.3	78.2 ± 0.4	79.0 ± 0.3
AMZP	9.5 ± 0.0	63.5 ± 0.2	63.5 ± 0.3	66.1 ± 0.4	70.0 ± 0.1	70.0 ± 0.1
AMZF	19.0 ± 0.0	70.3 ± 0.1	64.3 ± 0.2	69.6 ± 0.1	65.6 ± 0.2	72.6 ± 0.2

Table 6: Intersection of query strategies across acquisition functions. We observe that the % intersection among samples in the Ent-LC is comparable to those Ent-Ent. Similarly, the Ent-DelEnt (entropy with deletion) is comparable to both DelEnt-DelLC and DelEnt-DelEnt showing robustness of FastText to query functions (beyond minor variation). DelEnt-DelEnt obtains similar intersections as compared to Ent-Ent, showing the robustness of the acquired samples to deletion.

3 and 5 present overlaps from different initial sets while 4 and 6 from same initial sets. We note from column 4 and 6 that due to the stochasticity of training in FTZ, we expect non-identical final sets even with same initial samples as well. The results demonstrate that samples obtained using FastText are largely initialization independent (low variation between columns 3 and 4) consistently across datasets while the samples obtained with Naive Bayes can be vastly different showing relatively heavy dependence on the initial seed. This indicates the relative stability of train set obtained with the posterior uncertainty of the actively trained FTZ as an acquisition function.

3.2.2 Query size

Since the sampled data is sequentially constructed by training models on previously sampled data, large query sizes were expected to impact samples collected by uncertainty sampling and the performance thereof (Hoi et al., 2006). We experiment with various query sizes - (0.25%, 0.5%, 1%) for DBP, SGN, YRP and AMZP and (0.5%, 1%, 2%) for the rest corresponding to 9, 19 and 39 iterations. Figure 1 shows that FastText (top row) has very stable performance across sample sizes while MNB (bottom row) show more erratic performance. Table 5 presents the intersection of samples obtained with different query sizes across multiple runs. We observe a high overlap of the acquired samples across different query sizes indicating that the performance is independent of the query size (compare column 3 to column 4 where the size is held constant) while MNB results in lower overlap with more erratic behavior due to change in the query size (compare column 5 compared to column 6).

3.2.3 Query strategy

We now investigate the impact of various query strategies using FastText by evaluating and comparing the correlation between the respective actively selected sample sets.

Acquisition Functions: We compare four uncertainty query strategies: Least Confidence (LC) and Entropy (Ent), with and without deletion of least uncertain samples from the training set. Deletion of least uncertain samples reduces the dependence on the initial randomly selected set. The results are presented in Table 6. We present five of

Dsets	Chance	FTZ-FTZ Ent	FTZ-5F TZ Ent	5FTZ-5FTZ Ent-LC	5FTZ-5FTZ Ent-Ent
SGN	9.4 ± 0.0	84.6 ± 0.2	86.3 ± 0.2	85.4 ± 0.4	85.8 ± 0.0
DBP	9.3 ± 0.0	85.7 ± 0.2	86.6 ± 0.3	86.78 ± 0.1	87.8 ± 0.2
YRP	9.3 ± 0.0	58.4 ± 0.6	58.1 ± 0.7	58.3 ± 0.3	58.2 ± 0.2
YRF	19.0 ± 0.0	77.8 ± 0.2	79.0 ± 0.3	68.5 ± 1.1	77.6 ± 0.3
AGN	19.1 ± 0.0	78.3 ± 0.1	79.0 ± 0.2	79.1 ± 0.2	77.9 ± 0.2

Table 7: Intersection of query strategies across single and ensemble of 5FTZ models. We observe that the % intersection of samples selected by ensembles and single models is comparable to intersection among either. The 5-model committee does not seem to add any additional value over selection by a single model.

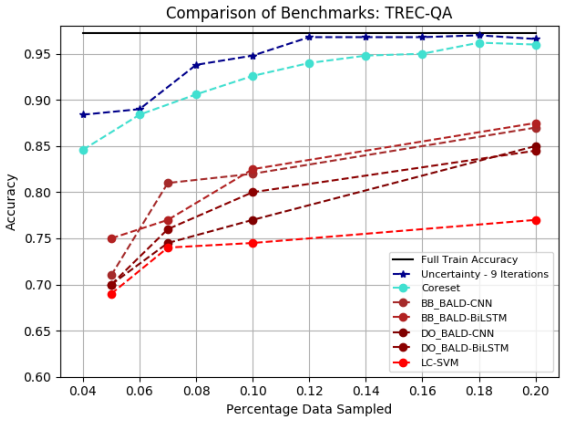

Figure 2: Active text classification: Comparison with K-Center Coreset, BALD and SVM algorithms. Accuracy is plotted against percentage data sampled. We reach full-train accuracy using 12% of the data, compared to BALD which requires 50% data and perform significantly worse in terms of accuracy. We also outperform K-center greedy Coreset at all sampling percentages without utilizing additional diversity-based augmentation.

the ten possible combinations and again observe the high degree of overlap in the collected samples. It can be concluded that the approach is fairly robust to these variations in the query strategy.

Ensembles versus Single Models: A similar experiment was conducted to investigate the overlap between a single FTZ model and a probabilistic committee of models (5-model ensemble with FTZ (Lakshminarayanan et al., 2017)) to identify comparative advantages of using ensemble methods. The results are presented in Table 7 showing little to no difference in sample overlaps. [5] We conclude that more expensive sampling strategies commonly used, like ensembling, may offer little benefit compared to using a single FTZ model with posterior uncertainty as a query function.

The experiments in this section demonstrate that uncertainty based sampling using deep models like FTZ show no class bias or an undesirable feature bias (and favorable bias to class boundaries). There is also a high degree of robustness to algorithmic factors, especially query size, a surprisingly high degree of overlap in the resulting training samples and stable performances (classification accuracy). Additionally, all uncertainty query strategies perform well, and expensive sampling strategies like ensembling offer little benefit. We conclude that sampling biases demonstrated in active learning literature do hold well with traditional models, however, they do not seem to translate to deep models like FTZ using (posterior) uncertainty.

4 Application: Active Text Classification

Experimental results from the previous sections suggest that entropy function with a single FTZ model would be a good baseline for active text classification. We compare our baseline with the latest work in deep active learning for text classification - BALD (Siddhant and Lipton, 2018) and with the recent diversity based Coreset query function (Sener and Savarese, 2018) which uses a costly K-center algorithm to build the query. Experiments are performed on TREC-QA for a fair comparison (used by (Siddhant and Lipton, 2018)). Table 8 shows that the results of our study generalize to small datasets like TREC-QA.

The results are shown in Figure 2 using the baseline with the query size of 2% of the full dataset (b=9 queries). Note that uncertainty sampling converges to full accuracy using just 12% of the data, whereas (Siddhant and Lipton, 2018) required 50% of the data. There is also a remarkable accuracy improvement over (Siddhant and Lipton, 2018) which can be largely attributed to the models used (FastText versus 1-layer CNN/BiLSTM). Also, uncertainty sampling outperforms diversity-based augmentations like Coreset Sampling (Sener and Savarese, 2018) before convergence. Thus, we establish a new state-of-the-art baseline for further research in deep active text classification.

5 Application: Training of Large Models

The cost and time needed to get and label vast amounts of data to train large DNNs is a serious

[5] The ensembles were too costly to run on larger datasets, so the results for YHA, AMZP and AMZF could not be obtained.

Dsets	Chance	FTZ-Ent-Ent	FTZ Ent-LC	SV Chce%	SV Com%
TQA	15.1 ± 0.0	$\mathbf{59.7 \pm 0.5}$	$\mathbf{56.3 \pm 1.4}$	18.7 ± 6.1	$\mathbf{79.0 \pm 3.6}$

Table 9: Comparison of accuracies with state-of-the-art approaches (earliest-latest) for text classification (%dataset in brackets). We are competitive with state-of-the-art models while using 5x-40x compressed datasets.

ULMFiT	AGN	DBP	YRP	YRF
Full	**95.0**	**99.2**	**97.8**	**70.0**
Ours-Small	93.7 (20)	**99.2 (10)**	**97.1 (10)**	67.6 (20)
Ours-Tiny	91.7 (8)	**98.6 (2.3)**	96.7 (4)	66.3(8)

Table 10: ULMFiT: Resulting sample $\hat{\mathcal{S}}_b$ compared to reported accuracies in (Howard and Ruder, 2018) (%dataset in brackets). We observe that using our cheaply obtained compressed datasets, we can achieve similar accuracies with 25x-200x speedup (5x less epochs, 5x-40x less data). Transferability to other models is evidence of the generalizability of the subset collected using FTZ to other deep models.

impediment to creating new and/or better models. Our study suggests that the training samples collected with uncertainty sampling (entropy) on a single model FTZ may provide a good representation (surrogate) for the entire dataset. Buoyed by this, we investigate if we can speedup training of ULMFiT (Howard and Ruder, 2018) using the surrogate dataset. We show these results in Table 10. We achieve 25x-200x speedup[6] (5x fewer epochs, 5x-40x smaller training size). We also benchmark the performance against the state-of-the-art on text classification as shown in Table 9. We conclude that we can significantly compress the training datasets and speedup classifier training time with little tradeoff in accuracy.

Implementation Details: We use the official github repository for ULMFiT[7], use default hyperparameters and train on one NVIDIA Tesla V100 16GB GPU. Further details are provided in supplementary material.

[6]The cost of acquiring the training data using FTZ-Ent is negligible in comparison.

6 Related Work

We now expand on the brief literature review in Section 1 to better contextualize our work. We divide the past works into (i) Traditional Models and (ii) Deep Models.

Sampling Bias in Classical AL in NLP: Active learning (AL) in text classification started with greedy uncertainty query strategy from a pool using decision trees (Lewis and Gale, 1994), which was shown to be effective and led to widespread adoption with classifiers like SVMs (Tong and Koller, 2001), Naive Bayes (Roy and McCallum, 2001) and KNN (Fujii et al., 1998). This strategy was also applied to other NLP tasks like parse selection (Baldridge and Osborne, 2004), sequence labeling (Settles and Craven, 2008) and information extraction (Thompson and Mooney, 1999). These early papers popularized two greedy uncertainty query methods: Least Confident and Entropy.

Issues of lack of diversity (large redudancy in sampling) (Zhang and Oles, 2000) and lack of robustness (high variance in sample quality)(Krogh and Vedelsby, 1994) guided subsequent efforts. The two most popular directions were: (i) augmenting uncertainty with diversity measures (Hoi et al., 2006; Brinker, 2003; Tang et al., 2002) and (ii) using query-by-committee (McCallum and Nigam, 1998; Liere and Tadepalli, 1997). For a comprehensive survey of classical AL methods for NLP, please refer to (Settles, 2009).

Sampling Bias in Deep AL: Deep active learning approach adapt the above framework to the

training of DNNs on large data. Two main query strategies are used: (i) ensemble based greedy uncertainty, which represents a probabilistic query-by-committee paradigm (Gal et al., 2017; Beluch et al., 2018), and (ii) diversity based measures (Sener and Savarese, 2018; Ducoffe and Precioso, 2018). Papers proposing diversity based approaches find that greedy uncertainty based sampling (using ensemble and single model) perform significantly worse than random (See Figures 4 and 2 respectively in (Sener and Savarese, 2018; Ducoffe and Precioso, 2018)). They attribute the poor performance to redundant, highly correlated sampling selected using uncertainty based methods and justify the need for prohibitively expensive diversity-based approaches (Refer section 2 of (Sener and Savarese, 2018) for details on the expensiveness of various diversity sampling methods). However, K-center greedy coreset sampling scales poorly: we were only able to use it on TREC-QA (a small dataset). On the other hand, ensemble-based greedy uncertainty methods find that probabilistic averaging from a committee (Gal et al., 2017; Beluch et al., 2018) performs better than single model as with on diversity based methods like coreset(Gissin and Shalev-Shwartz, 2019; Beluch et al., 2018). Current approaches in text classification literature mostly adopt the ensemble based greedy uncertainty framework (Siddhant and Lipton, 2018; Lowell et al., 2018; Zhang et al., 2017).

However, our work demonstrates the problems of sampling bias and efficiency may not translate from shallow to deep approaches. Recent evidence from image domain (Gissin and Shalev-Shwartz, 2019) demonstrates atleast a subset of our findings generalize to other DNNs (class bias and query functions). Uncertainty sampling using a deep model like FTZ demonstrates surprisingly good sampling properties without using ensembles or bayesian methods. Ensembles do not seem to significantly affect sampling. Whether this behavior generalizes to other deep models and tasks is yet to be seen.

Other Related Works: An interesting set of papers (Soudry et al., 2018; Xu et al., 2018) show that deep neural networks trained with SGD converge to the maximum margin solution in the linearly separable case. Several works investigate the possibility that deep networks give high importance to a subset of the training dataset (Toneva et al., 2019; Vodrahalli et al., 2018; Birodkar et al., 2019), resembling supports in support vector machines. In our experiments, we find that active learning with uncertainty sampling with deep models like FTZ has a (surprisingly) large overlap with the support vectors of an SVM. Thus, it seems to have a inductive bias for class boundaries, similar to the above works. Whether this property generalizes to other deep models is yet to be seen.

7 Conclusion

We conducted a large empirical study of sampling bias and efficiency, along with algorithmic factors which impacting active text classification. We conclude that uncertainty sampling with deep models like FastText.zip exhibits negligible class bias, seems to be favorably biased to sampling data points near class boundaries, is robust to various algorithmic factors and expensive sampling strategies like ensembling offer little benefit. Also, we find a surprisingly large overlap of actively acquired points with supports of a SVM. We additionally show that uncertainty sampling can be effectively used to bootstrap the training of large DNN models by generating compact surrogate datasets (5x-40x compression). Finally, FTZ-Ent provides a strong baseline for deep active text classification, outperforming previous results by a margin of 4x less data.

The current work opens up several directions for future investigations. To list a few: (a) a deeper look into the nature of sampled data - their distribution in the feature space, as well as their importance for the task at hand; (b) the creation of surrogate datasets for a variety of applications, including hyperparameter and architecture search, etc; (c) an extension to other deep models (beyond FTZ) and beyond classification models; and, (d) an extension to semi-supervised, online and continual learning.

Abstract

State-of-the-art models often make use of superficial patterns in the data that do not generalize well to out-of-domain or adversarial settings. For example, textual entailment models often learn that particular key words imply entailment, irrespective of context, and visual question answering models learn to predict prototypical answers, without considering evidence in the image. In this paper, we show that if we have prior knowledge of such biases, we can train a model to be more robust to domain shift. Our method has two stages: we (1) train a naive model that makes predictions exclusively based on dataset biases, and (2) train a robust model as part of an ensemble with the naive one in order to encourage it to focus on other patterns in the data that are more likely to generalize. Experiments on five datasets with out-of-domain test sets show significantly improved robustness in all settings, including a 12 point gain on a changing priors visual question answering dataset and a 9 point gain on an adversarial question answering test set.

1 Introduction

While recent neural models have shown remarkable results, these achievements have been tempered by the observation that they are often exploiting dataset-specific patterns that do not generalize well to out-of-domain or adversarial settings. For example, entailment models trained on MNLI (Bowman et al., 2015) will guess an answer based solely on the presence of particular keywords (Gururangan et al., 2018) or whether sentences pairs contain the same words (McCoy et al., 2019), while QA models trained on SQuAD (Rajpurkar et al., 2016) tend to select text near question-words as answers, regardless of context (Jia and Liang, 2017).

We refer to these kinds of superficial patterns as bias. Models that rely on bias can perform well on in-domain data, but are brittle and easy to fool (e.g., SQuAD models are easily distracted by irrelevant sentences that contain many question words). Recent concern about dataset bias has led researchers to re-examine many popular datasets, resulting in the discovery of a wide variety of biases (Agrawal et al., 2018; Anand et al., 2018; Min et al., 2019; Schwartz et al., 2017).

In this paper, we build on these works by showing that, once a dataset bias has been identified, we can improve the out-of-domain performance of models by preventing them from making use of that bias. To do this, we use the fact that these biases can often be explicitly modelled with simple, constrained baseline methods to factor them out of a final model through ensemble-based training.

Our method has two stages. First, we build a bias-only model designed to capture a naive solution that performs well on the training data, but generalizes poorly to out-of-domain settings. Next, we train a second model in an ensemble with the pre-trained bias-only model, which incentivizes the second model to learn an alternative strategy, and use the second model alone on the test set. We explore several different ensembling methods, building on product-of-expert style approaches (Hinton, 2002; Smith et al., 2005). Figure 1 shows an example of applying this procedure to prevent a visual question answering (VQA) model from guessing answers because they are typical for the question, a flaw observed in VQA models (Goyal et al., 2018; Agrawal et al., 2018).

We evaluate our approach on a diverse set of tasks, all of which require models to overcome a challenging domain-shift between the train and test data. First, we build a set of synthetic datasets that contain manually constructed biases by adding artificial features to MNLI. We then consider three challenge datasets proposed by prior work (Agrawal et al., 2018; McCoy et al.,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4069–4082, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

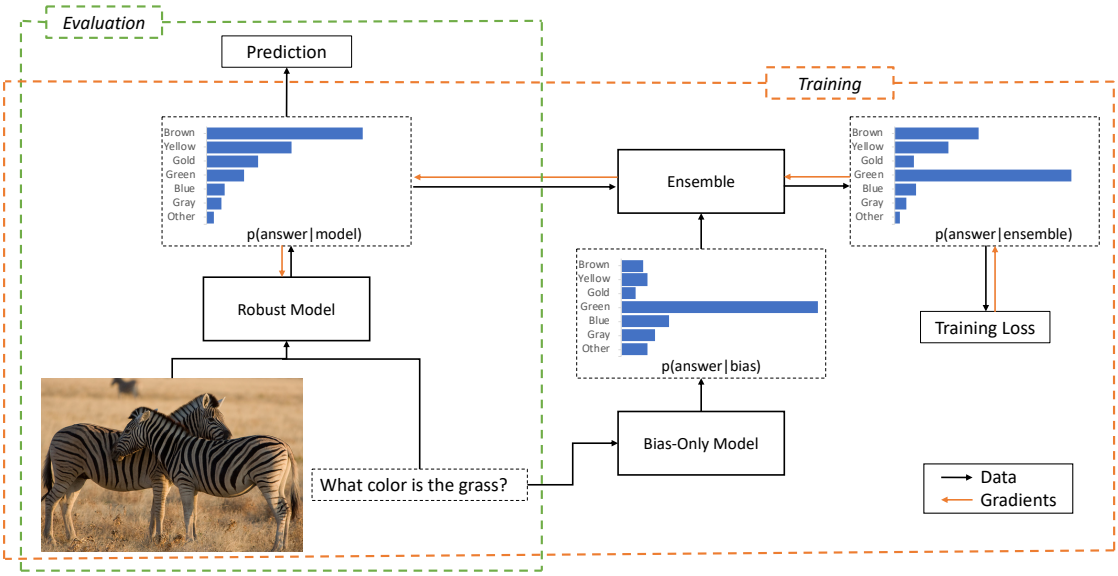

Figure 1: An example of applying our method to a Visual Question Answering (VQA) task. We assume predicting green for the given question is almost always correct on the training data. To prevent a model from learning this bias, we first train a bias-only model that only uses the question as input, and then train a robust model in an ensemble with the bias-only model. Since the bias-only model will have already captured the target pattern, the robust model has no incentive to learn it, and thus does better on test data where the pattern is not reliable.

2019; Jia and Liang, 2017), which were designed to break models that adopt superficial strategies on well known textual entailment (Bowman et al., 2015), reading comprehension (Rajpurkar et al., 2016), and VQA (Antol et al., 2015) datasets.

We additionally construct a new QA challenge dataset, TriviaQA-CP (for TriviaQA changing priors). This dataset was built by holding out questions from TriviaQA (Joshi et al., 2017) that ask about particular kinds of entities from the train set, and evaluating on those questions in the dev set, in order to challenge models to generalize between different types of questions.

We are able to improve out-of-domain performance in all settings, including a 6 and 9 point gain on the two QA datasets. On the VQA challenge set, we achieve a 12 point gain, compared to a 3 point gain from prior work. In general, we find using an ensembling method that can dynamically choose when to trust the bias-only model is the most effective, and we present synthetic experiments and qualitative analysis to illustrate the advantages of that approach. We release our datasets and code to facilitate future work.[1]

2 Related Work

Researchers have raised concerns about bias in many datasets. For example, many joint natural language processing and vision datasets can be partially solved by models that ignore the vision aspect of the task (Jabri et al., 2016; Zhang et al., 2016; Anand et al., 2018; Caglayan et al., 2019). Some questions in recent multi-hop QA datasets (Yang et al., 2018; Welbl et al., 2018) can be solved by single-hop models (Chen and Durrett, 2019; Min et al., 2019). Additional examples include story completion (Schwartz et al., 2017) and multiple choice questions (Clark et al., 2016, 2018). Recognizing that bias is a concern in diverse domains, our work is the first to perform an evaluation across multiple datasets spanning language and vision.

Recent dataset construction protocols have tried to avoid certain kinds of bias. For example, both CoQA (Reddy et al., 2019) and QuAC (Choi et al., 2018) take steps to prevent annotators from using words that occur in the context passage, VQA 2.0 (Goyal et al., 2018) selects examples to limit the effectiveness of question-only models, and others have filtered examples solvable by simple baselines (Yang et al., 2018; Zhang et al., 2018b; Clark et al., 2018; Zellers et al., 2018). While reducing bias is important, developing ways to prevent models from using known biases will allow us to continue to leverage existing datasets, and update our methods as our understanding of what biases we want to avoid evolve.

[1] github.com/chrisc36/debias

Recent work has focused on biases that come from ignoring parts of the input (e.g., guessing the answer to a question before seeing the evidence). Solutions include generative objectives to force models to understand all the input (Lewis and Fan, 2019), carefully designed model architecture (Agrawal et al., 2018; Zhang et al., 2016), or adversarial removal of class-indicative features from model's internal representations (Ramakrishnan et al., 2018; Zhang et al., 2018a; Belinkov et al., 2019; Grand and Belinkov, 2019). In contrast, we consider biases beyond partial-input cases (Feng et al., 2019), and show our method is superior on VQA-CP. Concurrently, He et al. (2019) also suggested using a product-of-experts ensemble to train unbiased models, but we consider a wider variety of ensembling approaches and test on additional domains.

A related task is preventing models from using particular problematic dataset features, which is often studied from the perspective of fairness (Zhao et al., 2017; Burns et al., 2018). A popular approach is to use an adversary to remove information about a target feature, often gender or ethnicity, from a model's internal representations (Edwards and Storkey, 2016; Wang et al., 2018; Kim et al., 2019). In contrast, the biases we consider are related to features that are essential to the overall task, so they cannot simply be ignored.

Evaluating models on out-of-domain examples built by applying minor perturbations to existing examples has also been the subject of recent study (Szegedy et al., 2014; Belinkov and Bisk, 2018; Carlini and Wagner, 2018; Glockner et al., 2018). The domain shifts we consider involve larger changes to the input distribution, built to uncover higher-level flaws in existing models.

3 Methods

This section describes the two stages of our method, (1) building a bias-only model and (2) using it to train a robust model through ensembling.

3.1 Training a Bias-Only Model

The goal of the first stage is to build a model that performs well on training data, but is likely to perform very poorly on the out-of-domain test set. Since we assume we do not have access to examples from the test set, we must apply *a-priori* knowledge to meet this goal.

The most straightforward approach is to identify a set of features that are correlated with the class label during training, but are known to be uncorrelated or anticorrelated with the label on the test set, and then train a classifier on those features.[2] For example, our VQA-CP (Agrawal et al., 2018) bias-only model (see Section 5.2) uses the question type as input, because the correlations between question types and answers is very different in the train set than the test set (e.g., 2 is a common answer to "How many..." questions on the train set, but is rare for such questions on the test set).

However, a benefit of our method is that the bias can be modelled using any kind of predictor, giving us a way to capture more complex intuitions. For example, on SQuAD our bias-only model operates on a view of the input built from TF-IDF scores (see Section 5.4), and on our changing prior TriviaQA dataset our bias-only model makes use of a pre-trained named entity recognition (NER) tagger (see Section 5.5).

3.2 Training a Robust Model

This stage trains a robust model that avoids using the method learned by the bias-only model.

3.2.1 Problem Definition

We assume n training examples $\langle x_1, x_2, \ldots, x_n \rangle$, each of which has an integer label y_i, where $y_i \in \{1, 2, \ldots, C\}$ and C is the number of classes. We additionally assume a pre-trained bias-only predictor, h, where $h(x_i) = b_i = \langle b_{i1}, b_{i2}, ..b_{iC} \rangle$ and b_{ij} is the bias-only model's predicted probability of class j for example i. Finally we have a second predictor function, f, with parameters θ, where $f(x_i, \theta) = p_i$ and p_i is a similar probability distribution over the classes. Our goal is to construct a training objective to optimize θ so that f will learn to select the correct class without using the strategy captured by the bias-only model.

3.2.2 General Approach

We train an ensemble of h and f. In particular, for each example, a new class distribution, $\hat{p_i}$, is computed by combining p_i and b_i. During training, the loss is computed using $\hat{p_i}$ and the gradients are backproped through f. During evaluation f is used alone. We propose several different ensembling methods.

[2] Since the bias-only model is trained on the same trainset as the robust model care should also be taken to minimize overfitting, although the bias-only model is typically simple enough that this is not an issue.

3.2.3 Bias Product

Our simplest ensemble is a product of experts (Hinton, 2002):

$$\hat{p_i} = softmax(\log(p_i) + \log(b_i))$$

Equivalently, $\hat{p_i} \propto p_i \circ b_i$, where $\circ$ is element-wise multiplication.

Probabilistic Justification: For a given example, x, let x^b be the bias of the example. That is, it is the features we will use in our bias-only model. Let x^{-b} be a view of the example that captures all information about that example except the bias. Assume that x^{-b} and x^b are conditionally independent given the label, c. Then to compute $p(c|x)$ we have:

$$\begin{aligned} p(c|x) &= p(c|x^b, x^{-b}) && (1)\\ &\propto p(c|x^{-b})p(x^b|c, x^{-b}) && (2)\\ &= p(c|x^{-b})p(x^b|c) && (3)\\ &= p(c|x^{-b})\frac{p(c|x^b)p(x^b)}{p(c)} && (4)\\ &\propto p(c|x^{-b})\frac{p(c|x^b)}{p(c)} && (5) \end{aligned}$$

Where 2 is from applying Bayes Rule while conditioning on x^{-b}, 3 follows from the conditional independence assumption, and 4 applies Bayes Rule a second time to $p(x^b|c)$.

We cannot directly model $p(c|x^{-b})$ because it is usually not possible to create a view of the data that excludes the bias. Instead, with the goal of encouraging the model to fall into the role of computing $p(c|x^{-b})$, we compute $p(c|x^b)/p(c)$ using the bias-only model, and train the product of the two models to compute $p(c|x)$.

In practice, we ignore the $p(c)$ factor because, on our datasets, either the classes are uniformly distributed (MNLI), the bias-only model cannot easily capture a class prior since it is using a pointer network (QA), or because we want to remove class priors from model anyway (VQA).

3.2.4 Learned-Mixin

The assumption of conditional independence (Equation 3) will often be too strong. For example, in some cases the robust model might be able to predict the bias-only model will be unreliable for certain kinds of training examples. We find that this can cause the robust model to selectively adjust its behavior in order to compensate for the inaccuracy of the bias-only model, leading to errors in the out-of-domain setting (see Section 5.1).

Instead we allow the model to explicitly determine how much to trust the bias given the input:

$$\hat{p_i} = softmax(\log(p_i) + g(x_i)\log(b_i))$$

where g is a learned function. We compute g as $softplus(w \cdot h_i)$ where w is a learned vector, h_i is the last hidden layer of the model for example x_i, and the $softplus(x) = \log(1+e^x)$ function is used to prevent the model reversing the bias by multiplying it by a negative weight. w is trained with the rest of the model parameters. This reduces to bias product when $g(x_i) = 1$.

A difficulty with this method is that the model could learn to integrate the bias into p_i and set $g(x_i) = 0$. We find this does sometimes occurs in practice, and our next method alleviates this challenge.

3.2.5 Learned-Mixin +H

To prevent the learned-mixin ensemble from ignoring b_i, we add an entropy penalty to the loss:

$$R = wH(softmax(g(x_i)\log(b_i)))$$

Where $H(z) = -\sum_j z_j \log(z_j)$ is the entropy and w is a hyperparameter. Penalizing the entropy encourages the bias component to be non-uniform, and thus have a greater impact on the ensemble.

4 Evaluation Methodology

We evaluate our methods on several datasets that have out-of-domain test sets. Some of these tasks, such as HANS (McCoy et al., 2019) or Adversarial SQuAD (Jia and Liang, 2017), can be solved easily by generating additional training examples similar to the ones in the test set (e.g., Wang and Bansal (2018)). We, instead, demonstrate that it is possible to improve performance on these tasks by exploiting knowledge of general, biased strategies the model is likely to adopt.

Our evaluation setup consists of a training set, an out-of-domain test set, a bias-only model, and a main model. To run an evaluation we train the bias-only model on the train set, train the main model on the train set while employing one of the methods in Section 3, and evaluate the main model on the out-of-domain test set. We also report performance on the in-domain test set, when available. We use models that are known to work well for their respective tasks for the main model, and

Task	Dataset	Domain Shift	Bias-Only Model	Main Model
NLI	Synthetic MNLI	Synthetic indicator features are randomized	Indicator features	Co-Attention
VQA	VQA-CP v2.0	Correlations between question-types and answers are altered	Question-type	BottomUpTopDown
NLI	HANS	Sentence pairs always contain the same words	Shared word features	BERT & Co-Attention
QA	Adv. SQuAD	Distractor sentences are added to the context	TF-IDF sentence selector	Modified BiDAF
QA	TriviaQA-CP	Questions ask about different kinds of entities	NER answer detector	Modified BiDAF

Table 1: Summary of the evaluations we perform, Domain Shift refers to what changes between the train and test data, and Bias-Only Model specifies how the bias model we use was constructed. See the main text for details.

do not further tune their hyperparameters or perform early stopping.

We consider two extractive QA datasets, which we treat as a joint classification task where the model must select the start and end answer token (Wang and Jiang, 2017). For these datasets, we build independent bias-only models for selecting the start and end token, and separately ensemble those biases with the classifier's start token and end token output distributions. We apply a ReLU layer to the question and passage embeddings, followed by max-pooling, to construct a hidden state for computing the learned-mixin weights.

We compare our methods to a reweighting baseline described below, and to training the main model without any modifications. On VQA we also compare to the adversarial methods from Ramakrishnan et al. (2018) and Grand and Belinkov (2019). The other biases we consider are not based on observing only part of the input, so these adversarial methods cannot be directly applied.

4.1 Reweight Baseline

As a non-ensemble baseline, we train the main model on a weighted version of the data, where the weight of example x_i is $1 - b_{iy_i}$ (i.e., we weigh examples by one minus the probability the bias-only model assigns the correct label). This encourages the main model to focus on examples the bias-only model gets wrong.

4.2 Hyperparameters

One of our methods (Learned-Mixin +H) requires hyperparameter tuning. However hyperparameter tuning is challenging in our setup since our assumption is that we have no access to out-of-domain test examples during training. A plausible option would be to tune hyperparameters on a dev set that exhibits a related, but not identical, domain shift to the test set, but unfortunately none of our datasets have such dev sets. Instead we follow prior work (Grand and Belinkov, 2019; Ramakrishnan et al., 2018) and perform model selection on the test set. Although this presents an important caveat to the results of this method, we think it is still of interest to observe that the entropy regularizer can be very impactful. Future work may be able to either construct suitable development sets, or propose other hyperparameter-tuning methods to relieve this issue. The hyperparameters selected are shown in Appendix A.

5 Experiments

We provide experiments on five different domains, summarized in Table 1, each of which requires models to overcome a challenging domain-shift between train and test data. In the following sections we provide summaries of the datasets, main models and bias-only models, but leave low-level details to the appendix.

5.1 Synthetic Data

Data: We experiment with a synthetic dataset built by modifying MNLI (Bowman et al., 2015). In particular, we add a feature that is correlated with the class label to the train set, and build an out-of-domain test set by adding a randomized version of that feature to the MNLI matched dev set. We additionally construct an in-domain test set by modifying the matched dev set in the same way as was done in the train set. We build three variations of this dataset:

Indicator: Adds the token "0", "1", or "2" to the start of the hypothesis, such that 80% of the

time the token corresponds to the example's label (i.e., "0" if the class is "entailment", "1" if the class is contradiction, ect.). In the out-of-domain test set, the token is selected randomly.

Excluder: The same as Indicator, but with a 3% chance the added token corresponds to the example's label, meaning the token can usually be used to eliminate one of the three output classes.

Dependent: In the previous two settings, the added bias is independent of the example given the example's label. To simulate a case where this independence is broken, we experiment with adding an additional feature that is correlated with the bias feature, but is not treated as being part of the bias (i.e., it is not used by the bias-only model). In particular, 80% of the time a token is added to the start of the hypothesis that matches the label with 90% probability, and the "0" token is appended to the end of the hypothesis. The other 20% of the time a random token is prepended and "1" is appended.

Bias-Only Model: The bias-only model predicts the label using the first token of the hypothesis.

Main Model: We use a recurrent co-attention model, similar to ESIM (Chen et al., 2017). Details are given in Appendix B.

Results: Table 2 shows the results. All ensembling methods work well on the Indicator bias. The reweight method performs poorly on the Excluder bias, likely because the bias-only model assigns the correct class approximately 50% probability for almost all the training examples, making the weights mostly uniform. This illustrates a general weakness with reweighting methods: they require at least a small number of bias-free examples for the model to learn from.

The bias product method performs poorly on the Dependent bias. Inspection shows that, when the indicator is 1, the bias product model is anti-correlated with the bias. In particular, it assigns an average of 22.5% probability to the class indicated by the bias, where an unbaised model would assign an average of 33% since the bias is random. The root cause is that, if the indicator is 1, the model knows the bias is likely to be wrong, so it learns to subtract the value the bias-only model will produce from its own output in order to cancel out the bias-only model's effect on the ensemble's output.

The learned-mixin model does not suffer from this issue, and assigns the class indicated by the bias an average of 34.5% probability. Analysis shows that $g(x_i)$ is set to 0.00 ± 0.0001 when the indicator is turned off, and to 1.91 ± 0.285 otherwise, showing that the model learns to turn off the bias-only component of the ensemble as needed, thus avoiding this over-compensating issue. The entropy regularizer appears to be unnecessary on this dataset because $g(x_i)$ does not go to zero.

5.2 VQA-CP

Data: We evaluate on the VQA-CP v2 (Agrawal et al., 2018) dataset, which was constructed by re-splitting the VQA 2.0 (Goyal et al., 2018) train and validation sets into new train and test sets such that the correlations between question types and answers differs between each split. For example, "tennis" is the most common answer for questions that start with "What sport..." in the train set, whereas "skiing" is the most common answers for those questions in the test set. Models that choose answers because they are typical in the training data will perform poorly on this test set.

Bias-Only Model: VQA-CP comes with questions annotated with one of 65 question types, corresponding to the first few words of the question (e.g., "What color is"). The bias-only model uses this categorical label as input, and is trained on the same multi-label objective as the main model.

Main Model: We use a popular implementation[3] of the BottomUpToDown (Anderson et al., 2018) VQA model. This model uses a multi-label objective, so we apply our ensemble methods by treating each possible answer as a two-class classification problem.[4]

Results: Table 3 shows the results. The learned-mixin method was highly effective, boosting performance on VQA-CP by about 9 points, and the entropy regularizer can increase this by another 3 points, significantly surpassing

[3] github.com/hengyuan-hu/bottom-up-attention-vqa

[4] Since the bias sometimes assigns a zero probability to an answer, we additionally add $\sigma(\alpha)$ to the bias probabilities where α is learned parameter to allow the model to soften the bias as needed

Debiasing Method	Indicator		Excluder		Dependent	
	Acc.	w/Bias	Acc.	w/Bias	Acc.	w/Bias

prior work. For the learned-mixin ensemble, we find $g(x_i)$ is strongly correlated with the bias's expected accuracy[5], with a spearmanr correlation of 0.77 on the test data. Qualitative examples (Figure 2) further suggest the model increases $g(x_i)$ when it knows if can rely on the bias-only model.

5.3 HANS

Data: We evaluate on the HANS adversarial MNLI dataset (McCoy et al., 2019). This dataset was built by constructing templated examples of entailment and non-entailment, such that the hypothesis sentence only includes words that are also in the premise sentence. Naively trained models tend to classify all such examples as "entailment" because detecting the presence of many shared words is an effective tactic on MNLI.

Bias-Only Model: The bias-only model is a shallow linear classifier using the following features: (1) whether the hypothesis is a sub-sequence of the premise, (2) whether all words in the hypothesis appear in the premise, (3) the percent of words from the hypothesis that appear in the premise, (4) the average of the minimum distance between each premise word with each hypothesis word, measured using cosine distance with the fasttext (Mikolov et al., 2018) word vectors, and (5) the max of those same distances. We constrain the bias-only model to put the same amount of probability mass on the neutral and contradiction classes so it focuses on distinguishing entailment and non-entailment, and reweight the dataset so that the entailment and non-entailment examples have an equal total weight to prevent a class prior from being learned.

Main Models: We experiment with both the uncased BERT base model (Devlin et al., 2019), and the same recurrent model used for the synthetic data (see Appendix B). We use the default hyperparameters for BERT since they work well for MNLI.

Results: Table 4 shows the results. We show scores for individual heuristics used in HANS in Appendix C. For the recurrent method, both the bias product and learned-mixin +H methods result in about a three point gain. However, for the BERT model, the simpler reweight method is more effective. We noticed high variance in performance between runs in this setting, and speculate the ensemble methods might be compounding this instability by introducing additional complexity.

[5]Computed as $\sum_j s_{ij} b_{ij} / \sum_j b_{ij}$ where s_{ij} is the score for class j on example i

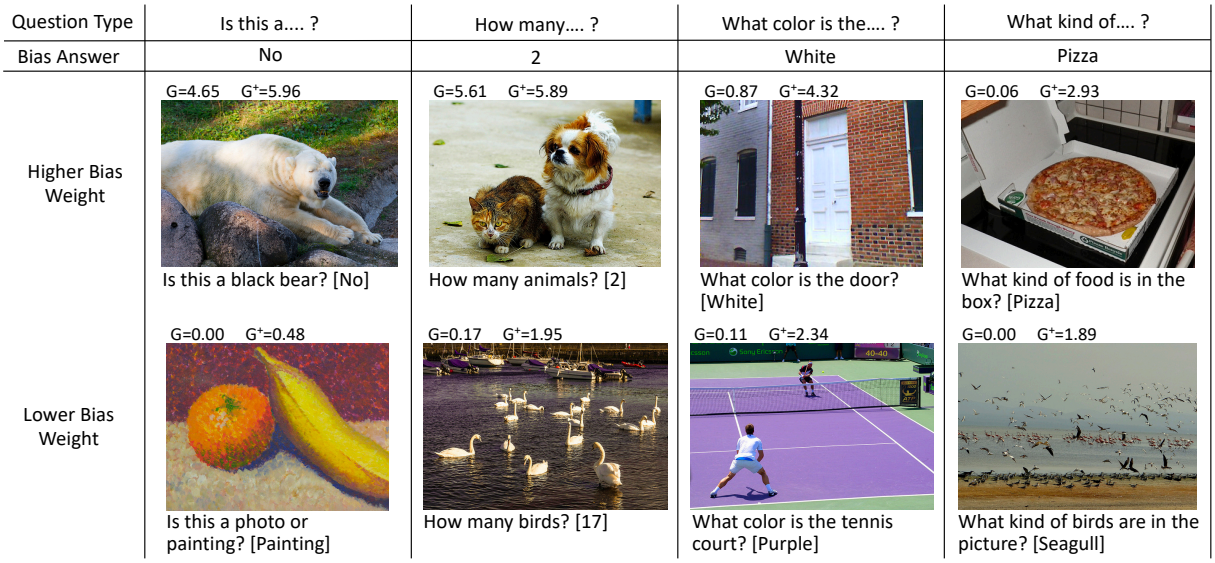

Figure 2: Qualitative examples of the values of $g(x_i)$ on the VQA-CP training data for the learned-mixin model (labelled "G") and learned-mixin +H model (labelled "G+"). The question type and the bias model's highest ranked answer for that type are shown above. We find $g(x_i)$ is larger when the bias answers are likely to be correct.

5.4 Adversarial SQuAD

Data: We evaluate on the Adversarial SQuAD (Jia and Liang, 2017) dataset, which was built by adding distractor sentences to the passages in SQuAD (Rajpurkar et al., 2016). The sentences are built to closely resemble the question and contain a plausible answer candidate, but with a few key semantic changes to ensure they do not incidentally answer the question. Models that naively focus on sentences that contain many question words are often fooled by the new sentence.

Bias-Only Models: We consider two bias-only models: (1) TF-IDF: the TF-IDF score between each sentence and question is used to select an answer (meaning tokens within the same sentence all get the same score) and (2) TF-IDF Filtered: the same but excluding pronouns and numbers from the words used to compute the TF-IDF scores. The second model is motivated by the fact distractor sentences never include numbers or pronouns that occur in the question.

Main Model: We use an updated version of BiDAF (Seo et al., 2017), that uses the fasttext words vectors (Mikolov et al., 2018), includes an additional recurrent layer, and simplifies the prediction stage (see Appendix D).

Results: Table 5 shows the results. We find the bias product method improves performance by up to 3 points, and the learned-mixin +H model achieves up to a 9 point gain. The importance of including the entropy penalty is explained by the fact that, without the penalty, the model learns to ignore the bias by settings $g(x_i)$ close to zero. For example, on the AddSent dataset with the TF-IDF filtered bias, the learned-mixin ensemble sets $g(x_i)$ to an average of 0.13, while the learned-mixin +H ensemble increases that to 5.16. The high values are likely caused by the fact the bias-only model is very weak, since it assigns the same score to each token in each sentence, so the model can often scale it by large values. As expected, we get better results using the TF-IDF Filtered bias which is more closely tailored to how the test set was constructed.

5.5 TriviaQA-CP

Data: We construct a changing-prior QA dataset from TriviaQA (Joshi et al., 2017) by categorizing questions into three classes, Person, Location, and Other, based on what kind of entity they are asking about. During training, we hold out all the person questions or all the location questions from the train set, and evaluate on the person or location questions in the TriviaQA dev set. Details can be found in Appendix E.

Bias-Only Model: The bias-only model uses NER tags, identified by running the Stanford NER Tagger (Finkel et al., 2005) on the passage, as input.

Debiasing Method	TF-IDF Filtered			TF-IDF		
	AddSent	AddSentOne	Dev	AddSent	AddSentOne	Dev
None	42.54	53.91	80.61	42.54	53.91	80.61
Reweight	41.55	53.06	80.59	42.74	53.83	80.51
Bias Product	47.17	57.74	78.63	44.41	55.73	78.22
Learned-Mixin	42.25	53.51	80.39	42.00	53.46	80.46
Learned-Mixin +H	51.84	60.66	75.94	48.30	58.26	74.14

Table 5: F1 scores on Adversarial SQuAD and the standard SQuAD dev set using two different bias-only models.

Debiasing Method	Location		Person	
	CP	Dev	CP	Dev
None	41.23	59.27	39.69	55.26
Reweight	40.14	59.18	39.96	55.38
Bias Product	44.42	60.02	40.58	55.20
Learned-Mixin	41.15	61.64	41.31	56.08
Learned-Mixin +H	47.77	57.74	44.37	54.83

Table 6: EM scores on two changing priors TriviaQA datasets. The CP column shows scores on the changing priors test set, and Dev shows in-domain scores.

We only apply the model to tokens that have a NER tag, and assign all other tokens the average score given to the tokens with NER tags in order to prevent the model from reflecting a preference for entity tokens in general.

Main Model: We use a larger version of the model used for Adversarial SQuAD (see Appendix D), to account for the larger dataset.

Results: Table 6 shows the results. Similar to adversarial SQuAD, the bias product method is moderately effective, and the ensemble method is superior as long as a suitable regularizer is applied. We again observe that the learned-mixin method tends to push $g(x_i)$ close to zero without the entropy penalty (average of 0.25 without the penalty vs. 5.01 with the penalty on the Location dev set). We see smaller gains on the person dataset. One possible cause is that differentiating between people and other named entities, such as organizations or groups, is difficult for the main model, and as a result it does not learn a strong non-person prior even without the use of a debiasing method.

5.6 Discussion

Despite tackling a diverse range of problems, we were able to improve out-of-domain performance in all settings. The bias product method works consistently, but can almost always be significantly out-performed by the learned-mixin method with an appropriate entropy penalty. The reweight baseline improved performance on HANS, but was relatively ineffective in other cases.

Increasing the out-of-domain performance usually comes at the cost of losing some in-domain performance, which is unsurprising since the biased approaches we are removing are helpful on the in-domain data. TriviaQA-CP stands out as a case where this trade-off is minimal.

A possible issue is that our methods reduce the need for the model to solve examples the bias-only model works well on (since the ensemble's prediction will already be mostly correct for those examples), which effectively reduces the amount of training data. An ideal approach would be to block the model from using the bias-only method, and require it to solve examples the bias-only method solves through other means. We suspect this will necessitate a more clear-box method since it requires doing fine-grained regularization of how the model is solving individual examples.

6 Conclusion

Our key contribution is a method of using human knowledge about what methods will not generalize well to improve model robustness to domain-shift. Our approach is to train a robust model in an ensemble with a pre-trained naive model, and then use the robust model alone at test time. Extensive experiments show that our method works well on two adversarial datasets, and two changing-prior datasets, including a 12 point gain on VQA-CP. Future work includes learning to automatically detect dataset bias, which would allow our method to be applicable with less specific prior knowledge.

A Entropy Penalty Weights

The strength of the entropy penalty used for the learned-mixin +H model can be found in Table 7.

Dataset	Experiment	Penalty
Synthetic	Indicator	0.01
Synthetic	Excluder	0.005
Synthetic	Dependent	0.005
VQA-CP	-	0.36
HANS	Recurrent	0.03
HANS	BERT	0.03
Adver. SQuAD	TF-IDF Filtered	2.0
Adver. SQuAD	TF-IDF	2.0
TriviaQA-CP	Location	0.4
TriviaQA-CP	Person	0.2

Table 7: Entropy penalty weight for the learned-mixin +H ensemble on all our experiments.

B Co-Attention NLI Model

The model we use for NLI is based on ESIM (Chen et al., 2017). It has the following stages:

Embed: Embed the words using a character CNN, following what was done by Seo et al. (2017), and the fasttext crawl word embeddings (Mikolov et al., 2018), then run a shared BiLSTM over the results.

Co-Attention: Compute an attention matrix using the formulation from Seo et al. (2017), and use it to compute a context vector for each premise word (Bahdanau et al., 2015). Then build an augmented vector for each premise word by concatenating the word's embedding, the context vector, and the elementwise product of the two. Augmented vectors for the hypothesis are built in the same way using the transpose of the attention matrix.

Pool: Run another shared BiLSTM over the augmented vectors, and max-pool the results. The max-pooled vectors from the premise and hypothesis are fed into a fully-connected layer, and then into a softmax layer with three outputs to compute class probabilities.

We apply variational dropout at a rate of 0.2 between all layers, and to the recurrent states of the LSTM, and train the model for 30 epochs using the Adam optimizer (Kingma and Ba, 2015) with a batch size of 32. The learning rate is decayed by 0.999 every 100 steps. We use 200 dimensional LSTMs and a 50 dimensional fully connected layer.

C Fine-Grained HANS Results

We show the scores our methods achieve for the various heuristics used in HANS in Table 8. Our methods reduce the extent to which models naively guess entailment in all cases. Interestingly, the BERT model shows significantly degraded performance on the entailment examples when using the reweight and bias product method, but largely maintains its performance on those examples when using the learned-mixin method.

D Modified BiDAF QA Model

The model we use for QA is based on BiDAF (Seo et al., 2017). It has the following stages:

Embed: Embed the words using a character CNN following Seo et al. (2017) and the fasttext crawl word embeddings (Mikolov et al., 2018). Then run a BiLSTM over the results to get context-aware question embeddings and passage embeddings.

Bi-Attention: Apply the bi-directional attention mechanism from Seo et al. (2017) to produce question-aware passage embeddings.

Predict: Apply a fully connected layer, then two more BiLSTM layers, then a two dimensional linear layer to produce start and end scores for each token.

We apply variational dropout at a rate of 0.2 between all layers. We use the Adam optimizer (Kingma and Ba, 2015) with a batch size of 45, while decaying the learning rate by 0.999 every 100 steps.

For SQuAD, we use a 200 dimensional fully connected layer and 100 dimensional LSTMs.

For TriviaQA we use a 256 dimensional fully connected layer and 128 dimensional LSTMs, with highway connections between each BiLSTM (Srivastava et al., 2015) and a recurrent dropout rate of 0.2.

E TriviaQA-CP

In this section we discuss our changing-prior TriviaQA dataset, TriviaQA-CP. This dataset was built by training a classifier to identify TriviaQA (Joshi et al., 2017) questions as being about people,

Model	Debiasing Method	MNLI	Correct: *Entailment*			Correct: *Non-entailment*

Num Test	1,992	2,865
Avg. Passage Length	318	317
Avg. Question Length	16.7	16.0

Table 9: Statistics for the TriviaQA-CP datasets.

locations, or other topics, and then selecting an answer-containing passage for each question as context. There are two versions of this dataset: a person changing-priors dataset that was built by removing the person questions from the train set and using only person questions from the dev set for evaluation, and a location changing-priors dataset that was built by repeating this process for location questions. Statistics for these two sets are shown in Table 9. We review the three-step procedure we used to construct this dataset below.

Distantly Supervised Classification: We first train a preliminary question-type classifier using distant supervision. We noisily label person and location questions using a manually constructed set of patterns (e.g., questions with the phrase "What is the family name of..." are almost always about people), and by attempting to look up the answers in the Yago database (Suchanek et al., 2007) and checking if the answer belongs to a person or location category. Questions that did not match either of these heuristics are labelled as other.

We use these labels to train a simple recurrent model that embeds the question using the fasttext words vectors, applies a 100 dimensional BiLSTM, max-pools, and then applies a softmax layer with 3 outputs. We train the model for 3 epochs using the Adam optimizer (Kingma and Ba, 2015), and apply 0.5 dropout to the embeddings and 0.2 dropout to the recurrent states and the output of the max-pooling layer.

Supervised Classification: Next we use higher quality labels to train a second linear classifier to re-calibrate the recurrent model's predictions, and to integrate its predictions with the distantly supervised heuristics. An author manually labelled 1,100 questions, then a classifier was trained on those questions using the predictions from the recurrent model as features, as well as two additional features built from looking up the category of the answer in Yago as before. This classifier was then used to decide the final question classifications.

Table 10 shows the accuracy of these classifiers. The final model achieves about 95% accuracy. We find about 25% of the questions are about people and about 20% of the questions are about locations.

Paragraph Selection: In TriviaQA, each question is paired with multiple documents. We simplify the task by selecting a single answer-containing paragraph for each question. We use the approach of Clark and Gardner (2018) to break up the documents into passages of at most 400 tokens, and rank the passages for each question using their linear paragraph ranker. Each question is then paired with the highest ranking paragraph that contains an answer.

Method	Accuracy	Location			Person		
		Precision	Recall	F1	Precision	Recall	F1
Patterns	72.84	98.30	70.61	82.19	99.12	33.43	50.00
Yago	88.56	95.87	85.31	90.28	94.70	80.00	86.73

Abstract

Neural networks are part of many contemporary NLP systems, yet their empirical successes come at the price of vulnerability to adversarial attacks. Previous work has used adversarial training and data augmentation to partially mitigate such brittleness, but these are unlikely to find worst-case adversaries due to the complexity of the search space arising from discrete text perturbations. In this work, we approach the problem from the opposite direction: to formally verify a system's robustness against a predefined class of adversarial attacks. We study text classification under synonym replacements or character flip perturbations. We propose modeling these input perturbations as a simplex and then using Interval Bound Propagation – a formal model verification method. We modify the conventional log-likelihood training objective to train models that can be efficiently verified, which would otherwise come with exponential search complexity. The resulting models show only little difference in terms of nominal accuracy, but have much improved verified accuracy under perturbations and come with an efficiently computable formal guarantee on worst case adversaries.

1 Introduction

Deep models have been shown to be vulnerable against adversarial input perturbations (Szegedy et al., 2013; Kurakin et al., 2016). Small, semantically invariant input alterations can lead to drastic changes in predictions, leading to poor performance on adversarially chosen samples. Recent work (Jia and Liang, 2017; Belinkov and Bisk, 2018; Ettinger et al., 2017) also exposed the vulnerabilities of neural NLP models, e.g. with small character perturbations (Ebrahimi et al., 2018) or paraphrases (Ribeiro et al., 2018; Iyyer et al., 2018). These adversarial attacks highlight often unintuitive model failure modes and present a challenge to deploying NLP models.

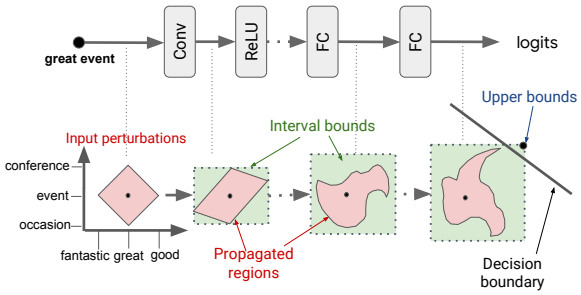

Figure 1: Illustration of verification with the input simplex and Interval Bound Propagation. From the left, input perturbations define the extreme points of a simplex (in red, projected to 2D here) around the statement "great event" that is propagated through a model. At each layer, this shape deforms itself, but can be bounded by axis-parallel bounding boxes, which are propagated similarly. Finally, in logit space, we can compute an upper bound on the worst-case specification violation (e.g., prediction changes).

Common attempts to mitigate the issue are adversarial training (Ebrahimi et al., 2018) and data augmentation (Belinkov and Bisk, 2018; Li et al., 2017), which lead to improved accuracy on adversarial examples. However, this might cause a false sense of security, as there is generally no guarantee that stronger adversaries could not circumvent defenses to find other successful attacks (Carlini and Wagner, 2017; Athalye et al., 2018; Uesato et al., 2018). Rather than continuing the race with adversaries, *formal verification* (Baier and Katoen, 2008; Barrett and Tinelli, 2018; Katz et al., 2017) offers a different approach: it aims at providing provable guarantees to a given model specification. In the case of adversarial robustness, such a specification can be formulated as prediction consistency under

[§]Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4083–4093, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

any altered – but semantically invariant – input change.

In this paper, we study verifiable robustness, i.e., providing a certificate that for a given network and test input, no attack or perturbation under the specification can change predictions, using the example of text classification tasks, Stanford Sentiment Treebank (SST) (Socher et al., 2013) and AG News (Zhang et al., 2015). The *specification* against which we verify is that a text classification model should preserve its prediction under character (or synonym) substitutions in a character (or word) based model. We propose modeling these input perturbations as a simplex and then using Interval Bound Propagation (IBP) (Gowal et al., 2018; Mirman et al., 2018; Dvijotham et al., 2018) to compute worst case bounds on specification satisfaction, as illustrated in Figure 1. Since these bounds can be computed efficiently, we can furthermore derive an auxiliary objective for models to *become* verifiable. The resulting classifiers are efficiently verifiable and improve robustness on adversarial examples, while maintaining comparable performance in terms of nominal test accuracy.

The contributions of this paper are twofold:

- To the best of our knowledge, this paper is the first to introduce verification and verifiable training for neural networks in natural language processing (§3).
- Through a series of experiments (§4), we demonstrate (a) the effectiveness of modeling input perturbations as a simplex and using simplex bounds with IBP for training and testing, (b) the weakness of adversarial training under exhaustive verification, (c) the effects of perturbation space on the performance of different methods, and (d) the impact of using GloVe and counter-fitted embeddings on the IBP verification bounds.

2 Related Work

Adversarial Examples in NLP. Creating adversarial examples for NLP systems requires identifying semantically invariant text transformations to define an input perturbation space. In this paper, given our specification, we study word- and character-level *HotFlip* attacks (Ebrahimi et al., 2018) – which consist of character and synonym replacements – on text classification tasks. We compare our verifiable approach to other defenses including adversarial training (Goodfellow et al., 2014) and data augmentation (Li et al., 2017; Belinkov and Bisk, 2018). Note that some existing adversarial perturbations such as syntactically controlled paraphrasing (Iyyer et al., 2018), exploiting backtranslation systems (Ribeiro et al., 2018), or using targeted keyword attack (Cheng et al., 2018) are beyond the specification in this paper.

Formal Verification of Neural Networks. Formal verification provides a provable guarantee that models are consistent with a *specification* for all possible model inputs. Previous work can be categorised into complete methods that use Mixed-Integer Programming (MIP) (Bunel et al., 2017; Cheng et al., 2017) or Satisfiability Modulo Theory (SMT) (Katz et al., 2017; Carlini et al., 2017), and incomplete methods that solve a convex relaxation of the verification problem (Weng et al., 2018; Wong and Kolter, 2018; Wang et al., 2018). Complete methods perform exhaustive enumeration to find the worst case. Hence, complete methods are expensive and difficult to scale, though they provide exact robustness bounds. Incomplete methods provide loose robustness bounds, but can be more scalable and used inside the training loop for training models to be robust and verifiable (Raghunathan et al., 2018; Wong and Kolter, 2018; Dvijotham et al., 2018; Gowal et al., 2018). Our work is the first to extend incomplete verification to text classification, considering input perturbations on a simplex and minimising worst case bounds to adversarial attacks in text classification. We highlight that the verification of neural networks is an extremely challenging task, and that scaling complete and incomplete methods to large models remains an open challenge.

Representations of Combinatorial Spaces. Word lattices and hypergraphs are data structures that have often been used to efficiently represent and process exponentially large numbers of sentences without exhaustively enumerating them. Applications include automatic speech recognition (ASR) output rescoring (Liu et al., 2016), machine translation of ASR outputs (Bertoldi et al., 2007), paraphrase variants (Onishi et al., 2010), and word segmentation alternatives (Dyer et al., 2008). The specifications used to characterise the space of adversarial attacks are likewise a compact representation, and the algorithms discussed below operate on them without exhaustive enumeration.

3 Methodology

We assume a fixed initial vector representation $\mathbf{z}_0$ of a given input sentence z[1] (e.g. the concatenation of pretrained word embeddings) and use a neural network model, i.e. a series of differentiable transformations h_k:

$$\mathbf{z}_k = h_k(\mathbf{z}_{k-1}) \quad k = 1, \ldots, K \tag{1}$$

where $\mathbf{z}_k$ is the vector of activations in the k-th layer and the final output $\mathbf{z}_K$ consists of the logits for each class. Typically each h_k will be an affine transformation followed by an activation function (e.g. ReLU or sigmoid). The affine transformation can be a convolution (with the inputs and outputs having an implied 2D structure) of a vector of activations at each point in a sequence; in what follows these activations will be concatenated along the sequence to form a vector $\mathbf{z}_k$.

3.1 Verification

Verification is the process of examining whether the output of a model satisfies a given specification. Formally, this means establishing whether the following holds true for a given *normal* model input $\mathbf{x}_0$: $\forall \mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0) : \mathbf{z}_K \in \mathcal{X}_{\text{out}}$, where $\mathcal{X}_{\text{out}}$ characterizes a constraint on the outputs, and $\mathcal{X}_{\text{in}}(\mathbf{x}_0)$ defines a neighbourhood of $\mathbf{x}_0$ throughout which the constraint should be satisfied.

In our concrete use case, we consider a specification of robustness against adversarial attacks which are defined by bounded input perturbations (synonym flips up to δ words, or character flips up to δ characters) of the original sentence x. The attack space $\mathcal{X}_{\text{in}}(\mathbf{x}_0)$ is the set of vector representations (embeddings) of all such perturbed sentences. Denoting by $z_{K,y}$ the logit of label y, we formulate the output constraint that for all classes $y : z_{K,y_{\text{true}}} \geq z_{K,y}$. This specification establishes that the prediction of *all* perturbed sentences $\mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0)$ should correspond to the correct label y_{true}. This specification may equivalently be formulated as a set of half-space constraints on the logits: for each class y

$$(\mathbf{e}_y - \mathbf{e}_{y_{\text{true}}})^\top \mathbf{z}_K \leq 0 \quad \forall \mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0) \tag{2}$$

where $\mathbf{e}_i$ is a one-hot vector with 1 in the i-th position. In other words, the true class logit should be greater or equal than those for all other classes y, which means the prediction remains constant.

[1]For brevity, we will refer both to the original symbol sequence and its corresponding vector representation with the same variable name, distinguishing them by styling.

3.2 Verification as Optimisation

Verifying the specification in Eq. (2) can be done by solving the following constrained optimisation problem to find the input that would most strongly violate it:

$$\begin{aligned} \underset{\mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0)}{\text{maximize}} \quad & \mathbf{c}^\top \mathbf{z}_K \\ \text{subject to} \quad & \mathbf{z}_k = h_k(\mathbf{z}_{k-1}) \quad k = 1, \ldots, K \end{aligned} \tag{3}$$

where $\mathbf{c}$ is a vector with entries $c_y = 1$, $c_{y_{\text{true}}} = -1$ and 0 everywhere else. If the optimal value of the above optimisation problem is smaller than 0, then the specification in Eq. (2) is satisfied, otherwise a counter-example has been found. In our case, this corresponds to a successful adversarial attack.

3.3 Modeling Input Perturbations using Simplices

In the interests of computational feasibility, we will actually attempt to verify the specification on a larger, but more tractable input perturbation space $\bar{\mathcal{X}}_{\text{in}} \supseteq \mathcal{X}_{\text{in}}$. Any data point that is verifiable on this larger input perturbation space is necessarily verifiable with respect to the original specification.

In the domain of image classification, $\mathcal{X}_{\text{in}}$ is often modeled as an L_∞-ball, corresponding to input perturbations in which each pixel may be independently varied within a small interval. However, using such interval bounds is unsuitable for our situation of perturbations consisting of a small number δ of symbol substitutions. Although we could construct an axis-aligned bounding box $\bar{\mathcal{X}}_{\text{in}}$ in embedding space that encompasses all of $\mathcal{X}_{\text{in}}$, it would over-approximate the perturbation space to such an extent that it would contain perturbations where *all* symbols in the sentence have been substituted simultaneously.

To remedy this, we propose a tighter over-approximation in the form of a 'simplex' in embedding space. We first define this for the special case $\delta = 1$, in which $\mathcal{X}_{\text{in}} = \{\mathbf{x}_0\} \cup \{\mathbf{p}_0^{(m)} : 1 \leq m \leq M\}$ consists of the representations of all M sentences $p^{(m)}$ derived from x by performing a *single* synonym (or character) substitution, together with the unperturbed sentence x itself. In this case we define $\bar{\mathcal{X}}_{\text{in}}$ to be the convex hull $\mathcal{S}_1$ of $\mathcal{X}_{\text{in}}$. Note we are not considering contextual embeddings (Peters et al., 2018) here. Each 'vertex' $\mathbf{p}_0^{(m)}$ is a sequence of embedding vectors that differs from $\mathbf{x}_0$ at only one word (or character) position.

For a larger perturbation radius $\delta > 1$, the cardinality of $\mathcal{X}_{\text{in}}$ grows exponentially, so manipulating

its convex hull becomes infeasible. However, dilating $\mathcal{S}_1$ centered at $\mathbf{x}_0$, scaling it up by a factor of δ, yields a simplex $\mathcal{S}_\delta$ with $M+1$ vertices that contains $\mathcal{X}_{\text{in}}$.

More formally, we define a region in the input embedding space based on the M 'elementary' perturbations $\{\mathbf{p}_0^{(m)} : m = 1 \dots M\}$ of $\mathbf{x}_0$ defined earlier for the $\delta = 1$ case. For perturbations of up to δ substitutions, we define $\bar{\mathcal{X}}_{\text{in}}(\mathbf{x}_0)$ as the convex hull of $\{\mathbf{z}_0^{(m)} : m = 0 \dots M\}$, where $\mathbf{z}_0^{(0)} = \mathbf{x}_0$ denotes the original (unperturbed) sentence representation and, for $m \geq 1$, $\mathbf{z}_0^{(m)} = \mathbf{x}_0 + \delta \cdot (\mathbf{p}_0^{(m)} - \mathbf{x}_0)$. The convex hull is an over-approximation of $\mathcal{X}_{\text{in}}(\mathbf{x}_0)$: it contains the representations of all sentences derived from x by performing up to δ substitutions at distinct word (or character) positions.

3.4 Interval Bound Propagation

To estimate the optimal value of the problem (3), given an input $\mathbf{z}_0$, we can propagate the upper/lower bounds on the activations $\mathbf{z}_k$ of each layer using interval arithmetic (Gowal et al., 2018).

We begin by computing interval bounds on the first layer's activations. Recall that any input $\mathbf{z}_0 \in \mathcal{X}_{\text{in}}$ will lie within the convex hull of certain vertices $\{\mathbf{z}_0^{(m)} : m = 0 \dots M\}$. Then, assuming that the first layer h_1 is an affine transformation (e.g. linear or convolutional) followed by a monotonic activation function, the lower and upper bounds on the components $z_{1,i}$ of the first layer's activations $\mathbf{z}_1$ are as follows:

$$\begin{aligned} \underline{z}_{1,i}(\delta) &= \min_{m=0,\dots,M} \mathbf{e}_i^\top h_1(\mathbf{z}_0^{(m)}) \\ \overline{z}_{1,i}(\delta) &= \max_{m=0,\dots,M} \mathbf{e}_i^\top h_1(\mathbf{z}_0^{(m)}) \end{aligned} \tag{4}$$

Note that these bounds are efficient to compute (by passing each perturbation $\mathbf{z}_0^{(m)}$ through the first layer); in particular there is no need to compute the convex hull polytope.

For subsequent layers $k > 1$, the bounds on the components $z_{k,i}$ of $\mathbf{z}_k$ are:

$$\begin{aligned} \underline{z}_{k,i}(\delta) &= \min_{\underline{\mathbf{z}}_{k-1}(\delta) \leq \mathbf{z}_{k-1} \leq \overline{\mathbf{z}}_{k-1}(\delta)} \mathbf{e}_i^\top h_k(\mathbf{z}_{k-1}) \\ \overline{z}_{k,i}(\delta) &= \max_{\underline{\mathbf{z}}_{k-1}(\delta) \leq \mathbf{z}_{k-1} \leq \overline{\mathbf{z}}_{k-1}(\delta)} \mathbf{e}_i^\top h_k(\mathbf{z}_{k-1}) \end{aligned} \tag{5}$$

The above optimisation problems can be solved in closed form quickly for affine layers and monotonic activation functions, as illustrated in Gowal et al. (2018). Finally, the lower and upper bounds of the output logits $\mathbf{z}_K$ can be used to construct an upper bound on the solution of (3):

$$\underset{\underline{\mathbf{z}}_K(\delta) \leq \mathbf{z}_K \leq \overline{\mathbf{z}}_K(\delta)}{\text{maximize}} \; \mathbf{c}^\top \mathbf{z}_K \tag{6}$$

Verifiable Training. The upper bound in (6) is fast to compute (only requires two forward passes for upper and lower bounds through the network). Hence, we can define a loss to optimise models such that the models are trained to be verifiable. Solving (6) is equivalent to finding the worst-case logit difference, and this is achieved when the logit of the true class is equal to its lower bound, and all other logits equal to their upper bounds. Concretely, for each class $y \neq y_{\text{true}}$: $\hat{\mathbf{z}}_{K,y}(\delta) = \overline{\mathbf{z}}_{K,y}(\delta)$, and $\hat{\mathbf{z}}_{K,y_{\text{true}}}(\delta) = \underline{\mathbf{z}}_{K,y_{\text{true}}}(\delta)$. The training loss can then be formulated as

$$L = \kappa \underbrace{\ell(\mathbf{z}_K, y_{\text{true}})}_{L_{\text{normal}}} + (1-\kappa) \underbrace{\ell(\hat{\mathbf{z}}_K(\delta), y_{\text{true}})}_{L_{\text{spec}}} \tag{7}$$

where ℓ is the cross-entropy loss, κ a hyperparameter that controls the relative weights between the classification loss L_{normal} and specification loss L_{spec}. If $\delta = 0$ then $\mathbf{z}_K = \hat{\mathbf{z}}_K(\delta)$, and thus L reduces to a standard classification loss. Empirically, we found that a curriculum-based training, starting with κ=1 and linearly decreasing to 0.25, is effective for verifiable training.

4 Experiments

We conduct verification experiments on two text classification datasets, Stanford Sentiment Treebank (SST) (Socher et al., 2013) and AG News corpus, processed in (Zhang et al., 2015). We focus on word-level and character-level experiments on SST and character-level experiments on AG News. Our specification is that models should preserve their prediction against up to δ synonym substitutions or character typos, respectively.

4.1 A Motivating Example

We provide an example from Table 2 to highlight different evaluation metrics and training methods. Given a sentence, "you ' ve seen them a million times .", that is predicted correctly (called *Nominal Accuracy*[2]) by a classification model, we want to further examine whether the model is robust against character typos (e.g., up to $\delta = 3$ typos) to

[2]We use the term "nominal accuracy" to indicate the accuracy under various adversarial perturbations is much lower.

this example. One way is to use some heuristic to search for a valid example with up to 3 typos that can change the prediction the most (called *adversarial example*). We evaluate the model using this adversarial example and report the performance (called *Adversarial Accuracy*). However, even if the adversarial example is predicted correctly, one can still ask: is the model truly robust against *any* typos (up to 3) to this example? In order to have a certificate that the prediction will not change under any $\delta = 3$ character typos (called *verifiably robust*), we could in theory exhaustively search over all possible cases and check whether any of the predictions is changed (called *Oracle Accuracy*). If we only allow a character to be replaced by another character nearby on the keyboard, already for this short sentence we need to exhaustively search over 2,951 possible perturbations. To avoid this combinatorial growth, we can instead model all possible perturbations using the proposed simplex bounds and propagate the bounds through IBP at the cost of two forward passes. Following Eq. (3), we can check whether this example can be verified to be robust against all perturbations (called *IBP-Verified Accuracy*).

There are also a number of ways in which the training procedure can be enhanced to improve the verifiable robustness of a model against typos to the sentence. The baseline is to train the model with the original/normal sentence directly (called *Normal Training*). Another way is to randomly sample typo sentences among the 2,951 possible perturbations and add these sentences to the training data (called *Data Augmentation Training*). Yet another way is to find, at each training iteration, the adversarial example among the (subset of) 2,951 possible perturbations that can change the prediction the most; we then use the adversarial example alongside the training example (called *Adversarial Training*). Finally, as simplex bounds with IBP is efficient to run, we can train a model to be verifiable by minimising Eq. (7) (called *Verifiable Training*).

4.2 Baselines

In this section we detail our baseline models.

Adversarial Training. In adversarial training (Madry et al., 2018; Goodfellow et al., 2014), the goal is to optimise the following saddle point problem:

$$\min_{\theta} \mathop{\mathbb{E}}_{(\mathbf{x}_0, y)} \left[\max_{\mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0)} \ell_\theta(\mathbf{z}_0, y) \right] \tag{8}$$

where the inner maximisation problem is to find an adversarial perturbation $\mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0)$ that can maximise the loss. In the inner maximisation problem, we use HotFlip (Ebrahimi et al., 2018) with perturbation budget δ to find the adversarial example. The outer minimisation problem aims to update model parameters such that the adversarial risk of (8) is minimised. To balance between the adversarial robustness and nominal accuracy, we use an interpolation weight of 0.5 between the original cross-entropy loss and the adversarial risk.

Data Augmentation Training. In the data augmentation setup, we randomly sample a valid perturbation z with perturbation budget δ from a normal input x, and minimise the cross-entropy loss given the perturbed sample z (denoted as data augmentation loss). We also set the interpolation weight between the data augmentation loss and the original normal cross-entropy loss to 0.5.

Normal Training. In normal training, we use the likelihood-based training using the normal training input x.

4.3 Setup

We use a shallow convolutional network with a small number of fully-connected layers for SST and AG News experiments. The detailed model architectures and hyperparameter details are introduced in the supplementary material. Although we use shallow models for ease of verifiable training, our nominal accuracy is on par with previous work such as Socher et al. (2013) (85.4%) and Shen et al. (2018) (84.3%) in SST and Zhang et al. (2015) (87.18%) in AG News. During training, we set the maximum number of perturbations to $\delta = 3$, and evaluate performance with the maximum number of perturbations from $\delta = 1$ to 6 at test time.

For word-level experiments, we construct the synonym pairs using the PPDB database (Ganitkevitch et al., 2013) and filter the synonyms with fine-grained part-of-speech tags using Spacy (Honnibal and Montani, 2017). For character-level experiments, we use synthetic keyboard typos from Belinkov and Bisk (2018), and allow one possible alteration per character that is adjacent to it on an American keyboard. The allowable input perturbation space is much larger than for word-level synonym substitutions, as shown in Table 3.

	SST-Char-Level			SST-Word-Level			AG-Char-Level		
Training	**Acc.**	**Adv. Acc.**	**Oracle**	**Acc.**	**Adv. Acc.**	**Oracle**	**Acc.**	**Adv. Acc.**	**Oracle**

-	it ' s the kind of pigeonhole-resisting romp that hollywood too rarely **gives** .
-	sets up a nice concept for its fiftysomething leading ladies , but fails loudly in execution .
+	sets up a nice concept for its fiftysomething leading ladies , but fails **aloud** in execution .
Prediction	SST character level examples (by exhaustive verification, not by adversarial attack)
-	you ' ve seen them a million times .
+	you ' ve se**r**n them a million times .
+	choose your reaction : a.) that sure is funny !
-	choose **t**our reaction : a.) that sure is funny !

Table 2: Pairs of original inputs and adversarial examples for SST sentiment classification found via an exhaustive verification oracle, but not found by the HotFlip attack (i.e., the HotFlip attack does not change the model prediction). The bold words/characters represent the flips found by the adversary that change the predictions.

4.4 Evaluation Metrics

We use the following four metrics to evaluate our models: i) test set accuracy (called Acc.), ii) adversarial test accuracy (called Adv. Acc.), which uses samples generated by HotFlip attacks on the original test examples, iii) verifiable accuracy under IBP verification (called IBP-verified), that is, the ratio of test samples for which IBP can verify that the specification is not violated, and iv) exhaustively verified accuracy (called Oracle), computed by enumerating all possible perturbations given the perturbation budget δ, where a sample is verifiably robust if the prediction is unchanged under all valid perturbations.

4.5 Results

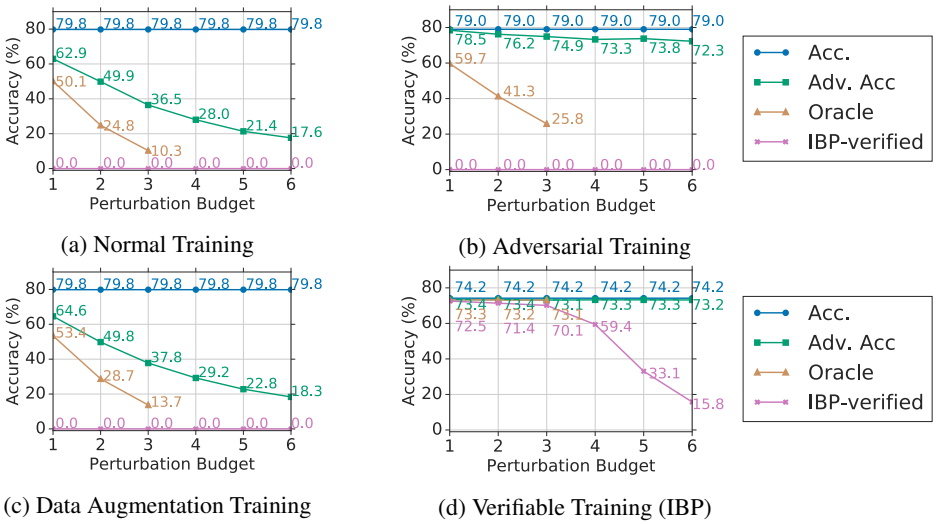

Table 1 shows the results of IBP training and baseline models under $\delta = 3$ and $\delta = 2$[3] perturbations on SST and AG News, respectively. Figures 2 and 3 show the character- and word-level results with δ between 1 and 6 under four metrics on the SST test set; similar figures for SST word-level (adversarial training, data augmentation) models and AG News dataset can be found in the supplementary material.

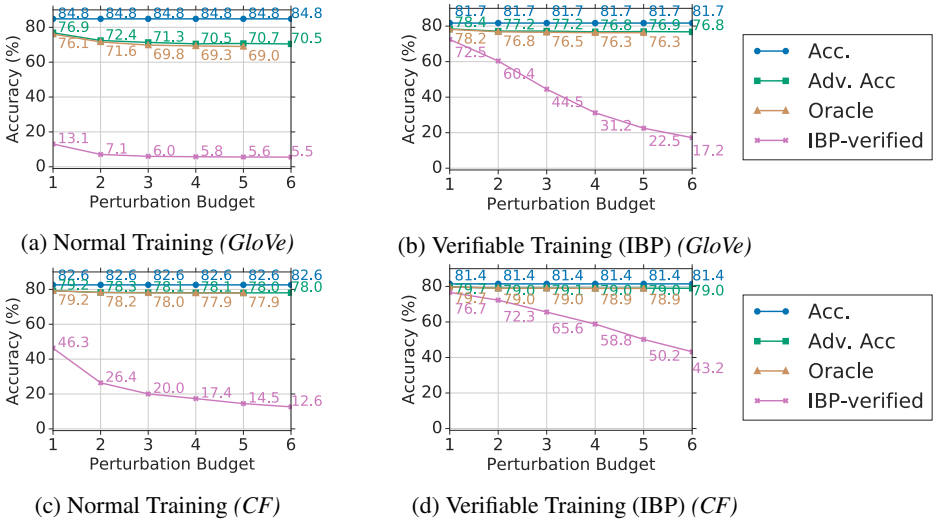
Oracle Accuracy and Adversarial Accuracy. In Table 1, comparing adversarial accuracy with exhaustive verification accuracy (oracle), we observe that although adversarial training is effective at defending against HotFlip attacks (74.9 / 76.8 / 85.5%), the oracle adversarial accuracy under exhaustive testing (25.8 / 74.6 / 81.6%) is much lower in SST-character / SST-word / AG-character level, respectively. For illustration, we show some concrete adversarial examples from the HotFlip attack in Table 2. For some samples, even though the model is robust with respect to HotFlip attacks, its predictions are incorrect for stronger adversarial examples obtained using the exhaustive verification oracle. This underscores the need for verification, as robustness with respect to suboptimal adversarial attacks alone might give a false sense of security.

Effectiveness of Simplex Bounds with IBP. Rather than sampling individual points from the perturbation space, IBP training covers the full space at once. The resulting models achieve the highest exhaustively verified accuracy at the cost of only moderate deterioration in nominal accuracy (Table 1). At test time, IBP allows for constant-time verification with arbitrary δ, whereas exhaustive verification requires evaluation over an exponentially growing search space.

Perturbation Space Size. In Table 1, when the perturbation space is larger (SST character-level vs. SST word-level), (a) across models, there is a larger gap in adversarial accuracy and true robustness



[3]Note that the exhaustive oracle is not computationally feasible beyond $\delta = 2$ on AG News.

Figure 3: SST word-level models with normal and verifiable training objectives (trained at δ=3) using *GloVe* and *counter-fitted (CF)* embeddings against different perturbation budgets in nominal accuracy, adversarial accuracy, exhaustively verified accuracy (Oracle), and IBP verified accuracy. Note that exhaustive verification is not scalable to perturbation budget 6 and beyond.

(oracle); (b) the difference in oracle robustness between IBP and adversarial training is even larger (73.1% vs. 25.8% and 76.5% vs. 74.6%).

Perturbation Budget. In Figures 2 and 3, we compare normal training, adversarial training, data augmentation, and verifiable training models with four metrics under various perturbation budgets on the SST dataset. Overall, as the perturbation budget increases, the adversarial accuracy, oracle accuracy, and IBP-verified accuracy decrease. We can observe that even for large perturbation budgets, verifiably trained models are still able to verify a sizable number of samples. Again, although adversarial accuracy flattens for larger perturbation budgets in the word level experiments, oracle verification can further find counterexamples to change the prediction. Note that exhaustive verification becomes intractable with large perturbation sizes.

Computational Cost of Exhaustive Verification. The perturbation space in NLP problems is discrete and finite, and a valid option to verify the specification is to exhaustively generate predictions for all $\mathbf{z}_0 \in \mathcal{X}_{\text{in}}(\mathbf{x}_0)$, and then check if at least one does not match the correct label. Conversely, such an

Perturbation radius	$\delta = 1$	$\delta = 2$	$\delta = 3$
SST-word	49	674	5,136
SST-character	206	21,116	1,436,026
AG-character	722	260,282	-

Table 3: Maximum perturbation space size in the SST and AG News test set using word / character substitutions, which is the maximum number of forward passes per sentence to evaluate in the exhaustive verification.

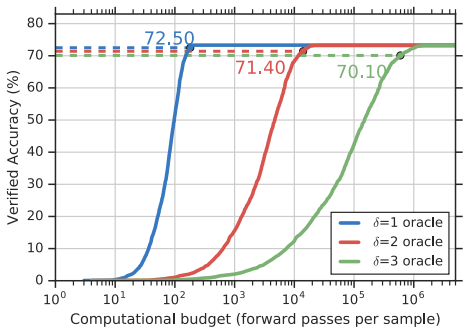

Figure 4: Verified accuracy vs. computation budget for exhaustive verification oracles on the SST character-level test set, for an IBP-trained model trained with δ=3. Solid lines represent the number of forward passes required to verify a given proportion of the test set using exhaustive search. Dashed lines indicate verification levels achievable using IBP verification, which comes at small and constant cost, and is thus orders of magnitude more efficient.

exhaustive (oracle) approach can also identify the strongest possible attack. But the size of $\mathcal{X}_{\text{in}}$ grows exponentially with δ, and exhaustive verification quickly becomes prohibitively expensive.

In Table 3, we show the maximum perturbation space size in the SST and AG News test set for different perturbation radii δ. This number grows exponentially as δ increases. To further illustrate this, Figure 4 shows the number of forward passes required to verify a given proportion of the SST test set for an IBP-trained model using exhaustive verification and IBP verification. IBP reaches verification levels comparable to an exhaustive verification oracle, but requires only two forward passes to verify any sample – one pass for computing the upper, and one for the lower bounds. Exhaustive verification, on the other hand, requires several orders of magnitude more forward passes, and there is a tail of samples with extremely large attack spaces.

4.6 Counter-Fitted Embeddings

As shown in Figures 2 and 3a, although IBP can verify arbitrary networks in theory, the verification bound is very loose except for models trained to be IBP-verifiable. One possible reason is the potentially large volume of the perturbation simplex. Since representations of substitution words/characters are not necessarily close to those of synonyms/typos in embedding space, the vertices of the simplex could be far apart, and thus cover a large area in representation space. Therefore, when propagating the interval bounds through the network, the interval bounds become too loose and fail to verify most of the examples if the models are not specifically trained. To test this hypothesis, we follow Mrkšić et al. (2016) and use fine-tuned GloVe embeddings trained to respect linguistic constraints; these representations (called counter-fitted embeddings) force synonyms to be closer and antonyms to be farther apart using word pairs from the PPDB database (Ganitkevitch et al., 2013) and WordNet (Miller, 1995). We repeat the word level experiments with these counter-fitted embeddings, Figures 3c and 3d show the experimental results. We observe that IBP verified accuracy is now substantially higher across models, especially for $\delta = 1, 2, 3$. The examples which IBP can verify increase by up to 33.2% when using the counter-fitted embeddings (normal training, $\delta = 1$). Moreover, adversarial and exhaustively verified accuracy are also improved, at the cost of a mild deterioration in nominal test accuracy. The IBP-trained model also further improves both its oracle accuracy and IBP verified accuracy. These results validate our hypothesis that reducing the simplex volume via soft linguistic constraints can provide even tighter bounds for IBP, resulting in larger proportions of verifiable samples.

5 Discussion

Our experiments indicate that adversarial attacks are not always the *worst* adversarial inputs, which can only be revealed via verification. On the other hand, exhaustive verification is computationally very expensive. Our results show that using the proposed simplex bounds with IBP can verify a sizable amount of test samples, and can be considered a potent verification method in an NLP context. We note however two limitations within the scope of this work: i) limited model depth: we only investigated models with few layers. IBP bounds are likely to become looser as the number of layers increases. ii) limited model types: we only studied models with CNN and fully connected layers.

We focused on the HotFlip attack to showcase specification verification in the NLP context, with the goal of understanding factors that impact its effectiveness (e.g. the perturbation space volume, see Section 4.6). It is worth noting that symbol substitution is general enough to encompass other threat models such as lexical entailment perturbations (Glockner et al., 2018), and could potentially be extended to the addition of pre/postfixes (Jia and Liang, 2017; Wallace et al., 2019).

Interesting directions of future work include: tightening IBP bounds to allow applicability to deeper models, investigating bound propagation in other types of neural architectures (e.g. those based on recurrent networks or self-attention), and exploring other forms of specifications in NLP.

6 Conclusion

We introduced formal verification of text classification models against synonym and character flip perturbations. Through experiments, we demonstrated the effectiveness of the proposed simplex bounds with IBP both during training and testing, and found weaknesses of adversarial training compared with exhaustive verification. Verifiably trained models achieve the highest exhaustive verification accuracy on SST and AG News. IBP verifies models in constant time, which is exponentially more efficient than naive verification via exhaustive search.

Abstract

Selective rationalization has become a common mechanism to ensure that predictive models reveal how they use any available features. The selection may be soft or hard, and identifies a subset of input features relevant for prediction. The setup can be viewed as a cooperate game between the selector (aka rationale generator) and the predictor making use of only the selected features. The co-operative setting may, however, be compromised for two reasons. First, the generator typically has no direct access to the outcome it aims to justify, resulting in poor performance. Second, there's typically no control exerted on the information left outside the selection. We revise the overall co-operative framework to address these challenges. We introduce an introspective model which explicitly predicts and incorporates the outcome into the selection process. Moreover, we explicitly control the rationale complement via an adversary so as not to leave any useful information out of the selection. We show that the two complementary mechanisms maintain both high predictive accuracy and lead to comprehensive rationales.[1]

1 Introduction

Rapidly expanding applications of complex neural models also bring forth criteria other than mere performance. For example, medical (Yala et al., 2019) and other high-value decision applications require some means of verifying reasons for the predicted outcomes. This area of self-explaining models in the context of NLP applications has primarily evolved along two parallel tracks. On one hand, we can design neural architectures that expose more intricate mechanisms of reasoning such as module networks (Andreas et al., 2016a,b; Johnson et al., 2017). While important, such approaches may still require adopting specialized designs and architectural choices that do not yet reach accuracies comparable to black-box approaches. On the other hand, we can impose limited architectural constraints in the form of selective rationalization (Lei et al., 2016; Li et al., 2016b; Chen et al., 2018a,b) where the goal is to only expose the portion of the text relevant for prediction. The selection is done by a separately trained model called rationale generator. The resulting text selection can be subsequently used as an input to an unconstrained, complex predictor, *i.e.*, architectures used in the absence of any rationalization.[2] The main challenge of this track is how to properly coordinating the rationale generator with the powerful predictor operating on the selected information during training.

Label: negative **Original Text:** *really cloudy , lots of sediment , washed out yellow color . looks pretty gross , actually , like swamp water . no head , no lacing .* **Rationale from (Lei et al., 2016)**: [*"really cloudy lots", "yellow", "no", "no"*] **Rationale from cooperative introspection model**: [*". looks", "no", "no"*] **Rationale from our full model**: [*"cloudy", "lots", "pretty gross", "no lacing"*]

Table 1: An example of the rationales extracted by different models on the sentiment analysis task of beer reviews (appearance aspect). *Red* words are human-labeled rationales. Details of the experiments can be found in Appendix B.

In this paper, we build on and extend selective rationalization. The selection process can be thought of as a cooperative game between the generator and the predictor operating on the selected,

[*]Authors contributed equally to this work.

[1]The code and data for our method is publicly available at https://github.com/Gorov/three_player_for_emnlp.

[2]Therefore the selective rationalization approach is easier to be adapted to new applications, such as question answering (Yu et al., 2018), image classification (Chen et al., 2018a) and medical image analysis (Yala et al., 2019).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4094–4103, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

partial input text. The two players aim for the shared goal of achieving high predictive accuracy, just having to operate within the confines imposed by rationale selection (a small, concise portion of input text). The rationales are learned entirely in an unsupervised manner, without any guidance other than their size, form. An example of ground-truth and learned rationales are given in Table 1.

The key motivation for our work arises from the potential failures of cooperative selection. Since the generator typically has no direct access to the outcome it aims to justify, the learning process may converge to a poorly performing solution. Moreover, since only the selected portion is evaluated for its information value (via the predictor), there is typically no explicit control over the remaining portion of the text left outside the rationale. These two challenges are complementary and should be addressed jointly.

Performance The clues in text classification tasks are typically short phrases (Zaidan et al., 2007). However, diverse textual inputs offer a sea of such clues that may be difficult to disentangle in a manner that generalizes to evaluation data. Indeed, the generator may fail to disentangle the information about the correct label, offering misleading rationales instead. Moreover, as confirmed by the experiments presented in this paper, the collaborative nature of the game may enable the players to select a sub-optimal communication code that does not generalize, rather overfits the training data. Regression tasks considered in prior work typically offer greater feedback for the generator, making it less likely that such communication patterns would arise.

We address these concerns by proposing an *introspective rationale generator*. The key idea is to force the generator to explicitly understand what to generate rationales for. Specifically, we make the label that would be predicted with the full text as an additional input to the generator thereby ensuring better overall performance.

Rationale quality The cooperative game setup does not explicitly control the information left out of the rationale. As a result, it is possible for the rationales to degenerate as in containing only select words without the appropriate context. In fact, the introspective generator proposed above can aggravate this problem. With access to the predicted label as input, the generator and the predictor can find a communication scheme by encoding the predicted label with special word patterns (*e.g.* highlighting "." for positive examples and "," negative ones). Table 1 shows such degenerate cases for the two cooperative methods.

In order to prevent degenerate rationales, we propose a *three-player game* that renders explicit control over the unselected parts. In addition to the generator and the predictor as in conventional cooperative rationale selection schemes, we add a third adversarial player, called the *complement predictor*, to regularize the cooperative communication between the generator and the predictor. The goal of the complement predictor is to predict the correct label using only words left out of the rationale. During training, the generator aims to fool the complement predictor while still maintaining high accuracy for the predictor. This ensures that the selected rationale must contain all/most of the information about the target label, leaving out irrelevant parts, within size constraints imposed on the rationales.

We also theoretically show that the equilibrium of the three-player game guarantees good properties for the extracted rationales. Moreover, we empirically show that (1) the three-player framework on its own helps cooperative games such as (Lei et al., 2016) to improve both predictive accuracy and rationale quality; (2) by combining the two solutions – introspective generator and the three player game – we can achieve high predictive accuracy and non-degenerate rationales.

2 Problem Formulation

This section formally defines the problem of rationalization, and then proposes a set of conditions that desirable rationales should satisfy, which addresses problems of previous cooperative frameworks. Here are some notations throughout this paper. Bolded upper-cased letters, *e.g.* $\boldsymbol{X}$, denote random vectors; unbolded upper-cased letters, *e.g.* X, denote random scalar variables; bolded lower-cased letters, *e.g.* $\boldsymbol{x}$, denote deterministic vectors or vector functions; unbolded lower-cased letters, *e.g.* x, denote deterministic scalars or scalar functions. $p_X(\cdot|Y)$ denotes conditional probability density/mass function conditional on Y. $H(\cdot)$ denotes Shannon entropy. $\mathbb{E}[\cdot]$ denotes expectation.

2.1 Problem Formulation of Rationalization

The target application here is text classification on data tokens in the form of $\{(\boldsymbol{X}, Y)\}$. Denote

$\boldsymbol{X} = \boldsymbol{X}_{1:L}$ as a sequence of words in an input text with length L. Denote Y as a label. Our goal is to generate a rationale, denoted as $\boldsymbol{r}(\boldsymbol{X}) = \boldsymbol{r}_{1:L}(\boldsymbol{X})$, which is a selection of words in $\boldsymbol{X}$ that accounts for Y. Formally, $\boldsymbol{r}(\boldsymbol{X})$ is a hard-masked version of $\boldsymbol{X}$ that takes the following form at each position i:

$$\boldsymbol{r}_i(\boldsymbol{X}) = \boldsymbol{z}_i(\boldsymbol{X}) \cdot \boldsymbol{X}_i, \tag{1}$$

where $\boldsymbol{z}_i \in \{0,1\}^N$ is the binary mask. Many previous works (Lei et al., 2016; Chen et al., 2018a) follows the above definition of rationales. In this work, we further define the complement of rationale, denoted as $\boldsymbol{r}^c(\boldsymbol{X})$, as

$$\boldsymbol{r}_i^c(\boldsymbol{X}) = (1 - \boldsymbol{z}_i(\boldsymbol{X})) \cdot \boldsymbol{X}_i. \tag{2}$$

For notational ease, define

$$\boldsymbol{R} = \boldsymbol{r}(\boldsymbol{X}), \quad \boldsymbol{R}^c = \boldsymbol{r}^c(\boldsymbol{X}), \quad \boldsymbol{Z} = \boldsymbol{z}(\boldsymbol{X}). \tag{3}$$

2.2 Rationale Conditions

An ideal rationale should satisfy the following conditions.

Sufficiency: $\boldsymbol{R}$ is sufficient to predict Y, *i.e.*

$$p_Y(\cdot|\boldsymbol{R}) = p_Y(\cdot|\boldsymbol{X}). \tag{4}$$

Comprehensiveness: $\boldsymbol{R}^c$ does not contain sufficient information to predict Y, *i.e.*

$$H(Y|\boldsymbol{R}^c) \geq H(Y|\boldsymbol{R}) + h, \tag{5}$$

for some constant h.

Compactness: the segments in $\boldsymbol{X}$ that are included in $\boldsymbol{R}$ should be sparse and consecutive, *i.e.,*

$$\sum_i \boldsymbol{Z}_i \leq s, \quad \sum_i |\boldsymbol{Z}_i - \boldsymbol{Z}_{i-1}| \leq c, \tag{6}$$

for some constants s and c.

Here is an explanation of what each of these conditions means. The sufficiency condition is the core one of a legitimate rationale, which essentially stipulates that the rationale maintains the same predictive power as $\boldsymbol{X}$ to predict Y. The compactness condition stipulates that the rationale should be continuous and should not contain more words than necessary. For example, without the compactness condition, a trivial solution to Eq. (4) would be $\boldsymbol{X}$ itself. The first inequality in Eq. (6) constrains the sparsity of rationale, and the second one constrains the continuity. The comprehensiveness condition requires some elaboration, which we will discuss in the next subsection.

2.3 Comprehensiveness and Degeneration

There are two justifications of the comprehensiveness condition. First, it regulates the information outside the rationale, so that the rationale contains all the relevant and useful information, hence the name comprehensiveness. Second and more importantly, we will show there exists a failure case, called degeneration, which can only be prevented by the comprehensiveness condition.

Degeneration refers to the situation where, rather than finding words in $\boldsymbol{X}$ that explains Y, $\boldsymbol{R}$ attempts to encode the probability of Y using trivial information, *e.g.* punctuation and position. Consider the following toy example of binary classification ($Y \in \{0,1\}$), where $\boldsymbol{X}$ can always perfectly predict Y. Then the following rationale satisfies the sufficiency and compactness: $\boldsymbol{R}$ includes only the first word of $\boldsymbol{X}$ when $Y = 0$, and only the last word when $Y = 1$. It is obvious that this $\boldsymbol{R}$ is sufficient to predict $\boldsymbol{Y}$ (by looking at if the first word or the last word is chosen), and thus satisfies the sufficiency condition. Apparently this $\boldsymbol{R}$ is perfectly compact (only one word). However, this rationale does not provide a valid explanation.

Theoretically, any previous cooperative framework may suffer from the above ill-defined problem, if the generator has the potential to accurately guess Y with sufficient capacity.[3] This problem happens because they have no control of the words unselected by $\boldsymbol{R}$. Intuitively, in the presence of degeneration, some key predictors in $\boldsymbol{X}$ will be left unselected by $\boldsymbol{R}$. Thus by looking at the predictive power of $\boldsymbol{R}^c$, we can determine if degeneration occurs. Specifically, when degeneration is present, all the useful information is left unselected by $\boldsymbol{R}$, and so $H(Y|\boldsymbol{R}^c)$ is low. That is why the lower bound in Eq. (5) rules out the degeneration cases.

3 The Proposed Three-Player Models

This section introduces our new rationalization solutions, which is theoretically guaranteed to be able to find the rationales that satisfy Eqs. (4-6).

3.1 The Basic Three-Player Model

This section introduces our basic three-player model. The model consists of three players: a **rationale generator** that generates the rationale $\boldsymbol{R}$ and its complement $\boldsymbol{R}^c$ from text, a **predictor** that predicts the probability of Y based on $\boldsymbol{R}$, a **com-**

[3] We show such cases of (Lei et al., 2016) in Appendix B.

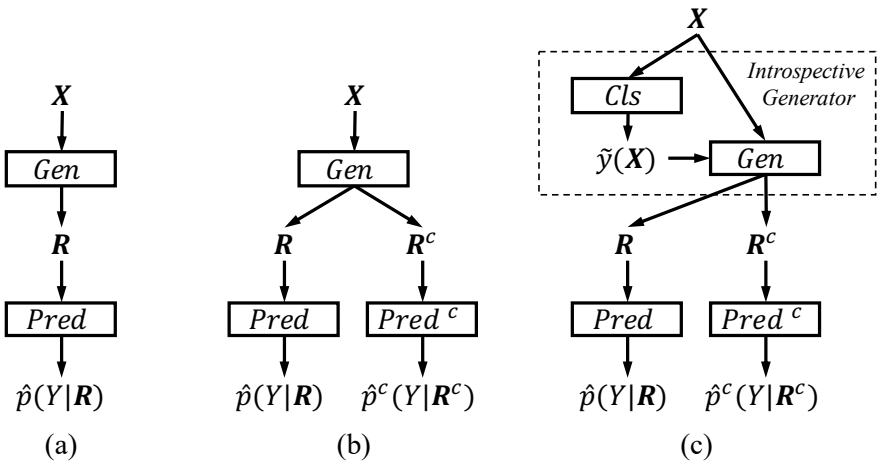

Figure 1: Illustration of different rationalization frameworks. (a) The cooperative framework from (Lei et al., 2016), which consists of two players, *i.e.,* a generator (*Gen*) and a predictor (*Pred*). (b) A straightforward extension of the model (a) with a compliment predictor (*Pred* ^{c}). The generator plays a cooperative game with the predictor and plays a mini-max game with the compliment predictor. (c) The introspective three-player framework. The introspective module first predicts the possible outcome $\tilde{y}$ based on the full texts x and then generate rationales using both x and $\tilde{y}$. The third framework (c) is a special case of (b). Such an inductive bias in model design preserves the predictive performance.

plement predictor that predicts the probability of Y based on $\boldsymbol{R}^c$.

Figure 1(b) illustrates the basic three-player model. Compared with (Lei et al., 2016), as shown in Figure 1(a), the three-player model introduces an additional complement predictor, which plays a minimax game in addition to the cooperative game in (Lei et al., 2016). For clarity, we will describe the game backward, starting from the two predictors followed by the generator.

Predictors: The predictor estimates probability of Y conditioned on $\boldsymbol{R}$, denoted as $\hat{p}(Y|\boldsymbol{R})$. The complement predictor estimates probability of Y conditioned on $\boldsymbol{R}^c$, denoted as $\hat{p}^c(Y|\boldsymbol{R})$. Both predictors are trained using the cross entropy loss, *i.e.*

$$\begin{aligned}\mathcal{L}_p &= \min_{\hat{p}(\cdot,\cdot)} -H(p(Y|\boldsymbol{R}); \hat{p}(Y|\boldsymbol{R})) \\ \mathcal{L}_c &= \min_{\hat{p}^c(\cdot,\cdot)} -H(p(Y|\boldsymbol{R}^c); \hat{p}^c(Y|\boldsymbol{R}^c)),\end{aligned} \tag{7}$$

where $H(p;q)$ denotes the cross entropy between p and q. $p(\cdot|\cdot)$ denotes the empirical distribution. It is worth emphasizing that $\mathcal{L}_p$ and $\mathcal{L}_c$ are both functions of the generator.

Generator: The generator extracts $\boldsymbol{R}$ and $\boldsymbol{R}^c$ by generating the rationale mask, $\boldsymbol{z}(\cdot)$, as shown in Eqs. (1-2). Specifically, $\boldsymbol{z}(\cdot)$ is determined by minimizing the weighted combination of four losses:

$$\min_{\boldsymbol{z}(\cdot)} \mathcal{L}_p + \lambda_g \mathcal{L}_g + \lambda_s \mathcal{L}_s + \lambda_c \mathcal{L}_c, \tag{8}$$

where $\mathcal{L}_g$ encourages the gap between $\mathcal{L}_p$ and $\mathcal{L}_c$ to be large, *i.e.*

$$\mathcal{L}_g = \max\{\mathcal{L}_p - \mathcal{L}_c + h, 0\}. \tag{9}$$

It stipulates the comprehensiveness property of the rationale (Eq. (5)). Intuitively, if the complement rationale is less informative of Y than the rationale, then $\mathcal{L}_c$ should be larger than $\mathcal{L}_p$.

$\mathcal{L}_s$ and $\mathcal{L}_c$ impose the sparsity and continuity respectively, which correspond to Eq. (6):

$$\begin{aligned}\mathcal{L}_s &= \max\Big\{\sum_i \boldsymbol{Z}_i - s, 0\Big\}, \\ \mathcal{L}_c &= \sum_i \max\{||\boldsymbol{Z}_i - \boldsymbol{Z}_{i-1}|| - c, 0\}.\end{aligned} \tag{10}$$

From Eq. (7), we can see that the generator plays a *cooperative game* with the predictor, because both tries to maximize the predictive performance of $\boldsymbol{R}$. On the other hand, the generator plays an *adversarial game* with the complement predictor, because the latter tries to maximize the predictive performance of $\boldsymbol{R}^c$, but the former tries to reduce it. Without the complement predictor, and thus the loss $\mathcal{L}_g$, the framework reduces to the method in (Lei et al., 2016).

Training During training, the three players perform gradient descent steps with respect to their own losses. For the generator, Since $\boldsymbol{z}(\boldsymbol{X})$ is a set of binary variables, we cannot apply the regular gradient descent algorithm. Instead we will use policy gradient (Williams, 1992) to optimize the models. We maximize the reward that is defined as the negative loss in Eq. (8). In order to have bounded rewards for training stability, the negative losses $\mathcal{L}_p$ and $\mathcal{L}_c$ are replaced with accuracy.

Theoretical guarantees The proposed framework is able to obtain a rationale that simultane-

ously satisfies the conditions in Eqs. (4) to (6), as stated in the following theorem:

Theorem 1. *A rationalization scheme $\boldsymbol{z}(\boldsymbol{X})$ that simultaneously satisfies Eqs.* (4)-(6) *is the global optimizer of Eq.* (8)*.*

The proof is given in Appendix A. The basic idea is that there is a correspondence between each term in Eq. (8) and each of the properties Eqs. (4)-(6). The minimization of each loss term is equivalent to satisfying the corresponding property.

3.2 The Introspection Generator

As discussed in Section 1, in the existing generator-predictor framework, the generator may fail to disentangle the information about the correct label, offering misleading rationales instead. To address this problem, we propose a new generator module, called the **Introspective Generator**, which explicitly predicts the label before making rationale selections.

Figure 1(c) illustrates the model with the introspection generator. Specifically, the improved generator still fits into the basic three-player framework in Section 3.1. The only difference is in how the generator generates the mask $\boldsymbol{z}(\boldsymbol{X})$, which now breaks down into two steps.

First, the module uses a *regular classifier* that takes the input $\boldsymbol{X}$ and predicts the label, denoted $\tilde{y}(\boldsymbol{X})$. For classification tasks, we use the maximum likelihood estimate, *i.e.*

$$\tilde{y}(\boldsymbol{X}) = \underset{y}{\operatorname{argmax}}\ \tilde{p}(Y = y|\boldsymbol{X}), \tag{11}$$

where $\tilde{p}(Y = y|\boldsymbol{X})$ is the predicted probability by maximizing the cross entropy, which is pretrained.

Second, a label-aware rationale generator generates the binary mask of the rationales, *i.e.*

$$z(\boldsymbol{X}) = \tilde{z}(\boldsymbol{X}, \tilde{y}(\boldsymbol{X})). \tag{12}$$

Note that $\tilde{y}$ is a function of $\boldsymbol{X}$, so the entire introspective generator is essentially a function of $\boldsymbol{X}$. In this way, all the formulations in Section 3.1 and the Theorem 1 still hold for the three-player game with the introspective generator.

In the implementation, the classifier can use the same architecture like the predictor and the complement predictor. The generator is of the same architecture in Section 3.1, but with the additional input of $\hat{y}(\boldsymbol{X})$.

Remark on degeneration Obviously, when working in a cooperative game, the introspection generator will make the degeneration problem more severe: when the classifier $\tilde{p}(\cdot|\boldsymbol{X})$ becomes sufficiently accurate during training, the generator only needs to encode the information of $\tilde{y}$ into $\boldsymbol{R}$. Therefore our three-player game, while improving over any existing generator-predictor frameworks on its own, is critical for the introspective model.

4 Experimental Settings

4.1 Datasets

We construct three text classification tasks, including two sentiment classification tasks from the BeerAdvocate review dataset (McAuley et al., 2012)[4], and a more complex relation classification task from SemEval 2010 Task 8 (Hendrickx et al., 2009). Table 2 gives examples of the above tasks. Finally, as suggested by an anonymous reviewer, we evaluate on the text matching benchmark AskUbuntu, following Lei et al. (2016). The experimental setting and results are reported in Appendix F.

Multi-aspect beer review This is the same data used in (Lei et al., 2016). Each review evaluates multiple aspects of a kind of beer, including appearance, smell, palate, and an overall score. For each aspect, a rating $\in$ [0,1] is labeled. We limit ourselves to the appearance aspect only and use a threshold of 0.6 to create balanced binary classification tasks for each aspect. Then, the task becomes to predict the appearance aspect of a beer based on multi-aspect text inputs. The advantage of this dataset is that it enables automatic evaluation of rationale extraction. The dataset provides sentence-level annotations on about 1,000 reviews, where each sentence is labeled by the aspect it covers. Note that in this dataset, each aspect is often described by a single sentence with clear polarity. Thus, a generator can select a sentence based on the topic distribution of words. The selected sentence often has very high overlap with the ground truth annotations and also contains sufficient information for predicting the sentiment. This characteristic of the dataset makes it a relatively easy task, and thus we further consider two more challenging tasks.

Single-aspect beer review To construct a more challenging task, for each review, we extract the

[4]http://snap.stanford.edu/data/web-BeerAdvocate.html

Task	Label	Input Texts
Multi-Aspect Beer Review	positive (regarding the aspect of *appearance*)	***Clear, burnished copper-brown topped by a large beige head that displays impressive persistance and leaves a small to moderate amount of lace in sheets when it eventually departs***. *The nose is sweet and spicy and the flavor is malty sweet, accented nicely by honey and by abundant caramel/toffee notes. There's some spiciness (especially cinnamon), but it's not overdone. The finish contains a moderate amount of bitterness and a trace of alcohol. The mouthfeel is exemplary* $\cdots$

Relation Classification	Message-Topic(e1,e2)	*It was a friendly* ***call***$_{e_1}$ ***to remind*** *them* ***about the bill***$_{e_2}$ *and make sure they have a copy of the invoice*

Table 2: Example of the three tasks used for evaluation. The ***red bold*** words are sample rationales (created by the authors for illustration purpose only for the last two tasks).

sentences that are specifically about the appearance aspect from the aforementioned BeerAdvocate dataset[5], and the task is to predict the sentiment of the appearance only on the extracted sentences. The details of the dataset construction can be found in Appendix C. This new dataset is obviously more challenging in terms of generating meaningful rationales. This is because the generator is required to select more find-grained rationales. Since there are no rationale annotations, we rely on subjective evaluations to test the quality of the extracted rationales.

Multi-class relation classification To show the generalizability of our proposed approaches to other NLP applications, we further consider the SemEval 2010 Task 8 dataset (Hendrickx et al., 2009). Given two target entities e_1 and e_2 in a sentence, the goal is to classify the relation type (with directions) between the two entities (including None if there is no relation). Similar to the single-aspect beer review, it is also a fine-grained rationalization task. The major difference is that the number of class labels in this task is much larger, and we hope to investigate its effects on degeneration and performance downgrade.

4.2 Implementation Details

For both the generators and the two predictors, we use bidirectional LSTMs with hidden dimension 400. In the introspection generator, the classifier consists of the same bidirectional LSTM, and $\boldsymbol{z}(\boldsymbol{X}, \tilde{y})$ is implemented as an LSTM sequential labeler with the label $\tilde{y}$ transformed to an embedding vector that serves as the initial hidden states of the LSTM. For the relation classification task, since the model needs to be aware of the two target entities, we add the relative position features following Nguyen and Grishman (2015). We map the relative position features to learnable embedding vectors and concatenate them with word embeddings as the inputs to the LSTM encoder of each player. All hyper-parameters are tuned on the development sets according to predictive accuracy. In other words, all the models are tuned **without** seeing any rationale annotations.

[5]We will release the single-aspect dataset.

Model	10% Highlighting Acc	10% Highlighting Prec	20% Highlighting Acc	20% Highlighting Rec
Random	65.70	17.75	72.31	19.84
Lei2016	82.05	86.14	83.88	79.98
+minimax	83.45	86.54	84.25	85.16
Intros	87.10	68.37	87.50	59.63
+minimax	86.16	85.67	86.86	79.40

Table 3: Main results of binary classification on multi-aspect beer reviews. The *Acc* column shows the accuracy of prediction. The *Prec* and *Rec* are precision and recall on the extracted rationales compared to the human annotations. The accuracy of sentiment prediction with the full texts is **87.59**.

5 Experiments

5.1 Multi-Aspect Beer Review

Table 3 summarizes the main results on the multi-aspect beer review task. In this task, a desirable rationale should be both appearance-related and sufficient for sentiment predictions. Since the average sparsity level of human-annotated rationales is about 18%, we consider the following evaluation settings. Specifically, we compare the generated rationales to human annotations by measuring the precision when extracting 10% of words and the

recall for 20%[6]. In addition to the precision/recall, we also report the predictive accuracy of the extracted rationales on predicting the sentiment.

When only 10% of the words are used, Lei et al. (2016) has a significant performance downgrade compared to the accuracy when using the whole passage (82.05 v.s. 87.59). With the additional third player added, the accuracy is slightly improved, which validates that controlling the unselected words improves the robustness of rationales. On the other hand, our introspection models are able to maintain higher predictive accuracy (86.16 v.s. 82.05) compared to (Lei et al., 2016), while only sacrificing a little loss on highlighting precision (0.47% drop).

Similar observations are made when 20% of the words required to highlight with one exception. Comparing the model of (Lei et al., 2016) with and without the proposed mini-max module, there is a huge gap of more than 5% on recall of generated rationales. This confirms the motivation that the original cooperative game tends to generate less comprehensive rationales, where the three-player framework controls the unselected words to be less informative so the recall is significantly improved.

It is worth mentioning that when a classifier is trained with randomly highlighted rationales (*i.e.* random dropout (Srivastava et al., 2014) on the inputs), it performs significantly worse on both predictive accuracy and highlighting qualities. This confirms that extracting concise and sufficient rationales is not a trivial task. Moreover, our re-implementation of (Lei et al., 2016) for the original regression task achieves 90.1% precision when highlighting 10% words, which suggest that rationalization for binary classification is more challenging compared to the regression where finer supervision is available.

In summary, our three-player framework consistently improves the quality of extracted rationales on both of the original (Lei et al., 2016) and the introspective framework. Particularly, without controlling the unselected words, the introspection model experiences a serious degeneration problem as expected. With the three-player framework, it manages to maintain both high predictive accuracy and high quality of rationalization.

[6]Previous work in (Lei et al., 2016) only evaluates the precision for the 10% extraction.

Model	Single-Aspect Beer		Relation	
	Acc	Acc^c	Acc	Acc^c
All (100%)	87.1	51.3	77.8	4.9
Random	74.3	83.1	51.8	64.9
Lei2016	81.4	74.6	73.5	36.8
+minimax	82.9	73.2	75.0	30.9
Intros	87.0	85.8	75.2	56.6
+minimax	85.3	73.6	76.2	29.1

Table 4: Predictive accuracy on the single-aspect beer appearance review (left) and the relation classification (right). Acc^c refers to the accuracy of the complement predictor. We restrict the extracted rationales to be on average eight words and four continuous pieces for the beer review and six words and three pieces for relation classification. A desired rationalization method will have high Acc and low Acc^c.

5.2 Single-Aspect Beer Review

In this section, we evaluate the proposed methods on the more challenging single-aspect beer dataset. Similar to previous experiments, we force all the methods to have comparable highlighting ratio and continuity constraints for fair evaluation. The highlighting ratio is determined from human estimation on a small set of data. We report two classification results, which are the accuracy of the predictor and complement predictor. For both cooperative methods, *i.e.* (Lei et al., 2016) with and without introspection , we train an independent extra predictor on the unselected words from the generator, which does not affect the training of the generator-predictor framework.

From the left part of Table 4, we observe that the original model of (Lei et al., 2016) has a hard time maintaining the accuracy compared to the classifier trained with full texts. Transforming it into a three-player game helps to improve the performance of the evaluation set while lower the accuracy of the complement predictor. Since the extracted rationales are in a similar length, these results suggest that learning with a three-player game successfully enforces the generator not to leave informative words unselected. Similar to the multi-aspect results, the cooperative introspection model suffers from the degeneration problem, which produces a high complement accuracy. The three-player game yields a more comprehensive rationalization with small losses in accuracy.

Human evaluation We further conduct subjective evaluations by comparing the original model of (Lei et al., 2016) with our introspective three-player model. We mask the extracted rationales and present the unselected words only to the hu-

Model	%UNK	Acc	$\text{Acc}_{\text{w/o UNK}}$
Lei2016	43.5	63.5	69.0
Intros+minimax	**54.0**†	**58.0**	**66.3**

Table 5: Subjective evaluations on the task of controlling the unselected rationale words. Acc denotes the accuracy in guessing sentiment labels. $\text{Acc}_{\text{w/o UNK}}$ denotes the sentiment accuracy for these samples that are not selected as "UNK" for the secondary task. † denotes p-value < 0.005 in t-test. A desired rationalization method achieves high "UNK" rate and performance randomly for the Acc predictions.

man evaluators. The evaluators are asked to predict the sentiment label as their first task. If a rationalizing method successfully includes all informative pieces in the rationale, subjects should have around 50% of accuracy in guessing the label. In addition, after providing the sentiment label, subjects are then asked to answer a secondary question, which is whether the provided text spans are sufficient for them to predict the sentiment. If they believe there are not enough clues and their sentiment classification is based on a random guess, they are instructed to select unknown (denoted as "UNK") as the answer to the second question. Appendix E elaborates why we design subjective evaluations in such a way in more details.

Table 5 shows the performance of subjective evaluations. Looking at the first column of the table, our model is better in confusing human, which gives a higher rate in selecting "UNK". It confirms that the three-player introspective model selects more comprehensive rationales and leave less informative texts unattended. Furthermore, the results also show that human evaluators offer worse sentiment predictions on the proposed approach, which is also desired and expected.

5.3 Relation Classification

The predictive performances on the relation classification task are shown in the right part of the Table 4. We observe consistent results as in previous datasets. Clearly, the introspective generator helps the accuracy and the three-player game regularize the complement of the rationale selections.

Examples of the extracted rationales For relation classification, it is difficult to conduct subjective evaluations because the task requires people to have sufficient knowledge of the schema of relation annotation. To further demonstrate the quality of generated rationales, we provide some illustrative examples. Since there is a rich form of supervised signal, *i.e.,* the number of class labels is large, the chance of any visible degeneration of the Lei et al. (2016)'s model should be low. However, we still spot quite a few cases. In the first example, Lei et al. (2016) fails to highlight the second entity while ours does. In the second example, the introspective three-player model selects more words than (Lei et al., 2016). In this case, the two entities themselves suffice to serve as the rationales. However, our model preserves the words like "working". This problem might due to the bias of the dataset. For example, some words that are not relevant to the target entities may still correlate with the labels. In the case, our model will pick these words as a part of the rationale.

6 Related Work

Model interpretability Besides the two major categories of self-explaining models discussed in Section 1, model interpretability is widely studied in the general machine learning field. For example, evaluating feature importance with gradient information (Simonyan et al., 2013; Li et al., 2016a; Sundararajan et al., 2017) or local perturbations (Kononenko et al., 2010; Lundberg and Lee, 2017); and interpreting deep networks by locally fitting interpretable models (Ribeiro et al., 2016; Alvarez-Melis and Jaakkola, 2018).

Besides selective rationalization, the cooperative game has been studied in the latter direction above (Lee et al., 2018). It has also been applied to a relevant problem on summarization (Arumae and Liu, 2019), where the selected summary should be sufficient for answering questions related to the document. In this problem, the sum-

mary is a special type of rationale of a document. Another related concurrent work (Bastings et al., 2019) proposes differentiable solution to optimize the cooperative rationalization method.

Game-theoretical methods Though not having been explored much for self-explaining models, the minimax game setup has been widely used in many machine learning problems, such as self-playing for chess games (Silver et al., 2017), generative models (Goodfellow et al., 2014) and many tasks that can be formulated as multi-agent reinforcement learning (Busoniu et al., 2006). Our three-player game framework also shares a similar idea with (Zhang et al., 2017; Zhao et al., 2017), which aim to learn domain-invariant representations with both cooperative and minimax games.

7 Conclusion

We proposed a novel framework for improving the predictive accuracy and comprehensiveness of the selective rationalization methods. This framework (1) addresses the degeneration problem in previous cooperative frameworks by regularizing the unselected words via a three-player game; and (2) augments the conventional generator with introspection, which can better maintain the performance for down-stream tasks. Experiments with both automatic evaluation and subjective studies confirm the advantage of our proposed framework.

Experimenting with Power Divergences for Language Modeling

Matthieu Labeau **Shay B. Cohen**

School of Informatics, University of Edinburgh
{mlabeau,scohen}@inf.ed.ac.uk

Abstract

Neural language models are usually trained using Maximum-Likelihood Estimation (MLE). The corresponding objective function for MLE is derived from the Kullback-Leibler (KL) divergence between the empirical probability distribution representing the data and the parametric probability distribution output by the model. However, the word frequency discrepancies in natural language make performance extremely uneven: while the perplexity is usually very low for frequent words, it is especially difficult to predict rare words.

To address that, we experiment with several families (α, β and γ) of *power divergences*, generalized from the KL divergence, for learning language models with an objective different than standard MLE. Intuitively, these divergences should affect the way the probability mass is spread during learning, notably by prioritizing performance on high or low-frequency words. In addition, we implement and experiment with various sampling-based objectives, where the computation of the output layer is only done on a small subset of the vocabulary.

They are derived as *power* generalizations of a softmax approximated via Importance Sampling, and Noise Contrastive Estimation, for accelerated learning. Our experiments on the Penn Treebank and Wikitext-2 show that these power divergences can indeed be used to prioritize learning on the frequent or rare words, and lead to general performance improvements in the case of sampling-based learning.

1 Introduction

Language models are an important component in many NLP tasks, where they provide prior knowledge on the language used. They are conditional models that aim to predict the next token in a sequence: they can be applied to basic units ranging from individual characters to full words, each approach coming with its own benefits and limitations (Merity et al., 2018a). Word-level language models have traditionally been based on n-gram counts, obtaining good performance with smoothing techniques (Kneser and Ney, 1995; Goodman, 2001). Recently, neural networks have shown strong results in language modeling (Bengio et al., 2001), especially recurrent neural networks (Mikolov et al., 2011b). As previous approaches, like maximum entropy models (Berger et al., 1996), neural language models are trained via Maximum Likelihood Estimation (MLE). Thus, their training cost grows linearly with the number of words in the vocabulary, often making it prohibitively slow. This motivated a large amount of research work, bringing a variety of solutions (Chen et al., 2016).

The large vocabulary sizes encountered in training corpora arguably stem from the fact that the frequency distribution of words in a corpus of natural language follows Zipf's law (Powers, 1998). This also implies that the discrepancy between counts of high-frequency and low-frequency words increases with the size of the corpus, as well as the number of those low-frequency words. As a consequence, distributed word representations of low-frequency words are difficult to learn. Numerous approaches use decomposition of words with various sub-word units (Sennrich et al., 2016; Kim et al., 2016), but the same phenomenon exists for low-frequency subwords. In order to deal with this issue and to accelerate training, Grave et al. (2017a) implement a dependency between embedding sizes and word frequencies in the output layer, while Baevski and Auli (2019) apply it to the input layer, comparing the possible choices of which units to model. Using a different approach, Gong et al. (2018) attempt to learn word representations that are less affected by these large discrepancies in word frequencies, with an adver-

sarial training method to force the model to make frequent and rare word embeddings hard to differentiate based on word frequency alone.

These improvements have been obtained by explicitly incorporating in the model different ways of treating words according to their frequency. However, learning is always made via (or approximating) Maximum Likelihood Estimation, which finds the distribution that maximizes entropy subject to the constraints given by training examples. In this work, we explore the possibility of affecting how words are learned depending on their frequency by using alternative loss functions. We specifically explore *power divergences*, obtained through various generalizations of the Kullback-Leibler divergence, which is traditionally used to obtain the MLE objective function. This is motivated by the intuition that a well-suited power factor may direct learning towards prioritizing high or low-frequency words, instead of learning uniformally.

In this paper, we derive and experiment with the objective functions obtained from three power-divergences: the α, β and γ divergences. We also derive objective functions for the corresponding generalizations of two sampling-based methods: an Approximated Softmax obtained with importance sampling, and Noise Contrastive Estimation. We conduct a set of experiments comparing these objectives and their effect of various parts of the word frequency distribution, by training and evaluating models on two corpora: the Penn Treebank and Wikitext-2. Our experiments show that depending on the vocabulary used and the choice of power divergence, it is indeed possible to gear learning to focus on the most frequent or infrequent words. We also observe that, while the MLE gives the best overall performance for exact objectives, derived from the KL-divergence, our generalized objectives yield perplexity improvements compared to baselines for both sampling-based methods, up to 1 point in perplexity on both corpora.

2 Background

Language modeling aims to learn a probability distribution over a sequence of tokens from a finite target vocabulary $\mathcal{Y}$. Such a distribution is decomposed into a product of conditional distributions of tokens over $\mathcal{Y}$ given the previous tokens in the sequence. Hence, we learn a parametric model of the form $p_\theta(y|x)$, where $x \in \mathcal{X}$ represents the sequence of previous tokens, y is a target label belonging to $\mathcal{Y}$, and θ is the set of model parameters. They are obtained via maximum likelihood estimation (MLE), which consists in minimizing the *negative likelihood* objective function:

$$\mathrm{NLL}(\theta) = -\sum_{(x,y)\in\mathcal{D}} \log p_\theta(y|x)$$

over examples (x, y) corresponding to sequences of tokens drawn from the data $\mathcal{D}$. This can be seen as minimizing the *Kullback-Leibler* divergence between the parametrized probability distribution p_θ that we are learning and the distribution $p_\mathcal{D}$ described by our training data:

$$D_{KL}(p_\mathcal{D}||p_\theta) = \sum_{(x,y)\in\mathcal{X}\times\mathcal{Y}} p_\mathcal{D}(y|x) \log \frac{p_\mathcal{D}(y|x)}{p_\theta(y|x)},$$

since $p_\mathcal{D}(y|x) = 1$ if the sequence (x, y) appears in the training data, and equals 0 otherwise. Hence, the set of parameters θ^* minimizing $D_{KL}(p_\mathcal{D}||p_\theta)$ is the maximum likelihood distribution on the training data $\mathcal{D}$.

In this work, we will use several classes of divergences. A measure of discrepancy D between two probability densities p and q is a divergence if $D(p||q) \geq 0$ with equality if and only if $p = q$.[1] In the following, we will derive an objective function from a divergence D with the data distribution as first argument, and the second being the distribution of the parametric model:

$$Obj(\theta) = D(p_\mathcal{D}||p_\theta).$$

3 Power Divergences

A large number of divergence measures has been introduced for a variety of applications (Basseville, 2013). Several families of divergences are notably obtained from generalizing the Kullback-Leibler divergence by using a *generalized logarithm* function, which is a power function:

$$\log_\alpha(x) = \frac{1}{1-\alpha}(x^{1-\alpha} - 1), \qquad (1)$$

defined by a parameter α, and that converges to the logarithm as $\alpha \to 1$. In this section, we will consider three families of divergences that can be generated from this function; see Cichocki and Amari

[1] Divergences are not necessarily metrics: they are defined only by non-negativity and positive definiteness.

(2010) for a review. For now, they are to be applied only to *normalized* probability densities, implying that $\sum_{y \in \mathcal{Y}} p_\theta(y|x) = 1$.

3.1 α-divergences

The notion of α-divergence was introduced by Csiszar (1967). The full expression of $D_\alpha(p||q)$ is shown in Table 1. It is a special case of f-divergence (Ali and Silvey, 1966), derived from a standardized version of the generalized logarithm[2] (Eq. 1). Applying α-divergences to parameter estimation generalizes MLE, and can be shown to have similar properties, as consistency and asymptotic normality of the estimation error (Keziou, 2003). Intuitively, the choice of α will impact the importance of the likelihood ratio p/q: while the limiting cases $\alpha \to 1$ and $\alpha \to 0$ are the Kullback-Leibler $D_{KL}(p||q)$ and the reverse Kullback-Leibler divergences $D_{KL}(q||p)$, having $\alpha \geq 1$ will make learning zero-avoiding[3] for q, and $\alpha \leq 0$ zero-forcing[4] (Minka, 2005). We should also note that $D_\alpha(p||q) = D_{1-\alpha}(q||p)$. When working with normalized densities, the α-divergence is linked to the Rényi divergence (Rényi, 1961), which has been used to measure domain similarity (Van Asch and Daelemans, 2010). Given that we are trying to learn from conditional distributions which are zero everywhere except for one target token, we are interested in experimenting with values of $\alpha > 1$, which should push the model towards generalizing, while having $\alpha \in (0.5, 1)$ should force the model to concentrate probability mass on training examples. Since we are here working with normalized distribution, we obtain the following objective:

$$Obj_\alpha(\theta) = \frac{1}{\alpha(\alpha-1)} \sum_{(x,y)\in\mathcal{D}} (p_\theta(y|x))^{1-\alpha}.$$

3.2 β-divergences

The β-divergence, also called *density power divergence* was introduced by Basu et al. (1998) as a robust estimation method, which showed it to be consistent for parameter estimation, with asymptotic normality of the estimation error (Basu et al., 1998, Theorem 2). The full expression of $D_\beta(p||q)$ is shown in Table 1.[5] It can be seen as a *Bregman* divergence (Bregman, 1967) also derived using the generalized logarithm[2] (Eq. 1). The motivation is to obtain divergences that are robust to outliers, which is the case for values of $\beta > 1$; choosing $\beta = 2$ gives us the L_2-loss, while $\beta \to 1$ gives the Kullback-Leibler divergence $D_{KL}(p||q)$ as a limiting case. Hence, choosing a value close to 1 while larger is supposed to provide a compromise between the efficiency of the Kullback-Leibler divergence and the robustness of the L_2-loss. Similarly, we can expect to give more importance to outliers (which we suppose to be the low-frequency tokens) by choosing $\beta < 1$. The objective becomes:

$$Obj_\beta(\theta) = \frac{1}{\beta(\beta-1)} \times \sum_{(x,y)\in\mathcal{D}} \left[(\beta-1) \sum_{y'\in\mathcal{Y}} (p_\theta(y'|x))^\beta - \beta (p_\theta(y|x))^{\beta-1} \right].$$

3.3 γ-divergences

Eguchi and Kato (2010) introduced the γ-divergence as a modification of the β-divergence, with the specific goal of obtaining a *scale-invariant* version of the robust β-divergence,[6] also showing it to be consistent for parameter estimation, with asymptotic normality of the estimation error (Eguchi and Kato, 2010, Section 3). This divergence has notably been used for the estimation of parameters without normalizing the output probability distribution (Takenouchi and Kanamori, 2015).[7] The general expression of the γ-divergence is shown in Table 1. While the use of the log non-linearity makes this divergence non-separable, which at first glance could be thought to complicate computation in practice, our motivation for using it is its scale-invariance, which we will discuss in Section 4.3. Applied to our prob-

[2] α and β-divergences are related to the *Tsallis* entropy, which can be seen as a deformation of the Shannon entropy using this same generalized logarithm: see Appendix A from Cichocki and Amari (2010) . Recently, Blondel et al. (2018) showed how to build Fenchel-Young Losses from the same Tsallis entropies.

[3] Having $p_i > 0$ will enforce $q_i > 0$.

[4] Having $p_i = 0$ will enforce $q_i = 0$.

[5] For readability, we keep the notation and values used in Cichocki and Amari (2010) instead of Basu et al. (1998).

[6] 'Scale-invariance' here means that the divergence should remain unchanged when one or both of the measures it is applied to are multiplied by scalars.

[7] However, this particular method is not suitable in our case because of the sparsity of our data.

lem, the objective becomes:

$$Obj_\gamma(\theta) = \sum_{(x,y)\in\mathcal{D}} \left[\log p_\theta(y|x) - \frac{1}{\gamma} \log \sum_{y'\in\mathcal{Y}} (p_\theta(y'|x))^\gamma \right]. \tag{2}$$

4 Accelerating Learning

In order to use the previously defined objectives, we need to compute the model probabilities $p_\theta(y|x)$, which are usually obtained using a softmax function:

$$p_\theta(y|x) = \frac{\exp\left(s_\theta(x,y)\right)}{\sum_{y'\in\mathcal{Y}} \exp\left(s_\theta(x,y')\right)}$$

applied on scores (or logits) $s_\theta(x,y')$ output by the model for every possible target token $y' \in \mathcal{Y}$. However, as explained earlier, $\mathcal{Y}$ can be very large, hence computing all the scores and summing them is extremely slow. We choose to follow the strategies employed by Jozefowicz et al. (2016): approximating the softmax using importance sampling (Bengio and Sénécal, 2003, 2008), and Noise Contrastive Estimation (NCE; Gutmann and Hyvärinen 2010; Mnih and Teh 2012). Besides, the divergences presented in Section 3 can be applied to *positive measures*. Hence, a possible third direction is to instead approximate the objectives to the *un-normalized* model distributions. All the objectives presented in this section are explained in Appendix A.4.

4.1 Approximated softmax

Plugging the first solution into our objectives is straightforward: using self-importance sampling to approximate directly the multinomial classification probability, we compute p_θ via an *approximated softmax*:[8]

$$p_\theta(y|x) \approx \frac{\frac{\exp\left(s_\theta(x,y)\right)}{p_n(y)}}{\frac{\exp\left(s_\theta(x,y)\right)}{p_n(y)} + \sum\limits_{\substack{i=1 \\ \hat{y}_i\sim p_n}}^{k} \frac{\exp\left(s_\theta(x,\hat{y}_i)\right)}{p_n(\hat{y}_i)}}$$

where p_n is an auxiliary distribution chosen to reflect the training data while still being easy to sample from, and $k \ll |\mathcal{Y}|$ is the number of samples drawn.

[8]The same objective is called 'Ranking NCE' by Ma and Collins (2018).

4.2 Adapting Noise-Contrastive Estimation

Noise-Contrastive Estimation consists of training the model for a surrogate binary classification task where, given examples from the mixture:

$$\frac{1}{k+1} p_\mathcal{D} + \frac{k}{k+1} p_n$$

we learn to discriminate between examples coming from data and samples coming from the auxiliary noise distribution p_n. Minimizing the NCE loss function has been shown to be equivalent to minimizing a Bregman divergence (Gutmann and Hirayama, 2011); however, the transformation that we need to apply to the associated generating function (Pihlaja et al., 2012) in order to obtain a power divergence is not straigthforward. Instead, with the posterior classification probability:

$$p_\theta(C = \text{True}|y,x) = \frac{p_\theta(y|x)}{p_\theta(y|x) + k p_n(y)} \tag{3}$$

Noting p_θ^C the positive measure on $\mathcal{X}\times\mathcal{Y}$:

$$p_\theta^C : (x,y) \to p_\theta(C = \text{True}|y,x)$$

we can show that the NCE objective function can be derived from the following expression:[9]

$$D_{KL}(p_\mathcal{D}^C || p_\theta^C) + D_{KL}(1 - p_\mathcal{D}^C || 1 - p_\theta^C)$$

Knowing this, we simply need to replace D_{KL} by the other divergences to derive the α, β and γ objective functions associated to this surrogate classification task. It is interesting to note that the power transformations will here be applied on the posterior classification probabilities p_θ^C instead of categorical probabilities p_θ.

4.3 Working With Positive Measures

The three divergences presentend in Section 3 are defined on positive measures: in theory, we can simply use the exp function on the scores s_θ and do not need to normalize them:

$$Obj(\theta) = D(p_\mathcal{D} || \exp\left(s_\theta\right))$$

However, neither the α and β divergences are scale invariant (see right column of Table 1 and Cichocki and Amari 2010). We can show that working with an un-normalized model distribution will, in both those cases, give an objective proportional to the scale of the model, allowing the divergence

[9]The full derivation is given in Appendix A.2.

	Expression	Scaling properties
$\alpha \in \mathbb{R} \setminus \{0, 1\}$	$\frac{1}{\alpha(\alpha-1)} \sum_{i=1}^{n} \left[p_i^\alpha q_i^{1-\alpha} - \alpha p_i + (\alpha - 1) q_i\right]$	$D_\alpha(c \times p \| \| c \times q) = c \times D_\alpha(p \| \| q)$
$\beta \in \mathbb{R} \setminus \{0, 1\}$	$\frac{1}{\beta(\beta-1)} \sum_{i=1}^{n} \left[p_i^\beta + (\beta - 1) q_i^\beta - \beta p_i q_i^{\beta-1}\right]$	$D_\alpha(c \times p \| \| c \times q) = c^\beta \times D_\alpha(p \| \| q)$
$\gamma \in \mathbb{R} \setminus \{0, 1\}$	$\frac{1}{\gamma(\gamma-1)} \log \sum_{i=1}^{n} p_i^\gamma + \frac{1}{\gamma} \log \sum_{i=1}^{n} q_i^\gamma - \frac{1}{\gamma-1} \log \sum_{i=1}^{n} p_i q_i^{\gamma-1}$	$D_\gamma(c_1 \times p \| \| c_2 \times q) = D_\gamma(p \| \| q)$

Table 1: Complete expressions of α, β, and γ divergences between two positive measures $p = (p_i)_{i=1}^n$ and $q = (q_i)_{i=1}^n$ on $\mathbb{R}_+^n$, as well as their scaling properties. Note that the α-divergence simplifies if we restrict them to the set of normalized probability densities (if $\sum_{i=1}^n p_i = \sum_{i=1}^n q_i = 1$).

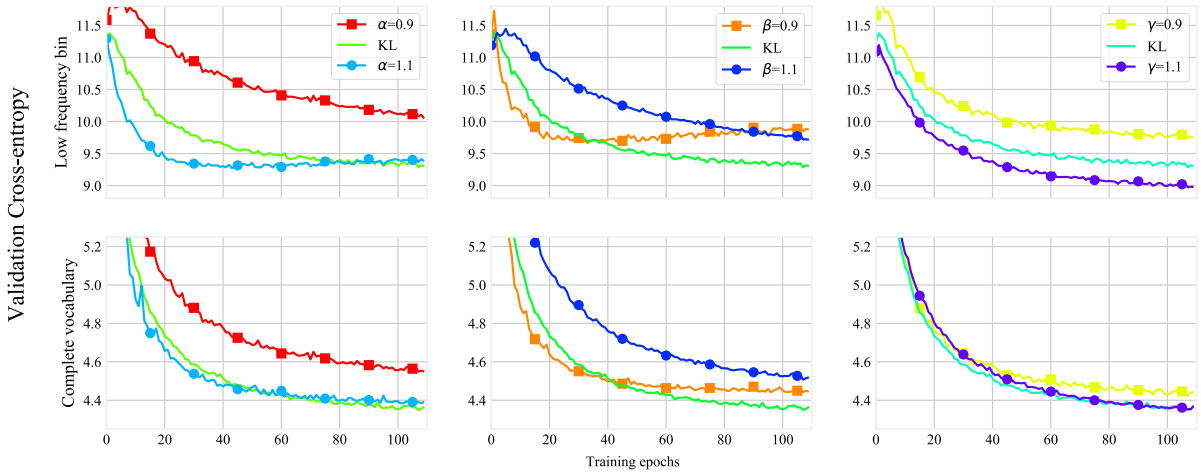

Figure 1: Validation cross-entropy values obtained during the beginning of training models with Obj_α (left), Obj_β (center) and Obj_γ (right) on the PTB with a full vocabulary. Words are grouped into 5 buckets of equal size, following their frequencies. On the top is shown the cross-entropy obtained on the bucket of lowest frequency words, while the global cross-entropy is displayed on the bottom.

to be minimized by minimizing the scale alone, with no actual learning.[10] This is not an issue for the γ-divergence, since $D_\gamma(p_\mathcal{D} || \exp(s_\theta)) = D_\gamma(p_\mathcal{D} || p_\theta)$. Hence, the objective of Eq. 2 may be simplified as following:

$$Obj_\gamma(\theta) = \sum_{(x,y)\in\mathcal{D}} \left[s_\theta(x, y) - \frac{1}{\gamma} \log \sum_{y' \in \mathcal{Y}} \exp\left(\gamma s_\theta(x, y')\right) \right].$$

We can further accelerate learning by using importance sampling on the second term, and because of the logarithm applied to the sum, we obtain an objective that is equivalent to composing the approximated softmax with γ-divergence, as can be seen in Appendix A.4.

[10] The proof is given in Appendix A.1.

5 Experiments

Our goal is to compare the effect of the various objective functions we proposed in Sections 3 and 4, and especially study how the values of α, β and γ affect learning and performance, overall as well as on low-frequency words. Since each model is trained with a different objective function, the training scores are not comparable. Hence, we use the validation cross-entropy and perplexity at each epoch as a way to track progress during training.

5.1 Datasets

We perform our experiments on two widely used, reasonably sized datasets: the Penn Treebank (PTB; Mikolov et al. 2011a) and WikiText-2 (WT2; Merity et al. 2017). The PTB, heavily preprocessed, retains the $10k$ most frequent words in its vocabulary, while the others tokens are replaced by a common $<unk>$ token. The WT2,

about two times larger, retains words that appear at least three times in the training data in its vocabulary, which makes it $33,278$ words. To study the impact of our various objective functions on a vocabulary containing very rare words, we also experiment with a version on the PTB to which we only apply limited preprocessing, allowing us to keep its full training vocabulary, which contains 39030 words.

5.2 Experimental setup

We based our setup on the ASGD weight-dropped LSTM (AWD-LSTM) models of Merity et al. (2018b), since to the best of our knowledge they give state-of-the-art results on the PTB and WT2 for models that are build with a softmax output layer and do not use any adaptative method (as the pointer sentinel LSTM (Merity et al., 2017), the neural cache (Grave et al., 2017b) and the dynamic evaluation (Krause et al., 2018)). Our models[11], replications of their 3-layer LSTMs with tied input and output representations, were built using their implementation.[12] For each dataset, we follow their choice of hyperparameters, only modifying the objective functions.

For our sampling-based objectives, we use $k = 1024$ samples, and the unigram distribution as p_n. In the case of objectives derived from binary NCE, to avoid issues with the phenomenon of *self-normalization* and consistency issues (Ma and Collins, 2018) we chose to use *blackout* (Ji et al., 2015). Indeed, this method amounts to using a noise distribution which depends on the model probabilities, making the normalization term disappear from the posterior classification probabilities of Eq. 3. Hence, we have an objective function that is fast to compute without any supplementary assumption, and the negative samples are still drawn from the unigram distribution. For both AS and NCE, in our setting, the computation time is reduced to about 40% of the time taken by MLE on the WT2, and 50% on the PTB.

6 Results and discussion

We turn to describe the results of our experiments.

[11] https://github.com/MatthieuLabeau/power-divergences-LM

[12] https://github.com/salesforce/awd-lstm-lm.

6.1 Qualitative results on the full vocabulary PTB

To observe the behavior of the proposed objectives for various choices of α, β and γ, we plot the validation cross-entropy at the beginning of learning of models on PTB equipped with a full training vocabulary. We choose values of 0.9 and 1.1 for the power parameters, to experiment with an objective on each side of the baseline MLE objective. We split the words according to frequency into 5 buckets, in order for the buckets to represent have equal size based on word counts, and display both the global cross-entropy and the cross-entropy on the lowest frequency bin in Figure 1. A value of $\alpha > 1$ seems to initially behave better, especially for rare words. This could be expected: intuitively, these values of α should make the model 'stretch' the probability mass. However, as learning progresses, this phenomenon lessens, and the performance on rare words gets worse. A value of $\beta < 1$, supposed to make the model less robust to outliers, seems to make learning faster initially, particularly on rare words, but again improvements lessen. Choosing $\alpha < 1$ or $\beta > 1$ gives a worse cross-entropy overall. This 'inverted' similarity between the behaviors induced by choices of α and β, and the links between the two divergences, have been explored by Patra et al. (2013). Finally, choosing $\gamma > 1$ gives very interesting results, allowing for a better cross-entropy on rare words while retaining the same overall performance than MLE.

6.2 Penn Treebank and WikiText-2

In this section, we present the results of exploratory experiments. We fully train models with the proposed objectives, for a variety of power parameters. For the PTB, the final validation perplexities are presented in Table 2, while we present the final validation cross-entropies for the objectives derived from MLE, on 5 frequency buckets, in Figure 2. For the WT2, they are shown in Table 3 and Figure 3.

With exact objectives: for both corpora, the results for the high and low-frequency buckets seem to confirm that values of α, γ that are smaller and larger than 1 can help prioritizing learning towards the frequent and rare words. The effect of β depending on frequency seems lighter, especially on the PTB: we hypothesize that this is due to the vocabulary being cut short, and containing no very

Table 4: Final validation results obtained on the PTB and WT2, with the exact objectives Obj_α, Obj_β, and Obj_γ, derived from MLE. In each cell we give on top the validation perplexity, and below, the 'counterpart' to perplexity corresponding to the training objective — which is the value being optimized. Each color corresponds to a different objective: values cannot be compared for varying α, β and γ.

rare words, which reduces the discrepancies between higher and lower scoring examples. However, no objective seems to be able to improve on MLE for overall performance.

To explain these results, we may argue that perplexity is a biased measure as MLE directly optimizes it. Hence, we compute the 'counterparts' to perplexity corresponding to each objective. Equivalently to perplexity for MLE, they are directly optimized by their respective objectives, and should decrease to 1 as the model distribution gets closer to the data distribution. Again, since they vary for each objective, they are not comparable between themselves and with perplexity. We display these values for our models trained with exact objectives in Table 4. As α, β and γ are closer to 1, these values get closer to the perplexity of the model. Besides, they are especially close across all values of γ: we can assume that this indicates that the corresponding Obj_γ are 'closer' to the MLE objective. However, tracking these values during training[13] shows that they all behave very similarly to perplexity.

With approximated objectives: for objectives derived from AS and NCE, we observe far less impact of the choice of the power parameter on frequent or rare words,[14] which is probably due to the fact that only a small subset of the vocab-

ulary is updated during learning — and this subset is drawn according to word frequency. However, some objectives provide modest improvements over the corresponding KL-based baseline.

6.3 Searching for the Optimal Power Parameter

In order to verify the potential benefits of our generalization of sampling-based objectives, we use these preliminary results to search for the 'best' power parameter, and check that improvements are consistent for several versions of the model,

		Objective	Validation	Test
PTB		MLE	60.7	58.6
	AS	KL	62.2	59.8
		$\alpha = 0.95$	61.2	58.9
	NCE	KL	61.5	59.2
		$\beta = 1.1$	61.2	59.0
WT2		MLE	65.5	62.8
	AS	KL	65.1	62.6
		$\gamma = 1.075$	64.8	62.1
	NCE	KL	65.8	63.4
		$\alpha = 1.1$	64.7	62.0

Table 5: Best validation and test perplexities obtained on the best performing configurations of power parameter for both corpora and each category of objectives, averaged over 5 models with different initializations.

initialized with different seeds. This search is shown in Figure 4 for 4 different configurations chosen using the preliminary results presented earlier. In each case, we can see that the perplexity seems to decrease, reach a minimum, and then increase monotonously. While verifying this would require a deeper investigation, we can make the hypothesis that the sampling procedure induces noise that some of our proposed objectives can be better suited for. In Table 5, we present perplexity results averaged for different seeds, in order to check that model initialization does not discernibly affect these improvements. They show gains of up to 1 point in perplexity, and a slight improvement over the MLE baseline for WT2, confirming the results obtained on a single model. However, it is tedious to find the optimal power parameter for a given configuration, and we can expect it to shift sensibly when hyper-parameters are modified. The size of the vocabulary and the distribution of word frequencies should intuitively have the biggest influence, as we can see that the behavior of α, β and γ is quite different on the PTB and WT2. In general, finding the optimal divergence with the optimal parameter for a given problem is very difficult. Methods for doing so have only been recently explored; for example, Dikmen et al. (2015) use the Tweedie Likelihood to find the optimal β, which can lead to the optimal α and γ.

7 Conclusion

We explore the use of generalizations of KL-divergence into power (α, β and γ) divergences for training language models. We derive exact but also approximated objectives, based on an approximated softmax using importance sampling, and noise contrastive estimation. We show that in the case of exact objectives, a well-chosen γ-divergence can be used to prioritize learning low or high-frequency words. In the case of approximated objective, we show that our proposed objectives can improve on perplexity, and demonstrate it is the case for several configurations. Further research should investigate the potential gains of using γ-divergences for appropriate downstream tasks.

Abstract

CRF has been used as a powerful model for statistical sequence labeling. For neural sequence labeling, however, BiLSTM-CRF does not always lead to better results compared with BiLSTM-softmax local classification. This can be because the simple Markov label transition model of CRF does not give much information gain over strong neural encoding. For better representing label sequences, we investigate a hierarchically-refined label attention network, which explicitly leverages label embeddings and captures potential long-term label dependency by giving each word incrementally refined label distributions with hierarchical attention. Results on POS tagging, NER and CCG supertagging show that the proposed model not only improves the overall tagging accuracy with similar number of parameters, but also significantly speeds up the training and testing compared to BiLSTM-CRF.

1 Introduction

Conditional random fields (CRF) (Lafferty et al., 2001) is a state-of-the-art model for statistical sequence labeling (Toutanova et al., 2003; Peng et al., 2004; Ratinov and Roth, 2009). Recently, CRF has been integrated with neural encoders as an output layer to capture label transition patterns (Zhou and Xu, 2015; Ma and Hovy, 2016). This, however, sees mixed results. For example, previous work (Reimers and Gurevych, 2017; Yang et al., 2018) has shown that BiLSTM-softmax gives better accuracies compared to BiLSTM-CRF for part-of-speech (POS) tagging. In addition, the state-of-the-art neural Combinatory Categorial Grammar (CCG) supertaggers do not use CRF (Xu et al., 2015; Lewis et al., 2016).

One possible reason is that the strong representation power of neural sentence encoders such as BiLSTMs allow models to capture implicit long-range label dependencies from input word sequences alone (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016; Teng and Zhang, 2018), thereby allowing the output layer to make local predictions. In contrast, though explicitly capturing output label dependencies, CRF can be limited by its Markov assumptions, particularly when being used on top of neural encoders. In addition, CRF can be computationally expensive when the number of labels is large, due to the use of Viterbi decoding.

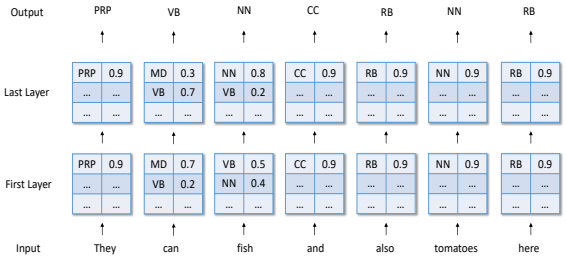

Figure 1: Visualization of hierarchically-refined Label Attention Network for POS tagging. The numbers indicate the label probability distribution for each word.

One interesting research question is whether there is neural alternative to CRF for neural sequence labeling, which is both faster and more accurate. To this question, we investigate a neural network model for output label sequences. In particular, we represent each possible label using an embedding vector, and aim to encode sequences of label distributions using a recurrent neural network. One main challenge, however, is that the number of possible label sequences is exponential to the size of input. This makes our task essentially to represent a full-exponential search space without making Markov assumptions.

We tackle this challenge using a hierarchically-refined representation of marginal label distributions. As shown in Figure 1, our model consists of a multi-layer neural network. In each layer, each input words is represented together with its

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4115–4128,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

marginal label probabilities, and a sequence neural network is employed to model unbounded dependencies. The marginal distributions space are refined hierarchically bottom-up, where a higher layer learns a more informed label sequence distribution based on information from a lower layer.

For instance, given a sentence "They$_1$ can$_2$ fish$_3$ and$_4$ also$_5$ tomatoes$_6$ here$_7$", the label distributions of the words *can*$_2$ and *fish*$_3$ in the first layer of Figure 1 have higher probabilities on the tags MD (modal verb) and VB (base form verb), respectively, though not fully confidently. The initial label distributions are then fed as the inputs to the next layer, so that long-range label dependencies can be considered. In the second layer, the network can learn to assign a noun tag to *fish*$_3$ by taking into account the highly confident tagging information of *tomatoes*$_6$ *(NN)*, resulting in the pattern "*can*$_2$ *(VB) fish*$_3$ *(NN)*".

As shown in Figure 2, our model consists of stacked attentive BiLSTM layers, each of which takes a sequence of vectors as input and yields a sequence of hidden state vectors together with a sequence of label distributions. The model performs attention over label embeddings (Wang et al., 2015; Zhang et al., 2018a) for deriving a marginal label distributions, which are in turn used to calculate a weighted sum of label embeddings. Finally, the resulting packed label vector is used together with input word vectors as the hidden state vector for the current layer. Thus our model is named *label attention network* (LAN). For sequence labeling, the input to the whole model is a sentence and the output is the label distributions of each word in the final layer.

BiLSTM-LAN can be viewed as a form of multi-layered BiLSTM-softmax sequence labeler. In particular, a single-layer BiLSTM-LAN is identical to a single-layer BiLSTM-softmax model, where the label embedding table serves as the softmax weights in BiLSTM-softmax, and the label attention distribution is the softmax distribution in BiLSTM-softmax. The traditional way of making a multi-layer extention to BiLSTM-softmax is to stack multiple BiLSTM encoder layers before the softmax output layer, which learns a deeper input representation. In contrast, a multi-layer BiLSTM-LAN stacks both the BiLSTM encoder layer and the softmax output layer, learning a deeper representation of both the input and candidate output sequences.

On standard benchmarks for POS tagging, NER and CCG supertagging, our model achieves significantly better accuracies and higher efficiencies than BiLSTM-CRF and BiLSTM-softmax with similar number of parameters. It gives highly competitive results compared with top-performance systems on WSJ, OntoNotes 5.0 and CCGBank without external training. In addition to accuracy and efficiency, BiLSTM-LAN is also more interpretable than BiLSTM-CRF thanks to visualizable label embeddings and label distributions. Our code and models are released at `https://github.com/Nealcly/LAN`.

2 Related Work

Neural Attention. Attention has been shown useful in neural machine translation (Bahdanau et al., 2014), sentiment classification (Chen et al., 2017; Liu and Zhang, 2017), relation classification (Zhou et al., 2016), read comprehension (Hermann et al., 2015), sentence summarization (Rush et al., 2015), parsing (Li et al., 2016), question answering (Wang et al., 2018b) and text understanding (Kadlec et al., 2016). Self-attention network (SAN) (Vaswani et al., 2017) has been used for semantic role labeling (Strubell et al., 2018), text classification (Xu et al., 2018; Wu et al., 2018) and other tasks. Our work is similar to Vaswani et al. (2017) in the sense that we also build a hierarchical attentive neural network for sequence representation. The difference lies in that our main goal is to investigate the encoding of exponential *label* sequences, whereas their work focuses on encoding of a *word* sequence only.

Label Embeddings. Label embedding was first used in the field of computer vision for facilitating zero-shot learning (Palatucci et al., 2009; Socher et al., 2013; Zhang and Saligrama, 2016). The basic idea is to improve the performance of classifying previously unseen class instances by learning output label knowledge. In NLP, label embeddings have been exploited for better text classification (Tang et al., 2015; Nam et al., 2016; Wang et al., 2018a). However, relatively little work has been done investigating label embeddings for sequence labeling. One exception is Vaswani et al. (2016b), who use supertag embeddings in the output layer of a CCG supertagger, through a combination of local classification model rescored using a supertag language model. In contrast, we model deep label interactions using a dynamically refined

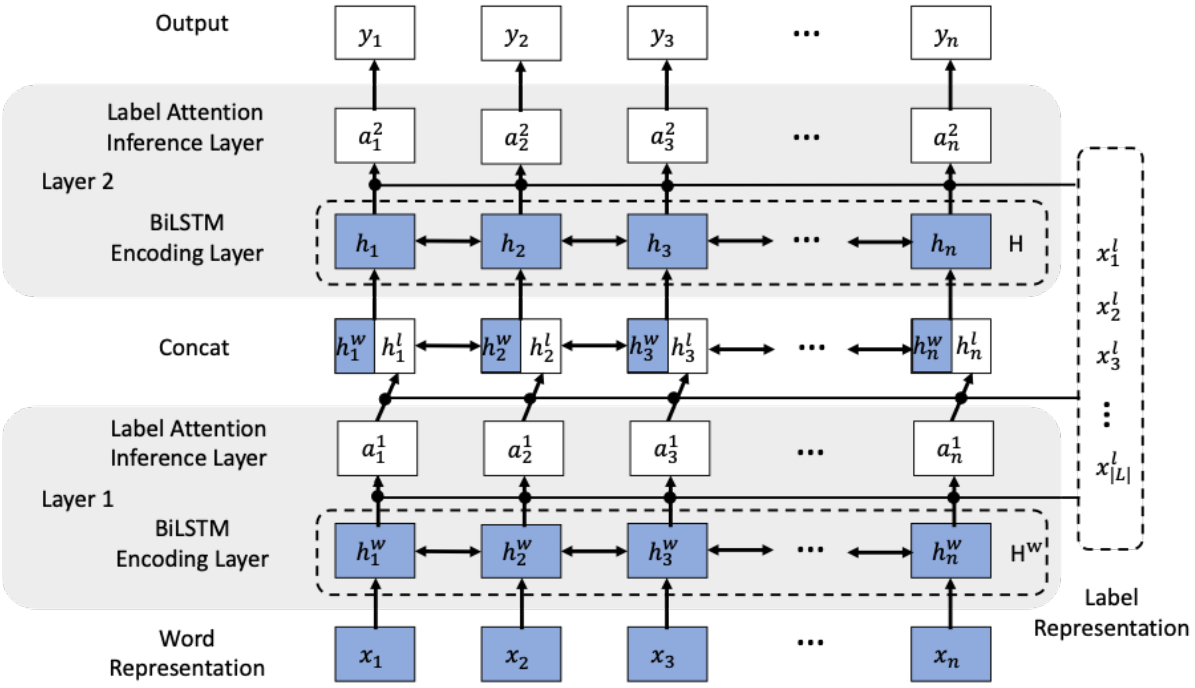

Figure 2: Architecture of hierarchically-refined label attention network.

sequence representation network. To our knowledge, we are the first to investigate a hierarchical attention network over a label space.

Neural CRF. There has been methods that aim to speed up neural CRF (Tu and Gimpel, 2018), and to solve the Markov constraint of neural CRF. In particular, Zhang et al. (2018b) predicts a sequence of labels as a sequence to sequence problem; Guo et al. (2019) further integrates global input information in encoding. Capturing non-local dependencies between labels, these methods, however, are slower compared with CRF. In contrast to these lines of work, our method is both asymptotically faster and empirically more accurate compared with neural CRF.

3 Baseline

We implement BiLSTM-CRF and BiLSTM-softmax baseline models with character-level features (Dos Santos and Zadrozny, 2014; Lample et al., 2016), which consist of a word representation layer, a sequence representation layer and a local softmax or CRF inference layer.

3.1 Word Representation Layer

Following Dos Santos and Zadrozny (2014) and Lample et al. (2016), we use character information for POS tagging. Given a word sequence $w_1, w_2, ..., w_n$, where c_{ij} denotes the jth character in the ith word, each c_{ij} is represented using

$$\mathbf{x}^c_{ij} = \mathbf{e}^c(c_{ij})$$

where $\mathbf{e}^c$ denotes a character embedding lookup table.

We adopt BiLSTM for character encoding. x^c_i denotes the output of character-level encoding.

A word is represented by concatenating its word embedding and its character representation:

$$\mathbf{x}_i = [\mathbf{e}^w(w_i); \mathbf{x}^c_i]$$

where $\mathbf{e}^w$ denotes a word embedding lookup table.

3.2 Sequence Representation Layer

For sequence encoding, the input is a sentence $\mathbf{x} = \{\mathbf{x}_1, \cdots, \mathbf{x}_n\}$. Word representations are fed into a BiLSTM layer, yielding a sequence of forward hidden states $\{\overrightarrow{\mathbf{h}^w_1}, \cdots, \overrightarrow{\mathbf{h}^w_n}\}$ and a sequence of backward hidden states $\{\overleftarrow{\mathbf{h}^w_1}, \cdots, \overleftarrow{\mathbf{h}^w_n}\}$, respectively. Finally, the two hidden states are concatenated for a final representation

$$\mathbf{h}^w_i = [\overrightarrow{\mathbf{h}^w_i}; \overleftarrow{\mathbf{h}^w_i}]$$
$$\mathbf{H}^w = \{\mathbf{h}^w_1, \cdots, \mathbf{h}^w_n\}$$

3.3 Inference Layer

CRF. A CRF layer is used on top of the hidden vectors $\mathbf{H}^w$. The conditional probabilities of label distribution sequences $y = \{y_1, \cdots, y_n\}$ is

$$P(y|x) = \frac{\exp(\sum_i (\mathbf{W}_{CRF}^{l_i} \mathbf{h_i}^w + b_{CRF}^{(l_{i-1}, l_i)}))}{\sum_{y'} \exp(\sum_i (\mathbf{W}_{CRF}^{l_i'} \mathbf{h_i}^w + b_{CRF}^{(l'_{i-1}, l_i')}))}$$

Here y' represents an arbitrary label distribution sequence, $\mathbf{W}_{CRF}^{l_i}$ is a model parameter specific to l_i, and $b_{CRF}^{(l'_{i-1}, l_i')}$ is a bias specific to l_{i-1} and l_i.

The first-order Viterbi algorithm is used to find the highest scored label sequence over an input word sequence during decoding.

Softmax. Independent local softmax classification can give competitive result on sequence labeling (Reimers and Gurevych, 2017). For each node, $\mathbf{h}_i^w$ is fed to a softmax layer to find

$$\hat{y}_i = \text{softmax}(\mathbf{W}\mathbf{h}_i^w + \mathbf{b}) \quad (1)$$

where $\hat{y}_i$ is the predicted label for w_i; $\mathbf{W}$ and $\mathbf{b}$ are the parameters for softmax layer.

4 Label Attention Network

The structure of our refined label attention network is shown in Figure 2. We denote our model as BiLSTM-LAN (namely BiLSTM-label attention network) for the remaining of this paper. We use the same input word representations for BiLSTM-softmax, BiLSTM-CRF and BiLSTM-LAN, as described in Section 3.1. Compared with the baseline models, BiLSTM-LAN uses a set of BiLSTM-LAN layers for both encoding and label prediction, instead of a set of traditional sequence encoding layers and an inference layer.

4.1 Label Representation.

Given the set of candidates output labels $L = \{l_1, \cdots, l_{|L|}\}$, each label l_k is represented using an embedding vector:

$$\mathbf{x}_k^l = \mathbf{e}^l(l_k)$$

where $\mathbf{e}^l$ denotes a label embedding lookup table. Label embeddings are randomly initialized and tuned during model training.

4.2 BiLSTM-LAN Layer

The model in Figure 2 consists of 2 BiLSTM-LAN layers. As discussed earlier, each BiLSTM-LAN layer is composed of a BiLSTM encoding sublayer and a label-attention inference sublayer. In paticular, the former is the same as the BiLSTM layer in the baseline model, while the latter uses multi-head attention (Vaswani et al., 2017) to jointly encode information from the word representation subspace and the label representation subspace. For each head, we apply a dot-product attention with a scaling factor to the inference component, deriving label distributions for BiLSTM hidden states and label embeddings.

BiLSTM Encoding Sublayer. Denote the input to each layer as $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$. BiLSTM (Section 3.2) is used to calculate $\mathbf{H}^w \in \mathbb{R}^{n \times d_h}$, where n and d_h denote the word sequence length and BiLSTM hidden size (same as the dimension of label embedding), respectively.

Label-Attention Inference Sublayer. For the label-attention inference sublayer, the attention mechanism produces an attention matrix $\boldsymbol{\alpha}$ consisting of a potential label distribution for each word. We define $\mathbf{Q} = \mathbf{H}^w$, $\mathbf{K} = \mathbf{V} = \mathbf{x}^l$. $\mathbf{x}^l \in \mathbb{R}^{|L| \times d_h}$ is the label set representation, where $|L|$ is the total number of labels. As shown in Figure 2, outputs are calculated by

$$\mathbf{H}^l = \text{attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \boldsymbol{\alpha}\mathbf{V}$$
$$\boldsymbol{\alpha} = \text{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_h}})$$

Instead of the standard attention mechanism above, it can be beneficial to use multi-head for capturing multiple possible of potential label distributions in parallel.

$$\mathbf{H}^l = \text{concat}(\text{head}, \ldots, \text{head}_k) + \mathbf{H}^w$$
$$\text{head}_i = \text{attention}(\mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}\mathbf{W}_i^K, \mathbf{V}\mathbf{W}_i^V)$$

where $\mathbf{W}_i^Q \in \mathbb{R}^{d_h \times \frac{d_h}{k}}$, $\mathbf{W}_i^K \in \mathbb{R}^{d_h \times \frac{d_h}{k}}$ and $\mathbf{W}_i^V \in \mathbb{R}^{d_h \times \frac{d_h}{k}}$ are parameters to be learned during the training, k is the number of parallel heads.

The final representation for each BiLSTM-LAN layer is the concatenation of BiLSTM hidden states and attention outputs :

$$\mathbf{H} = [\mathbf{H}^w; \mathbf{H}^l]$$

$\mathbf{H}$ is then fed to a subsequent BiLSTM-LAN layer as input, if any.

Output. In the last layer, BiLSTM-LAN directly predicts the label of each word based on the attention weights.

$$\begin{bmatrix} \hat{y_1}^1 \cdots \hat{y_1}^{|L|} \\ \cdots\cdots \\ \cdots\cdots \\ \cdots\cdots \\ \hat{y_i}^1 \cdots \hat{y_i}^{|L|} \end{bmatrix} = \boldsymbol{\alpha}$$

$$\hat{y_i} = \text{argmax}_j(\hat{y_i}^1, ..., \hat{y_i}^n)$$

where $\hat{y_i}^j$ denotes the jth candidate label for the ith word and $\hat{y_i}$ is the predicted label for ith word in the sequence.

4.3 Training

BiLSTM-LAN can be trained by standard back-propagation using the log-likelihood loss. The training object is to minimize the cross-entropy between y_i and $\hat{y_i}$ for all labeled gold-standard sentences. For each sentence,

$$L = -\sum_i \sum_j y_i^j \log \hat{y}_i^j$$

where i is the word index, j is the index of labels for each word.

4.4 Complexity

For decoding, the asymptotic time complexity is $O(|L|^2 n)$ and $O(|L|n)$ for BiLSTM-CRF and BiLSTM-LAN, respectively, where $|L|$ is the total number of labels and n is the sequence length. Compared with BiLSTM-CRF, BiLSTM-LAN can significantly increase the speed for sequence labeling, especially for CCG supertagging, where the sequence length can be much smaller than the total number of labels.

4.5 BiLSTM-LAN and BiLSTM-softmax

As mentioned in the introduction, a single-layer BiLSTM-LAN is identical to a single-layer BiLSTM-softmax sequence labeling model. In particular, the BiLSTM-softmax model is given by Eq 1. In a BiLSTM-LAN model, we arrange the set of label embeddings into a matrix as follows:

$$\mathbf{x}^l = [x_1^l; x_2^l; ..., x_{|L|}^l]$$

A naive attention model over X has:

$$\boldsymbol{\alpha} = \text{softmax}(\mathbf{H}\mathbf{x}^l)$$

It is thus straightforward to see that the label embedding matrix $\mathbf{x}^l$ corresponds to the weight matrix $\mathbf{W}$ is Eq 1, and the distribution $\boldsymbol{\alpha}$ corresponds to y in Eq 1.

5 Experiments

We empirically compare BiLSTM-CRF, BiLSTM-softmax and BiLSTM-LAN using different sequence labelling tasks, including English POS tagging, multilingual POS tagging, NER and CCG supertagging.

5.1 Dataset

For English POS tagging, we use the Wall Street Journal (WSJ) portion of the Penn Treebank (PTB) (Marcus et al., 1993), which has 45 POS tags. We adopt the same partitions used by previous work (Manning, 2011; Yang et al., 2018), selecting sections 0-18 as the training set, sections 19-21 as the development set and sections 22-24 as the test set. For multilingual POS tagging, we use treebanks from Universal Dependencies(UD) v2.2 (Silveira et al., 2014; Nivre et al., 2018) with the standard splits, choosing 8 resource-rich languages in our experiments. For NER, we use the OntoNotes 5.0 (Hovy et al., 2006; Pradhan et al., 2013). Following previous work,we adopt the official OntoNotes data split used for co-reference resolution in the CoNLL-2012 shared task (Pradhan et al., 2012). We train our CCG supertagging

Model	train (s)	test (st/s)
BiLSTM-CRF (POS)	181.32	781.90
BiLSTM-LAN (POS)	128.75	805.32
BiLSTM-CRF (CCG)	884.67	599.18
BiLSTM-LAN (CCG)	369.98	713.70

Table 4: Comparison of the training time for one iteration and decoding speed. st indicates sentences

model on CCGBank (Hockenmaier and Steedman, 2007). Sections 2-21 are used for training, section 0 for development and section 23 as the test set. The performance is calculated on the 425 most frequent labels. Table 1 shows the numbers of sentences, tokens and labels for training, development and test, respectively.

5.2 Settings

Hyper-Parameters. We use 100-dimensional GloVe (Pennington et al., 2014) word embeddings for English POS tagging (WSJ, UD v2.2 EN) and name entity recognition, 300-dimensional Glove word embeddings for CCG supertagging and 64-dimensional Polyglot (Al-Rfou et al., 2013) word embeddings for multilingual POS tagging. The detail values of the hyper-parameters for all experiments are summarized in Appendix A.

Evaluation. F-1 score are used for NER. Other tasks are evaluated based on the accuracy. We repeat the same experiment five times with the same hyperparameters and report the max accuracy, average accuracy and standard deviation for POS tagging. For fair comparison, all experiments are implemented in NCRF++ (Yang and Zhang, 2018) and conducted using a GeForce GTX 1080Ti with 11GB memory.

5.3 Development Experiments

We report a set of WSJ development experiments to show our investigation on key configurations of BiLSTM-LAN and BiLSTM-CRF.

Label embedding size. Table 2 shows the effect of the label embedding size. Notable improvement can be achieved when the label embedding size increases from 200 to 400 in our model, but the accuracy does not further increase when the size increases beyond 400. We fix the label embedding size to 400 for our model.

Number of Layers. For BiLSTM-CRF, previous work has shown that one BiLSTM layer is the most effecitve for POS tagging (Ma and Hovy, 2016; Yang et al., 2018). Table 2 compares different numbers of BiLSTM layers and hidden sizes.

Model	Mean±std	Max
BiLSTM-CRF†	97.47±0.02	97.49
BiLSTM-CRF‡	97.50±0.03	97.51
BiLSTM-softmax†	97.48±0.02	97.51
BiLSTM-LAN	**97.58±0.04**	**97.65**

Table 5: Result for POS tagging on WSJ. † Yang et al. (2018) and ‡ Yasunaga et al. (2018) are baseline models re-implemented in NCRF++ (Yang and Zhang, 2018). Our results are same as Table 6 of Yang et al. (2018).

Model	Accuracy
Plank et al. (2016)	97.22
Huang et al. (2015)	97.55
Ma and Hovy (2016)	97.55
Liu et al. (2017)	97.53
Yang et al. (2018)	97.51
Zhang et al. (2018c)	97.55
Yasunaga et al. (2018)	97.58
Xin et al. (2018)	97.58
Transformer-softmax (Guo et al., 2019)	97.04
BiLSTM-softmax (Yang et al., 2018)	97.51
BiLSTM-CRF (Yang et al., 2018)	97.51
BiLSTM-LAN	**97.65**

Table 6: Main results on WSJ.

As can be seen, a multi-layer model with larger hidden sizes does not give significantly better results compared to a 1-layer model with a hidden size of 400. We thus chose the latter for the final model.

For BiLSTM-LAN, each layer learns a more abstract representation of word and label distribution sequences. As shown in Table 2, for POS tagging, it is effective to capture label dependencies using two layers. More layers do not empirically improve the performance. We thus set the final number of layers to 3.

The effectiveness of Model Structure. To evaluate the effect of BiLSTM-LAN layers, we conduct ablation experiments as shown in Table 3. In BiLSTM-LAN w/o attention, we remove the attention inference sublayers from BiLSTM-LAN except for the last BiLSTM-LAN layer. This model is reminiscent to BiLSTM-softmax except that the output is based on label embeddings. It gives an accuracy slightly higher than that of LSTM-softmax, which demonstrates the advantage of label embeddings. On the other hand, it significantly underperforms BiLSTM-LAN (p-value$<$0.01), which shows the advantage of hierarchically-refined label distribution sequence encoding.

Model Size vs CRF. Table 2 also compares the effect of model sizes. We observe that: (1) As

		cs	da	en	fr	nl	no	pt	sv
BiLSTM-CRF	mean	98.42	95.77	95.41	96.94	94.65	97.07	97.78	96.06
	± std	0.03	0.12	0.06	0.08	0.11	0.11	0.04	0.07
(Yasunaga et al., 2018)	training(s)	268.74	18.17	58.20	70.10	44.49	56.06	51.59	15.54
BiLSTM-softmax	mean	98.48	95.90	95.36	97.01	94.76	97.26	97.78	95.98
	± std	0.04	0.09	0.17	0.09	0.17	0.03	0.05	0.08
	training(s)	129.14	9.27	25.02	33.65	23.00	28.84	23.13	8.16
BiLSTM-LAN	mean	**98.75**	**96.26**	**95.59**	**97.28**	**94.94**	**97.59**	**98.04**	**96.55**
	± std	0.02	0.12	0.13	0.08	0.11	0.04	0.04	0.01
	training(s)	165.64	11.32	33.04	40.48	29.71	37.06	27.48	10.40

Table 7: Multilingual POS tagging result on UD v2.2 treebanks, compared on 8 resource-rich languages.

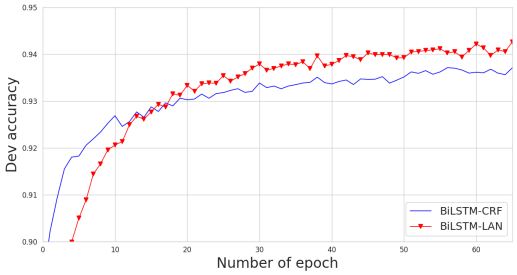

Figure 3: Training on the WSJ development set.

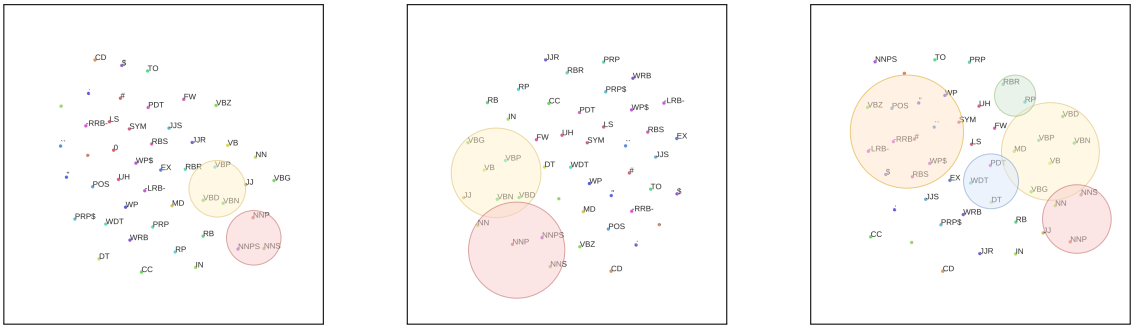
the model size increases, both BiLSTM-CRF and BiLSTM-LAN see a peak point beyond which further increase of model size does not bring better results, which is consistent with observations from prior work, demonstrating that the number of parameters is *not* the decisive factor to model accuracy; and (2) the best-performing BiLSTM-LAN model size is comparable to that of the BiLSTM-CRF model size, which indicates that the model structure is more important for the better accuracy of BiLSTM-LAN.

Speed vs CRF. Table 4 shows a comparison of training and decoding speeds. BiLSTM-LAN processes 805 and 714 sentences per second on the WSJ and CCGBank development data, respectively, outperforming BiLSTM-CRF by 3% and 19%, respectively. The larger speed improvement on CCGBank shows the benefit of lower asymptotic complexity, as discussed in Section 4.

Training vs CRF. Figure 3 presents the training curves on the WSJ development set. At the beginning, BiLSTM-LAN converges slower than BiLSTM-CRF, which is likely because BiLSTM-LAN has more complex layer structures for label embedding and attention. After around 15 training iterations, the accuracy of BiLSTM-LAN on the development sets becomes increasingly higher than BiLSTM-CRF. This demonstrates the effect of label embeddings, which allows more structured knowledge to be learned in modeling.

5.4 Final Results



WSJ. Table 5 shows the final POS tagging results on WSJ. Each experiment is repeated 5 times. BiLSTM-LAN gives significant accuracy improvements over both BiLSTM-CRF and BiLSTM-softmax (p <0.01), which is consistent with observations on development experiments.

Table 6 compares our model with top-performing methods reported in the literature. In particular, Huang et al. (2015) use BiLSTM-CRF. Ma and Hovy (2016), Liu et al. (2017) and Yang et al. (2018) explore character level representations on BiLSTM-CRF. Zhang et al. (2018c) use S-LSTM-CRF, a graph recurrent network encoder. Yasunaga et al. (2018) demonstrate that adversarial training can improve the tagging accuracy. Xin et al. (2018) proposed a compositional character-to-word model combined with LSTM-CRF. BiLSTM-LAN gives highly competitive result on WSJ without training on external data.

Universal Dependencies(UD) v2.2. We design a multilingual experiment to compare BiLSTM-softmax, BiLSTM-CRF (strictly following Yasunaga et al. (2018) [1], which is the state-of-the-art on multi-lingual POS tagging) and BiLSTM-LAN. The accuracy and training speeds are shown in Table 7. Our model outperforms all the baselines on all the languages. The improvements are statistically significant for all the languages (p <0.01), suggesting that BiLSTM-LAN is generally effective across languages.

OntoNotes 5.0. In NER, BiLSTM-CRF is widely used, because local dependencies between neighboring labels relatively more important that POS tagging and CCG supertagging. BiLSTM-LAN also significantly outperforms BiLSTM-CRF by 1.17 F1-score (p <0.01). Table 8 compares BiLSTM-LAN to other published results on

[1] Note that our results are different from Table 2 of Yasunaga et al. (2018), since they reported results on UD v1.2

(a) 5 iterations (b) 15 iterations (c) 38 iterations

Figure 4: t-SNE plot of label embeddings after different numbers of training iterations.

OntoNotes 5.0. Durrett and Klein (2014) propose a joint model for coreference resolution, entity linking and NER. Chiu and Nichols (2016) use a BiLSTM with CNN character encoding. Shen et al. (2017) introduce active learning to get better performance. Strubell et al. (2017) present an iterated dilated convolutions, which is a faster alternative to BiLSTM. Ghaddar and Langlais (2018) demonstrate that lexical features are actually quite useful for NER. Clark et al. (2018) present a cross-view training for neural sequence models. BiLSTM-LAN obtains highly competitive results compared with various of top-performance models without training on external data.

CCGBank. In CCG supertagging, the major challenge is a larger set of lexical tags $|L|$ and supertag constraints over long distance dependencies. As shown in Table 9, BiLSTM-LAN significantly outperforms both BiLSTM-softmax and BiLSTM-CRF (p <0.01), showing the advantage of LAN. Xu et al. (2015) and Vaswani et al. (2016a) explore BiRNN-softmax and BiLSTM-softmax, respectively. Søgaard and Goldberg (2016) present a multi-task learning architecture with BiRNN to improve the performance. Lewis et al. (2016) train BiLSTM-softmax using tri-training. Vaswani et al. (2016b) combine a LSTM language model and BiLSTM over the supertags. Tu and Gimpel (2019) introduce the inference network (Tu and Gimpel, 2018) in CCG supertagging to speed up the training and decoding for BiLSTM-CRF. Compared with these methods, BiLSTM-LAN obtains new state-of-the-art results on CCGBank, matching the tri-training performance of Lewis et al. (2016), without training on external data.

Table 9: Supertagging accuracy on CCGbank test set. * indicates that further gains follow from semi-supervised tri-training (improving the accuracy from 94.3% to 94.7%).

6 Discussion

Visualization. A salient advantage of LAN is more interpretable models. We visualize the label embeddings as well as label attention weights for POS tagging. We use t-SNE to visualize the 45 different English POS tags (WSJ) on a 2D map after 5, 15, 38 training iteration, respectively. Each dot represents a label embedding. As can be seen in Figure 4, label embeddings are increasingly more meaningful during training. Initially, the vectors sit in random locations in the space. After 5 iterations, small clusters emerge, such as

Sentence	Gold Standard	LSTM-softmax	LSTM-CRF	LSTM-LAN
it	NP	NP	NP	NP
settled	(S[dcl]\NP)/PP	(S[dcl]\NP)/PP	(S[dcl]\NP)/PP	(S[dcl]\NP)/PP
with	((S\NP)\(S\NP))/NP	PP/NP	PP/NP	((S\NP)\(S\NP))/NP
a	NP[nb]/N	NP[nb]/N	NP[nb]/N	NP[nb]/N
loss	N	N	N	N
of	(NP\NP)/NP	(NP\NP)/NP	(NP\NP)/NP	(NP\NP)/NP
4.95	N / N	N / N	N / N	N / N
cents	N	N	N	N
at	PP/NP	(NP\NP)/NP	PP/NP	PP/NP
$	N / N[num]	N / N[num]	N / N[num]	N / N[num]

a	(NP\NP) / N	(NP\NP) / N	(NP\NP) / N	(NP\NP) / N
pound	N	N	N	N
.	.	.	.	.

Table 10: CCG case analysis. The error are in yellow.

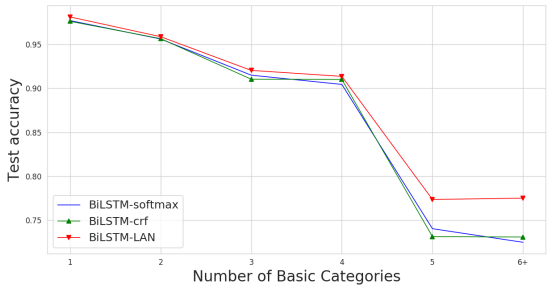

Figure 5: Accuracy against supercategory complexity.

"NNP" and "NNPS", "VBD" and "VBN", "JJS" and "JJR" etc. The clusters grow absorbing more related tags after more training iterations. After 38 training iterations, most similar POS tags are grouped together, such as "VB", "VBD", "VBN", "VBG" and "VBP". More attention visualization are shown in Appendix B.

Supercategory Complexity. We also measure the complexity of supercategories by the number of basic categories that they contain. According to this definition, "S", "S/NP" and "(S \NP)/NP" have complexities of 1, 2 and 3, respectively. Figure 5 shows the accuracy of BiLSTM-softmax, BiLSTM-CRF and BiLSTM-LAN against the supertag complexity. As the complexity increases, the performance of all the models decrease, which conforms to intuition. BiLSTM-CRF does not show obvious advantages over BiLSTM-softmax on complex categories. In contrast, BiLSTM-LAN outperforms both models on complex categories, demonstrating its advantage in capturing more sophisticated label dependencies.

Case Study. Some predictions of BiLSTM-softmax, BiLSTM-CRF and BiLSTM-LAN are shown in Table 10. The sentence contains two prepositional phrases "with ..." and "at ...", thus exemplifies the PP-attachment problem, one of the hardest sub-problems in CCG supertagging. As can be seen, BiLSTM-softmax fails to learn the long-range relation between "settled" and "at". BiLSTM-CRF strictly follows the hard constraint between neighbor categories thanks to Markov label transition. However, it predicts "with" incorrectly as "PP/NP" with the former supertag ending with "/PP". In contrast, BiLSTM-LAN can capture potential long-term dependency and better determine the supertags based on global label information. In this case, our model can effectively represent a full label search space without making Markov assumptions.

7 Conclusion

We investigate a hierarchically-refined label attention network (LAN) for sequence labeling, which leverages label embeddings and captures potential long-range label dependencies by deep attentional encoding of label distribution sequences. Both in theory and empirical results prove that BiLSTM-LAN effective solve label bias issue. Results on POS tagging, NER and CCG supertagging show that BiLSTM-LAN outperforms BiLSTM-CRF and BiLSTM-softmax.

Certified Robustness to Adversarial Word Substitutions

Robin Jia **Aditi Raghunathan** **Kerem Göksel** **Percy Liang**

Abstract

State-of-the-art NLP models can often be fooled by adversaries that apply seemingly innocuous label-preserving transformations (e.g., paraphrasing) to input text. The number of possible transformations scales exponentially with text length, so data augmentation cannot cover all transformations of an input. This paper considers one exponentially large family of label-preserving transformations, in which every word in the input can be replaced with a similar word. We train the first models that are provably robust to *all* word substitutions in this family. Our training procedure uses Interval Bound Propagation (IBP) to minimize an upper bound on the worst-case loss that any combination of word substitutions can induce. To evaluate models' robustness to these transformations, we measure accuracy on adversarially chosen word substitutions applied to test examples. Our IBP-trained models attain 75% adversarial accuracy on both sentiment analysis on IMDB and natural language inference on SNLI. In comparison, on IMDB, models trained normally and ones trained with data augmentation achieve adversarial accuracy of only 8% and 35%, respectively.

1 Introduction

Machine learning models have achieved impressive accuracy on many NLP tasks, but they are surprisingly brittle. Adding distracting text to the input (Jia and Liang, 2017), paraphrasing the text (Iyyer et al., 2018; Ribeiro et al., 2018), replacing words with similar words (Alzantot et al., 2018), or inserting character-level "typos" (Belinkov and Bisk, 2017; Ebrahimi et al., 2017) can significantly degrade a model's performance. Such perturbed inputs are called *adversarial examples*, and have shown to break models in other domains as well, most notably in vision (Szegedy et al., 2014; Goodfellow et al., 2015). Since humans are not fooled by the same perturbations, the widespread existence of adversarial examples exposes troubling gaps in models' understanding.

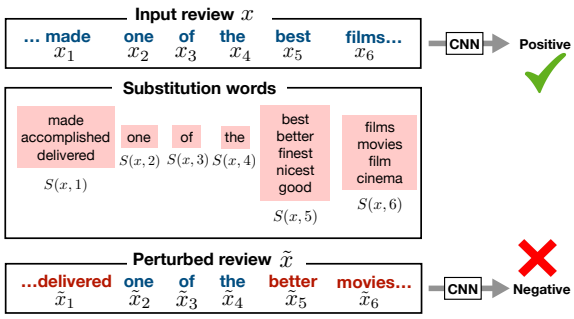

Figure 1: Word substitution-based perturbations in sentiment analysis. For an input x, we consider perturbations $\tilde{x}$, in which *every* word x_i can be replaced with any similar word from the set $S(x, i)$, without changing the original sentiment. Models can be easily fooled by adversarially chosen perturbations (e.g., changing "*best*" to "*better*", "*made*" to "*delivered*", "*films*" to "*movies*"), but the ideal model would be robust to all combinations of word substitutions.

In this paper, we focus on the word substitution perturbations of Alzantot et al. (2018). In this setting, an attacker may replace every word in the input with a similar word (that ought not to change the label), leading to an exponentially large number of possible perturbations. Figure 1 shows an example of these word substitutions. As demonstrated by a long line of work in computer vision, it is challenging to make models that are robust to very large perturbation spaces, even when the set of perturbations is known at training time (Goodfellow et al., 2015; Athalye et al., 2018; Raghunathan et al., 2018; Wong and Kolter, 2018).

Our paper addresses two key questions. First, is it possible to guarantee that a model is robust against *all* adversarial perturbations of a given in-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4129–4142, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

put? Existing methods that use heuristic search to attack models (Ebrahimi et al., 2017; Alzantot et al., 2018) are slow and cannot provide guarantees of robustness, since the space of possible perturbations is too large to search exhaustively. We obtain guarantees by leveraging Interval Bound Propagation (IBP), a technique that was previously applied to feedforward networks and CNNs in computer vision (Dvijotham et al., 2018). IBP efficiently computes a tractable *upper bound* on the loss of the worst-case perturbation. When this upper bound on the worst-case loss is small, the model is guaranteed to be robust to all perturbations, providing a *certificate* of robustness. To apply IBP to NLP settings, we derive new interval bound formulas for multiplication and softmax layers, which enable us to compute IBP bounds for LSTMs (Hochreiter and Schmidhuber, 1997) and attention layers (Bahdanau et al., 2015). We also extend IBP to handle discrete perturbation sets, rather than the continuous ones used in vision.

Second, can we train models that are robust in this way? Data augmentation can sometimes mitigate the effect of adversarial examples (Jia and Liang, 2017; Belinkov and Bisk, 2017; Ribeiro et al., 2018; Liu et al., 2019), but it is insufficient when considering very large perturbation spaces (Alzantot et al., 2018). Adversarial training strategies from computer vision (Madry et al., 2018) rely on gradient information, and therefore do not extend to the discrete perturbations seen in NLP. We instead use *certifiably robust training*, in which we train models to optimize the IBP upper bound (Dvijotham et al., 2018).

We evaluate certifiably robust training on two tasks—sentiment analysis on the IMDB dataset (Maas et al., 2011) and natural language inference on the SNLI dataset (Bowman et al., 2015). Across various model architectures (bag-of-words, CNN, LSTM, and attention-based), certifiably robust training consistently yields models which are provably robust to all perturbations on a large fraction of test examples. A normally-trained model has only 8% and 41% accuracy on IMDB and SNLI, respectively, when evaluated on adversarially perturbed test examples. With certifiably robust training, we achieve 75% adversarial accuracy for both IMDB and SNLI. Data augmentation fares much worse than certifiably robust training, with adversarial accuracies falling to 35% and 71%, respectively.

2 Setup

We consider tasks where a model must predict a label $y \in \mathcal{Y}$ given textual input $x \in \mathcal{X}$. For example, for sentiment analysis, the input x is a sequence of words $x_1, x_2, \ldots, x_L$, and the goal is to assign a label $y \in \{-1, 1\}$ denoting negative or positive sentiment, respectively. We use $z = (x, y)$ to denote an example with input x and label y, and use θ to denote parameters of a model. Let $f(z, \theta) \in \mathbb{R}$ denote some loss of a model with parameters θ on example z. We evaluate models on $f^{\text{0-1}}(z, \theta)$, the zero-one loss under model θ.

2.1 Perturbations by word substitutions

Our goal is to build models that are robust to label-preserving perturbations. In this work, we focus on perturbations where words of the input are substituted with similar words. Formally, for every word x_i, we consider a set of allowed substitution words $S(x, i)$, including x_i itself. We use $\tilde{x}$ to denote a perturbed version of x, where each word $\tilde{x}_i$ is in $S(x, i)$. For an example $z = (x, y)$, let $B_{\text{perturb}}(z)$ denote the set of *all* allowed perturbations of z:

$$B_{\text{perturb}}(z) = \{(\tilde{x}, y) : \tilde{x}_i \in S(x, i) \ \ \forall i\}. \quad (1)$$

Figure 1 provides an illustration of word substitution perturbations. We choose $S(x, i)$ so that $\tilde{x}$ is likely to be grammatical and have the same label as x (see Section 5.1).

2.2 Robustness to all perturbations

Let $\mathcal{F}(z, \theta)$ denote the set of losses of the network on the set of perturbed examples defined in (1):

$$\mathcal{F}(z, \theta) = \{f(\tilde{z}, \theta) : \tilde{z} \in B_{\text{perturb}}(z)\}. \quad (2)$$

We define the *robust loss* as $\max \mathcal{F}(z, \theta)$, the loss due to worst-case perturbation. A model is robust at z if it classifies all inputs in the perturbation set correctly, i.e., the robust zero-one loss $\max \mathcal{F}^{\text{0-1}}(z, \theta) = 0$. Unfortunately, the robust loss is often intractable to compute, as each word can be perturbed independently. For example, reviews in the IMDB dataset (Maas et al., 2011) have a median of 10^{31} possible perturbations and max of 10^{271}, far too many to enumerate. We instead propose a tractable *upper bound* by constructing a set $\mathcal{O}(z, \theta) \supseteq \mathcal{F}(z, \theta)$. Note that

$$\max \mathcal{O}^{\text{0-1}}(z, \theta) = 0 \Rightarrow \max \mathcal{F}^{\text{0-1}}(z, \theta) = 0 \Leftrightarrow \text{robust at } z. \quad (3)$$

Therefore, whenever $\max \mathcal{O}^{0\text{-}1}(z, \theta) = 0$, this fact is sufficient to *certify* robustness to all perturbed examples $B_{\text{perturb}}(z)$. However, since $\mathcal{O}^{0\text{-}1}(z, \theta) \supseteq \mathcal{F}^{0\text{-}1}(z, \theta)$, the model could be robust even if $\max \mathcal{O}^{0\text{-}1}(z, \theta) \neq 0$.

3 Certification via Interval Bound Propagation

We now show how to use Interval Bound Propagation (IBP) (Dvijotham et al., 2018) to obtain a superset $\mathcal{O}(z, \theta)$ of the losses of perturbed inputs $\mathcal{F}(z, \theta)$, given z, θ, and $B_{\text{perturb}}(z)$. For notational convenience, we drop z and θ. The key idea is to compute upper and lower bounds on the activations in each layer of the network, in terms of bounds computed for previous layers. These bounds *propagate* through the network, as in a standard forward pass, until we obtain bounds on the final output, i.e., the loss f. While IBP bounds may be loose in general, Section 5.2 shows that training networks to minimize the upper bound on f makes these bounds much tighter (Gowal et al., 2018; Raghunathan et al., 2018).

Formally, let g^i denote a scalar-valued function of z and θ (e.g., a single activation in one layer of the network) computed at node i of the computation graph for a given network. Let $\text{dep}(i)$ be the set of nodes used to compute g^i in the computation graph (e.g., activations of the previous layer). Let $\mathcal{G}^i$ denote the set of possible values of g^i across all examples in $B_{\text{perturb}}(z)$. We construct an interval $\mathcal{O}^i = [\ell^i, u^i]$ that contains all these possible values of g^i, i.e., $\mathcal{O}^i \supseteq \mathcal{G}^i$. $\mathcal{O}^i$ is computed from the intervals $\mathcal{O}^{\text{dep}(i)} = \{\mathcal{O}^j : j \in \text{dep}(i)\}$ of the dependencies of g^i. Once computed, $\mathcal{O}^i$ can then be used to compute intervals on nodes that depend on i. In this way, bounds propagate through the entire computation graph in an efficient forward pass.

We now discuss how to compute interval bounds for NLP models and word substitution perturbations. We obtain interval bounds for model inputs given $B_{\text{perturb}}(z)$ (Section 3.1), then show how to compute $\mathcal{O}^i$ from $\mathcal{O}^{\text{dep(i)}}$ for elementary operations used in standard NLP models (Section 3.2). Finally, we use these bounds to certify robustness and train robust models.

3.1 Bounds for the input layer

Previous work (Gowal et al., 2018) applied IBP to continuous image perturbations, which are naturally represented with interval bounds (Dvijotham et al., 2018). We instead work with discrete word substitutions, which we must convert into interval bounds $\mathcal{O}^{\text{input}}$ in order to use IBP. Given input words $x = x_1, \ldots, x_L$, we assume that the model embeds each word as $g^{\text{input}} = [\phi(x_1), \ldots, \phi(x_L)] \in \mathbb{R}^{L \times d}$, where $\phi(x_i) \in \mathbb{R}^d$ is the word vector for word x_i. To compute $\mathcal{O}^{\text{input}} \supseteq \mathcal{G}^{\text{input}}$, recall that each input word x_i can be replaced with any $\tilde{x}_i \in S(x, i)$. So, for each coordinate $j \in \{1, \ldots, d\}$, we can obtain an interval bound $\mathcal{O}^{\text{input}}_{ij} = [\ell^{\text{input}}_{ij}, u^{\text{input}}_{ij}]$ for g^{input}_{ij} by computing the smallest axis-aligned box that contains all the word vectors:

$$\ell^{\text{input}}_{ij} = \min_{w \in S(x,i)} \phi(w)_j, \quad u^{\text{input}}_{ij} = \max_{w \in S(x,i)} \phi(w)_j. \tag{4}$$

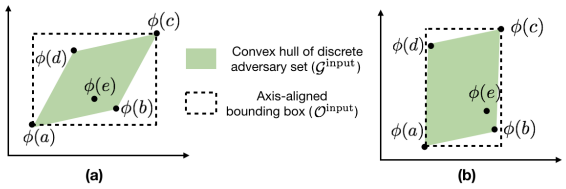

Figure 2: Bounds on the word vector inputs to the neural network. Consider a word (sentence of length one) $x = a$ with the set of substitution words $S(x, 1) = \{a, b, c, d, e\}$. (a) IBP constructs axis-aligned bounds around a set of word vectors. These bounds may be loose, especially if the word vectors are pre-trained and fixed. (b) A different word vector space can give tighter IBP bounds, if the convex hull of the word vectors is better approximated by an axis-aligned box.

Figure 2 illustrates these bounds. We can view this as relaxing a set of discrete points to a convex set that contains all of the points. Section 4.2 discusses modeling choices to make this box tighter.

3.2 Interval bounds for elementary functions

Next, we describe how to compute the interval of a node i from intervals of its dependencies. Gowal et al. (2018) show how to efficiently compute interval bounds for affine transformations (i.e., linear layers) and monotonic elementwise nonlinearities (see Appendix 3). This suffices to compute interval bounds for feedforward networks and CNNs. However, common NLP model components like LSTMs and attention also rely on softmax (for attention), element-wise multiplication (for LSTM gates), and dot product (for computing attention scores). We show how to compute interval bounds for these new operations. These building blocks can be used to compute interval bounds

not only for LSTMs and attention, but also for any model that uses these elementary functions.

For ease of notation, we drop the superscript i on g^i and write that a node computes a result $z^{\text{res}} = g(z^{\text{dep}})$ where $z^{\text{res}} \in \mathbb{R}$ and $z^{\text{dep}} \in \mathbb{R}^m$ for $m = |\text{dep}(i)|$. We are given intervals $\mathcal{O}^{\text{dep}}$ such that $z_j^{\text{dep}} \in \mathcal{O}_j^{\text{dep}} = [\ell_j^{\text{dep}}, u_j^{\text{dep}}]$ for each coordinate j and want to compute $\mathcal{O}^{\text{res}} = [\ell^{\text{res}}, u^{\text{res}}]$.

Softmax layer. The softmax function is often used to convert activations into a probability distribution, e.g., for attention. Gowal et al. (2018) uses unnormalized logits and does not handle softmax operations. Formally, let z^{res} represent the normalized score of the word at position c. We have $z^{\text{res}} = \frac{\exp(z_c^{\text{dep}})}{\sum_{j=1}^m \exp(z_j^{\text{dep}})}$. The value of z^{res} is largest when z_c^{dep} takes its largest value and all other words take the smallest value:

$$u^{\text{res}} = \frac{\exp(u_c^{\text{dep}})}{\exp(u_c^{\text{dep}}) + \sum_{j \neq c} \exp(\ell_j^{\text{dep}})}. \quad (5)$$

We obtain a similar expression for ℓ^{res}. Note that ℓ^{res} and u^{res} can each be computed in a forward pass, with some care taken to avoid numerical instability (see Appendix A.2).

Element-wise multiplication and dot product. Models like LSTMs incorporate gates which perform element-wise multiplication of two activations. Let $z^{\text{res}} = z_1^{\text{dep}} z_2^{\text{dep}}$ where $z^{\text{res}}, z_1^{\text{dep}}, z_2^{\text{dep}} \in \mathbb{R}$. The extreme values of the product occur at one of the four points corresponding to the products of the extreme values of the inputs. In other words,

$$\begin{aligned} \mathcal{C} = \{&\ell_1^{\text{dep}} \ell_2^{\text{dep}}, \quad \ell_1^{\text{dep}} u_2^{\text{dep}} \\ &u_1^{\text{dep}} \ell_2^{\text{dep}}, \quad u_1^{\text{dep}} u_2^{\text{dep}}\} \\ \ell^{\text{res}} = \min(\mathcal{C}) \quad & u^{\text{res}} = \max(\mathcal{C}). \end{aligned} \quad (6)$$

Propagating intervals through multiplication nodes therefore requires four multiplications.

Dot products between activations are often used to compute attention scores.[1] The dot product $(z_1^{\text{dep}})^\top z_2^{\text{dep}}$ is just the sum of the element-wise product $z_1^{\text{dep}} \odot z_2^{\text{dep}}$. Therefore, we can bound the dot product by summing the bounds on each element of $z_1^{\text{dep}} \odot z_2^{\text{dep}}$, using the formula for element-wise multiplication.

[1]This is distinct from an affine transformation, because both vectors have associated bounds; in an affine layer, the input has bounds, but the weight matrix is fixed.

3.3 Final layer

Classification models typically output a single logit for binary classification, or k logits for k-way classification. The final loss $f(z, \theta)$ is a function of the logits $s(x)$. For standard loss functions, we can represent this function in terms of element-wise monotonic functions (Appendix 3) and the elementary functions described in Section 3.2.

1. Zero-one loss: $f(z, \theta) = \mathbb{I}[\max(s(x)) = y]$ involves a max operation followed by a step function, which is monotonic.

2. Cross entropy: For multi-class, $f(z, \theta) = \text{softmax}(s(x))$. In the binary case, $f(z, \theta) = \sigma(s(x))$, where the sigmoid function σ is monotonic.

Thus, we can compute bounds on the loss $\mathcal{O}(z, \theta) = [\ell^{\text{final}}, u^{\text{final}}]$ from bounds on the logits.

3.4 Certifiably Robust Training with IBP

Finally, we describe certifiably robust training, in which we encourage robustness by minimizing the upper bound on the worst-case loss (Dvijotham et al., 2018; Gowal et al., 2018). Recall that for an example z and parameters θ, $u^{\text{final}}(z, \theta)$ is the upper bound on the loss $f(z, \theta)$. Given a dataset D, we optimize a weighted combination of the normal loss and the upper bound u^{final},

$$\min_\theta \sum_{z \in D} (1 - \kappa) f(z, \theta) + \kappa\, u^{\text{final}}(z, \theta), \quad (7)$$

where $0 \leq \kappa \leq 1$ is a scalar hyperparameter.

As described above, we compute u^{final} in a modular fashion: each layer has an accompanying function that computes bounds on its outputs given bounds on its inputs. Therefore, we can easily apply IBP to new architectures. Bounds propagate through layers via forward passes, so the entire objective (7) can be optimized via backpropagation.

Gowal et al. (2018) found that this objective was easier to optimize by starting with a smaller space of allowed perturbations, and make it larger during training. We accomplish this by artificially shrinking the input layer intervals $\mathcal{O}_{ij}^{\text{input}} = [\ell_{ij}^{\text{input}}, u_{ij}^{\text{input}}]$ towards the original value $\phi(x_i)_j$ by a factor of ϵ:

$$\begin{aligned} \ell_{ij}^{\text{input}} &\leftarrow \phi(x_i)_j - \epsilon(\phi(x_i)_j - \ell_{ij}^{\text{input}}) \\ u_{ij}^{\text{input}} &\leftarrow \phi(x_i)_j + \epsilon(u_{ij}^{\text{input}} - \phi(x_i)_j). \end{aligned}$$

Standard training corresponds to $\epsilon = 0$. We train for T^{init} epochs while linearly increasing ϵ from 0

to 1, and also increasing κ from 0 up to a maximum value of $\kappa^\star$, We then train for an additional T^{final} epochs at $\kappa = \kappa^\star$ and $\epsilon = 1$.

To summarize, we use IBP to compute an upper bound on the model's loss when given an adversarially perturbed input. This bound is computed in a modular fashion. We efficiently train models to minimize this bound via backpropagation.

4 Tasks and models

Now we describe the tasks and model architectures on which we run experiments. These models are all built from the primitives in Section 3.

4.1 Tasks

Following Alzantot et al. (2018), we evaluate on two standard NLP datasets: the IMDB sentiment analysis dataset (Maas et al., 2011) and the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). For IMDB, the model is given a movie review and must classify it as positive or negative. For SNLI, the model is given two sentences, a premise and a hypothesis, and is asked whether the premise entails, contradicts, or is neutral with respect to the hypothesis. For SNLI, the adversary is only allowed to change the hypothesis, as in Alzantot et al. (2018), though it is possible to also allow changing the premise.

4.2 Models

IMDB. We implemented three models for IMDB. The bag-of-words model (BOW) averages the word vectors for each word in the input, then passes this through a two-layer feedforward network with 100-dimensional hidden state to obtain a final logit. The other models are similar, except they run either a CNN or bidirectional LSTM on the word vectors, then average their hidden states. All models are trained on cross entropy loss.

SNLI We implemented two models for SNLI. The bag-of-words model (BOW) encodes the premise and hypothesis separately by summing their word vectors, then feeds the concatenation of these encodings to a 3-layer feedforward network. We also reimplement the Decomposable Attention model (Parikh et al., 2016), which uses attention between the premise and hypothesis to compute richer representations of each word in both sentences. These context-aware vectors are used in the same way BOW uses the original word vectors to generate the final prediction. Both models are trained on cross entropy loss. Implementation details are provided in Appendix A.4.

Word vector layer. The choice of word vectors affects the tightness of our interval bounds. We choose to define the word vector $\phi(w)$ for word w as the output of a feedforward layer applied to a fixed pre-trained word vector $\phi^{\text{pre}}(w)$:

$$\phi(w) = \text{ReLU}(g^{\text{word}}(\phi^{\text{pre}}(w))), \qquad (8)$$

where g^{word} is a learned linear transformation. Learning g^{word} with certifiably robust training encourages it to orient the word vectors so that the convex hull of the word vectors is close to an axis-aligned box. Note that g^{word} is applied *before* bounds are computed via (4).[2] Applying g^{word} after the bound calculation would result in looser interval bounds, since the original word vectors $\phi^{\text{pre}}(w)$ might be poorly approximated by interval bounds (e.g., Figure 2a), compared to $\phi(w)$ (e.g., Figure 2b). Section 5.7 confirms the importance of adding g^{word}. We use 300-dimensional GloVe vectors (Pennington et al., 2014) as our $\phi^{\text{pre}}(w)$.

5 Experiments

5.1 Setup

Word substitution perturbations. We base our sets of allowed word substitutions $S(x, i)$ on the substitutions allowed by Alzantot et al. (2018). They demonstrated that their substitutions lead to adversarial examples that are qualitatively similar to the original input and retain the original label, as judged by humans. Alzantot et al. (2018) define the neighbors $N(w)$ of a word w as the $n = 8$ nearest neighbors of w in a "counter-fitted" word vector space where antonyms are far apart (Mrkšić et al., 2016).[3] The neighbors must also lie within some Euclidean distance threshold. They also use a language model constraint to avoid nonsensical perturbations: they allow substituting x_i with $\tilde{x}_i \in N(x_i)$ if and only if it does not decrease the log-likelihood of the text under a pre-trained language model by more than some threshold.

We make three modifications to this approach. First, in Alzantot et al. (2018), the adversary applies substitutions one at a time, and the neighborhoods and language model scores are computed

[2] Equation (4) must be applied before the model can combine information from multiple words, but it can be delayed until after processing each word independently.

[3] Note that the model itself classifies using a different set of pre-trained word vectors; the counter-fitted vectors are only used to define the set of allowed substitution words.

relative to the current altered version of the input. This results in a hard-to-define attack surface, as changing one word can allow or disallow changes to other words. It also requires recomputing language model scores at each iteration of the genetic attack, which is inefficient. Moreover, the same word can be substituted multiple times, leading to semantic drift. We define allowed substitutions relative to the original sentence x, and disallow repeated substitutions. Second, we use a faster language model that allows us to query longer contexts; Alzantot et al. (2018) use a slower language model and could only query it with short contexts. Finally, we use the language model constraint only at test time; the model is trained against all perturbations in $N(w)$. This encourages the model to be robust to a larger space of perturbations, instead of specializing for the particular choice of language model. See Appendix A.3 for further details.

Analysis of word neighbors. One natural question is whether we could guarantee robustness by having the model treat all neighboring words the same. We could construct equivalence classes of words from the transitive closure of $N(w)$, and represent each equivalence class with one embedding. We found that this would lose a significant amount of information. Out of the 50,000 word vocabulary, 19,122 words would be in the same equivalence class, including the words "good", "bad", "excellent", and "terrible." Of the remaining words, 24,389 (79%) have no neighbors.

Baseline training methods. We compare certifiably robust training (Section 3) with both standard training and data augmentation, which has been used in NLP to encourage robustness to various types of perturbations (Jia and Liang, 2017; Belinkov and Bisk, 2017; Iyyer et al., 2018; Ribeiro et al., 2018). In data augmentation, for each training example z, we augment the dataset with K new examples $\tilde{z}$ by sampling $\tilde{z}$ uniformly from $B_{\text{perturb}}(z)$, then train on the normal cross entropy loss. For our main experiments, we use $K = 4$. We do not use adversarial training (Goodfellow et al., 2015) because it would require running an adversarial search procedure at each training step, which would be prohibitively slow.

Evaluation of robustness. We wish to evaluate robustness of models to all word substitution perturbations. Ideally, we would directly measure *robust accuracy*, the fraction of test examples z for which the model is correct on all $\tilde{z} \in B_{\text{perturb}}(z)$. However, evaluating this exactly involves enumerating the exponentially large set of perturbations, which is intractable. Instead, we compute tractable upper and lower bounds:

1. Genetic attack accuracy: Alzantot et al. (2018) demonstrate the effectiveness of a genetic algorithm that searches for perturbations $\tilde{z}$ that cause model misclassification. The algorithm maintains a "population" of candidate $\tilde{z}$'s and repeatedly perturbs and combines them. We used a population size of 60 and ran 40 search iterations on each example. Since the algorithm does not exhaustively search over $B_{\text{perturb}}(z)$, accuracy on the perturbations it finds is an *upper bound* on the true robust accuracy.

2. Certified accuracy: To complement this upper bound, we use IBP to obtain a tractable lower bound on the robust accuracy. Recall from Section 3.3 that we can use IBP to get an upper bound on the zero-one loss. From this, we obtain a *lower bound* on the robust accuracy by measuring the fraction of test examples for which the zero-one loss is guaranteed to be 0.

Experimental details. For IMDB, we split the official train set into train and development subsets, putting reviews for different movies into different splits (matching the original train/test split). For SNLI, we use the official train/development/test split. We tune hyperparameters on the development set for each dataset. Hyperparameters are reported in Appendix A.4.

5.2 Main results

Table 1 and Table 2 show our main results for IMDB and SNLI, respectively. We measure accuracy on perturbations found by the genetic attack (upper bound on robust accuracy) and IBP-certified accuracy (lower bound on robust accuracy) on 1000 random test examples from IMDB,[4] and all 9824 test examples from SNLI. Across many architectures, our models are more robust to perturbations than ones trained with data augmentation. This effect is especially pronounced on IMDB, where inputs can be hundreds of words long, so many words can be perturbed. On IMDB, the best IBP-trained model gets 75.0% accuracy on perturbations found by the genetic at-

[4] We downsample the test set because the genetic attack is slow on IMDB, as inputs can be hundreds of words long.

System	Genetic attack (Upper bound)	IBP-certified (Lower bound)
Standard training		
BOW	9.6	0.8
CNN	7.9	0.1
LSTM	6.9	0.0
Robust training		
BOW	70.5	68.9
CNN	**75.0**	**74.2**
LSTM	64.7	63.0
Data augmentation		
BOW	34.6	3.5
CNN	35.2	0.3
LSTM	33.0	0.0

Table 1: Robustness of models on IMDB. We report accuracy on perturbations obtained via the genetic attack (upper bound on robust accuracy), and certified accuracy obtained using IBP (lower bound on robust accuracy) on 1000 random IMDB test set examples. For all models, robust training vastly outperforms data augmentation ($p < 10^{-63}$, Wilcoxon signed-rank test).

System	Genetic attack (Upper bound)	IBP-certified (Lower bound)
Normal training		
BOW	40.5	2.3
DECOMPATTN	40.3	1.4
Robust training		
BOW	**75.0**	**72.7**
DECOMPATTN	73.7	72.4
Data augmentation		
BOW	68.5	7.7
DECOMPATTN	70.8	1.4

Table 2: Robustness of models on the SNLI test set. For both models, robust training outperforms data augmentation ($p < 10^{-10}$, Wilcoxon signed-rank test).

tack, whereas the best data augmentation model gets 35.2%. Normally trained models are even worse, with adversarial accuracies below 10%.

Certified accuracy. Certifiably robust training yields models with tight guarantees on robustness—the upper and lower bounds on robust accuracy are close. On IMDB, the best model is *guaranteed* to be correct on all perturbations of 74.2% of test examples, very close to the 75.0% accuracy against the genetic attack. In contrast, for data augmentation models, the IBP bound cannot guarantee robustness on almost all examples. It is possible that a stronger attack (e.g., exhaustive search) could further lower the accuracy of these models, or that the IBP bounds are loose.

LSTM models can be certified with IBP, though they fare worse than other models. IBP bounds may be loose for RNNs because of their long computation paths, along which looseness of bounds can get amplified. Nonetheless, in Appendix A.7, we show on synthetic data that robustly trained LSTMs can learn long-range dependencies.

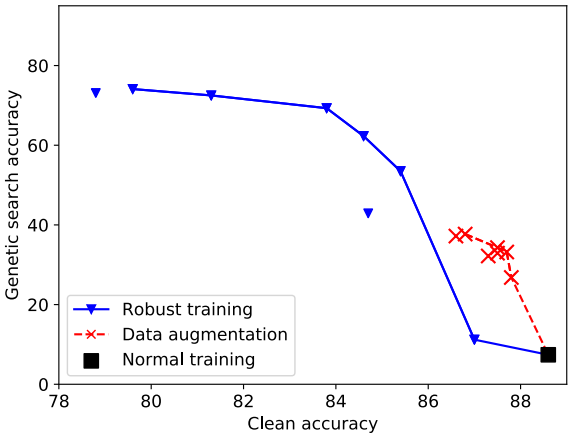

Figure 3: Trade-off between clean accuracy and genetic attack accuracy for CNN models on IMDB. Data augmentation cannot achieve high robustness. Certifiably robust training yields much more robust models, though at the cost of some clean accuracy. Lines connect Pareto optimal points for each training strategy.

5.3 Clean versus robust accuracy

Robust training does cause a moderate drop in clean accuracy (accuracy on unperturbed test examples) compared with normal training. On IMDB, our normally trained CNN model gets 89% clean accuracy, compared to 81% for the robustly trained model. We also see a drop on SNLI: the normally trained BOW model gets 83% clean accuracy, compared to 79% for the robustly trained model. Similar drops in clean accuracy are also seen for robust models in vision (Madry et al., 2017). For example, the state-of-the-art robust model on CIFAR10 (Zhang et al., 2019) only has 85% clean accuracy, but comparable normally-trained models get $> 96\%$ accuracy.

We found that the robustly trained models tend to underfit the training data—on IMDB, the CNN model gets only 86% clean training accuracy, lower than the *test* accuracy of the normally trained model. The model continued to underfit when we increased either the depth or width of the network. One possible explanation is that the attack surface adds a lot of noise, though a large enough model should still be able to overfit the training set. Better optimization or a tighter way to compute bounds could also improve training accuracy. We leave further exploration to future work.

Next, we analyzed the trade-off between clean and robust accuracy by varying the importance

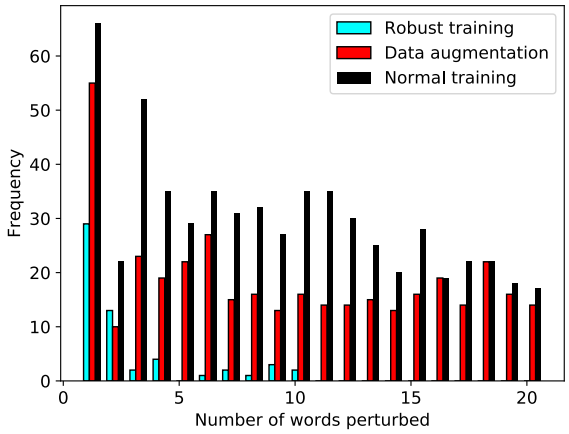

Figure 4: Number of words perturbed by the genetic attack to cause errors by CNN models on 1000 IMDB development set examples. Certifiably robust training reduces the effect of many simultaneous perturbations.

placed on perturbed examples during training. We use accuracy against the genetic attack as our proxy for robust accuracy, rather than IBP-certified accuracy, as IBP bounds may be loose for models that were not trained with IBP. For data augmentation, we vary K, the number of augmented examples per real example, from 1 to 64. For certifiably robust training, we vary $\kappa^\star$, the weight of the certified robustness training objective, between 0.01 and 1.0. Figure 3 shows trade-off curves for the CNN model on 1000 random IMDB development set examples. Data augmentation can increase robustness somewhat, but cannot reach very high adversarial accuracy. With certifiably robust training, we can trade off some clean accuracy for much higher robust accuracy.

5.4 Runtime considerations

IBP enables efficient computation of $u^{\text{final}}(z, \theta)$, but it still incurs some overhead. Across model architectures, we found that one epoch of certifiably robust training takes between $2\times$ and $4\times$ longer than one epoch of standard training. On the other hand, IBP certificates are much faster to compute at test time than genetic attack accuracy. For the robustly trained CNN IMDB model, computing certificates on 1000 test examples took 5 seconds, while running the genetic attack on those same examples took over 3 hours.

5.5 Error analysis

We examined development set examples on which models were correct on the original input but incorrect on the perturbation found by the genetic attack. We refer to such cases as *robustness errors*. We focused on the CNN IMDB models trained normally, robustly, and with data augmentation. We found that robustness errors of the robustly trained model mostly occurred when it was not confident in its original prediction. The model had $> 70\%$ confidence in the correct class for the original input in only 14% of robustness errors. In contrast, the normally trained and data augmentation models were more confident on their robustness errors; they had $> 70\%$ confidence on the original example in 92% and 87% of cases, respectively.

We next investigated how many words the genetic attack needed to change to cause misclassification, as shown in Figure 4. For the normally trained model, some robustness errors involved only a couple changed words (e.g., "*I've finally found a movie worse than . . .*" was classified negative, but the same review with "*I've finally* ***discovered*** *a movie worse than. . .*" was classified positive), but more changes were also common (e.g., part of a review was changed from "*The creature looked very cheesy*" to "*The creature* ***seemed supremely dorky***", with 15 words changed in total). Surprisingly, certifiably robust training nearly eliminated robustness errors in which the genetic attack had to change many words: the genetic attack either caused an error by changing a couple words, or was unable to trigger an error at all. In contrast, data augmentation is unable to cover the exponentially large space of perturbations that involve many words, so it does not prevent errors caused by changing many words.

5.6 Training schedule

We investigated the importance of slowly increasing ϵ during training, as suggested by Gowal et al. (2018). Fixing $\epsilon = 1$ during training led to a 5 point reduction in certified accuracy for the CNN. On the other hand, we found that holding κ fixed did not hurt accuracy, and in fact may be preferable. More details are shown in Appendix A.5.

5.7 Word vector analysis

We determined the importance of the extra feed-forward layer g^{word} that we apply to pre-trained word vectors, as described in Section 4.2. We compared with directly using pre-trained word vectors, i.e. $\phi(w) = \phi^{\text{pre}}(w)$. We also tried using g^{word} but applying interval bounds on $\phi^{\text{pre}}(w)$, then computing bounds on $\phi(w)$ with the IBP for-

mula for affine layers. In both cases, we could not train a CNN to achieve more than 52.2% certified accuracy on the development set. Thus, transforming pre-trained word vectors and applying interval bounds *after* is crucial for robust training. In Appendix A.6, we show that robust training makes the intervals around transformed word vectors smaller, compared to the pre-trained vectors.

6 Related Work and Discussion

Recent work on adversarial examples in NLP has proposed various classes of perturbations, such as insertion of extraneous text (Jia and Liang, 2017), word substitutions (Alzantot et al., 2018), paraphrasing (Iyyer et al., 2018; Ribeiro et al., 2018), and character-level noise (Belinkov and Bisk, 2017; Ebrahimi et al., 2017). These works focus mainly on demonstrating models' lack of robustness, and mostly do not explore ways to increase robustness beyond data augmentation. Data augmentation is effective for narrow perturbation spaces (Jia and Liang, 2017; Ribeiro et al., 2018), but only confers partial robustness in other cases (Iyyer et al., 2018; Alzantot et al., 2018). Ebrahimi et al. (2017) tried adversarial training (Goodfellow et al., 2015) for character-level perturbations, but could only use a fast heuristic attack at training time, due to runtime considerations. As a result, their models were still be fooled by running a more expensive search procedure at test time.

Provable defenses have been studied for simpler NLP models and attacks, particularly for tasks like spam detection where real-life adversaries try to evade detection. Globerson and Roweis (2006) train linear classifiers that are robust to adversarial feature deletion. Dalvi et al. (2004) analyzed optimal strategies for a Naive Bayes classifier and attacker, but their classifier only defends against a fixed attacker that does not adapt to the model.

Recent work in computer vision (Szegedy et al., 2014; Goodfellow et al., 2015) has sparked renewed interest in adversarial examples. Most work in this area focuses on L_∞-bounded perturbations, in which each input pixel can be changed by a small amount. The word substitution attack model we consider is similar to L_∞ perturbations, as the adversary can change each input word by a small amount. Our work is inspired by work based on convex optimization (Raghunathan et al., 2018; Wong and Kolter, 2018) and builds directly on interval bound propagation (Dvijotham et al., 2018; Gowal et al., 2018), which has certified robustness of computer vision models to L_∞ attacks. Adversarial training via projected gradient descent (Madry et al., 2018) has also been shown to improve robustness, but assumes that inputs are continuous. It could be applied in NLP by relaxing sets of word vectors to continuous regions.

This work provides certificates against word substitution perturbations for particular models. Since IBP is modular, it can be extended to other model architectures on other tasks. It is an open question whether IBP can give non-trivial bounds for sequence-to-sequence tasks like machine translation (Belinkov and Bisk, 2017; Michel et al., 2019). In principle, IBP can handle character-level typos (Ebrahimi et al., 2017; Pruthi et al., 2019), though typos yield more perturbations per word than we consider in this work. We are also interested in handling word insertions and deletions, rather than just substitutions. Finally, we would like to train models that get state-of-the-art clean accuracy while also being provably robust; achieving this remains an open problem.

In conclusion, state-of-the-art NLP models are accurate on average, but they still have significant blind spots. Certifiably robust training provides a general, principled mechanism to avoid such blind spots by encouraging models to make correct predictions on all inputs within some known perturbation neighborhood. This type of robustness is a necessary (but not sufficient) property of models that truly understand language. We hope that our work is a stepping stone towards models that are robust against an even wider, harder-to-characterize space of possible attacks.

A Supplemental material

A.1 Additional interval bound formulas

Gowal et al. (2018) showed how to compute interval bounds for affine transformations and monotonic element-wise functions. Here, we review their derivations, for completeness.

Affine transformations. Affine transformations are the building blocks of neural networks. Suppose $z^{\text{res}} = a^\top z^{\text{dep}} + b$ for weight $a \in \mathbb{R}^m$ and bias $b \in \mathbb{R}$. z^{res} is largest when positive entries of a are multiplied with u^{dep} and negative with ℓ^{dep}:

$$\begin{aligned} u^{\text{res}} &= \underbrace{0.5(a+|a|)^\top}_{\text{positive}} u^{\text{dep}} + \underbrace{0.5(a-|a|)^\top}_{\text{negative}} \ell^{\text{dep}} + b \\ &= \mu + r, \end{aligned} \tag{9}$$

where $\mu = 0.5a^\top(\ell^{\text{dep}} + u^{\text{dep}}) + b$ and $r = 0.5|a|^\top(u-l)$. A similar computation yields that $\ell^{\text{res}} = \mu - r$. Therefore, the interval $\mathcal{O}^{\text{res}}$ can be computed using two inner product evaluations: one with a and one with $|a|$.

Monotonic scalar functions. Activation functions such as ReLU, sigmoid and tanh are monotonic. Suppose $z^{\text{res}} = \sigma(z^{\text{dep}})$ where $z^{\text{res}}, z^{\text{dep}} \in \mathbb{R}$, i.e. the node applies an element-wise function to its input. The intervals can be computed trivially since z^{res} is minimized at ℓ^{dep} and maximized at u^{dep}.

$$\ell^{\text{res}} = \sigma(\ell^{\text{dep}}), \;\; u^{\text{res}} = \sigma(u^{\text{dep}}). \tag{10}$$

A.2 Numerical stability of softmax

In this section, we show how to compute interval bounds for softmax layers in a numerically stable way. We will do this by showing how to handle log-softmax layers. Note that since softmax is just exponentiated log-softmax, and exponentiation is monotonic, bounds on log-softmax directly yield bounds on softmax.

Let z^{dep} denote a vector of length m, let c be an integer $\in \{1, \ldots, m\}$, and let z^{res} represent the log-softmax score of index c, i.e.

$$z^{\text{res}} = \log \frac{\exp(z_c^{\text{dep}})}{\sum_{j=1}^m \exp(z_j^{\text{dep}})} \tag{11}$$

$$= z_c^{\text{dep}} - \log \sum_{j=1}^m \exp(z_j^{\text{dep}}). \tag{12}$$

Given interval bounds $\ell_j \le z_j^{\text{dep}} \le u_j$ for each j, we show how to compute upper and lower bounds on z^{res}. For any vector v, we assume access to a subroutine that computes

$$\text{logsumexp}(v) = \log \sum_i \exp(v_i)$$

stably. The standard way to compute this is to normalize v by subtracting $\max_i(v_i)$ before taking exponentials, then add it back at the end. logsumexp is a standard function in libraries like PyTorch. We will also rely on the fact that if v is the concatenation of vectors u and w, then $\text{logsumexp}(v) = \text{logsumexp}([\text{logsumexp}(u), \text{logsumexp}(w)])$.

Upper bound. The upper bound u^{res} is achieved by having the maximum value of z_c^{dep}, and minimum value of all others. This can be written as:

$$u^{\text{res}} = u_c^{\text{dep}} - \log \left(\exp(u_c^{\text{dep}}) + \sum_{1 \le j \le m, j \ne c} \exp(\ell_j^{\text{dep}}) \right). \tag{13}$$

While we could directly compute this expression, it is difficult to vectorize. Instead, with some rearranging, we get

$$u^{\text{res}} = u_c^{\text{dep}} - \log \left(\exp(u_c^{\text{dep}}) - \exp(\ell_c^{\text{dep}}) + \sum_{j=1}^m \exp(\ell_j^{\text{dep}}) \right). \tag{14}$$

The second term is the logsumexp of

$$\log \left(\exp(u_c^{\text{dep}}) - \exp(\ell_c^{\text{dep}}) \right) \tag{15}$$

and

$$\text{logsumexp}(\ell^{\text{dep}}). \tag{16}$$

Since we know how to compute logsumexp, this reduces to computing (15). Note that (15) can be rewritten as

$$u_c^{\text{dep}} + \log\left(1 - \exp(\ell_c^{\text{dep}} - u_c^{\text{dep}})\right) \tag{17}$$

by adding and subtracting u_c^{dep}. To compute this quantity, we consider two cases:

1. $u_c^{\text{dep}} \gg \ell_c^{\text{dep}}$. Here we use the fact that stable methods exist to compute $\log1\text{p}(x) = \log(1+x)$ for x close to 0. We compute the desired value as

$$u_c^{\text{dep}} + \log 1p(-\exp(\ell_c^{\text{dep}} - u_c^{\text{dep}})),$$

since $\exp(\ell_c^{\text{dep}} - u_c^{\text{dep}})$ will be close to 0.

2. u_c^{dep} close to ℓ_c^{dep}. Here we use the fact that stable methods exist to compute $\text{expm1}(x) = \exp(x) - 1$ for x close to 0. We compute the desired value as

$$u_c^{\text{dep}} + \log(-\text{expm1}(\ell_c^{\text{dep}} - u_c^{\text{dep}})),$$

since $\ell_c^{\text{dep}} - u_c^{\text{dep}}$ may be close to 0.

We use case 1 if $u_c^{\text{dep}} - \ell_c^{\text{dep}} > \log 2$, and case 2 otherwise.[5]

Lower bound. The lower bound ℓ^{res} is achieved by having the minimum value of z_c^{dep}, and the maximum value of all others. This can be written as:

$$\ell^{\text{res}} = \ell_c^{\text{dep}} - \log\left(\exp(\ell_c^{\text{dep}}) + \sum_{1\le j\le m, j\neq c} \exp(u_j^{\text{dep}})\right). \tag{18}$$

The second term is just a normal logsumexp, which is easy to compute. To vectorize the implementation, it helps to first compute the logsumexp of everything except ℓ_c^{dep}, and then logsumexp that with ℓ_c^{dep}.

A.3 Attack surface differences

In Alzantot et al. (2018), the adversary applies replacements one at a time, and the neighborhoods and language model scores are computed relative to the current altered version of the input. This results in a hard-to-define attack surface, as the same word can be replaced many times, leading to semantic drift. We instead pre-compute the allowed substitutions $S(x, i)$ at index i based on the original x. We define $S(x, i)$ as the set of $\tilde{x}_i \in N(x_i)$ such that

$$\log P(x_{i-W:i-1}, \tilde{x}_i, x_{i+1:i+W}) \geq \log P(x_{i-W:i+W}) - \delta \tag{19}$$

where probabilities are assigned by a pre-trained language model, and the window radius W and threshold δ are hyperparameters. We use $W = 6$ and $\delta = 5$. We also use a different language model[6] from Alzantot et al. (2018) that achieves perplexity of 50.79 on the One Billion Word dataset (Chelba et al., 2013). Alzantot et al. (2018) use a different, slower language model, which compels them to use a smaller window radius of $W = 1$.

A.4 Experimental details

We do not run training for a set number of epochs but do early stopping on the development set instead. For normal training, we early stop on normal development set accuracy. For training with data augmentation, we early stop on the accuracy on the augmented development set. For certifiably robust training, we early stop on the certifiably robust accuracy on the development set. We use the Adam optimizer (Kingma and Ba, 2014) to train all models.

On IMDB, we restrict the model to only use the 50,000 words that are in the vocabulary of the counter-fitted word vector space of Mrkšić et al. (2016). This is because perturbations are not allowed for any words not in this vocabulary, i.e. $N(w) = \{w\}$ for $w \notin V$. Therefore, the model is strongly incentivized to predict based on words outside of this set. While this is a valid way to achieve high certified accuracy, it is not a valid robustness strategy in general. We simply delete all words that are not in the vocabulary before feeding the input to the model.

For SNLI, we use 100-dimensional hidden state for the BOW model and a 3-layer feedforward network. These values were chosen by a hyperparameter search on the dev set. For DECOMPATTN, we use a 300-dimensional hidden state and a 2-layer feedforward network on top of the context-aware vectors. These values were chosen to match Parikh et al. (2016).

[5] See https://cran.r-project.org/web/packages/Rmpfr/vignettes/log1mexp-note.pdf for further explanation.

Table 3: Training hyperparameters for training the models. The same hyperparameters were used for all training settings(plain, data augmentation, robust training)

Our implementation of the Decomposable Attention follows the original described in (Parikh et al., 2016) except for a few differences listed below;

- We do not normalize GloVe vectors to have norm 1.
- We do not hash out-of-vocabulary words to randomly generated vectors that we train, instead we omit them.
- We do randomly generate a null token vector that we then train. (Whether the null vector is trained is unspecified in the original paper).
- We use the Adam optimizer (with a learning rate of 1×10^{-4}) instead of AdaGrad.
- We use a batch size of 256 instead of 4.
- We use a dropout probability of 0.1 instead of 0.2
- We do not use the intra-sentence attention module.

A.5 Training schedule

In Table 4, we show the effect of holding ϵ or κ fixed during training, as described in Section 5.6. All numbers are on 1000 randomly chosen examples from the IMDB development set. Slowly increasing ϵ is important for good performance. Slowly increasing κ is actually slightly worse than holding $\kappa = \kappa^*$ fixed during training, despite earlier experiments we ran suggesting the opposite. Here we only report certified accuracy, as all models are trained with certifiably robust training, and certified accuracy is much faster to compute for development purposes.

A.6 Word vector bound sizes

To better understand the effect of g^{word}, we checked whether g^{word} made interval bound boxes around neighborhoods $N(w)$ smaller. For each word w with $|N(w)| > 1$, and for both the pre-trained vectors $\phi^{\text{pre}}(\cdot)$ and transformed vectors $\phi(\cdot)$, we compute

$$\frac{1}{d}\sum_{i=1}^{d}\frac{1}{\sigma_i}\left(u_w^{\text{word}} - \ell_w^{\text{word}}\right)$$

where ℓ_w^{word} and u_w^{word} are the interval bounds around either $\{\phi^{\text{pre}}(\tilde{w}) : \tilde{w} \in N(w)\}$ or $\{\phi(\tilde{w}) : \tilde{w} \in N(w)\}$, and σ_i is the standard deviation across the vocabulary of the i-th coordinate of the embeddings. This quantity measures the average width of the IBP bounds for the word vectors of w and its neighbors, normalized by the standard deviation in each coordinate. On 78.2% of words with $|N(w)| > 1$, this value was smaller for the transformed vectors learned by the CNN on IMDB with robust training, compared to the GloVe vectors. For same model with normal training, the value was smaller only 54.5% of the time, implying that robust training makes the transformation produce tighter bounds. We observed the same pattern for other model architectures as well.

System	IBP-certified (Lower bound)
BOW	68.8
$\rightarrow$ Fixed ϵ	46.6
$\rightarrow$ Fixed κ	69.8
$\rightarrow$ Fixed ϵ and κ	66.3
CNN	72.5
$\rightarrow$ Fixed ϵ	67.6
$\rightarrow$ Fixed κ	74.5
$\rightarrow$ Fixed ϵ and κ	65.3
LSTM	62.5
$\rightarrow$ Fixed ϵ	43.7
$\rightarrow$ Fixed κ	63.0
$\rightarrow$ Fixed ϵ and κ	62.0

Table 4: Effects of holding ϵ and κ fixed during training. All numbers are on 1000 randomly chosen IMDB development set examples.

A.7 Certifying long-term memory

We might expect that LSTMs are difficult to certify with IBP, due to their long computation paths. To test whether robust training can learn recurrent models that track state across many time steps, we created a toy binary classification task where the input is a sequence of words $x_1, \ldots, x_L$, and the label y is 1 if $x_1 = x_L$ and 0 otherwise. We trained an LSTM model that reads the input left-to-right, and tries to predict y with a two-layer feedforward network on top of the final hidden state. To do this task, the model must encode the first word in its state and remember it until the final timestep; a bag of words model cannot do this task. For perturbations, we allow replacing every middle word $x_2, \ldots, x_{L-1}$ with any word in the vocabulary. We use robust training on 4000 randomly generated examples, where the length of each example is sampled uniformly between 3 and 10. The model obtains 100% certified accuracy on a test set of 1000 examples, confirming that robust training can learn models that track state across many time steps.

For this experiment, we found it important to first train for multiple epochs with no certified objective, before increasing ϵ and κ. Otherwise, the model gets stuck in bad local optima. We trained for 50 epochs using the normal objective, 50 epochs increasing ϵ towards 1 and κ towards 0.5, then 17 final epochs (determined by early stopping) with these final values of ϵ and κ.[7] We leave further exploration of these learning schedule tactics to future work. We also found it necessary to use a larger LSTM—we used one with 300-dimensional hidden states.

[7] Note that this dataset is much smaller than IMDB and SNLI, so each epoch corresponds to many fewer parameter updates.

Visualizing and Understanding the Effectiveness of BERT

Abstract

Language model pre-training, such as BERT, has achieved remarkable results in many NLP tasks. However, it is unclear why the pre-training-then-fine-tuning paradigm can improve performance and generalization capability across different tasks. In this paper, we propose to visualize loss landscapes and optimization trajectories of fine-tuning BERT on specific datasets. First, we find that pre-training reaches a good initial point across downstream tasks, which leads to wider optima and easier optimization compared with training from scratch. We also demonstrate that the fine-tuning procedure is robust to overfitting, even though BERT is highly over-parameterized for downstream tasks. Second, the visualization results indicate that fine-tuning BERT tends to generalize better because of the flat and wide optima, and the consistency between the training loss surface and the generalization error surface. Third, the lower layers of BERT are more invariant during fine-tuning, which suggests that the layers that are close to input learn more transferable representations of language.

1 Introduction

Language model pre-training has achieved strong performance in many NLP tasks (Peters et al., 2018; Howard and Ruder, 2018a; Radford et al., 2018; Devlin et al., 2018; Baevski et al., 2019; Dong et al., 2019). A neural encoder is trained on a large text corpus by using language modeling objectives. Then the pre-trained model either is used to extract vector representations for input, or is fine-tuned on the specific datasets.

Recent work (Tenney et al., 2019b; Liu et al., 2019a; Goldberg, 2019; Tenney et al., 2019a) has shown that the pre-trained models can encode syntactic and semantic information of language. However, it is unclear why pre-training is effective on downstream tasks in terms of both trainability and generalization capability. In this work, we take BERT (Devlin et al., 2018) as an example to understand the effectiveness of pre-training. We visualize the loss landscapes and the optimization procedure of fine-tuning on specific datasets in three ways. First, we compute the one-dimensional (1D) loss curve, so that we can inspect the difference between fine-tuning BERT and training from scratch. Second, we visualize the two-dimensional (2D) loss surface, which provides more information about loss landscapes than 1D curves. Third, we project the high-dimensional optimization trajectory of fine-tuning to the obtained 2D loss surface, which demonstrate the learning properties in an intuitive way.

The main findings are summarized as follows. First, visualization results indicate that BERT pre-training reaches a good initial point across downstream tasks, which leads to wider optima on the 2D loss landscape compared with random initialization. Moreover, the visualization of optimization trajectories shows that pre-training results in easier optimization and faster convergence. We also demonstrate that the fine-tuning procedure is robust to overfitting. Second, loss landscapes of fine-tuning partially explain the good generalization capability of BERT. Specifically, pre-training obtains more flat and wider optima, which indicates the pre-trained model tends to generalize better on unseen data (Chaudhari et al., 2017; Li et al., 2018; Izmailov et al., 2018). Additionally, we find that the training loss surface correlates well with the generalization error. Third, we demonstrate that the lower (i.e., close to input) layers of BERT are more invariant across tasks than the higher layers, which suggests that the lower layers learn transferable representations of language. We verify the point by visualizing the loss landscape with respect to different groups of layers.

2 Background: BERT

We use BERT (Bidirectional Encoder Representations from Transformers; Devlin et al. 2018) as an example of pre-trained language models in our experiments. BERT is pre-trained on a large corpus by using the masked language modeling and next-sentence prediction objectives. Then we can add task-specific layers to the BERT model, and fine-tune all the parameters according to the downstream tasks.

BERT employs a Transformer (Vaswani et al., 2017) network to encode contextual information, which contains multi-layer self-attention blocks. Given the embeddings $\{\mathbf{x}_i\}_{i=1}^{|x|}$ of input text, we concatenate them into $\mathbf{H}^0 = [\mathbf{x}_1, \cdots, \mathbf{x}_{|x|}]$. Then, an L-layer Transformer encodes the input: $\mathbf{H}^l = \mathrm{Transformer_block}_l(\mathbf{H}^{l-1})$, where $l = 1, \cdots, L$, and $\mathbf{H}^L = [\mathbf{h}_1^L, \cdots, \mathbf{h}_{|x|}^L]$. We use the hidden vector $\mathbf{h}_i^L$ as the contextualized representation of the input token x_i. For more implementation details, we refer readers to Vaswani et al. (2017).

3 Methodology

We employ three visualization methods to understand why fine-tuning the pre-trained BERT model can achieve better performance on downstream tasks compared with training from scratch. We plot both one-dimensional and two-dimensional loss landscapes of BERT on the specific datasets. Besides, we project the optimization trajectories of the fine-tuning procedure to the loss surface. The visualization algorithms can also be used for the models that are trained from random initialization, so that we can compare the difference between two learning paradigm.

3.1 One-dimensional Loss Curve

Let $\boldsymbol{\theta}_0$ denote the initialized parameters. For fine-tuning BERT, $\boldsymbol{\theta}_0$ represents the the pre-trained parameters. For training from scratch, $\boldsymbol{\theta}_0$ represents the randomly initialized parameters. After fine-tuning, the model parameters are updated to $\boldsymbol{\theta}_1$. The one-dimensional (1D) loss curve aims to quantify the loss values along the optimization direction (i.e., from $\boldsymbol{\theta}_0$ to $\boldsymbol{\theta}_1$).

The loss curve is plotted by linear interpolation between $\boldsymbol{\theta}_0$ and $\boldsymbol{\theta}_1$ (Goodfellow and Vinyals, 2015). The curve function $f(\alpha)$ is defined as:

$$f(\alpha) = \mathcal{J}(\boldsymbol{\theta}_0 + \alpha\boldsymbol{\delta}_1) \tag{1}$$

where α is a scalar parameter, $\boldsymbol{\delta}_1 = \boldsymbol{\theta}_1 - \boldsymbol{\theta}_0$ is the optimization direction, and $\mathcal{J}(\boldsymbol{\theta})$ is the loss function under the model parameters $\boldsymbol{\theta}$. In our experiments, we set the range of α to $[-4, 4]$ and sample 40 points for each axis. Note that we only consider the parameters of BERT in $\boldsymbol{\theta}_0$ and $\boldsymbol{\theta}_1$, so $\boldsymbol{\delta}_1$ only indicates the updates of the original BERT parameters. The effect of the added task-specific layers is eliminated by keeping them fixed to the learned values.

3.2 Two-dimensional Loss Surface

The one-dimensional loss curve can be extended to the two-dimensional (2D) loss surface (Li et al., 2018). Similar as in Equation (1), we need to define two directions ($\boldsymbol{\delta}_1$ and $\boldsymbol{\delta}_2$) as axes to plot the loss surface:

$$f(\alpha, \beta) = \mathcal{J}(\boldsymbol{\theta}_0 + \alpha\boldsymbol{\delta}_1 + \beta\boldsymbol{\delta}_2) \tag{2}$$

where α, β are scalar values, $\mathcal{J}(\cdot)$ is the loss function, and $\boldsymbol{\theta}_0$ represents the initialized parameters. Similar to Section 3.1, we are only interested in the parameter space of the BERT encoder, without taking into consideration task-specific layers. One of the axes is the optimization direction $\boldsymbol{\delta}_1 = \boldsymbol{\theta}_1 - \boldsymbol{\theta}_0$ on the target dataset, which is defined in the same way as in Equation (1). We compute the other axis direction via $\boldsymbol{\delta}_2 = \boldsymbol{\theta}_2 - \boldsymbol{\theta}_0$, where $\boldsymbol{\theta}_2$ represents the fine-tuned parameters on another dataset. So the other axis is the optimization direction of fine-tuning on another dataset. Even though the other dataset is randomly chosen, experimental results confirm that the optimization directions $\boldsymbol{\delta}_1, \boldsymbol{\delta}_2$ are divergent and orthogonal to each other because of the high-dimensional parameter space.

The direction vectors $\boldsymbol{\delta}_1$ and $\boldsymbol{\delta}_2$ are projected onto a two-dimensional plane. It is beneficial to ensure the scale equivalence of two axes for visualization purposes. Similar to the filter normalization approach introduced in (Li et al., 2018), we address this issue by normalizing two direction vectors to the same norm. We re-scale $\boldsymbol{\delta}_2$ to $\frac{\|\boldsymbol{\delta}_1\|}{\|\boldsymbol{\delta}_2\|}\boldsymbol{\delta}_2$, where $\|\cdot\|$ denotes the Euclidean norm. We set the range of both α and β to $[-4, 4]$ and sample 40 points for each axis.

3.3 Optimization Trajectory

Our goal is to project the optimization trajectory of the fine-tuning procedure onto the 2D loss surface obtained in Section 3.2. Let $\{(d_i^\alpha, d_i^\beta)\}_{i=1}^T$ denote the projected optimization trajectory, where

(d_i^α, d_i^β) is a projected point in the loss surface, and $i = 1, \cdots, T$ represents the i-th epoch of fine-tuning.

As shown in Equation (2), we have known the optimization direction $\boldsymbol{\delta}_1 = \boldsymbol{\theta}_1 - \boldsymbol{\theta}_0$ on the target dataset. We can compute the deviation degrees between the optimization direction and the trajectory to visualize the projection results. Let $\boldsymbol{\theta}^i$ denote the BERT parameters at the i-th epoch, and $\boldsymbol{\delta}^i = \boldsymbol{\theta}^i - \boldsymbol{\theta}_0$ denote the optimization direction at the i-th epoch. The point (d_i^α, d_i^β) of the trajectory is computed via:

$$v_{cos} = \frac{\boldsymbol{\delta}^i \times \boldsymbol{\delta}_1}{\|\boldsymbol{\delta}^i\| \cdot \|\boldsymbol{\delta}_1\|} \tag{3}$$

$$d_i^\alpha = v_{cos} \frac{\left\|\boldsymbol{\delta}^i\right\|}{\|\boldsymbol{\delta}_1\|} = \frac{\boldsymbol{\delta}^i \times \boldsymbol{\delta}_1}{\|\boldsymbol{\delta}_1\|^2} \tag{4}$$

$$d_i^\beta = \sqrt{(\frac{\|\boldsymbol{\delta}^i\|}{\|\boldsymbol{\delta}_1\|})^2 - (d_i^\alpha)^2} \tag{5}$$

where $\times$ denotes the cross product of two vectors, and $\|\cdot\|$ denotes the Euclidean norm. To be specific, we first compute cosine similarity between $\boldsymbol{\delta}^i$ and $\boldsymbol{\delta}_1$, which indicates the angle between the current optimization direction and the final optimization direction. Then we get the projection values d_i^α and d_i^β by computing the deviation degrees between the optimization direction $\boldsymbol{\delta}^i$ and the axes.

4 Experimental Setup

We conduct experiments on four datasets: Multi-genre Natural Language Inference Corpus (MNLI; Williams et al. 2018), Recognizing Textual Entailment (RTE; Dagan et al. 2006; Bar-Haim et al. 2006; Giampiccolo et al. 2007; Bentivogli et al. 2009), Stanford Sentiment Treebank (SST-2; Socher et al. 2013), and Microsoft Research Paraphrase Corpus (MRPC; Dolan and Brockett 2005). We use the same data split as in (Wang et al., 2019). The accuracy metric is used for evaluation.

We employ the pre-trained BERT-large model in our experiments. The cased version of tokenizer is used. We follow the settings and the hyper-parameters suggested in (Devlin et al., 2018). The Adam (Kingma and Ba, 2015) optimizer is used for fine-tuning. The number of fine-tuning epochs is selected from $\{3, 4, 5\}$. For RTE and MRPC, we set the batch size to 32, and the learning rate to 1e-5. For MNLI and SST-2, the batch size is 64, and the learning rate is 3e-5.

For the setting of training from scratch, we use the same network architecture as BERT, and randomly initialize the model parameters. Most hyper-parameters are kept the same. The number of training epochs is larger than fine-tuning BERT, because training from scratch requires more epochs to converge. The number of epochs is set to 8 for SST-2, and 16 for the other datasets, which is validated on the development set.

5 Pre-training Gets a Good Initial Point Across Downstream Tasks

Fine-tuning BERT on the usually performs significantly better than training the same network with random initialization, especially when the data size is small. Results indicate that language model pre-training objectives learn good initialization for downstream tasks. In this section, we inspect the benefits of using BERT as the initial point from three aspects.

5.1 Pre-training Leads to Wider Optima

As described in Section 3.2, we plot 2D training loss surfaces on four datasets in Figure 1. The figures in the top row are the models trained from scratch, while the others in bottom are based on fine-tuning BERT. The start point indicates the training loss of the initialized model, while the end point indicates the final training loss. We observe that the optima obtained by fine-tuning BERT are much wider than training from scratch. A wide optimum of fine-tuning BERT implicates that the small perturbations of the model parameters cannot hurt the final performance seriously, while a thin optimum is more sensitive to these subtle changes. Moreover, in Section 6.1, we further discuss about the width of the optima can contribute to the generalization capability.

As shown in Figure 1, the fine-tuning path from the start point to the end point on the loss landscape is more smooth than training from scratch. In other words, the training loss of fine-tuning BERT tends to monotonously decrease along the optimization direction, which eases optimization and accelerates training convergence. In contrast, the path from random initial point to the end point is more rough, which requires a more carefully tweaked optimizer to obtain reasonable performance.

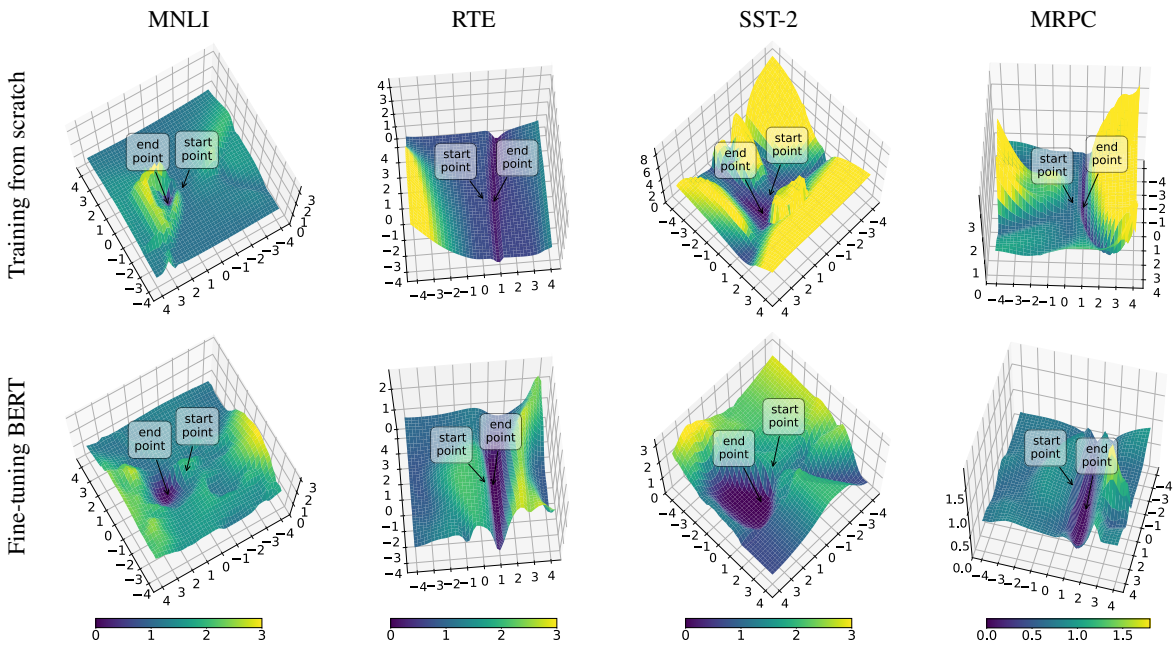

Figure 1: Training loss surfaces of training from scratch (top) and fine-tuning BERT (bottom) on four datasets. We annotate the start point (i.e., initialized model) and the end point (i.e., estimated model) in the loss surfaces. Pre-training leads to wider optima, and eases optimization compared with random initialization.

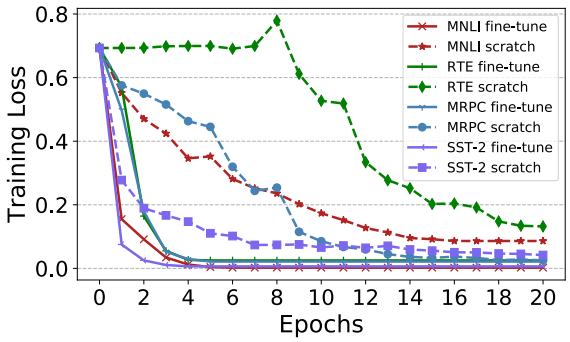

Figure 2: Training loss of fine-tuning BERT and training from scratch on four datasets.

5.2 Pre-training Eases Optimization on Downstream Tasks

We fine-tune BERT and train the same network from scratch on four datasets. The learning curves are shown in Figure 2. We find that training from scratch requires more iterations to converge on the datasets, while pre-training-then-fine-tuning converges faster in terms of training loss. We also notice that the final loss of training from scratch tends to be higher than fine-tuning BERT, even if it undergoes more epochs. On the RTE dataset, training the model from scratch has a hard time decreasing the loss in the first few epochs.

In order to visualize the dynamic convergence process, we plot the optimization trajectories using the method described in Section 3.3. As shown in Figure 3, for training from scratch, the optimization directions of the first few epochs are divergent from the final optimization direction. Moreover, the loss landscape from the initial point to the end point is more rough than fine-tuning BERT, we can see that the trajectory of training from scratch on the MRPC dataset crosses an obstacle to reach the end point.

Compared with training from scratch, fine-tuning BERT finds the optimization direction in a more straightforward way. The optimization process also converges faster. Besides, the fine-tuning path is unimpeded along the optimization direction. In addition, because of the wider optima near the initial point, fine-tuning BERT tends to reach the expected optimal region even if it optimizes along the direction of the first epoch.

5.3 Pre-training-then-fine-tuning is Robust to Overfitting

The BERT-large model has 345M parameters, which is over-parameterized for the target datasets. However, experimental results show fine-tuning BERT is robust to over-fitting, i.e., the generalization error (namely, the classification error rate on the development set) does not dramatically increase for more training epochs, despite the huge number of model parameters.

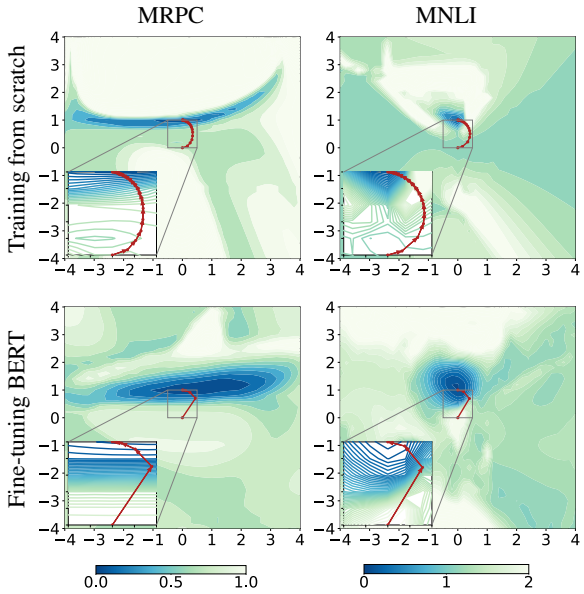

Figure 3: The optimization trajectories on the training loss surfaces of training from scratch (top) and fine-tuning BERT (bottom) on the MRPC and MNLI datasets. Darker color represents smaller training loss.

We use the MRPC dataset as a case study, because its data size is relatively small, which is prone to overfitting if we train the model from scratch. As shown in Figure 4, we plot the optimization trajectory of fine-tuning on the generalization error surface. We first fine-tune the BERT model for five epochs as suggested in (Devlin et al., 2018). Then we continue fine-tuning for another twenty epochs, which still obtains comparable performance with the first five epochs. Figure 4 shows that even though we fine-tune the BERT model for twenty more epochs, the final estimation is not far away from its original optimum. Moreover, the optimum area is wide enough to avoid the model from jumping out the region with good generalization capability, which explains why the pre-training-then-fine-tuning paradigm is robust to overfitting.

6 Pre-training Helps to Generalize Better

Although training from scratch can achieve comparable training losses as fine-tuning BERT, the model with random initialization usually has poor performance on the unseen data. In this section, we use visualization techniques to understand why the model obtained by pre-training-then-fine-tuning tends to have better generalization capability.

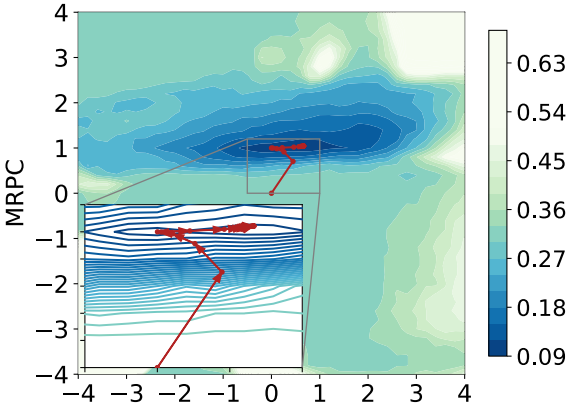

Figure 4: The optimization trajectory of fine-tuning $5 + 20$ epochs on MRPC. The two-dimensional generalization error surface is presented. We find that pre-training-then-fine-tuning is robust to overfitting.

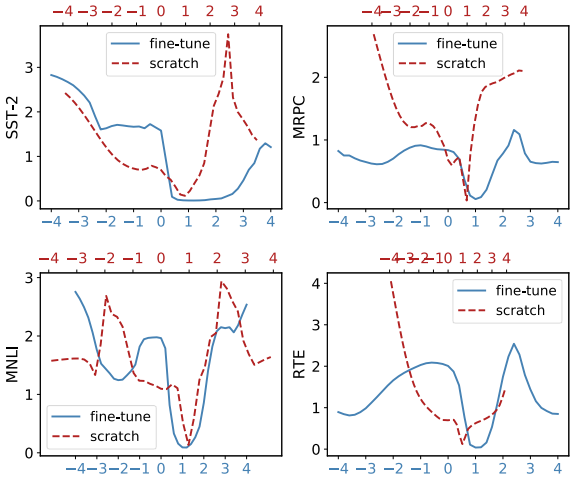

Figure 5: One-dimensional training loss curves. Dash lines represent training from scratch, and solid lines represent fine-tuning BERT. The scales of axes are normalized for comparison. The optima of training from scratch are sharper than fine-tuning BERT.

6.1 Wide and Flat Optima Lead to Better Generalization

Previous work (Hochreiter and Schmidhuber, 1997; Keskar et al., 2016; Li et al., 2018) shows that the flatness of a local optimum correlates with the generalization capability, i.e., more flat optima lead to better generalization. The finding inspires us to inspect the loss landscapes of BERT fine-tuning, so that we can understand the generalization capability from the perspective of the flatness of optima.

Section 5.1 presents that the optima obtained by fine-tuning BERT are wider than training from scratch. As shown in Figure 5, we further plot one-dimensional training loss curves of

both fine-tuning BERT and training from scratch, which represents the transverse section of two-dimensional loss surface along the optimization direction. We normalize the scale of axes for flatness comparison as suggested in (Li et al., 2018). Figure 5 shows that the optima of fine-tuning BERT are more flat, while training from scratch obtains more sharp optima. The results indicate that pre-training-then-fine-tuning tends to generalize better on unseen data.

6.2 Consistency Between Training Loss Surface and Generalization Error Surface

To further understand the effects of geometry of loss functions to the generalization capability, we make comparisons between the training loss surfaces and the generalization error surfaces on different datasets. The classification error rate on the development set is used as an indicator of the generalization capability.

As shown in Figure 6, we find the end points of fine-tuning BERT fall into the wide areas with smaller generalization error. The results show that the generalization error surfaces are consistent with the corresponding training loss surfaces on the datasets, i.e., smaller training loss tends to decrease the error on the development set. Moreover, the fine-tuned BERT models tend to stay approximately optimal under subtle perturbations. The visualization results also indicate that it is preferred to converge to wider and more flat local optima, as the training loss surface and the generalization error surface are shifted with respect to each other (Izmailov et al., 2018). In contrast, training from scratch obtains thinner optimum areas and poorer generalization than fine-tuning BERT, especially on the datasets with relatively small data size (such as MRPC, and RTE). Intuitively, the thin and sharp optima on the training loss surfaces are hard to be migrated to the generalization surfaces.

For training from scratch, it is not surprising that on larger datasets (such as MNLI, and SST-2) the generalization error surfaces are more consistent with the training loss surfaces. The results suggest that training the model from scratch usually requires more training examples to generalize better compared with fine-tuning BERT.

7 Lower Layers of BERT are More Invariant and Transferable

The BERT-large model has 24 layers. Different layers could have learned different granularities or perspectives of language during the pre-training procedure. For example, Tenney et al. (2019a) observe that most local syntactic phenomena are encoded in lower layers while higher layers capture more complex semantics. They also show that most examples can be classified correctly in the first few layers. From above, we conjecture that lower layers of BERT are more invariant and transferable across tasks.

We divide the layers of the BERT-large model into three groups: low layers (0th-7th layer), middle layers (8th-15th layer), and high layers (16th-23rd layer). As shown in Figure 7, we plot the two-dimensional loss surfaces with respect to different groups of layers (i.e., parameter subspace instead of all parameters) around the fine-tuned point. To be specific, we modify the loss surface function in Section 3.2 to $f(\alpha, \beta) = \mathcal{J}(\boldsymbol{\theta}_1 + \alpha\boldsymbol{\delta}_1^G + \beta\boldsymbol{\delta}_2^G)$, where $\boldsymbol{\theta}_1$ represents the fine-tuned parameters, $G \in \{\text{low layers, middle layers, high layers}\}$, and the optimization direction of the layer group is used as the axis. On the visualized loss landscapes, $f(0, 0)$ corresponds to the loss value at the fine-tuned point. Besides, $f(-1, 0)$ corresponds to the loss value with the corresponding layer group rollbacked to its original values in the pre-trained BERT model.

Figure 7 shows that the loss surface with respect to lower layers has the wider local optimum along the optimization direction. The results demonstrate that rollbacking parameters of lower layers to their original values (the star-shaped points in Figure 7) does not dramatically hurt the model performance. In contrast, rollbacking high layers makes the model fall into the region with high loss. This phenomenon indicates that the optimization of high layers is critical to fine-tuning whereas lower layers are more invariant and transferable across tasks.

In order to make a further verification, we rollback different layer groups of the fine-tuned model to the parameters of the original pre-trained BERT model. The accuracy results on the development set are presented in Table 1. Similar to Figure 7, the generalization capability does not dramatically decrease after rollbacking low layers or middle layers. Rollbacking low layers (0th-7th layer)

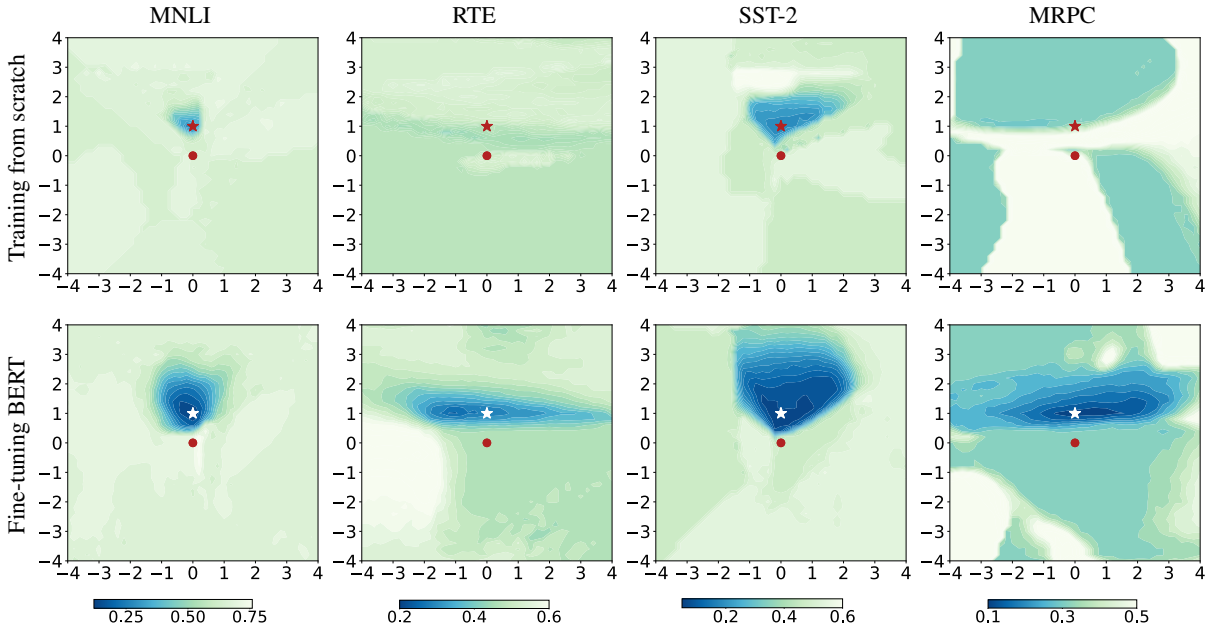

Figure 6: Two-dimensional generalization error surfaces of training from scratch (top) and fine-tuning BERT (bottom). The dot-shaped point and the star-shaped point indicate the generalization errors at the beginning and at the end of the training procedure, respectively.

Dataset	BERT	Layer Rollback		
		0-7	8-15	16-23
MNLI	86.54	86.73 (+0.19)	84.71 (-1.83)	32.85 (-53.88)
RTE	75.45	73.29 (-2.16)	70.04 (-5.41)	47.29 (-28.16)
SST-2	94.04	93.69 (-0.35)	93.12 (-0.92)	59.29 (-34.75)
MRPC	90.20	87.99 (-2.21)	80.15 (-10.05)	78.17 (-12.03)

Table 1: Accuracy on the development sets. The second column represents the fine-tuned BERT models on the specific datasets. The last column represents the fine-tuned models with rollbacking different groups of layers.

even improves the generalization capability on the MNLI dataset. By contrast, rollbacking high layers hurts the model performance. Evaluation results suggest that low layers that are close to input learn more transferable representations of language, which makes them more invariant across tasks. Moreover, high layers seem to play a more important role in learning task-specific information during fine-tuning.

8 Related Work

Pre-trained contextualized word representations learned from language modeling objectives, such as CoVe (McCann et al., 2017), ELMo (Peters et al., 2018), ULMFit (Howard and Ruder, 2018b), GPT (Radford et al., 2018, 2019), and BERT (Devlin et al., 2018), have shown strong performance on a variety of natural language processing tasks.

Recent work of inspecting the effectiveness of the pre-trained models (Linzen et al., 2016; Kuncoro et al., 2018; Tenney et al., 2019b; Liu et al., 2019a) focuses on analyzing the syntactic and semantic properties. Tenney et al. (2019b) and Liu et al. (2019a) suggest that pre-training helps the models to encode much syntactic information and many transferable features through evaluating models on several probing tasks. Goldberg (2019) assesses the syntactic abilities of BERT and draws the similar conclusions. Our work explores the effectiveness of pre-training from another angle. We propose to visualize the loss landscapes and optimization trajectories of the BERT fine-tuning procedure. The visualization results help us to understand the benefits of pre-training in a more intuitive way. More importantly, the geometry of loss landscapes partially explains why fine-tuning

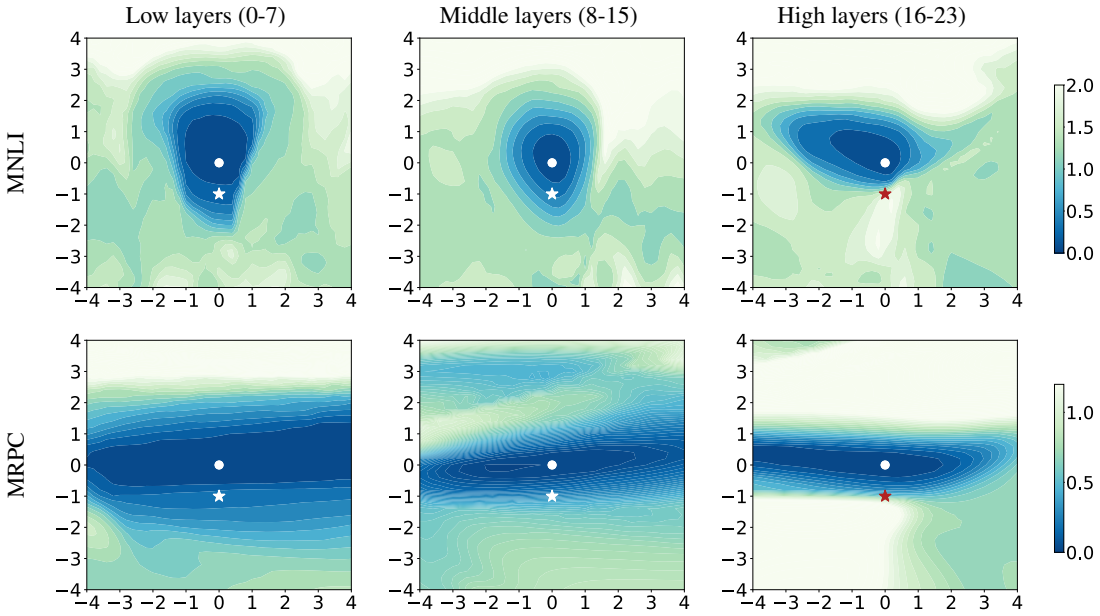

Figure 7: Layer-wise training loss surfaces on the MNLI dataset (top) and the MRPC dataset (bottom). The dot-shaped point represents the fine-tuned model. The star-shaped point represents the model with rollbacking different layer groups. Low layers correspond to the 0th-7th layers of BERT, middle layers correspond to the 8th-15th layers, and high layers correspond to the 16th-23rd layers.

BERT can achieve better generalization capability than training from scratch.

Liu et al. (2019a) find that different layers of BERT exhibit different transferability. Peters et al. (2019) show that the classification tasks build up information mainly in the intermediate and last layers of BERT. Tenney et al. (2019a) observe that low layers of BERT encode more local syntax, while high layers capture more complex semantics. Zhang et al. (2019) also show that not all layers of a deep neural model have equal contributions to model performance. We draw the similar conclusion by visualizing layer-wise loss surface of BERT on downstream tasks. Besides, we find that low layers of BERT are more invariant and transferable across datasets.

In the computer vision community, many efforts have been made to visualize the loss function, and figure out how the geometry of a loss function affects the generalization (Goodfellow and Vinyals, 2015; Im et al., 2016; Li et al., 2018). Hochreiter and Schmidhuber (1997) define the flatness as the size of the connected region around a minimum. Keskar et al. (2016) characterize the definition of flatness using eigenvalues of the Hessian, and conclude that small-batch training converges to flat minima, which leads to good generalization. Li et al. (2018) propose a filter normalization method to reduce the influence of parameter scale, and show that the sharpness of a minimum correlates well with generalization capability. The assumption is also used to design optimization algorithms (Chaudhari et al., 2017; Izmailov et al., 2018), which aims at finding broader optima with better generalization than standard SGD.

9 Conclusion

We visualize the loss landscapes and optimization trajectories of the BERT fine-tuning procedure, which aims at inspecting the effectiveness of language model pre-training. We find that pre-training leads to wider optima on the loss landscape, and eases optimization compared with training from scratch. Moreover, we give evidence that the pre-training-then-fine-tuning paradigm is robust to overfitting. We also demonstrate the consistency between the training loss surfaces and the generalization error surfaces, which explains why pre-training improves the generalization capability. In addition, we find that low layers of the BERT model are more invariant and transferable across tasks.

All our experiments and conclusions were derived from BERT fine-tuning. A further understanding of how multi-task training with BERT (Liu et al., 2019b) improves fine-tuning, and how it affects the geometry of loss surfaces are worthy of exploration, which we leave to future

work. Moreover, the results motivate us to develop fine-tuning algorithms that converge to wider and more flat optima, which would lead to better generalization on unseen data. In addition, we would like to apply the proposed methods for other pre-trained models.

Abstract

Despite impressive performance on many text classification tasks, deep neural networks tend to learn frequent superficial patterns that are specific to the training data and do not always generalize well. In this work, we observe this limitation with respect to the task of *native language identification*. We find that standard text classifiers which perform well on the test set end up learning topical features which are confounds of the prediction task (e.g., if the input text mentions Sweden, the classifier predicts that the author's native language is Swedish). We propose a method that represents the latent topical confounds and a model which "unlearns" confounding features by predicting both the label of the input text and the confound; but we train the two predictors adversarially in an alternating fashion to learn a text representation that predicts the correct label but is less prone to using information about the confound. We show that this model generalizes better and learns features that are indicative of the writing style rather than the content.[1]

1 Introduction

Text classification systems based on neural networks are biased towards learning frequent spurious correlations in the training data that may be confounds in the actual classification task (Leino et al., 2019). A major challenge in building such systems is to discover features that are not just correlated with the signals in the training data, but are true indicators of these signals, and therefore generalize well.

For example, Kiritchenko and Mohammad (2018) found that sentiment analysis systems implicitly overfit to demographic confounds, systematically amplifying the intensity ratings of posts written by women. Zhao et al. (2017) showed that visual semantic role labeling models implicitly capture actions stereotypically associated with men or women (e.g., *women are cooking* and *men are fixing a faucet*), and in cases of higher model uncertainty assign stereotypical labels to actions and objects, thereby amplifying social biases found in the training data.

We focus on the task of *native language identification* (L1ID), which aims at automatically identifying the native language (L1) of an individual based on their language production in a second language (L2, English in this work). The aim of this task is to discover stylistic features present in the input that are indicative of the author's L1. However, a model trained to predict L1 is likely to predict that a person is, say, a native Greek speaker, if the texts authored by that person mention Greece, because the training data exhibits such topical correlations (§2).

This problem is the focus of our work, and we address it in two steps. First, we introduce a novel method for representing *latent* confounds. Recent relevant work in the area of domain adaptation (Ganin et al., 2016) and deconfounding for text classification (Pryzant et al., 2018; Elazar and Goldberg, 2018) assumes that the set of confounds is known a priori, and their values are given as part of the training data. This is an unrealistic setting that limits the applicability of such models in real world scenarios. In contrast, we introduce a new method, based on log-odds ratio with Dirichlet prior (Monroe et al., 2008), for identifying and representing latent confounds as probability distributions (§3). Second, we propose a novel alternating learning procedure with multiple adversarial discriminators, inspired by adversarial learning (Goodfellow et al., 2014), that demotes latent confounds and results in textual representations that are invariant to the confounds (§4).

[1]The code is available at: https://github.com/Sachin19/adversarial-classify

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4153–4163,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Note that these two proposals are task-independent and can be extended to a vast array of text classification tasks where confounding factors are not known a priori. For concreteness, however, we evaluate our approach on the task of L1ID (§5). We experiment with two different datasets: a small corpus of student written essays (Malmasi et al., 2017) and a large and noisy dataset of Reddit posts (Rabinovich et al., 2018). We show that classifiers trained on these datasets without any intervention learn spurious topical correlations that are not indicative of style, and that our proposed deconfounded classifiers alleviate this problem (§6). We present an analysis of the features discovered after demoting these confounds in §7.

The main contributions of this work are:

1. We introduce a novel method for representing and identifying variables which are confounds in text classification tasks.

2. We propose a classification model and an algorithm aimed at learning textual representations that are invariant to the confounding variable.

3. We introduce a novel approach to adversarial training with multiple adversaries, to alleviate the problem of drifting parameters during alternating classifier–adversary optimization.

4. Finally, we analyze some linguistic features that are not only predictive of the author's L1 but are also devoid of topical bias.

2 Motivation

We study the general effect of *topical* confounds in text classification. To motivate the need to demote them, we introduce as a case study the L1ID task, in which the goal is to predict the native language of a writer given their texts in L2.

We begin with a subset of the L2-Reddit corpus (Rabinovich et al., 2018), consistsing of Reddit posts by authors with 23 different L1s, most of them European languages. Some of the posts come from Europe-related forums (e.g. r/Europe, r/AskEurope, r/EuropeanCulture), whereas others are from unrelated forums. We view the latter as out-of-domain data and use them to evaluate the generalization of our models. We use a subset of this corpus, with only the 10 most frequent L1s, to guarantee a large enough balanced training set. We remove all the posts with fewer than 50 words and sample the dataset to obtain a balanced distribution of labels: from this balanced dataset, we randomly sample 20% of examples from each class and divide them equally to create development and test sets. In total, there are around 260,000 examples in the training set and 32,000 examples each in the development, the in-domain test set, and the out-of-domain test set.

We trained a standard (non-adversarial) classifier, with a bidirectional LSTM encoder followed by two feedforward layers with a $\tanh$ activation function and a softmax in the final layer (full experimental details are given in §5.2). We refer to this model as NO-ADV. The results are shown in Table 1. Notice the huge drop in accuracy on the out-of-domain data, which indicates that the model is learning topical features.

To further verify this claim, we used *log-odds ratio with Dirichlet prior* (Monroe et al., 2008)—a common way to identify words that are statistically overrepresented in a particular population compared to others—to identify the top-K words that were most strongly associated with a specific L1 in the training set. (We refer the reader to (Monroe et al., 2008) for the details about the algorithm.) We experimented with $K \in \{20, 50, 100, 200\}$. Table 2 shows the top-10 words in each class; observe that almost all of these words are geographical (hence, topical) terms that have nothing to do with the L1.

Next, we masked such topical words (by replacing them with a special token) and evaluate the trained classifier on masked test sets. Accuracy (Table 1) degrades on both the in-domain and out-of-domain sets, even when only 20 words are removed. The drop in accuracy with the out-of-domain dataset is smaller since these data do not include many instances where the presence of topical words would help in identifying the label. These experiments confirm our hypothesis that the baseline classifier is primarily learning topical correlations, and motivate the need for a deconfounded classification approach which we describe next.

	In-Domain	**Out-of-Domain**
NO-ADV	52.5	25.7
+MASK TOP-20	32.8	21.0
+MASK TOP-50	31.6	20.4
+MASK TOP-100	30.1	19.7
+MASK TOP-200	28.5	18.7

Table 1: Motivation: accuracy (%) of L1ID on the L2-Reddit dataset.

3 Representing Confounds

Latent Dirichlet allocation (LDA; Blei et al., 2003) is a probabilistic generative model for discovering abstract topics that occur in a collection of documents. Under LDA, each document can be considered a mixture of a small (fixed) number of topics—each represented as a distribution over words—and each word's presence is assumed to be attributed to one of the document's topics. More precisely, LDA assigns each document a probability distribution over a fixed number of topics K.

LDA topics are known to be poor features for classification (McAuliffe and Blei, 2008), indicating that they do not encode all the topical information. Moreover, they can encode information which is not actually topical and can be a useful L1 marker. Motivated by our case study (§2), we propose a novel method to represent topic distributions, based on log-odds scores (Monroe et al., 2008), and compare it to LDA as a baseline.

For each class label y and each word type w, we calculate a log-odds score $lo(w, y) \in \mathbb{R}$. The higher this score, the stronger the association between the class and the word. As we saw in §2, the highest scored words are mostly topical and hence constitute superficial features which we want the classification model to "unlearn." We therefore define a distribution which assigns high probability to a document containing these high scoring words. For a label $y \in \mathcal{Y}$ and an input document $x = \langle w_1, \ldots, w_n \rangle$, we define $p(y \mid x)$:

$$p(y \mid x) \propto p(y) \cdot p(x \mid y) = p(y) \cdot \prod_{i=1}^{n} p(w_i \mid y)$$

The above expansion assumes a bag of words representation. When the dataset is balanced, $p(y)$ is equal for each label and can be omitted. Finally, we define $p(w_i \mid y) \propto \sigma(lo(w_i, y))$, where $\sigma(.)$ is the sigmoid function, which squashes the log-odds scores (whose values are in $\mathbb{R}$) to the range $[0, 1]$. We normalize the sigmoid values over the vocabulary to convert them to a probability distribution. In this distribution, the number of "topics" equals the number of labels, m.

4 Deconfounded Text Classification

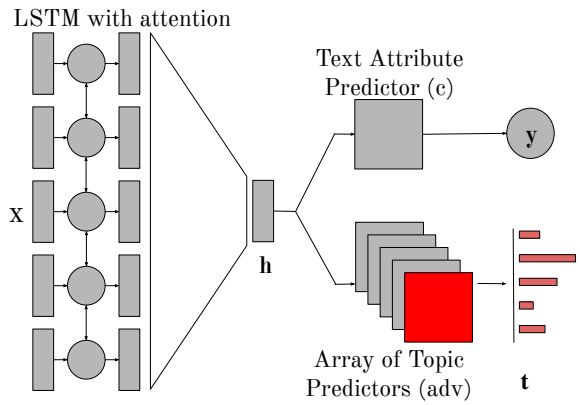
We now formalize the task setup and the classification model. We are given N labeled documents in the training set $\{(x_1, y_1), (x_2, y_2), \ldots, (x_N, y_N)\}$, where x_i is a document with label $y_i \in \mathcal{Y}$, where $m = |\mathcal{Y}|$ is the number of labels. For each document x_i, we represent latent (topical) confounds—domain-specific and superficial document features—as a K-dimensional multinomial distribution $t_i \in \{(t_1, \ldots, t_K) \mid \sum_{j=1}^{K} t_j = 1\}$. In our task, the confounds are *topics*, so that each t_j represents the proportion of document i associated with topic j but these topics are not given a priori. In this work, the number of topics K, equals m, but the methods presented in this work are valid for any number of topics.

Our goal is to train a classifier f, parameterized by θ, which learns to accurately predict the target label, while ignoring superficial topical correlations present in the training set. That is, for a text x we wish to predict $\hat{y} = f_\theta(x)$ which doesn't encode any information about t. Following Ganin et al. (2016), Pryzant et al. (2018), and Elazar and Goldberg (2018), we input x to an encoder neural network $h(x; \theta_h)$ to obtain a hidden representation $\mathbf{h}_x$ (see Figure 1), followed by two feedforward networks: (1) $c(h(x); \theta_c)$ to predict the label y; and (2) an adversary network $\text{adv}(h(x); \theta_a)$ to predict the topics. Departing from prior work which used predefined binary confounds, our adversary predicts the topic distribution t. If $\mathbf{h}_x$ does not encode any information to predict t, then $c(h(x))$ will not depend on t. Concretely, we want to optimize the following quantity:

$$\min_{c,h} \frac{1}{N} \sum_{i=1}^{N} \text{CE}(c(h(x_i)), y_i) + \text{CE}(\text{adv}_h^*(h(x_i)), \mathbb{U}_K)$$

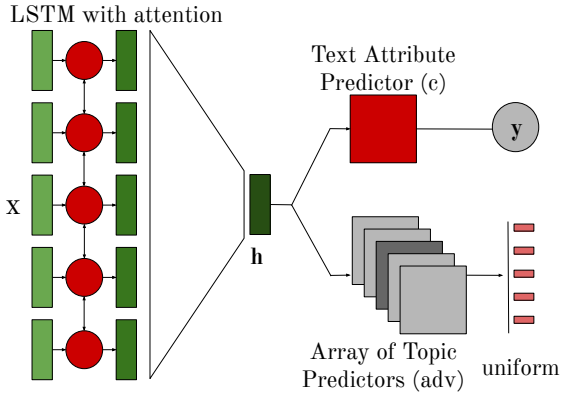
where CE denotes cross-entropy loss, and

$$\text{adv}_h^* = \arg\min_{\text{adv}} \frac{1}{N} \sum_{i=1}^{N} \text{CE}(\text{adv}(h(x_i)), t_i),$$



and $\mathbb{U}_K = (\frac{1}{K}, \ldots, \frac{1}{K})$. This objective seeks a representation $\mathbf{h}_x$ which is maximally predictive of the class label but not of the topical distribution (ideally, it should output a uniform topic distribution for every input).

4.1 Learning Schedule: Alternating Optimization of Classifier and Adversary



In practice, this optimization is done in an alternating fashion by minimizing the following two

English	ireland irish british britain russia scotland england states american london brexit
Finnish	finland finnish finns helsinki swedish finn nordic sweden sauna nokia estonian
French	french france paris sarkozy macron fillon hollande gaulle hamon marine valls breton
German	german germany austria merkel refugees asylum germans bavaria austrian berlin also
Greece	greek greece greeks syriza macedonia athens turkey macedonians fyrom turkish ancient
Dutch	dutch netherlands amsterdam wilders rotterdam holland rutte belgium bike hague
Polish	poland polish poles warsaw lithuanian lithuania judges jews ukranians imho tusk
Romanian	romania romanian romanians moldova bucharest hungarian hungarians transistria
Spanish	spain catalan spanish catalonia catalans madrid barcelona independence spaniards
Swedish	sweden swedish swedes stockholm swede malmo danish nordic denmark finland

Table 2: Top words based on log-odds scores for each label in the L2-Reddit dataset.

(a) Weights of the LSTM and of the discriminator are fixed. A new topic predictor is trained by minimizing the cross entropy of the output and the distribution of the input document over latent topics as described in §3.

(b) Weights of all the topic predictors are fixed, but the encoder is trained. The model is jointly minimizing the cross-entropy of the classifier and encouraging the topic predictor toward uniformity.

Figure 1: We alternate between training the topic predictor (left; (1)) and the deconfounded classifier/encoder (right; (2)). Pretraining is not shown in the figure.

quantities:

$$\min_{\text{adv}} \frac{1}{N} \sum_{i=1}^{N} \text{CE}(\text{adv}(h(x_i)), t_i) \quad (1)$$

$$\min_{c,h} \frac{1}{N} \sum_{i=1}^{N} \text{CE}(c(h(x_i)), y_i) + \text{CE}(\text{adv}(h(x_i)), \mathbb{U}_K) \quad (2)$$

The training schedule is critical in adversarial setups where the loss has two competing terms (Mescheder et al., 2018; Arjovsky and Bottou, 2017; Roth et al., 2017); here, these terms minimize classification loss while maximizing the topic prediction loss. Algorithm 1 details our proposed alternating learning procedure.

Inspired by generative adversarial networks (GANs; Goodfellow et al., 2014), the training procedure alternates between training the classifier and the adversary (see Figure 1). First (*pretraining*), we train the encoder along with the classifier using only classification loss, until convergence. After pretraining, $\mathbf{h}_x$ has encoded topical information which it uses for classification (as shown in our analysis in §2). Now, we train only $\text{adv}(h(x))$ to (accurately) predict t, keeping the parameters of $h(.)$ fixed. Once $\text{adv}(.)$ is trained, it should be able to successfully extract a topic distribution from $\mathbf{h}_x$ (topic training, see Figure 1a). The goal now is to modify $\mathbf{h}_x$ in such a way that $\text{adv}(\mathbf{h}_x)$ produces a uniform distribution (that is, fooling the adversary; similar to fooling the discriminator in GANs). We do that by keeping the weights of $\text{adv}(.)$ fixed, and training the network to produce the class label and a uniform topic distribution (*topic forgetting*, see Figure 1b). We then repeat this procedure for a fixed number of steps which was tuned using the validation set.

Algorithm 1: Alternating optimization of classifier and adversary.

end
for c *steps* **do**
  Sample a minibatch of b training samples;
  Fix θ_{a_u} for $u \in_R \{1, \ldots, j\}$ and update θ_c and θ_h using gradients with respect to $\frac{1}{b}\sum_{i=1}^{b} \mathrm{CE}(c(h(x_i)), y_i) + \mathrm{CE}(\mathrm{adv}_{\theta_{a_u}}(h(x_i)), \mathbb{U}_K)$;
end
$j \longleftarrow j + 1$;

4.2 Multiple Adversaries

In our experiments, we observe that after every "topic forgetting" stage, $\mathrm{adv}(.)$ does end up producing a uniform distribution, but in the next "topic training" phase, $\mathrm{adv}(.)$ is able to reproduce the topical distribution accurately. This is because, during "topic forgetting," the classifier does not really forget the topics in $\mathbf{h}_x$; it just encodes them in a different way.[2] This is a general problem in setups with alternating classifier-adversary optimization. To solve this issue, we propose using *multiple adversaries*, inspired by the "experience replay" approach used in reinforcement learning (O'Neill et al., 2010; Mnih et al., 2015). During the ith "topic training" phase, we train a new adversary adv_i (with parameters θ_{a_i} instead of retraining only one adversary over and over again. In the next "topic forgetting" phase, at each training step we pick adv_j at random from the pool of previously learned adversaries, $j \in_R \{1, \ldots, i\}$. By using multiple adversaries, we make it difficult for the classifier to encode topical information anywhere.

[2] We observe this in our analysis where the most salient features encoded after pretraining and topic forgetting phrase are the same.

5 Experimental Setup

5.1 Datasets

We evaluate our topical confound demotion method on the L1ID task. We show experiments with two datasets where L2 is English: the L2-Reddit dataset described in §2, and TOEFL17, a collection of essays authored by non-native English speakers who apply for academic studies in the US (Malmasi et al., 2017). This corpus reflects eleven L1s: Arabic, Chinese, French, German, Hindi, Italian, Japanese, Korean, Spanish, Telugu, and Turkish. The training data include 11,000 authors (1,000 per L1) and the development set has 1,100 essays per L1. We evaluate on the development set. Each essay is also marked with a prompt ID which was given to the authors to write the essay. There are 8 prompts in total, based on which we construct 8 versions of train and test set. In each version, we remove essays marked with one of the prompts from both the train and the development sets, and consider the removed essays from the development set an "out-of-domain" test set. We refer to the version where prompt "PK" is out-of-domain as "–PK" in the results (Table 3), $K \in \{0, \ldots, 7\}$.

5.2 Implementation Details

We tokenized and lowercased all the text using spaCy. Limiting our vocabulary to the most frequent 30,000 words in the training data, we replaced all out-of-vocabulary words with "UNK." We encoded each word using a word embedding layer (initialized at random and learned) and passed these embeddings to a bidirectional LSTM encoder (one layer for each direction) with attention ($h(x)$; Pryzant et al., 2018). Each LSTM layer had a hidden dimension of 128. We used two layered feed forward networks with a $\tanh$ activation function in the middle layer (of size 256), followed by a softmax in the final layer, as $c(.)$ and $\mathrm{adv}(.)$.

5.3 Baselines

We consider several baselines that are intended to capture the stylistic features of the texts, explicitly avoiding content.

Linear classifier with content-independent features (LR) Replicating Goldin et al. (2018), we trained a logistic regression classifier with three types of features: function words, POS trigrams, and sentence length, all of which are reflective of the style of writing. We deliberately avoided using content features (e.g., word frequencies).

Classification with no adversary on masked texts (LO-TOP-K) We mask the top-K words (based on log-odds scores) in *both* the train and the test sets (as in §2); we train the classification model again without training $\mathrm{adv}(.)$. After masking the top words, we expect patterns of writing style (and, therefore, L1) to become more apparent.

Adversarial training with gradient reversal (GR-LO) A common method of learning a confound-invariant representations is to use a gradient reversal layer (Beutel et al., 2017; Ganin et al., 2016; Pryzant et al., 2018; Elazar and Goldberg, 2018). The output of the encoder, $\mathbf{h}_x$, is passed through this layer before applying $\mathrm{adv}(.)$. This training setup usually proves too difficult to optimize, and often results in poor performance. That is, even if the performance of $\mathrm{adv}(.)$ is weak, $\mathbf{h}_x$ still ends up leaking information about the confound (Lample et al., 2019; Elazar and Goldberg, 2018). In the forward pass, this layer acts as identity whereas in the backward pass it multiplies the gradient values by $-\lambda$, essentially reversing the gradients before they go into the encoder. λ controls the intensity of the reversal (we used $\lambda = 0.2$).

LDA topics as confounds (ALT-LDA) We trained LDA on the training set and for each example in the training set, generated a probability distribution (over 50 topics), and used it as topical confound with our proposed learning setup, alternating classifier-adversary training.

6 Results

6.1 TOEFL17 Dataset

We begin with experiments on the TOEFL17 dataset, where predicting L1 is an easier task due to the lower proficiency of the authors. Table 3 reports the accuracy of our proposed model, denoted **ALT-LO**, compared to the logistic regression baseline (**LR**), and two adversarial baselines: one demotes latent log-odds-based topics via gradient reversal (**GR-LO**), and another uses our proposed novel learning procedure but demotes baseline LDA topics (**ALT-LDA**). We report both in-domain accuracy and out-of-domain results; the latter is obtained by averaging the accuracy of each set "–PK" over $K \in \{0, \ldots, 7\}$.

	In-Domain	Out-of-Domain
LR	55.3	50.9
GR-LO	12.7	13.6
ALT-LDA	59.1	50.1
ALT-LO	**61.9**	**60.4**

Table 3: Classification accuracy with topic-demoting methods, TOEFL dataset.

Our model strongly outperforms all baselines that demote confounds, in both classification setups. We observe in our experiments that gradient reversal is especially unstable and hyperparameter sensitive: it has been shown to work well with categorical confounds like domain type or binary gender, but in demoting continuous outputs like a topic distribution, we observe it is not effective. The proposed alternating training with multiple discriminators obtains better results, and replacing LDA with log-odds-based topics also improves both in-domain and (much more substantially) out-of-domain predictions, confirming the effectiveness of our proposed innovations.

A vanilla classifier without demoting confounds (denoted in §2 as NO-ADV) yields in-domain and out-of-domain accuracies of 62.0 and 58.3, respectively. We would expect that the better generalization power of our proposed model would come at a price of lower accuracy in-domain. Our goal is to capture the true signals of L1, rather than superficial patterns that are more frequent in the data and artificially boost the performance in NO-ADV settings. This is indeed what we observe.

For example, the text "…i agree with you on the prolonged war if the plc heartland (poland proper) was not as rich as it was i dont really see how we would been …" in the dataset is labeled as "Polish" instead of the gold label "Swedish" by the NO-ADV classifier, likely because of the mention of the term "poland", but the ADV-LO model predicts it correctly since it likely picks on other features that indicate non-fluency, like "we would been". Such naive classification errors become especially costly in making predictions about peo-

ple's demographic attributes: ethnicity, which often correlates with L1, but also gender, race, religion, and others (Hardt et al., 2016; Beutel et al., 2017).

6.2 L2-Reddit Dataset

Next, we experiment with L2-Reddit, a larger and more challenging dataset (since many speakers in the dataset are highly fluent, and the signal of their native language is weaker). The performance of the simple baselines on this dataset is shown in Table 4. The accuracy of the linear classifier is poor (compared to Table 1), perhaps because it fails to capture some contextual features learned by the neural network models. With LO-TOP-20, the performance on both test sets improves. It slightly degrades when more words are removed, perhaps because some words indicative of L1 are also removed.

	In-Domain	Out-of-Domain
LR	21.2	18.5
LO-TOP-20	38.7	21.9
LO-TOP-50	36.4	21.4
LO-TOP-100	35.8	21.2
LO-TOP-200	34.7	20.8

Table 4: Baseline classification accuracy on L2-Reddit.

Finally, we evaluate the impact of our novel training procedure and the quality of our proposed topical confound identification method. We compare our proposed solution, denoted ALT-LO, with two alternatives, as before, one with a different learning setup (GR-LO) and one with a different confound representation (ALT-LDA). Table 5 summarizes the results: our proposed learning procedure ALT-LO performs better than both the alternatives. Unsurprisingly, the model trained with gradient reversal (GR-LO) performs particularly poorly; this was our primary motivation to explore better learning techniques.

	In-Domain	Out-of-Domain
GR-LO	22.5	15.7
ALT-LDA	46.2	21.9
ALT-LO	**48.8**	**22.9**

Table 5: Classification accuracy with topic-demoting methods, L2-Reddit dataset.

To further confirm that the ALT-LO model is not learning topical features, we repeat the experiment presented in Table 1—masking the top K topical words (based on log-odds scores) from the test sets, but not retraining the models—now, with our proposed model ALT-LO. Table 6 shows that in contrast to standard models that do not demote topical confounds (as in Table 1), there is less degradation in the performance of ALT-LO. We conjecture that our model is stable to demoting topics because it learns relevant stylistic features, rather than spurious correlations.

	In-Domain	Out-of-Domain
ALT-LO	48.8	22.9
+MASK TOP-20	38.7	21.6
+MASK TOP-50	36.2	21.5
+MASK TOP-100	33.5	21.2
+MASK TOP-200	31.9	20.4

Table 6: Accuracy on the L2-Reddit dataset; the proposed model (ALT-LO) with different settings of the test sets.

7 Analysis

We present an analysis of what the models are learning, based on words they attend to for classification. We focus on the L2-Reddit dataset.

Following Pryzant et al. (2018), we generated a lexicon of most attended words by (1) running the model on the test set and saving the attention score for each word; and (2) for each word, computing its average attentional score and selecting the top-k words based on this score.

What emerges from this lexicon (Table 7) is a dramatic difference between the top indicative words in the various models. Whereas in the baseline model *all* the most indicative words are proper nouns, the ALT-LO model highlights exclusively function words. The proper nouns in the baseline model are all geographical terms directly associated with the L1s reflected in the L2-Reddit dataset: they are easy giveaways of the authors' L1s, but they are meaningless linguistically. In contrast, the function words highlighted in the ALT-LO model are mostly prepositions and determiners; it is well known that nonnative speakers are challenged by the use of prepositions (in any L2, English included). The distribution of determiners is also a challenge for nonnatives, and

the correct usage of *the* in particular is quite hard for learners to master. These challenges are evident from the most indicative words of our model. Observe also that the LO-TOP-50 model is somewhere in the middle: it includes some proper nouns (including geographical terms such as *eu* or *us*) but also several function words. A more detailed analysis of these observations is left for future work.

Recently, there has been a debate on whether attention can be used to explain model decisions (Serrano and Smith, 2019; Jain and Wallace, 2019; Wiegreffe and Pinter, 2019), we thus present additional analysis of our proposed method based on saliency maps (Ding et al., 2019). Saliency maps have been shown to better capture word alignment than attention probabilities in neural machine translation. This method is based on computing the gradient of the probability of the predicted label with respect to each word in the input text and normalizing the gradient to obtain probabilities. We use saliency maps to generate lexicons similar to the ones generated using attention. As shown in table 8, the top indicative words for baseline and LO-TOP-50 follow a similar pattern as the ones obtained with attention scores. In line with results in Table 7, salient words for ALT-LO are determiners and prepositions. However, saliency maps also reveal that our proposed approach still attends to some geographical terms that were not demoted by our classifier.

8 Related Work

Controlling for confounds in text Controlling for confounds is an active field of research, especially in the medical domain, where the common solution is to do random trials or propensity score matching (Rosenbaum and Rubin, 1985). Paul (2017) tackled the problem of learning causal associations between word features and class labels using propensity matching for the task of sentiment analysis. This method is not scalable to large text datasets as it involves training a logistic regression model for every word type. Tan et al. (2014) built models to estimate the number of retweets of Twitter messages and addressed confounding factors by matching tweets of the same author and topic. Reis and Culotta (2018) proposed a statistical technique called Pearl's back-door adjustment for text classification (Pearl, 2009). All these works focused on a bag-of-words model with lexical features only.

Adversarial training in text Much recent work focuses on learning textual representations that are invariant to selective properties of the text. This work used domain adaptation and transfer learning (Ganin et al., 2016; Tzeng et al., 2014; Xie et al., 2017), either to remove sensitive attributes such as demographic information (Li et al., 2018; Elazar and Goldberg, 2018; Beutel et al., 2017), or to understand costumer behavior for social science applications (Pryzant et al., 2018). Most of the work in this area, however, focuses on cases where these confounds are known in advance and their values are given along with the training data.

Native language identification The L1ID task was introduced by Koppel et al. (2005), who worked on the International Corpus of Learner English (Granger, 2003). The same experimental setup was adopted by several other authors (Tsur and Rappoport, 2007; Wong and Dras, 2009, 2011). Since the release of nonnative *TOEFL* essays by the Educational Testing Service (Blanchard et al., 2013), the task gained popularity and this dataset has been used for two L1ID Shared Tasks (Tetreault et al., 2013; Malmasi et al., 2017).

Malmasi and Dras (2017) report that the state of the art is a linear classifier with character n-grams and lexical and morphosyntactic features.

The best accuracy under cross-validation on the TOEFL17 dataset, which includes 11 native languages (with a rather diverse distribution of language families), was 85.2%.

The above works all identify the L1 of *learners*. Identifying the native language of advanced, fluent speakers is a much harder task. Goldin et al. (2018) addressed this task, using the L2-Reddit dataset with as many as 23 different L1s, all of them European and many which are typologically close, which makes the task even harder. They experimented with a variety of features, using logistic regression as the classifier, and achieved results as high as 69% accuracy with cross-validation; however, when testing their classifier outside the domain it was trained on (Reddit forums focusing on European issues), accuracy dropped to 36%.

9 Conclusion

We introduced a method to represent unknown confounds in text classification using topic models and log-odds scores, and a new general method

with alternating optimization to learn textual representations which are invariant of confounds. We evaluated the proposed solution on the task of native language identification, and showed that it learns to make predictions using stylistic features, rather than focus on topical information.

The learning procedure we presented is general and applicable to other tasks that require learning invariant representations with respect to some attribute of text (some of which are discussed in §8). We plan to evaluate our proposed solution on other tasks where topics can be latent confounds, like predicting gender bias (Voigt et al., 2018). We leave this exploration for future work.

Abstract

Natural language has recently been increasingly explored as a medium of supervision for training machine learning models. Here, we explore learning classification tasks using language in a conversational setting – where the automated learner does not simply receive language input from a teacher, but can proactively engage the teacher by asking template-based questions. We experiment with a reinforcement learning framework, where the learner's actions correspond to question types and the reward for asking a question is based on how the teacher's response changes performance of the resulting machine learning model on the learning task. In this framework, learning good question-asking strategies corresponds to asking sequences of questions that maximize the cumulative (discounted) reward, and hence quickly lead to effective classifiers. Empirical analysis shows that learned question-asking strategies can expedite classifier training by asking appropriate questions at different points in the learning process. The approach allows learning using a blend of strategies, including learning from observations, explanations and clarifications.

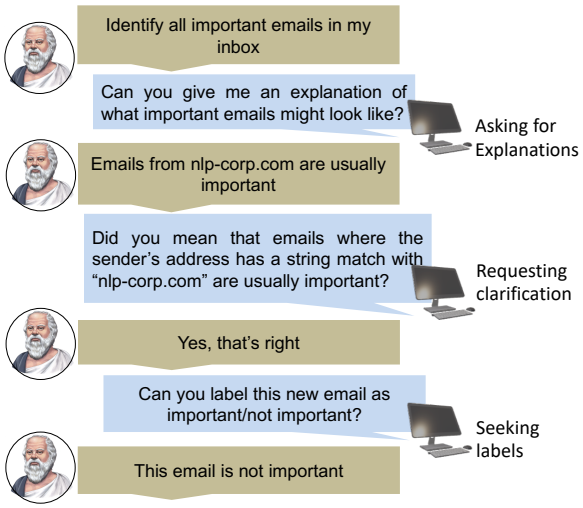

Figure 1: Question-Answer dialog can enable learning from a mix of strategies, including label observations (traditional supervised learning), explanations and clarifications (to overcome parsing limitations). The output from the teacher-learner interaction is a classification model (here, for important emails). We present a framework that (a) enables learning classifiers from a mix of such supervision; (b) learns to ask appropriate sequences of questions to accelerate this.

1 Introduction

The ability to learn new tasks and behaviors from language is characteristic of human intelligence. In recent years, the fields of machine learning and NLP have seen an renewed interest in incorporating natural language supervision in models of machine intelligence (Narasimhan et al., 2015; Elhoseiny et al., 2013; Goldwasser and Roth, 2014; Andreas et al., 2018; Fried et al., 2018; Wang et al., 2016). In particular, methods such as BabbleLabble (Hancock et al., 2018) and LNL (Srivastava et al., 2017) show progress towards realistic applications of supervised learning from language on tasks such as information extraction and email categorization. However, until now, such methods have been limited in two ways.

First, despite a body of work on leveraging language for tasks involving human robot interaction (She and Chai, 2017; Cakmak and Thomaz, 2012; Krishnamurthy and Kollar, 2013) and interactive learning in non-linguistic settings (see Section 2), existing approaches for training machine learning models from language are largely non-interactive, i.e. the learner agent receives statically collected text-based advice from a teacher as input, but does not directly engage with the

teacher.[1] In comparison, when humans learn, they do not rely only on passively receiving instruction from a teacher. Rather, the interaction takes the form of a mixed-initiative dialog, where they ask questions and proactively seek clarifications to simplify learning. These questions can generalize learning to novel situations, explore hypotheses, or fill information gaps. The ability to ask questions can, thus, fundamentally facilitate learning.

Second, existing approaches have focused on using language either as a standalone replacement for labeled data (Hancock et al., 2018), or to drive learning such as through specifying features for learning tasks (Eisenstein et al., 2009). In contrast, many realistic scenarios of learning from language would involve not learning from language alone, but learning from a mix of supervision, including both traditional labeled data, and natural language advice. Thus, automated learners should be capable of learning from a blend of observations, explanations and clarification.

In this work, we introduce a framework for learning from language in a conversational setting (*LiD*, for *Learning with Interactive Dialog*), which is a step towards alleviating these shortcomings. Language provides a natural medium for conversational interactions between a learner and a teacher, specifically in the form of question-answer dialog. The premise driving our work is that the ability to ask questions can be leveraged by an automated learner to accelerate its learning. We explore a data-driven approach for learning effective question-asking strategies in the specific context of learning classification tasks. The signal for learning to ask questions is grounded in the learning task itself. i.e., the value of a question is evaluated in utilitarian terms of how it affects performance on a downstream classification task. This follows a Wittgensteinian view of language as a cooperative game (Wittgenstein, 1953) between agents (here, the teacher and a learner) with a shared goal (here, building an effective classifier). While the space of questions that an interactive learner can ask can be vast in general, here we specifically focus on leveraging interactivity for three specific aspects (highlighted in Figure 1):

1. Seeking labels for specific examples.
2. Asking for explanations of a concept.
3. Requesting clarifications about explanations.

As illustrated in Figure 1, these dimensions can facilitate multiple aspects of the learning process: including learning from labeled examples (similar to traditional supervised learning), learning from natural language explanations (similar to recent work on learning from explanations) and alleviating limitations in the learner's semantic parsing abilities (in vein with work such as Labutov et al. (2018)). Learning systems that reify these abilities can enable users to interactively teach new concepts using a blend of traditional and language-based supervision. Our contributions are:

- A reinforcement learning formulation to guide question-asking strategies for learning from language.
- A method for interactively training classifiers using a mix of labeled data, natural language explanations and clarifications. Our exploration highlights some of the challenges involved in interactive learning from language.

2 Challenges in Relation to Previous Work

From the perspective of traditional supervised learning, the problem of asking questions can be seen as cognate with active learning. Methods in active learning have explored various criteria for choosing which of a set of unlabeled examples to label next while training supervised machine learning models (Settles, 2012; Collins et al., 2008). This can be seen as asking a specific kind of question (as illustrated in Figure 1). Learning to ask questions generalizes active learning in multiple ways by possibly soliciting a wider range of data measurements. These include feature labels ('Are emails with subject "urgent" usually important?'), label proportions ('Around what fraction of emails are important?'), constraints on model expectations ('Are you more likely to reply to important emails?'), etc. Approaches such as Srivastava et al. (2018) map such language to data measurements that computational models can reason over.[2] Statistical frameworks such as Generalized Expectation (Druck et al., 2008), Posterior Regularization (Ganchev et al., 2010) and Bayesian

[1] Zhang et al. (2018) diverge from prior work in this respect, and model language games between teachers and learners. However, their learning tasks are toylike, and the method does not generalize to realistic scenarios.

[2] For example, a statement such as 'Emails from my boss are usually important' may be mapped to a data measurement of form $P(y = important|sender = boss) \approx P_{usually}$.

Measurements (Liang et al., 2009) then allow for model training from a broad range of such data measurements in conjunction with unlabeled data, rather than using labeled examples. Other recent approaches such as Huang et al. (2015) and Siddiquie and Gupta (2010) have expanded pool-based active learning to learning from multiple types of queries, especially in the context of multi-label and multi-class learning. Similarly, Parikh and Grauman (2011) explore feature space construction for visual tasks in an interactive setting. Although in principle soliciting different types of data measurements can help learning, each type requires its own interface. The advantage of using natural language as a medium is that it allows us to unify the different modes of supervision into a single, familiar user interface. However, using natural language as a medium of supervision comes with its own set of challenges, as we discuss next.

2.1 Dependence on Language Interpreter

Since both generation and transmission of language advice can be noisy, the optimal question asking strategy may depend not only on the information content of data measurements, but also factors such as the quality of the learner's semantic parsing model and the teacher's skill.[3] To explain, while useful from an information theoretic sense, a teacher's explanations may be too complex to handle for the learning agent's parser, in which case it might be preferable to stick to asking about the teacher about instance labels (which would require minimal parsing). Thus, question-asking strategies need to be sensitive to the learner's own semantic parsing ability, which may also change during the course of interactions with users.

2.2 Context Dependence

Rather than learning a static criterion for choosing what question to ask (as in active learning), our focus is on asking questions in conversational settings, which are inherently dynamic processes. To explain, asking a teacher to rephrase an explanation only makes sense in specific contexts (when the interpretation of something said previously is unclear). Further, the question to ask can depend on factors such as the task domain, supervision previously received, etc. These factors motivated our choice of a reinforcement learning approach for learning question-asking strategies.

Relation to Question Generation approaches: The problem of learning to ask questions has previously been explored by several approaches. Vanderwende (2008) and Olney et al. (2012) explore generating reading comprehension questions conditioned on a given text. More recently, Romeo et al. (2016) and Rao and Daumé III (2018) present neural network models that rank questions in community QA forums, whereas Misra et al. (2018) generate questions for visual scene understanding. Our framework significantly differs from these in its sequential framework, and that the questions to be asked are grounded in quantitative performance on a downstream task.

3 Approach

In this section, we describe our framework for interactive learning from question-answer dialog. We first describe an approach to learn classifiers using a mix of explanations and labeled examples in Section 3.1. This is a preliminary towards question-asking strategies that subsume active learning as well as language advice; and constitutes a subroutine that is repeatedly invoked in our approach. Section 3.2 describes our reinforcement learning formulation for learning question-asking strategies in simulated conversational settings. The space of actions consists of a vocabulary of question types that a learner can ask, and reward is based on improvements in the classification model that the teacher's response to an asked question leads to.

3.1 Learning classifiers from a mix of observations and explanations

We base our learning framework on previous work by Srivastava et al. (2018), who train loglinear classifiers (with parameters θ) using natural language explanations of the individual classes and unlabeled data. Further, they use the semantics of linguistic quantifiers (such as 'usually','always', etc.) as priors in a Posterior Regularization objective to drive the model training. In particular, their training objective takes the following form:

$$J_Q(\theta) = \underbrace{\mathcal{L}(\theta)}_{\text{Explain data}} \underbrace{- \min_{q \in Q} KL(q \mid p_\theta(Y|X))}_{\text{Emulate human advice}} \quad (1)$$

[3] In this work, we are not interested in learning semantic parsing models. We presume the existence of pretrained semantic parsers for learning agents. Our focus is rather on whether some question asking strategies may be more effective than others for a learning agent with given capabilities.

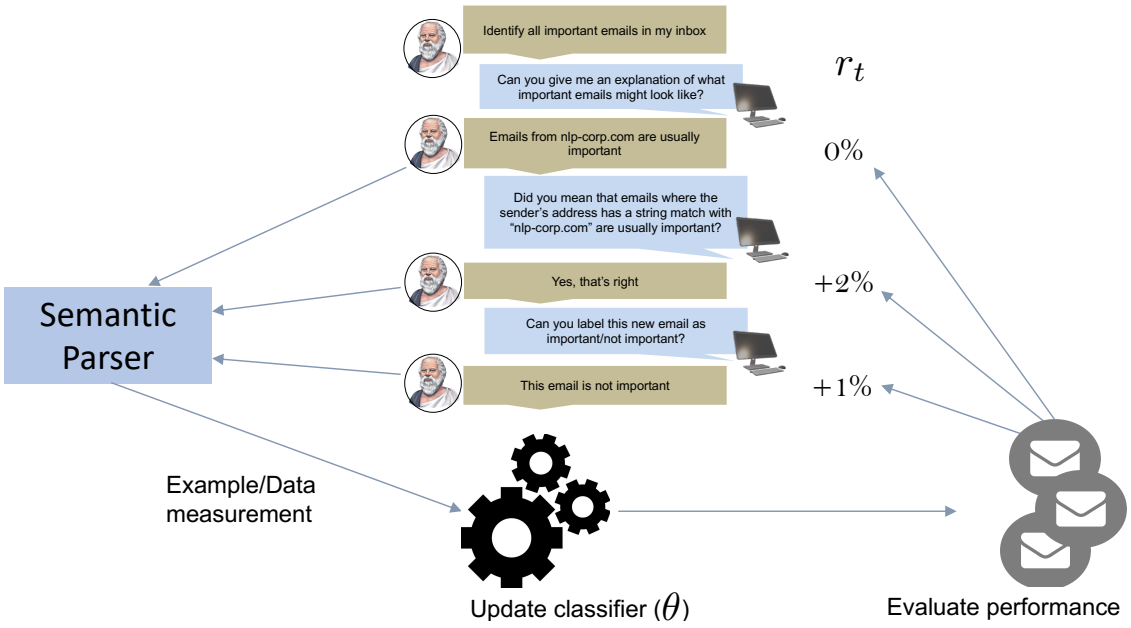

Figure 2: We assume that the dialog between the learner and the teacher is in the form of turn-wise conversations – consisting of a sequence of questions asked by the learner, and the teacher's responses to those questions. At each step in this process, the teacher's response is parsed by the learner (using a pre-trained semantic parser), and can be incorporated into the learner's concept model as either a labeled example or a data measurement (the learner can also choose to seek a clarification). A reward (denoted by r_t) can be computed at each step, which denotes the marginal change in classification performance on a held-out set of examples due to the last response. In this framework, learning good question-asking strategies corresponds to asking sequences of questions that maximize the cumulative (discounted) reward, and hence quickly lead to effective concept models. The framework also allows for asking sequences of multiple questions before seeing a major jump in model performance.

The objective reflects a tension between explaining the unlabeled data (likelihood term) and emulating the natural language advice provided by a teacher. The KL divergence represents difference between predictions from the trained model on unlabeled data $p_\theta(Y|X)$ and language advice (each explanation is incorporated as a data measurement; the conjunction of these defines the 'valid set' of posterior distributions Q that perfectly concur with the natural language advice). The second term essentially computes the minimum distance between the model posterior and the set Q.

Here, we show that we can naturally extend this approach to learn classifiers from a mix of both labeled and unlabeled data, and natural language explanations. To do this, we simply append a log-likelihood term for the labeled examples to the objective in Equation 1. The updated objective is:

$$J_Q(\theta) = \mathcal{L}_{labeled}(\theta) + \mu\Big(\mathcal{L}_{unlabeled}(\theta) - \min_{q \in Q} KL(q \mid p_\theta(Y|X))\Big) \quad (2)$$

Here, $\mathcal{L}_{labeled}(\theta)$ denotes the log-likelihood term for a set of $n_{labeled}$ labeled examples $\mathcal{X}_{labeled} = \{(x_k, y_k)\}_{labeled}^{n}$ (normalized by $n_{labeled}$), whereas the other two terms are as before: $\mathcal{L}_{unlabeled}(\theta)$ denoting log-likelihood over a set of $n_{unlabeled}$ unlabeled examples, and a posterior regularizer term (KL-divergence) penalizing violations of the parse natural language advice. In the E-step of the Posterior Regularization training (Ganchev et al., 2010), the computation of the posterior regularizer remains unchanged. However, the M-step is modified so that the classifier parameters θ are learned using both the inferred labels for the unlabeled data, and provided labels for the labeled examples.

In Equation 2, $\mu > 0$ determines the relative weights of provided example labels and natural language advice in the optimization objective and is a hyper-parameter for the method. In learning scenarios where there is little labeled data, we would like to rely primarily on constraints specified from natural language explanations, and unlabeled data. On the other hand, in scenarios where there is a lot of labeled data available enabling robust inductive inference, we would like

to primarily rely on it rather than explanations.[4] While setting up the optimization problem, the value of μ can be adapted to reflect this intuition. In our experiments, we found setting $\mu = 1/\max(n_{labeled}, 1)$ to work well across settings.

3.2 RL formulation for learning to ask

Figure 2 illustrates our framework for learning classification tasks in a question-answer dialog setting. We assume the presence of a teacher to answer questions posed by the learner. We restrict the structure of dialog to a sequence of questions $(q_1 \dots q_T)$ asked by the learner, and the teacher's responses $(u_1 \dots u_T)$ to them. We further assume the presence of a held-out set of labeled examples of the concept, which can be used to evaluate the learner's classification performance as the dialog progresses. At each step t, the learner's action a_t consists of choosing a question to ask the teacher. The teacher's response to the learner's question is parsed (in the form of a labeled example, or a data measurement), which is then incorporated into the learner's concept model (by retraining with the additional labeled example or the new data measurement). The classification performance, c_t, of the updated model is evaluated on the held-out set. The change in classification performance from the previous step, r_t approximates the marginal value of the question in learning the task, and constitutes the learner's reward at that step.

Our approach for learning question asking strategies models the dialog as a simple Markov Decision Process. Since our state and action spaces are discrete (as described in the following sections), we can use a table-based SARSA-learning procedure (which allows for on-policy learning over Q-learning) to estimate the state-action values $Q(s, a)$ of different question types in different contexts. We next describe the state-space, actions and rewards, and the learning procedure.

3.2.1 Action Space

As mentioned earlier, there can be a multitude of questions that a learner can ask a teacher. Here, we are interested in exploring three specific types of questions that are specially germane for facilitating learning from a mix of labeled examples and explanations. These consist of the following:

1. **Seeking labels for specific examples:** This is similar to traditional active learning. In particular, we can have a different action corresponding to every active learning criterion, which chooses which example to label next. In our experiments, we use two active learning techniques (with a corresponding action for each):
   - *Random:* Ask for class label for a randomly chosen unlabeled instance.
   - *Maximum Uncertainty:* Ask for class label for the instance in the data for which the current concept model is most uncertain (highest entropy). If there are multiple such instances, randomly pick one among them.
2. **Asking for an explanation for the concept:** This action seeks out from the teacher a short natural language explanation of the concept. This is then incorporated in the concept model as a quantitative constraint. In general, this can encompass several types of questions:
   - Asking for probability estimates about specific labels and features. e.g., 'How often are emails about meetings important?'
   - Asking for discriminative features for particular concept labels. e.g., 'Can you think of a feature that if present always denotes that an email is important?'
   - Asking about class probabilities. e.g., 'Around what fraction of emails in your inbox are important?'

   In principle, each of the above provide admissible constraints which the classifier training procedure (from Section 3.1) can handle. However, to simplify analysis, in our experiments, we conflate these actions into one category, and ask for general explanations of the form '*Can you give me an explanation of the concept?*', which could return a variety of data measurements (subsuming $P(y)$,$P(y|x)$ and $P(x|y)$, previously explored in Srivastava et al. (2018)).
3. **Requesting clarification about the previous explanation:** This action asks for a clarification about the interpretation of a previous explanation (which can be helpful in cases when the learner is uncertain about the interpretation). For this, the learner verifies if the interpretation of the previous explanation (using

[4] In the asymptotic case of infinite data with labels, an inductively learned Bayes Classifier would be optimal.

the learner's semantic parser) was correct or not. To do this, we generate a question of the form '*Did you mean ...*' using a synchronous grammar which deterministically maps logical forms to natural language descriptions (see Figure 1 for an example). The teacher responds with yes, if the parsed logical form matches the gold annotated logical form, and with no otherwise. In case the teacher responds with no, the current explanation is discarded (not used in model training), and the learner moves ahead to ask for a new label or explanation.

Simulating Interactions: We note that each of the question types described above – (1) asking for labels for examples, (2) asking for concept explanations, and (3) verifying interpretations of language explanations – can be simulated with corresponding statically collected data – consisting of (1) labeled examples for classification, (2) natural language explanations of classes, and (3) annotations of those explanations with logical forms. This has a significant implication: rather than relying on questioning human users in real-time, we can simulate the conversational exchange by asking questions to an oracle, which has access to previously pre-collected data of the above-described form for each classification task. While this is a coarse approximation of actual dialog between an automated learner and human teachers, it can serve as a useful proof-of-concept, and allows for quick experimentation. We rely on this simulated setting for learning policies for question asking.

3.2.2 Rewards

The reward, r_t, evaluates the change in classification performance due to an asked question at each step t of the dialog. The performance of the classification model is evaluated on a held out set of $n_{heldout} = 50$ labeled examples for each learning task. In our experiments, we use the model's F1 score as the metric for classification performance, c_t. We define the reward as the absolute change in model performance from the previous step:

$$r_t = c_t - c_{t-1} \tag{3}$$

3.2.3 State-space

Next, we describe the featurized state space for our reinforcement learning formulation. The best question to ask at a particular point can likely depend on the state of the conversation. This could include factors such as the pedagogical phase in the learning process (exploratory vs confirmatory), previous questions asked, etc. Thus, defining a rich enough state space is an important consideration for a formulation of conversational learning. In our treatment, we assume a discrete state-space, which is defined as the cross product of the following (also discrete) features.

- **Curricular stage in the Learning process:** We use a discrete variable to model the curricular stage of the learner, approximating it by the number of steps (questions previously asked) in the interaction at any point. We cluster the number of steps in the following five bins of values: BEGINNER (0 steps), NOVICE (1-5 steps), INTERMEDIATE (6-10 steps), ADVANCED (11-15 steps) and MATURE ($>$ 15 steps).[5]
- **Reward in the previous state:** We discretize the value of reward as belonging to one of four ranges (abstractly named GOOD, INCREASING, FLAT, and DECREASING), with thresholds chosen to correspond to the inter-quartile ranges for the value of rewards observed in evaluating a random policy.
- **Velocity of reward:** This is a ternary variable indicating whether the value of the discrete variable for the reward (above) is BETTER,WORSE or the SAME than the previous step.
- **Type of the previous two actions:** As mentioned in the description of the action space.
- **Domain of learning task:** Indicates the domain of the current classification task. We use datasets corresponding to three domains: EMAIL CATEGORIZATION, SHAPE CLASSIFICATION and BIRD SPECIES IDENTIFICATION; hence this variable can take these three values.
- **Confidence of previous parse:** We model the learner's confidence in parsing the response u_t from a teacher as the ratio of the probability of the highest probability (predicted) logical form from the learner's semantic parser and the next best logical form. We discretize this ratio into three values, corresponding to the upper (HIGH), lower (LOW) and middle two inter-quartile ranges (MEDIUM) for the value of the ratio over all explanations in our data.

[5]These threshold values were heuristically chosen based on the observation that for many datasets that we experiment with, classifier performance roughly begins to taper at around 20 training examples.

While our state space captures several facets, it does not model some other important factors:

- **Teacher behavior:** Whether the teacher provides correct information, and uses easily interpretable language.
- **Task difficulty:** This refers to how expressible a classification task is using language explanations. For example, some concept maybe significantly easier to explain using language than others, depending on the logical language available to the semantic parser. For example, it maybe impossible to explain digit recognition using pixel level features using language.

3.3 Model training

Since the action and state-spaces are discrete and not prohibitively large, we use the on-policy SARSA learning algorithm for policy control (Rummery and Niranjan, 1994), where we represent the state-action Q-values for pairs of states s and actions a as a table. We use an ϵ-greedy strategy ($\epsilon = 0.20$). i.e., the strategy balances between exploitation and exploration by picking the next action to be the estimated optimal one (having the maximum estimated Q-value for a state) with probability $1 - \epsilon$, and choosing the next action randomly with a probability of ϵ. The initial policy is defined by uniform randomly initializing $Q(s, a)$ values between 0 and 1.

4 Data

Our empirical analysis uses existing datasets for learning classifiers from language. These are datasets for email categorization from natural language explanations from Srivastava et al. (2017); and bird species classification and synthetic shape classification tasks from Srivastava et al. (2018). In all, thesee consist of 67 classification tasks belonging to these three domains.[6] For each task, the corresponding data consisting of natural language explanations of classes as well as annotated logical forms for these explanations are available. For each task, we hold out a random sample of 50 examples for evaluating classifier performance. The rest of the examples (ranging between 50 and 100 for individual tasks) are considered as unlabeled data at the start of each interaction. At each step in a simulated interaction, either (1) the label for a new example from this set is revealed by the teacher, (2) a new data measurement is provided as a natural language explanation by the teacher, or (3) the learner seeks a clarification about the parse of the previous explanation. Thus, from the learner's perspective, over time the size of the unlabeled data decreases, and the labeled examples increase (see Equation 2).

[6]The complexity of these problems varies considerably, ranging from marginally above chance to perfectly learnable.

5 Experiments

In this section, we evaluate *LiD*'s performance for three domains of classification tasks. As previously mentioned, for policy learning we simulate conversational interactions between teachers and learners by asking questions to a oracle, which has access to previously collected data about each classification task. One limitation of learning question-asking strategies from simulated interactions is that for some classification tasks, we may run out of explanations in the course of model training (since the number of explanations of a concept are limited). In these cases, we end the interaction as soon as all explanations are already provided to the learner.

5.1 Learned vs Random policy evaluation

First, we compare learned policies for question asking with a naive policy that randomly takes a new action at each step in the learning process.

Figure 3 shows averaged cumulative reward for question asking strategies on 20 unseen classification tasks, after SARSA learning for 10 epochs on the remaining 37 classification tasks. In the figure, the x-axis corresponds to the number of steps in a dialog, and the y-axis denotes the cumulative reward (averaged over 20 tasks) for a learned policy vs a random policy. We note that policy learning leads to consistently superior performance (on average, *LiD* achieves any given level of classification performance in fewer steps), which unambiguously indicates value in asking the right sequences of questions. We observed that the trend was also similar in most individual learning tasks. For example, the cumulative reward after 10 steps was higher for the learned policy than the random policy for 18 of the 20 learning tasks. The difference in performance was statistically significant at $p < 0.05$ using a signed permutation test. We characterize some learned behaviors that drive this improved performance in Section 5.4.

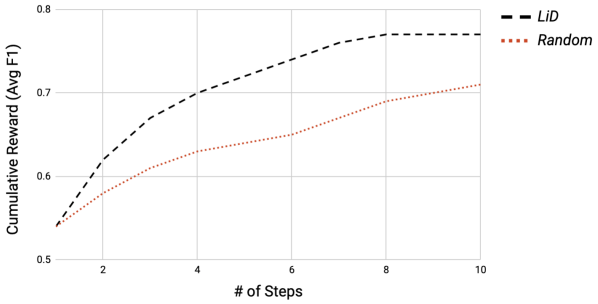

Figure 3: Cumulative Reward (averaged over 20 tasks) for interactive concept learning for learned question asking policy vs random policy.

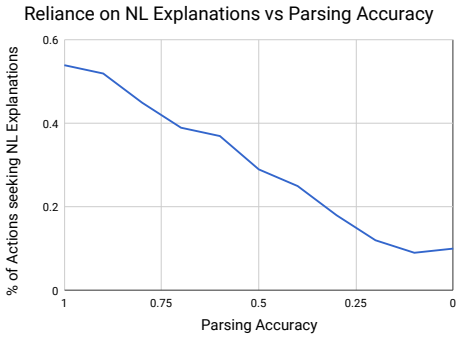

Figure 4: Fraction of actions seeking Natural Language Explanations vs competence of the learner's semantic parser.

5.2 Reliance on NL vs Parsing accuracy

Intuitively, semantic parsing competence of a learner should be a significant consideration in whether it should rely on explanations. To test this, we simulate scenarios of learners with different levels of semantic parsing ability by choosing the true logical form for any explanation with the corresponding probability, and choosing an alternative logical form from the remaining candidates in the k-best list from the semantic parser otherwise. Figure 4 depicts the effect of parsing competence on learned question-asking strategies. The empirical behavior largely corroborates our expectation, as the learned strategies increasingly avoid seeking natural language explanations of concepts as the parsing performance worsens. In the base case where the learner has no parsing competence, the model learns to exclusively ask for labeled examples only (In the figure, the fraction is seen to converge close to 0.1 rather than 0 due to the ϵ-greedy nature of the policy).

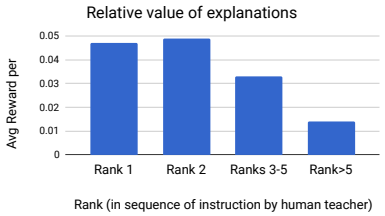

Figure 5: Average increase in classification performance from explanations of different positional orders.

5.3 Differential value of explanations

A notable issue in learning from explanations, which we do not model here is that a teacher's multiple explanations of a concept can have a large variance in their utility to a learner. In particular, we might expect that teachers would be more likely to provide the most useful explanations first, and minor explanations subsequently. From an ablation study, we observe that this is indeed a valid concern. Figure 5 shows the average marginal increase in classification performance over 50 visual shape classification tasks from explanations with different rank (based on the actual order of providing from human users). This indicates that explanations from teachers provided later contribute significantly less towards classification performance.

5.4 Examples of Learned behavior

From a qualitative analysis, learned policies are seen to be intuitive and interpretable. In particular, the policies overwhelmingly seek clarifications when confidence in the parser is low. On the other hand, there are strong inclinations to continue using an action type as long as it yields high returns. Interestingly, the optimal policy differs significantly in behavior across domains. As example, learned policies rely nearly twice as much on explanations for bird species identification as for email classification tasks. The probable reason is that parsing is harder for email explanations, as features in this domain are often compositional.

5.5 User study

We perform a small user-study to also evaluate performance of the learned policies on an email categorization task with actual human teachers. We still train the question-asking strategy using the simulated teacher framework (since learning the policy from crowdsourced human users would be expensive and slow). 20 users were asked to in-

	Avg. Reward	Natural	Avg. Rew (simulated)
LiD	0.524	3.2	0.607
Random	0.493	2.9	0.551

Table 1: Human teacher evaluation for learned and random question asking policy.

teract with the learned *LiD* policy to teach a chosen email-classification task. For each task, the system asked a sequence of 10 questions, and the human teacher's responses were incorporated into the system to update the classification model. The users were also asked to teach another task with questions asked through a random policy. Table 1 shows the average cumulative reward for humans interacting with *LiD* vs a random policy for this experiment. We note that *LiD* leads to better performance on average. This trend is the same as in the simulated analysis, although we note that the learning is slower with real teachers than in the simulated setting on the same tasks, and the gain in performance is substantially smaller. A contributing reason for this is likely annotator bias (Geva et al., 2019), since in the simulated testing scenarios, the teacher's explanations can often likely come from a small set of turkers whose language explanations for teaching other tasks were used for training the learner's semantic parsing model. We note that the learned policy was rated by human users as more natural than a random policy on a Likert scale (with range 1-5).

6 Conclusion

In this paper, we have provided a reinforcement learning formulation for learning to ask questions for interactive training of machine learning models. This framework is attractive in grounding the value of questions asked in a measurable downstream task. Further, change in model performance is a natural reward to drive this learning. While this provides a conceptually useful framework for framing question generation, in its current form the approach makes simplistic assumptions on the types of questions that can be asked, as well as on the structure of the dialog between the teacher and the learner. While the system outperforms a random policy on learning classification tasks, the dialog looks contrived from a human perspective. An interesting direction could be to pair the framework with neural text generation methods to model fine-grained question types, and generate more natural-looking interactions through dialog. An important scientific question is to characterize learning tasks for which learning from language is likely to outperform pure inductive learning. Future work can also extend the approach to other supervised learning tasks, as well as bootstrap from natural dialog data.

Abstract

We focus on the problem of language modeling for code-switched language, in the context of automatic speech recognition (ASR). Language modeling for code-switched language is challenging for (at least) three reasons: (1) lack of available large-scale code-switched data for training; (2) lack of a replicable evaluation setup that is ASR directed yet isolates language modeling performance from the other intricacies of the ASR system; and (3) the reliance on generative modeling. We tackle these three issues: we propose an ASR-motivated evaluation setup which is decoupled from an ASR system and the choice of vocabulary, and provide an evaluation dataset for English-Spanish code-switching. This setup lends itself to a discriminative training approach, which we demonstrate to work better than generative language modeling. Finally, we explore a variety of training protocols and verify the effectiveness of training with large amounts of monolingual data followed by fine-tuning with small amounts of code-switched data, for both the generative and discriminative cases.

1 Introduction

This work deals with neural language modeling of code-switched language, motivated by an application to speech recognition. Code-switching (CS) is a linguistic phenomenon defined as "the alternation of two languages within a single discourse, sentence or constituent." (Poplack, 1980). Since CS is widely used in spoken platforms, dealing with code-switched language becomes an important challenge for automatic speech recognition (ASR) systems. To get a feeling how an ASR system trained on monolingual data performs on code-switched language, we fed the IBM English and Spanish systems[1] with audio files of code-switched conversations from the Bangor Miami Corpus (see Section 7). The results (examples available in Table 1) exhibit two failure modes: (1) Words and sentences in the opposite language are not recognized correctly; and (2) Code-switch points also hurt recognition of words from the main language. This demonstrates the need for designated speech recognition systems for CS. A crucial component in such a CS ASR system is a strong CS language model, which is used to rank the bilingual candidates produced by the ASR system for a given acoustic signal.

Language models are traditionally evaluated with perplexity. However, this measure suffers from several shortcomings, in particular strong dependence on vocabulary size and lack of ability to directly evaluate scores assigned to malformed sentences. We address these deficiencies by presenting a new evaluation scheme for LM that simulates an ASR setup. Rather than requiring the LM to produce a probability for a gold sentence, we instead present the LM with a set of alternative sentences, including the gold one, and require it to rank the gold one higher. This evaluation is more realistic since it simulates the role a language model plays in the process of converting audio into text (Section 3). We create such an evaluation dataset for English-Spanish CS – SpanglishEval (Section 4).

Additionally, LM for CS poses a unique challenge: while data for training monolingual LMs is easy to obtain in large quantities, CS occurs primarily in spoken language. This severely limits its data availability, thus, small amounts of training data are an intrinsic property of CS LM. A natural approach to overcome this problem is to train monolingual language models—for which

Original sentence (audio)	English model output	Spanish model output
no pero vino porque he came to check on my machine	No but we no longer he came to check on my machine	Cual provino de que en dicha cámara chino
yo le invité pa Easter porque me daba pena el pobre aquí solo sin familia ni nada	feeling betrayed by eastern lap and I bought a new solo seem funny any now	y el envite país tampoco nada pero por aquí solo sin familia ni nada

Table 1: Examples of the output of IBM's English and Spanish speech recognition systems on code-switched audio.

we have huge amounts of data—for each language separately, and combine them somehow into a code-switched LM. While this is relatively straightforward to do in an n-gram language model, it is not obvious how to perform such an LM combination in a non-markovian, RNN-based language model. We use a protocol for LSTM-based CS LM training which can take advantage of monolingual data (Baheti et al., 2017) and verify its effectiveness (Section 5).

Based on the new evaluation scheme we present, we further propose to learn a model for this ranking task using discriminative training. This model, as opposed to LMs, no longer depends on estimating next-word probabilities for the entire vocabulary. Instead, during training the model is introduced with positive and negative examples and is encouraged to prefer the positive examples over the negative ones. This model gives significantly better results (Section 6).

Our contributions in this work are four-fold: (a) We propose a new, vocabulary-size independent evaluation scheme for LM in general, motivated by ASR. This evaluation scheme is ranking-based and also suits CS LM; (b) We describe a process for automatically creating such datasets, and provide a concrete evaluation dataset for English-Spanish CS (SpanglishEval); (c) We present a model for this new ranking task that uses discriminative training and is decoupled of probability estimations, this model surpasses the standard LMs; (d) We verify the effectiveness of pretraining CS LM for this ranking task with monolingual data and show significant improvement over various baselines. The CS LM evaluation dataset and the code for the model are available at `https://github.com/gonenhila/codeswitching-lm`.

2 Background

Code-Switching Code-switching (CS) is defined as the use of two languages at the same discourse (Poplack, 1980). The mixing of different languages in various levels has been widely studied from social and linguistic point of view (Auer, 1999; Muysken, 2000; Bullock and Toribio, 2009), and started getting attention also in the NLP community in the past few years (Solorio and Liu, 2008; Adel et al., 2013a; Cotterell et al., 2014).

Below is an example of code-switching between Spanish and English (taken from the Bangor Miami corpus described in Section 7). Translation to English follows:

- "that *es su tío* that has lived with him like I don't know how like *ya* several years..."
  that his uncle who has lived with him like, I don't know how, like several years already...

Code-switching is becoming increasingly popular, mainly among bilingual communities. Yet, one of the main challenges when dealing with CS is the limited data and its unique nature: it is usually found in non standard platforms such as spoken data and social media and accessing it is not trivial (Çetinoğlu et al., 2016).

Shortcomings of Perplexity-based Evaluation for LM The most common evaluation measure of language models is perplexity. Given a language model M and a test sequence of words $w_1, ..., w_N$, the perplexity of M over the sequence is defined as:

$$2^{-\frac{1}{N}\sum_{i=1}^{N}\log_2 M(w_i)}$$

where $M(w_i)$ is the probability the model assigns to w_i.

A better model is expected to give higher probability to sentences in the test set, that is, lower perplexity. However, this measure is not always well aligned with the quality of a language model as it should be. For example, Tran et al. (2018) show that RNNs capture long-distance syntactic dependencies better than attention-only LMs, despite having higher (worse) perplexity. Similarly, better perplexities often do not translate to better word-error-rate (WER) scores in an ASR system (Huang et al., 2018).

This highlights a shortcoming of perplexity-based evaluation: the method is rewarded for assigning high probability to gold sentences, but is not directly penalized for assigning high probability to highly implausible sentences. When used in a speech recognition setup, the LM is expected to do just that: score correct sentences above incorrect hypotheses.

Another shortcoming of perplexity-based evaluation is that it requires the compared models to have the same support (in other words, the same vocabulary). Simply adding words to the vocabulary, even if no additional change is done to the model, will likely result in higher perplexity for the same dataset. It is also sketchy to compare perplexities of word-based LMs and character-based LMs for the same reason.

Problem with WER-based evaluation Evaluating LM models based on the final WER of an ASR system side-steps these two issues: it evaluates the LM on incorrect sentences, and seamlessly compares LMs with different support. However, this makes the evaluation procedure highly dependent on a particular ASR system. This is highly undesirable, as ASR systems are hard to set up and tune and are not standardized. This both conflates the LM performance with performance of other aspects of the ASR system, and makes it hard to replicate the evaluation procedure and fairly compare results across different publications. Indeed, as discussed in Section 10, most previous works on CS LM use an ASR system as part of their evaluation setup, and none of them compares to any other work. Moreover, no standard benchmark or evaluation setup exists for CS LM.

3 An Alternative Evaluation Method

We propose an evaluation technique for language models which is ASR-system-independent, that does take into account incorrect sentences and allows to compare LMs with different support or OOV handling techniques.

We seek a method that meets the following requirements: (1) Prefers language models that prioritize correct sentences over incorrect ones; (2) Does not depend on the support (vocabulary) of the language model; (3) Is independent of and not coupled with a speech recognition system.

To meet these criteria, we propose to assemble a dataset comprising of gold sentences, where each gold sentence is associated with a set of alternative sentences, and require the LM to identify the gold sentence in each set. The alternative sentences in a set should be related to the gold sentence. Following the ASR motivation, we take the alternative set to contain sentences that are phonetically related (similar-sounding) to the gold sentence. This setup simulates the task an LM is intended to perform as a part of an ASR system: given several candidates, all originating from the same acoustic signal, the LM should choose the correct sentence over the others.

A New Evaluation metric Given this setup, we propose to use the *accuracy* metric: the percentage of sets in which the LM (or other method) successfully identified the gold sentence among the alternatives.[2] The natural way of using an LM for identifying the gold sentences is assigning a probability to each sentence in the set, and choosing the one with highest probability. Yet, the scoring mechanism is independent of perplexity, and addresses the two deficiencies of perplexity based evaluation discussed above.

Our proposed evaluation method is similar in concept to the NMT evaluation proposed by Sennrich (2016). There, the core idea is to measure whether a reference translation is more probable under an NMT model than a contrastive translation which introduces a specific type of error.

4 Evaluation Dataset

We now turn to construct such an evaluation dataset. One method of obtaining sentence-sets is feeding acoustic waves into an ASR system and tracking the resulting lattices. However, this requires access to the audio signals, as well as a trained system for the relevant languages. We propose instead a generation method that does not require access to an ASR system.

The dataset we create is designed for evaluating English-Spanish CS LMs, but the creation process can be applied to other languages and language pairs.[3]

[2] We chose accuracy over WER as the default metric since in our case, WER should be treated with caution: the alternatives created might be "too close" to the gold sentence (e.g. when only a small fraction of the gold sentence is sampled and replaced) or "too far" (e.g. a Spanish alternative for an English sentence), thus affecting the WER.

[3] The requirements for creating an evaluation dataset for a language pair L1,L2 is to have access to code-switched sentences where each word is tagged with a language ID (lan-

Example 1:
Gold: *pero* i thought *ella fue* like very good
Alt-CS: *pero* i thought a *llevó* alike very good
Alt-EN: peru i thought a of alike very could
Alt-SP: *pero azote la fue la que rico*
Example 2:
Gold: *vamos a ser juntos* twenty four seven
Alt-CS: *vamos a ser juntos* when de for *saben*
Alt-EN: follows a santos twenty for seven
Alt-SP: *vamos hacer junto sentí for saben*

Figure 1: Examples from SpanglishEval – the English-Spanish evaluation dataset. The first sentence in each example is the gold sentence, followed by a generated code-switched alternative, a generated English alternative, and a generated Spanish one. Blue (normal) marks English, while red (italic) marks Spanish.

The process of alternative sentence creation is as follows: (1) Convert a sequence of language-tagged words (either CS or monolingual) into a sequence of the matching phonemes (using pronunciation dictionaries); (2) Decode the sequence of phonemes into new sentences, which include words from either language (possibly both); (3) When decoding, allow minor changes in the sequence of phonemes to facilitate the differences between the languages.

These steps can be easily implemented using composition of finite-state transducers (FSTs).[4]

For each gold sentence (which can be either code-switched or monolingual) we create alternatives of all three types: (a) code-switched sentences, (b) sentences in L1 only, (c) sentences in L2 only.

We created such a dataset for English-Spanish with gold sentences from the Bangor Miami Corpus (Section 7). Figure 1 shows two examples from the dataset. In each, the gold sentence is followed by a single code-switched alternative, a single English alternative, and a single Spanish one (a subset of the full set).

guage ID is not mandatory, but helps in cases in which a word is found in the vocabulary of both languages and is pronounced differently), compatible pronunciation dictionaries and unigram word probabilities for each of the languages.

[4]Specifically, we compose the following FSTs: (a) an FST for converting a sentence into a sequence of phonemes, (b) an FST that allows minor changes in the phoneme sequence, (c) an FST for decoding a sequence of phonemes into a sentence, the inverse of (a).

	dev set	test set
no. of sets	1000	1000
no. of sentences	30884	30811
no. of CS alternatives	10000	10000
no. of English alternatives	9999	9993
no. of Spanish alternatives	9885	9818
no. of CS gold sentences	250/1000	250/1000

Table 2: Statistics of the dataset.

4.1 Technical details

When creating code-switched alternatives, we want to encourage the creation of sentences that include both languages, and that differ from each other. This is done with scores determined by some heuristics, such as preferring sentences that include more words from the language that was less dominant in the original one and vice versa. As part of this we also try to avoid noise from addition of short frequent words, by encouraging the average word length to be high[5]. We create 1000-best alternatives from the FST, re-score them according to the heuristic and keep the top 10.

We discard sets in which the gold sentence has less than three words (excluding punctuation), and also sets with less than 5 alternatives in one of the three types.

We randomly choose 250 sets in which the gold sentence is code-switched, and 750 sets in which the gold sentence is monolingual, both for the development set and for the test set. This percentage of CS sentences is higher than in the underlying corpus in order to aid a meaningful comparison between the models regarding their ability to prefer gold CS sentences over alternatives. The statistics of the dataset are detailed in Table 2.

Further details regarding the implementation can be found in the Appendix.

5 Using Monolingual Data for CS LM

Data for code-switching is relatively scarce, while monolingual data is easy to obtain. The question then is *how do we efficiently incorporate monolingual data when training a CS LM?*

We use an effective training protocol (FINETUNED) for incorporating monolingual data into the language model, similar to the best protocol introduced in (Baheti et al., 2017). We first pre-train a model with monolingual sentences

[5]The implementation of these heuristics is part of our code that is available online.

from both English and Spanish (with shared vocabulary for both languages). This essentially trains two monolingual models, one for English and one for Spanish, but with full sharing of parameters. Note that in this pre-training phase, the model is not exposed to any code-switched sentence.

We then use the little amount of available code-switched data to further train the model, making it familiar with code-switching examples that mix the two languages. This fine-tunning procedure enables the model to learn to correctly combine the two languages in a single sentence.

We show in Section 8 that adding the CS data only at the end, in the described manner, works substantially better than several alternatives, verifying the results from (Baheti et al., 2017).

6 Discriminative Training

Our new evaluation method gives rise to training models that are designated to the ranking task. As our main goal is to choose a single best sentence out of a set of candidate sentences, we can focus on training models that score whole sentences with discriminative training, rather than using the standard probability setting of LMs. Discriminative approach unbinds us from the burden of estimating probability distributions over all the words in the vocabulary and allows us to simply create representations of sentences and match them with scores.

Using negative examples is not straight forward in LM training, but is essential for speech recognition, where the language model needs to distinguish between "good" and "bad" sentences. Our discriminative training is based on the idea of using both positive and negative examples during training. The training data we use is similar in nature to that of our test data: sets of sentences in which only a single one is a genuine example collected from a real CS corpus, while all the others are synthetically created.

During training, we aim to assign the gold sentences with a higher score than the scores of the others. For each sentence, we require the difference between its score and the score of the gold sentence to be as large as its WER with respect to the gold sentence. This way, the farther a sentence is from the gold one, the lower its score is.

Formally, let s_1 be the gold sentence, and $s_2, ..., s_m$ be the other sentences in that set. The loss of the set is the sum of losses over all sentences, except for the gold one:

$$\sum_{i=2}^{m} \max(0, \text{WER}(s_1, s_i) - [\text{score}(s_1) - \text{score}(s_i)])$$

where $\text{score}(s_i)$ is computed by the multiplication of the representation of s_i and a learned vector w:

$$\text{score}(s_i) = w \cdot \text{repr}(s_i)$$

A sentence is represented with its BiLSTM representation – the concatenation of the final states of forward and backward LSTMs. Formally, a sentence $s = w_1, ..., w_n$ is represented as follows:

$$\text{repr}(s) = LSTM(w_1, ..., w_n) \circ LSTM(w_n, ..., w_1)$$

where $\circ$ is the concatenation operation.

Incorporating monolingual data In order to use monolingual data in the case of discriminative training, we follow the same protocol: as a first step, we create alternative sentences for each monolingual sentence from the monolingual corpora. We train a model using this data, and as a next step, we fine-tune this model with the sets of sentences that are created from the CS corpus.

7 Empirical Experiments

Models and Baselines We report results on two models that use discriminative training: CS-ONLY-DISCRIMINATIVE only trains on data that is created based on the small code-switched corpus, while FINE-TUNED-DISCRIMINATIVE first trains on data created based on the monolingual corpora and is then fine-tuned using the data created from the code-switched corpus.

We compare our models to several baselines, all of which use standard LM training: ENGLISHONLY-LM and SPANISHONLY-LM train on the monolingual data only. Two additional models train on a combination of the code-switched corpus and the two monolingual corpora: the first (ALL:SHUFFLED-LM) trains on all sentences (monolingual and code-switched) presented in a random order. The second (ALL:CS-LAST-LM) trains each epoch on the monolingual datasets followed by a pass on the small code-switched corpus. The models CS-ONLY-LM and FINE-TUNED-LM are the equivalents of CS-ONLY-DISCRIMINATIVE and FINE-TUNED-DISCRIMINATIVE but with standard LM training.

Code-switching corpus We use the Bangor Miami Corpus, consisting of transcripts of conversations by Spanish-speakers in Florida, all of whom are bilingual in English.[6]

We split the sentences (45,621 in total) to train/dev/test with ratio of 60/20/20 respectively, and evaluate perplexity on the dev and test sets.

The dataset described in Section 4 is based on sentences from the dev and test sets, and serves as our main evaluation method.

Monolingual corpora The monolingual corpora used for training the English and Spanish monolingual models are taken from the OpenSubtitles2018 corpus (Tiedemann, 2009),[7] of subtitles of movies and TV series.

We use 1M lines from each language, with a split of 60/20/20 for train/dev/test, respectively. The test set is reserved for future use. For discriminative training we use 1/6 of the monolingual training data (as creating the data results in roughly 30 sentences per gold sentence).

Additional details on preprocessing and statistics of the data can be found in the Appendix.

Training We implement our language models in DyNet (Neubig et al., 2017). Our basic configuration is similar to that of Gal and Ghahramani (2016) with minor changes. It has a standard architecture of a 2-layer LSTM followed by a softmax layer, and the optimization is done with SGD (see Appendix for details).

Tuning of hyper-parameters was done on the PTB corpus, in order to be on par with state-of-the-art models such as that of Merity et al. (2017). We then trained the same LM on our CS corpus with no additional tuning and got perplexity of 44.06, better than the 52.99 of Merity et al. (2017) when using their default parameters on the CS corpus.[8] We thus make no further tuning of hyper-parameters.

When changing to discriminative training, we perform minimal necessary changes: discarding weight decay and reducing the learning rate to 1. The weight vector in the discriminative setting is learned jointly with the other parameters of the network.

FINE-TUNED-DISC	–	**74.2**	**5.85**	–	**75.5**	**5.59**

Table 3: Results on the dev set and on the test set. "perp" stands for perplexity, "acc" stands for accuracy (in percents), and "wer" stands for word-error-rate.

As done in previous work, in order to be able to give a reliable probability to every next-token in the test set, we include all the tokens from the test set in our vocabulary and we do not use the "<unk>" token. We only train those that appear in the train set. Handling of unknown tokens becomes easier with discriminative training, as scores are assigned to full sentences. However, we leave this issue for future work.

8 Results

The results of the different models are presented in Table 3. For each model we report both perplexity and accuracy (except for discriminative training, where perplexity is not valid), where each of them is reported according to the best performing model on that measure (on the dev set). We also report the WER of all models, which correlates perfectly with the accuracy measure.

8.1 Using monolingual data

As mentioned above, both in standard LM and in discriminative training, using monolingual data in a correct manner (FINE-TUNED-LM and FINE-TUNED-DISCRIMINATIVE) significantly improves over using solely the code-switching data. In standard LM, adding monolingual data results in an improvement of 7.5 points (improving from an accuracy of 57.9% to 65.4%), and in the discriminative training it results in an improvement of 5 points (improving from an accuracy of 70.5% to 75.5%). Even though both ALL:SHUFFLED-LM and ALL:CS-LAST-LM use the same data as the FINE-TUNED-LM model, they perform even worse than CS-ONLY-LM that does not use the monolingual data at all. This emphasizes that the manner of integration of the monolingual data has a very strong influence.

Note that the FINE-TUNED-LM model also im-

	25% train		50% train		75% train		full train	
	dev	test	dev	test	dev	test	dev	test
CS-ONLY	58.4	58.9	65.2	63.6	70.8	68.8	72.0	70.5
FINE-TUNED	**68.4**	**67.7**	**71.9**	**70.1**	**72.8**	**73.0**	**74.2**	**75.5**

Table 4: Results on the dev set and on the test set using discriminative training with only subsets of the code-switched data.

proves perplexity. As perplexity is significantly affected by the size of the vocabulary—and to ensure fair comparison—we also add the additional vocabulary from the monolingual data to CS-ONLY-LM (CS-ONLY+VOCAB-LM). Extending the vocabulary without training those additional words, results in a 2.37-points loss on the perplexity measure, while our evaluation metric (accuracy) stays essentially the same. This demonstrates the utility of our proposed evaluation compared to using perplexity, allowing it to fairly compare models with different vocabulary sizes.

In order to examine the contribution of the monolingual data, we also experimented with subsets of the code-switching training data. Table 4 depicts the results when using subsets of the CS training data with discriminative training. The less code-switching data we use, the more the effect of using the monolingual data is significant: we gain 8.8, 6.5, 4.2 and 5 more accuracy points with 25%, 50%, 75% and 100% of the data, respectively. In the case of 25% of the data, the FINE-TUNED-DISCRIMINATIVE model improves over CS-ONLY-DISCRIMINATIVE by 17 relative percents.

8.2 Standard LMs vs. Discriminative Training

In the standard training setting, The FINE-TUNED-LM baseline is the strongest baseline, outperforming all others with an accuracy of 65.4%. Similarly, when using discriminative training, the FINE-TUNED-DISCRIMINATIVE model outperforms the CS-ONLY-DISCRIMINATIVE model. Note that using discriminative training, even with no additional monolingual data, leads to better performance than that of the best language model: the CS-ONLY-DISCRIMINATIVE model achieves an accuracy of 70.5%, 5.1 points more than the accuracy of the FINE-TUNED-LM model. We gain further improvement by adding monolingual data and get an even higher accuracy of 75.5%, which is 10.1 points higher than the best language model.

Limitations Our evaluation setup in the discriminative training case is not ideal: the negative samples in both the train and test sets are artificially created by the same mechanism. Thus, high performance on the test set in the discriminative case may result from "leakage" in which the model learns to rely on idiosyncrasies and artifcats of the data generation mechanism. As such, these results may not transfer as is to a real-world ASR scenario, and should be considered as an optimistic estimate of the actual gains.[9] Nevertheless, we do believe that the accuracy improvements of the discriminative setup are real, and should translate to improvements also in the real-world scenario.

To alleviate the concerns to some extent, we consider the case in which the leakage is in the induced negative words distribution.[10] We re-train the discriminative model using a BOW representation of the sentence. This results in accuracies of 52.1% and 47.4% for dev and test, respectively, far below those of the basic model. A model that leaks in word distribution would score much higher in this evaluation, indicating that the improvement is likely not due to this form of leakage, and that most of the improvement of the discriminative training is likely to translate to a real ASR scenario.

9 Analysis

Table 5 breaks down the results of the different models according to two conditions: when the gold sentence is code-switched, and when the gold sentence is monolingual.

As expected, the FINE-TUNED-DISCRIMINATIVE model is able to prioritize the gold sentence better than all other models, under both conditions. The improvement we get is most significant when the gold sentence is CS: in those cases we get a dramatic improvement of 27.73 accuracy points (a relative improvement of 58%). Note that for the standard LMs, the cases

[9] An ideal evaluation setup will use an artificial dataset for training, and a dataset obtained from an acoustic model of a code-switched ASR system for testing. However, such an evaluation setup requires access to a high-quality code-switched acoustic model, which we do not posses nor have the means to obtain. Furthermore, it would also tie the evaluation to a specific ASR system, which we aim to avoid.

[10] As our generation process, much like an acoustic model, makes only local word replacements, the choice of replacement words is the most salient difference from a real acoustic model, and has the largest leakage potential.

	dev		test	
	CS	mono	CS	mono
CS-ONLY-LM	45.20	65.87	43.20	62.80
FINE-TUNED-LM	49.60	72.67	47.60	71.33
CS-ONLY-DISC	**75.60**	70.40	70.80	70.53
FINE-TUNED-DISC	70.80	**74.40**	**75.33**	**75.87**

Table 5: Accuracy on the dev set and on the test set, according to the type of the gold sentence in the set: code-switched (CS) vs. monolingual (mono).

in which the gold sentence is CS are much harder, and they perform badly on this portion of the test set. However, using discriminative learning enable us to get improved performance on both portions of the test set and to get comparable results on both parts.

A closer examination of the mistakes of the FINE-TUNED-LM and FINE-TUNED-DISCRIMINATIVE models reveals the superiority of the discriminative training in various cases. Table 6 presents several examples in which FINE-TUNED-LM prefers a wrong sentence whereas FINE-TUNED-DISCRIMINATIVE identifies the gold one. In examples 1–4 the gold sentence was code-switched but FINE-TUNED-LM forced an improbable monolingual one. Examples 5 and 6 show mistakes in monolingual sentences.

While discriminative training is significantly better than the standard LM training, it can still be improved quite a bit. Table 7 lists some of the mistakes of the FINE-TUNED-DISCRIMINATIVE model: in examples 1, 2 and 3, the gold sentence was code-switched but the model preferred a monolingual one, in example 4 the model prefers a wrong CS sentence over the gold monolingual one, and in 5 and 6 the model makes mistakes in monolingual sentences.

10 Related Work

CS Most prior work on CS focused on Language Identification (LID) (Solorio et al., 2014; Molina et al., 2016) and POS tagging (Solorio and Liu, 2008; Vyas et al., 2014; Ghosh et al., 2016; Barman et al., 2016). In this work we focus on language modeling, which we find more challenging.

LM Language models have been traditionally created by using the n-grams approach (Brown et al., 1992; Chen and Goodman, 1996). Recently, neural models gained more popularity, both using a feed-forward network for an n-gram language model (Bengio et al., 2003; Morin and Bengio, 2005) and using recurrent architectures that are fed with the sequence of words, one word at a time (Mikolov et al., 2010; Zaremba et al., 2014; Gal and Ghahramani, 2016; Foerster et al., 2017; Melis et al., 2017).

Some work has been done also on optimizing LMs for ASR purposes, using discriminative training. Kuo et al. (2002), Roark et al. (2007) and Dikici et al. (2013) all improve LM for ASR by maximizing the probability of the correct candidates. All of them use candidates of ASR systems as "negative" examples and train n-gram LMs or use linear models for classifying candidates. A closer approach to ours is used by Huang et al. (2018). There, they optimize an RNNLM with a discriminative loss as part of training an ASR system. Unlike our proposed model, they still use the standard setting of LM. In addition, their training is coupled with an end-to-end ASR system, in particular, as in previous works, the "negative" examples they use are candidates of that ASR system.

LM for CS Some work has been done also specifically on LM for code-switching. In Chan et al. (2009), the authors compare different n-gram language models, Vu et al. (2012) suggest to improve language modeling by generating artificial code-switched text. Li and Fung (2012) propose a language model that incorporates a syntactic constraint and combine both a code-switched LM and a monolingual LM in the decoding process of an ASR system. Later on, they also suggest to incorporate a different syntactic constraint and to learn the language model from bilingual data using it (Li and Fung, 2014). Pratapa et al. (2018) also use a syntactic constraint to improve LM by augmenting synthetically created CS sentences in which this constraint is not violated. Adel et al. (2013a) introduce an RNN based LM, where the output layer is factorized into languages, and POS tags are added to the input. In Adel et al. (2013b), they further investigate an n-gram based factorized LM where each word in the input is concatenated with its POS tag and its language identifier. Adel et al. (2014; 2015) also investigate the influence of syntactic and semantic features in the framework of factorized language models. Sreeram and Sinha (2017) also use a factorize LM with the addition of POS tags. Baheti et al. (2017) explore several different training protocols for CS LM and find that fine-tuning with CS data after pretrain-

6	mono → mono	we have a peter lang .	we have a bitter lung .

Table 7: Examples of sentences that the FINE-TUNED-DISCRIMINATIVE model fails to identify.

ing on monolingual data works best. Finally, another line of works suggests using a dual language model, where two monolingual LMs are combined by a probabilistic model (Garg et al., 2017, 2018).

No standard benchmark or evaluation setup exists for CS LM, and most previous works use an ASR system as part of their evaluation setup. This makes comparison of methods very challenging. Indeed, all the works listed above use different setups and don't compare to each other, even for works coming from the same group. We believe the evaluation setup we propose in this work and our English-Spanish dataset, which is easy to replicate and decoupled from an ASR system, is a needed step towards meaningful comparison of CS LM approaches.

11 Conclusions and Future Work

We consider the topic of language modeling for code-switched data. We propose a novel ranking-based evaluation method for language models, motivated by speech recognition, and create an evaluation dataset for English-Spanish code-switching LM (SpanglishEval).

We further present a discriminative training for this ranking task that is intended for ASR purposes. This training procedure is not bound to probability distributions, and uses both positive and negative training sentences. This significantly improves performance. Such discriminative training can also be applied to monolingual data.

Finally, we verify the effectiveness of the training protocol for CS LM presented in Baheti et al. (2017): pre-training on a mix of monolingual sentences, followed by fine-tuning on a code-switched dataset. This protocol significantly outperforms various baselines. Moreover, we show that the less code-switched training data we use, the more effective it is to incorporate the monolingual data.

Our proposed evaluation framework and dataset will facilitate future work by providing the ability to meaningfully compare the performance of different methods to each other, an ability that was sorely missing in previous work.

Abstract

Query-based open-domain NLP tasks require information synthesis from long and diverse web results. Current approaches extractively select portions of web text as input to Sequence-to-Sequence models using methods such as TF-IDF ranking. We propose constructing a local graph structured knowledge base for each query, which compresses the web search information and reduces redundancy. We show that by linearizing the graph into a structured input sequence, models can encode the graph representations within a standard Sequence-to-Sequence setting. For two generative tasks with very long text input, long-form question answering and multi-document summarization, feeding graph representations as input can achieve better performance than using retrieved text portions.

1 Introduction

Effective information synthesis is at the core of many Natural Language Processing applications, such as open-domain question answering and multi-document summarization. In such tasks, a fundamental challenge is the ability to distill relevant knowledge from hundreds of thousands of tokens of noisy and redundant input such as webpages. Current approaches predominantly conduct TF-IDF-based information extraction to identify key portions of the information, and then provide this as sequential input to a Sequence-to-Sequence (Seq2Seq) model. The sub-selected portions are limited to a few thousand words, as models often struggle to encode much longer sequences.

In this work, we propose a mechanism to restructure free text into local knowledge graphs that are then linearized into sequences, creating a canonical form in which information is presented to models. By constructing a graph intermediary, redundant information can be merged or discarded, producing substantially compressed input

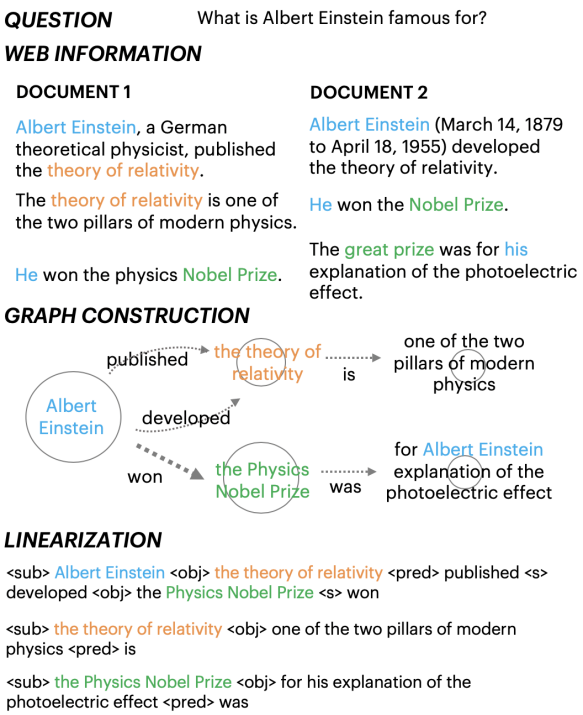

Figure 1: **Multi-Document Input to Linearized Graph** Multi-document input resulting from web search queries are converted to a graph structured knowledge base using coreference resolution and information extraction, then linearized into a sequence for Seq2Seq models. Color indicates coreference resolution. Node weight is indicated by circle radius and edge weight by line thickness.

— small enough to be fully encoded by Seq2Seq models. Such a method can be seen as merging previous work on symbolic knowledge bases for information extraction with newer approaches using deep neural networks to encode knowledge.

Our approach, shown in Figure 1, takes a query and its corresponding multi-document web search results and builds for each query a specific local knowledge graph. We present several modeling contributions to effectively encode the entire graph as a sequence and attend to the most relevant portions within this linearization. We demonstrate the effectiveness of this approach on two large-

scale generative tasks with both long and noisy multi-document web input and paragraph length output: long-form question answering on the ELI5 dataset (Fan et al., 2019) and Wikipedia lead paragraph generation as a multi-document summarization problem (Liu et al., 2018b).

2 Related Work

Interest in generative sequence modeling has intensified due to recent improvements (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2019), making the challenge of information synthesis more relevant. In contrast to extractive tasks which only require models to identify spans and can do so effectively on long documents by looking at the paragraphs independently, generative sequence models must combine multiple pieces of evidence from long and noisy multi-document input to generate correct and convincing responses.

2.1 Multi-Document Input

Previous work in multi-document summarization (Barzilay et al., 1999) applies various techniques to handle long input, including clustering to find similar information (Honarpisheh et al., 2008), extractive methods to select relevant sentences (Daumé III and Marcu, 2002; Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011; Di Fabbrizio et al., 2014; Bing et al., 2015; Cao et al., 2017) including maximal marginal relevance (Fabbri et al., 2019), and incorporating queries (Baumel et al., 2018) and graphs (Ganesan et al., 2010; Yasunaga et al., 2017). However, there are few large scale multi-document summarization datasets and many approaches have focused on extractive selection or hybrid extractive-abstractive models. In this work, we use graph construction to re-structure multi-document input for abstractive generation.

Advancements in question answering have examined performance on datasets with multi-document input, such as TriviaQA (Joshi et al., 2017). Various approaches have been proposed, including leveraging TF-IDF and bigram hashing with an RNN to find relevant information (Chen et al., 2017), models that score individual paragraphs for sub-selection (Clark and Gardner, 2017), and nearest neighbor search with paragraph re-ranking (Das et al., 2018a). However, these approaches have been applied to extractive question answering tasks that require span identification, rather than abstractive text generation in an information synthesis setting.

2.2 Using Knowledge Bases

Previous work has explored various ways of representing information in knowledge bases (Bordes et al., 2011) and improving these representations (Chen et al., 2013). Knowledge bases have been leveraged to improve performance on various tasks, from coreference resolution (Ng and Cardie, 2002) and question answering (Zheng, 2003; Bao et al., 2014; Cui et al., 2017; Sun et al., 2018) to signal processing (Bückner et al., 2002). Various works convert text into Abstract Meaning Representations (Liu et al., 2018a) for domains such as news (Vossen et al., 2015; Rospocher et al., 2016) and link nodes to large knowledge bases such as DBPedia (Auer et al., 2007). Wities et al. (2017) combine open information extraction with coreference and lexical inference to build knowledge representations. They apply this to tweets and analyze the accuracy on various aspects of graph construction. Das et al. (2018b) construct graphs from procedural text to track entity position to answer when and if entities are created, destroyed, or moved. In contrast, we build graphs from substantially longer multi-document input and use them for multi-sentence text generation.

Recently, many have explored neural architectures that can encode graph structured input (Bruna et al., 2013; Kipf and Welling, 2016; Beck et al., 2018; Zhou et al., 2018; Xu et al., 2018; Lai et al., 2019). These models often represent graphs as adjacency matrices to generalize architectures such as convolutional networks to graph inputs. Rather than encoding a static knowledge graph or leveraging external knowledge graphs, we build a local graph for each query and model these using standard Seq2Seq models. We leave the incorporation of graph networks for future work.

3 Graph Construction

We describe how symbolic graph representations of knowledge can be constructed from text. Our approach assumes a multi-document input (such as web pages) resulting from the execution of a query. The graph construction process (1) compresses the web search input to a significantly smaller size, allowing models to encode the entirety of the compression, and (2) reduces redundancy through merge operations, allowing relevant information to be more easily identified.

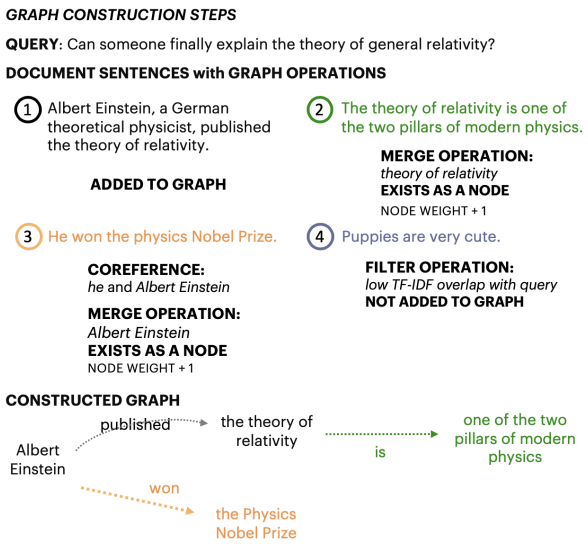

Figure 2: Steps of **Graph Construction**. Color relates the document sentence used to produce the graph output.

Text to Triples to Graph Graph construction proceeds in several steps outlined in Figure 2. We apply *Coreference Resolution* (Clark and Manning, 2016a,b)[1] and *Open Information Extraction* (Stanovsky et al., 2018)[2] to convert sentences into a *Triple* of the form (subject, predicate, object). The sentence *Albert Einstein, a German theoretical physicist, won the Nobel Prize* would become (*Albert Einstein, won, the Nobel Prize*).

A graph is constructed using the triples by representing subjects and objects as nodes connected by predicates as directed edges. For example, the triple would become *Albert Einstein* $\xrightarrow[\text{won}]{}$ *the Nobel Prize*. Nodes and edges have a *name* property that is the text they represent. They also have a *weight* property that denotes the number of times that node or edge has appeared. For example, in Figure 1, the node with name *Albert Einstein* has weight 4 and edge with name *won* has weight 2.

Merging Nodes and Edges When subsequent triples are added to the graph, they are merged with the existing graph if they already exist to reduce information replication. To merge nodes, the TF-IDF overlap of the new node's name is calculated with the existing graph node names, and the new node is merged into an existing node if the TF-IDF is higher than some threshold (see Figure 2, steps 2 and 3 for example merge operations). Edges are merged similarly with existing edges between the same two nodes. Such merge operations allow strings such as *the Nobel Prize* and *Nobel Prize* to be represented as one node rather than separately. Similarly, coreference resolution aids in merging — by identifying that *Albert Einstein* and *He* refer to the same entity and thus merging them, the construction of the graph reduces redundancy. The size of the graph can be modified by controlling which triples are added using TF-IDF overlap (see Figure 2, step 4). TF-IDF overlap of the triple with the question can be used to determine if the triple contains relevant information. This improves robustness to noisy web search input and helps filter entirely irrelevant portions, such as scraped HTML tags.

4 Modeling Graphs as Sequences

Current models for text generation often use Seq2Seq architectures such as the Transformer (Vaswani et al., 2017). These models are designed to encode sequences rather than graphs. We describe now how to convert a graph into a structured input sequence. Our complete model will take as input a linearized graph by encoding graph attributes such as node and edge weight as embeddings. We add hierarchical and memory-compressed attention mechanisms to scale Seq2Seq models to encode the full graph and attend to the most relevant information within it (Figure 4), and finally we integrate the benefits of language modeling using multi-task training.

4.1 Graph to Sequence

Linearization To represent the graph as a sequence for Seq2Seq, it is linearized into a structured standard form of subject node, object node, and predicate edge, separated by indicator tokens, as shown in Figure 1. For example, the linearization *<sub> Albert Einstein <obj> the Nobel Prize <pred> won* would be created. The linearization is accomplished through graph traversal in a breadth-first manner following the directed edges formed by predicates and starting from the node with the largest weight as the root. For two nodes that are connected by multiple predicates, the predicates are concatenated (shown in Figure 1), so a linearization such as *<pred> won <s> received* would indicate that Albert Einstein both won and received the Nobel Prize.

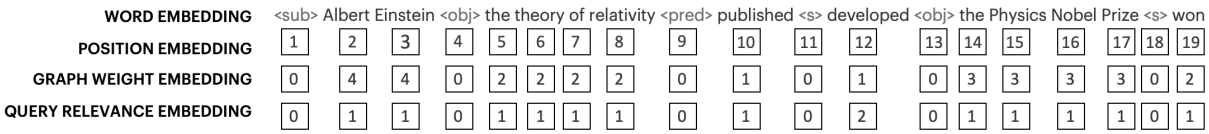

Figure 3: **Graph Attribute Embeddings**. In addition to word and position embeddings, models receive a Graph Weight embedding to encode node and edge weight and a Query Relevance embedding that encodes search result rank.

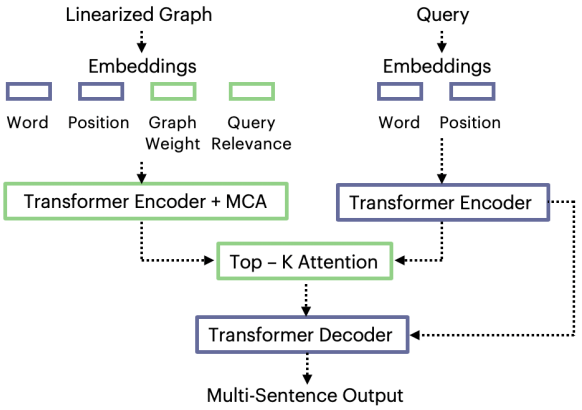

Figure 4: **Model Architecture**. Gray indicates standard Transformer elements, Green indicates modification.

Encoding Graph Information Transformer Seq2Seq models have two embeddings: a word embedding and a position embedding. Simply linearizing the graph, however, loses attribute information such as node and edge weight. Instead, we encode these attributes as embeddings in addition to the word and position embeddings.

To represent *Graph Weight* (GW), node and edge weight is provided as an embedding for each token. The node weight and edge weight are equivalent to the number of merge operations + 1. For example, if *Albert Einstein* occurred 4 times in the text, the GW embedding for the tokens *Albert* and *Einstein* would be 4, as shown in Figure 3.

We encode a *Query Relevance* (QR) embedding to represent the relevance of the web search to the query as ranked by the information retrieval system (e.g. search engine). Information from the top web search results is likely more relevant than information from the last web search results, so providing this embedding allows the model to distinguish between these different information sources. In Figure 3, tokens representing sentences from the first document have QR embedding 1, and tokens from the second document have value 2.

Models now have access to several different types of embeddings, but all embedding information contributes equally as there is no mechanism to distinguish between them. We introduce a mechanism for models to scale the graph embeddings. We denote the embedding for position t as e_t, such that e_t^{word} is the word embedding.

For the GW embedding, models learn a gating function g based on the word and GW embeddings. Such a mechanism provides capacity for the model to decide when the additional embeddings are useful based on the words in the input. The gate is calculated by applying an MLP W to the concatenation of the word and GW embeddings. The learned gate is then applied to GW embeddings to create the output h:

$$g_t^{\text{GW}} = W[e_t^{\text{GW}}; e_t^{\text{word}}]$$
$$h_t^{\text{GW}} = g_t^{\text{GW}} \circ e_t^{\text{GW}}$$

Models learn a gating mechanism for the QR embedding in a similar manner. The full embedding the model receives is as follows:

$$e_t^{\text{word}} + e_t^{\text{pos}} + [h_t^{\text{GW}}; h_t^{\text{QR}}]$$

4.2 Hierarchical Attention

One challenge in modeling long sequences is that attention mechanisms struggle to make sharp selections when softmax-ing over long sequences (Fan et al., 2018). When attention is blurry, there lacks a strong distinction between noise and relevant information.

We assume that graphs are constructed from query-based web search input and thus leverage this query to learn a subselection operation using *hierarchical top-k attention*, depicted in Figure 4. The query is encoded with a Transformer encoder and the linearized graph with another Transformer encoder. We model the interaction between the query and the input sequence (e.g. web search results or linearized graph) by computing an attention distribution between the question and the input, then selecting the top k positions with the most attention weight. Such a mechanism can be thought of as building a query-dependent representation of the most relevant knowledge, which is commonly done in question answering architectures like BiDAF (Seo et al., 2017). The top k

operation limits the number of tokens, making the attention mechanism sharper.

4.3 Scaling to Encode the Graph

Recent progress has improved the ability of language models to process longer sequences (Sukhbaatar et al., 2019; Dai et al., 2019), but models remain limited in their capacity to encode long documents. The multi-document results of query-based web search have hundreds of thousands of tokens, beyond the limit of current Seq2Seq models to handle. For example, the ELI5 dataset provides an average of 200K tokens of web search input. However, by compressing the web search results into a knowledge graph, we significantly reduce the number of tokens by an order of magnitude and make it possible for a model to access the entirety of the search information.

To represent the full graph, models must scale to encode around 10K input tokens. The attention mechanism in Transformer architectures becomes computationally expensive for sequences of this length. Instead, we experiment with the *Memory-Compressed Attention* (MCA) mechanism proposed for language models in (Liu et al., 2018b)[3] and apply it to the encoder side of Seq2Seq models. At each self-attention layer, MCA alternates between (1) local attention, computed between smaller chunks of tokens and (2) strided convolutions to reduce the number of keys and values used in attention computation. By adding the MCA mechanism to the encoder (*E-MCA*), we are able to encode the complete linearized graph.

4.4 Multi-tasking with KB Completion

Fan et al. (2019) used multi-task training on language modeling and various Seq2Seq tasks to incorporate the benefits of language modeling in Seq2Seq models. We extend this by training additionally on *knowledge graph completion*. Models receive at training time sequences of a linearized graph with nodes, edges, or both selectively masked and must predict the missing content words. For example, models might receive as input *<sub> Albert Einstein <obj> [mask] <pred> won* and need to predict *the Nobel Prize*. This can be seen as both a multi-word extension of the masked language model training proposed in (Devlin et al., 2018) and as learning the task of knowledge base completion (Lacroix et al., 2018; Bordes et al., 2011). At training time, the tasks are distinguished using an indicator token in the input.

5 Experimental Setup

We evaluate our approach on two datasets with multi-document web input and multi-sentence abstractive output. We use Seq2Seq models that leverage a query concatenated with web search results that have been processed into a supporting document — e.g. TF-IDF subselection, linearized graph, etc. — to generate long output.

5.1 Datasets and Evaluation

ELI5 First, we experiment with the *Explain Like I'm Five* (ELI5) (Fan et al., 2019) question answering dataset of 270K complex questions paired with multi-sentence, explanatory answers (130 words on average). To facilitate question answering, the dataset provides the top 100 web search hits from querying the question, which results in 200K words on average. See Appendix for examples.

Previous work (Fan et al., 2019) used TF-IDF to find sentences in the web search that have the largest overlap with the question and created a *TF-IDF extraction* of about 850 words as input for Seq2Seq models. Instead, we construct a local knowledge graph for each question from the 100 web search hits. Following the average length of the TF-IDF support document constructed in (Fan et al., 2019), we experiment with modeling the first $N = 850$ tokens of the linearized graph, then scale to encode the entire graph using E-MCA.

WikiSum Second, we experiment on the *WikiSum CommonCrawl* (Liu et al., 2018b) summarization dataset[4] with 1.5 million examples. This task formulates Wikipedia lead paragraph generation as a multi-document summarization problem, where the paragraph must be generated using the cited article references and other queried content from web search. The query used is the title of the Wikipedia article. See Appendix for examples.

Previous work (Liu et al., 2018b) applied *TF-IDF Ranking* to order the paragraphs of web search given a query. Models receive the reordered paragraphs ranked by TF-IDF as input. Liu et al. (2018b) model the first $N = 500$ words of this re-ranking and then $N = 11,000$ using

[3] In (Liu et al., 2018b), the mechanism is termed *DMCA* as it is applied on the decoder side

[4] https://github.com/tensorflow/tensor2tensor/tree/master/tensor2tensor/data_generators/wikisum

MCA. We construct the knowledge graph for each Wikipedia article from the first 200K words of the ranked web search results[5], and experiment with encoding 500 and 11,000 tokens.

Evaluation Both tasks evaluate the multi-sentence generation output against the gold output using F1 ROUGE. On WikiSum, we report only ROUGE-L following (Liu et al., 2018b).

We conduct a comparative human evaluation on the ELI5 dataset. We use crowdworkers to examine the responses of two models on 300 different questions from the test set. For each question, 3 evaluators are shown two answers and asked to choose the one they prefer. To reduce variance, answers are standardized at 150 words each.

5.2 Training and Generation

To reduce the vocabulary size of varied web document content, we apply byte-pair encoding (Sennrich et al., 2016) to generate 40K codes for each dataset. We implement our models in fairseq-py (Ott et al., 2019) using the Transformer Big architecture and training schedule described in (Vaswani et al., 2017). Detailed parameters are listed in the Appendix. For generation, we use beam search with beam size 5 and tune a minimum and maximum length on the validation set.

5.3 Baselines

We compare our results to the Transformer sequence models presented in (Fan et al., 2019) for ELI5 and (Liu et al., 2018b) for WikiSum.

We evaluate three additional baseline models:

- *Sentence Selection with Maximal Marginal Relevance:* (Fan et al., 2019) used TF-IDF to identify relevant sentences in the web documents to form a support document of around 850 words. However, recent work (Fabbri et al., 2019) has shown that using maximal marginal relevance is an effective strategy for selecting relevant information while reducing redundancy. We explore using MMR to select sentences from the web text to concatenate to form a support document.
- *Seq2Seq Multi-task Triples:* To examine the impact of solely restructuring the input into Open IE Triples but not leveraging graph construction to reduce redundancy, we experiment with a Triples Only baseline. The triples are concatenated to form the input.
- *Seq2Seq Multi-task Top 20 Triples:* As an alternative to using graph construction to compress the full set of Open IE Triples, we explore using TF-IDF overlap with the query to find the most relevant information. We select the top 20 triples to concatenate as input.

[5]Average length of provided web input is around 50K words, and maximum length is around 900K words

Model	Input Length	ROUGE 1	2	L
Q + D to A*, TF-IDF	avg 850	28.3	5.1	22.8
Q + D to A, MMR	avg 850	28.1	5.0	22.9

6 Results

We examine the performance of our proposed approach and the choices made in graph construction and modeling. We analyze the quality of the compression created by graph construction and the robustness and interpretability of this process.

6.1 Linearized Graph Improves Performance

In Table 1, we compare our methods to various baselines on the ELI5 dataset. Using MMR to select the most relevant non-redundant input is similar to the TF-IDF baseline from Fan et al. (2019).

The Seq2Seq Multi-task Triples baseline standardizes the input by forming triples but does not remove redundant triples. It produces marginally better results compared to the baseline Multi-Task model. Sub-selecting to the Top 20 Triples is harmful, as similar text has high TF-IDF overlap with the query so redundant information is selected. Creating the graph structure brings an improvement of around 0.6 ROUGE-1.

Similar trends are seen for the WikiSum dataset in Table 2, where graph construction improves the Multi-task model by 0.5 ROUGE-1. These improvements are statistically significant at the 95% confidence level.

For both datasets, a further improvement is seen by using the hierarchical attention mechanism to attend to only the most relevant information in the linearized graph input. For ELI5, it brings an additional 0.2 ROUGE-1 improvement and on WikiSum a 0.3 ROUGE-1 improvement.

By using MCA to scale Seq2Seq models to encode the entire graph, further gains can be seen. Particularly in information synthesis tasks, prior work has shown the importance of reading more information. Liu et al. (2018b) achieved a 2-point ROUGE improvement by reading 11K tokens instead of 500. In our setting, E-MCA improves our results around 0.3 ROUGE on ELI5 and 1.3 ROUGE on WikiSum. We display random generations from both datasets in the Appendix.

We use human evaluation to compare the Multi-task baseline to the Multi-task Graph + Top-k Attention model. **57.4%** of evaluations prefer the Multi-task Graph + Top-k Attention model. We conduct a two-tailed binomial test and find this result is statistically significant with $p = 0.003$.

6.2 Analysis of Modeling Choices

Ablation on Model Components Table 3(a) sequentially removes the graph embeddings, the knowledge-base completion multi-tasking, and the multi-tasking from (Fan et al., 2019) and reveals that each of these is important for performance.

Graph Attribute Embeddings Table 3(b) displays the effect of removing the graph attribute embeddings and gating mechanism. Removing each is slightly harmful, and the combination of all three together provide the best performance.

More Web Search Documents Figure 7 (right) shows that graph construction with more web search information is important for answer token coverage. The graph on the top search hit alone is missing 64% of the answer tokens, but this decreases as more search hits are used. Table 3(c) indicates that this lack of coverage of the answer tokens correlates with generation quality. Models receiving a graph built on the first 5 search hits alone are substantially worse than all 100 hits.

Top-k Attention Table 3(d) shows the effect of the Top-k Hierarchical Attention mechanism for various values of k. Attending to too many tokens lowers ROUGE — for the ELI5 task of writing approximately 130 word answers, attending to 1000 input tokens likely means the model is focusing on irrelevant information and 50 tokens is too few.

Model	ROUGE-1
(a) Iterative Removal of Model Components	
Multi-task Graph	29.4
- Graph Embeddings	29.1
- KB Completion Multi-tasking	28.9
- LM Multi-tasking from (Fan et al., 2019)	28.4
(b) Removing Graph Embedding Components	
Graph	
+ Gated Graph Weight + Query Relevance	28.6
No Graph Weight Embedding	28.4
No Query Relevance Embedding	28.3
No Gating	28.4
(c) Varying Number of Hits in Graph	
Multi-task Graph + Top-k Attention + E-MCA	
with Graph on 5 Search Hits	28.8
with Graph on 10 Search Hits	29.3
with Graph on 50 Search Hits	29.6
with Graph on 100 Search Hits	29.9
(d) Varying k in Hierarchical Top-k Atttention	
Multi-task Graph + E-MCA +	
Top-$k = 50$	29.1
Top-$k = 100$	29.5
Top-$k = 250$	29.4
Top-$k = 500$	29.3
Top-$k = 1000$	29.2

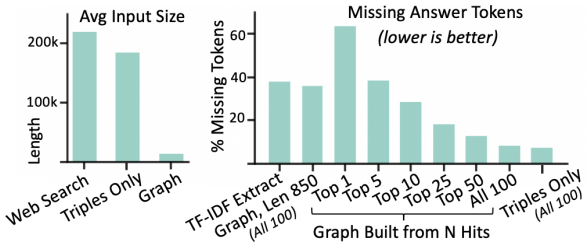

Figure 7: (Left) Graph construction drastically reduces input size by an order of magnitude. (Right) Graph construction encodes more tokens present in the answer compared to TF-IDF extraction and building the graph from more search hits increases answer token coverage. Analysis on ELI5 for both plots.

6.3 Graph Improves Answer Token Coverage Despite Compression

Figure 6 displays the distribution of the number of nodes, edges, and the largest node weight for each local graph built on the ELI5 dataset. The 100 web search results are compressed to a few hundred nodes. By merging redundancy and trimming irrelevant triples from the graph, the input is reduced by an order of magnitude (Figure 7, left).

Despite compression, the graph retains more answer tokens than TF-IDF subselection. Figure 7 (right) displays the percentage of answer tokens not present in the input. The TF-IDF Extraction from (Fan et al., 2019) is missing 38% of tokens. The graph constructed on all 100 web search results is only missing 8.7% of tokens, but has around 10K words. When analyzing just the first 850 tokens to match the average length of the TF-IDF extraction, the graph is better (only missing 35% of tokens). Further, the merging and discarding operations done during graph construction do not have a large effect on answer token coverage — the full set of triples marginally reduces the percentage of answer tokens missing to 7.3% instead of 8.7%. This indicates that much of the information in the full set triples is redundant and unnecessary for good answer token coverage.

6.4 Graph Representation is More Robust to Poor Search Relevance Ordering

We analyze the robustness of our approach to the ordering of web search results in Table 4. Instead of constructing the graph from the first web search result to the last, we shuffle the web search results and construct the graph on this shuffled input. We compare this to modeling the web search results directly (no TF-IDF retrieval) and a model that receives this shuffled web search input. The graph is more robust to shuffling — as more information can be encoded in the graph due to its compression effect, the search hit ordering is less critical.

6.5 Interpretable Attention on Subgraphs

Figure 5 shows an example of the nodes and edges the model focuses upon most when answering a question on ELI5. To construct this visualization, we calculate the top nodes the model attends to and then their top edges. The model attention on a sub-portion of the linearized input can be visualized as an interpretable graph that corresponds well to the model's generated answer. For example, the relationship *General Relativity* $\xrightarrow[\text{is}]{}$ *Einstein's theory* becomes the generated sentence *General Relativity is a theory of Albert Einstein*.

7 Conclusion

Many open-domain NLP tasks rely upon multi-document input from the web to facilitate tasks such as answering questions or writing summaries, but current approaches struggle to encode the entirely of this information. We propose constructing one knowledge graph per query and show that this method compresses information and reduces redundancy. We show on two abstractive generation tasks that using the linearized graph achieves better performance than TF-IDF retrieval.

Abstract

In sequence labeling, previous domain adaptation methods focus on the adaptation from the source domain to the entire target domain without considering the diversity of individual target domain samples, which may lead to negative transfer results for certain samples. Besides, an important characteristic of sequence labeling tasks is that different elements within a given sample may also have diverse domain relevance, which requires further consideration. To take the multi-level domain relevance discrepancy into account, in this paper, we propose a fine-grained knowledge fusion model with the domain relevance modeling scheme to control the balance between learning from the target domain data and learning from the source domain model. Experiments on three sequence labeling tasks show that our fine-grained knowledge fusion model outperforms strong baselines and other state-of-the-art sequence labeling domain adaptation methods. [1]

1 Introduction

Sequence labeling tasks, such as Chinese word segmentation (CWS), POS tagging (POS) and named entity recognition (NER), are fundamental tasks in natural language processing. Recently, with the development of deep learning, neural sequence labeling approaches have achieved pretty high accuracy (Chen et al., 2017; Zhang and Yang, 2018), relying on large-scale annotated corpora. However, most of the standard annotated corpora belong to the news domain, and models trained on these corpora will get sharp declines in performance when applied to other domains like social media, forum, literature or patents (Daume III, 2007; Blitzer et al., 2007), which limits their application in the real world. Domain adaptation aims to exploit the abundant information of well-studied source domains to improve the performance in target domains (Pan and Yang, 2010), which is suitable to handle this issue. Following Daume III (2007), we focus on the supervised domain adaptation setting, which utilizes large-scale annotated data from the source domain and small-scale annotated data from the target domain.

Types	Cases
Strongly	*Ops* **Steve Jobs resigned as CEO of Apple. Share prices are rising** *soooo* **fast**!
Weakly	*Alas* **as time goes by**, *hair's gone. Rock to 204 Section* **next week**!

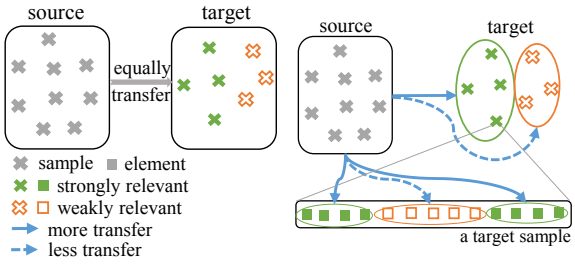

Table 1: Tweets from the social media domain have different degrees of relevance to the source domain (news). Within each case, the bold part is strongly relevant and the italic part is weakly relevant.

For sequence labeling tasks, each sample is usually a sentence, which consists of a sequence of words/Chinese characters, denoted as the element. We notice an interesting phenomenon: different target domain samples may have varying degrees of domain relevance to the source domain. As depicted in Table 1, there are some tweets similar to the news domain (i.e. strongly relevant). But there are also some tweets of their own style, which only appear in the social media domain (i.e. weakly relevant). The phenomenon can be more complicated for the cases where the whole sample is strongly relevant while contains some target domain specific elements, or vice versa, showing the diversity of relevance at the element-level. In the rest of this paper, we use 'domain relevance' to refer to the domain relevance to the source domain, unless specified otherwise.

Conventional neural sequence labeling domain adaptation methods (Liu and Zhang, 2012; Liu et al., 2014; Zhang et al., 2014; Chen et al., 2017; Peng and Dredze, 2017; Lin and Lu, 2018) mainly

(a) Previous methods (b) Our method

Figure 1: Previous methods transfer knowledge by the whole sample set, while our method consider diverse domain relevance within the target domain set and within every target sample to transfer knowledge respectively.

focus on reducing the discrepancy between the sets of source domain samples and target domain samples. However, they neglect the diverse domain relevance of individual target domain samples, let alone the element-level domain relevance. As depicted in Figure 1, obviously, strongly relevant samples/elements should learn more knowledge from the source domain, while weakly relevant samples/elements should learn less and keep their characteristics.

In this paper, we propose a fine-grained knowledge fusion model to control the balance between learning from the target domain data and learning from the source model, inspired by the knowledge distillation method (Bucila et al., 2006; Hinton et al., 2015). With both the sample-level and element-level domain relevance modeling and incorporating, the fine-grained knowledge fusion model can alleviate the *negative transfer* (Rosenstein et al., 2005) in sequence labeling domain adaptation.

We verify the effectiveness of our method on six domain adaptation experiments of three different tasks, i.e. CWS, POS and NER, in two different languages, i.e. Chinese and English, respectively. Experiments show that our method achieves better results than previous state-of-the-art methods on all tasks. We also provide detailed analyses to study the knowledge fusion process.

Contributions of our work are summarized as follows:

- We propose a fine-grained knowledge fusion model to balance the learning from the target data and learning from the source model.
- We also propose multi-level relevance modeling schemes to model both the sample-level and element-level domain relevance.
- Empirical evidences and analyses are provided on three different tasks in two different languages, which verify the effectiveness of our method.

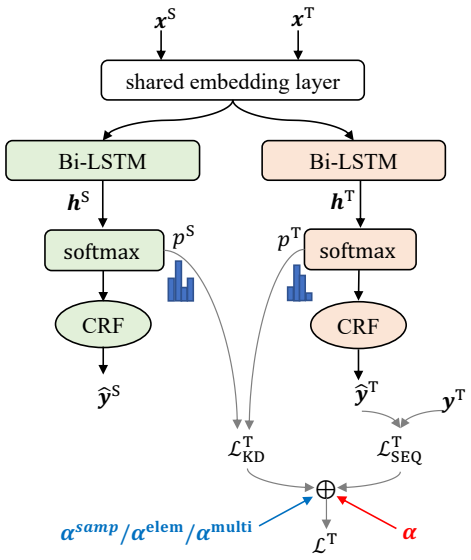

Figure 2: The architecture of basicKD (with the red α, see §2) or fine-grained knowledge fusion model (with the blue α, see §4), where the green part belongs to the source model, the orange part belongs to the target model and the white part is common. Better viewed in color.

2 Knowledge Distillation for Adaptation

Knowledge distillation (KD), which distills the knowledge from a sophisticated model to a simple model, has been employed in domain adaptation (Bao et al., 2017; Meng et al., 2018). Recently, online knowledge distillation(Furlanello et al., 2018; Zhou et al., 2018) is shown to be more effective, which shares lower layers between the two models and trains them simultaneously.

For sequence labeling domain adaptation, we utilize the online knowledge distillation method to distill knowledge from the source model to improve the target model, denoted as basicKD, which is depicted in Figure 2. We use the Bi-LSTM-CRF architecture (Huang et al., 2015), for both the source model and the target model, and share the embedding layer between them.

Notations For the rest of the paper, we use the superscript S and T to denote the source domain and the target domain, respectively. Source domain data is a set of m samples with gold la-

bel sequences, denoted as $(\mathbf{x}_j^S, \mathbf{y}_j^S)_{j=1}^m$. Similarly, target domain data has n samples, denoted as $(\mathbf{x}_i^T, \mathbf{y}_i^T)_{i=1}^n$, where $n \ll m$.

The training loss of the source model is the cross entropy between the predicted label distribution $\hat{\mathbf{y}}$ and the gold label $\mathbf{y}$:

$$\mathcal{L}^S = -\frac{1}{m}\sum_{j=1}^{m} \mathbf{y}_j^S \log \hat{\mathbf{y}}_j^S \tag{1}$$

The training loss of the target model is composed of two parts, namely the sequence labeling loss $\mathcal{L}_{\text{SEQ}}^T$ and the knowledge distillation loss $\mathcal{L}_{\text{KD}}^T$:

$$\mathcal{L}^T = (1-\alpha)\mathcal{L}_{\text{SEQ}}^T + \alpha\mathcal{L}_{\text{KD}}^T \tag{2}$$

$$\mathcal{L}_{\text{SEQ}}^T = -\frac{1}{n}\sum_{i=1}^{n} \mathbf{y}_i^T \log \hat{\mathbf{y}}_i^T \tag{3}$$

$$\mathcal{L}_{\text{KD}}^T = -\frac{1}{n}\sum_{i=1}^{n} \mathbf{p}_i^S \log \mathbf{p}_i^T \tag{4}$$

where $\mathcal{L}_{\text{SEQ}}^T$ is similar to $\mathcal{L}^S$, while $\mathcal{L}_{\text{KD}}^T$ is the cross entropy between the probability distributions predicted by the source model and the target model. α is a hyper-parameter scalar, which is used to balance the learning from the target domain data and the learning from the source model.

3 Relevance Modeling

BasicKD provides individual learning goals for every sample and element of the target domain, using a scalar α to weight. As a result, the source model has the same influence on all target samples, in which the diversity of domain relevance is neglected.

Here we present methods to model the domain relevance of target samples and elements, which could then be used to guide the knowledge fusion process (see §4). The overall architecture is shown in Figure 3. The relevance of each sample is a scalar, denoted as the sample-level relevance weight, $\mathbf{w}_i^{\text{samp}}$ for the i^{th} sample, which can be obtained by the sample-level domain classification. The relevance of each element is also a scalar, while the relevance weights of all elements within a sample form a weight vector $\mathbf{w}^{\text{elem}}$, which can be obtained by the similarity calculation.

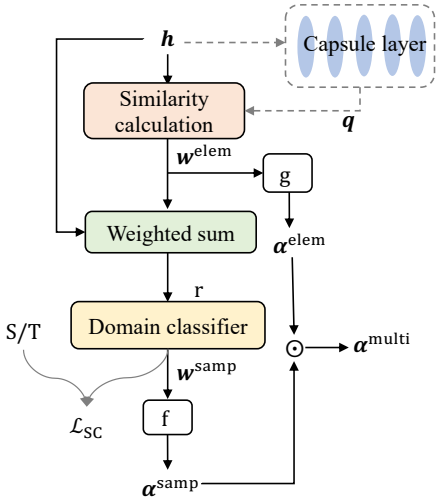

Figure 3: The relevance modeling process (see §3), where the block f denotes Eq.(10) and the block g denotes Eq.(14).

3.1 Element-level Relevance

To acquire the element-level relevance, we employ the domain representation $\boldsymbol{q} \in \mathbb{R}^{2d_h}$ (d_h is the dimension of the Bi-LSTM) and calculate the similarity between the element representation and the domain representation. We incorporate two methods to get $\boldsymbol{q}$: (1) Domain-q: $\boldsymbol{q}$ is a trainable domain specific vector, where every element within a domain share the same $\boldsymbol{q}$; (2) Sample-q: $\boldsymbol{q}$ is the domain relevant feature extracted from each sample, where every element within a sample share the same $\boldsymbol{q}$. Because of the superiority of the capsule network modeling abstract features (Gong et al., 2018; Yang et al., 2018), we use it to capture the domain relevant features within a sample. We incorporate the same bottom-up aggregation process as Gong et al. (2018) and the encoded vector is regarded as $\boldsymbol{q}$:

$$\mathbf{q} = \text{Capsule}(\mathbf{h}) \tag{5}$$

where $\mathbf{h}$ is the hidden state matrix of a sample.

The similarity calculation formula is the matrix dot [2]:

$$\mathbf{w}_j^{\text{elem}} = \mathbf{q}^\top \mathbf{B}\mathbf{h}_j \tag{6}$$

where $\boldsymbol{h}_j$ is the hidden states of the j^{th} element and $\mathbf{w}_j^{\text{elem}}$ is the relevance weight of it. $\mathbf{B} \in \mathbb{R}^{2d_h \times 2d_h}$ is a trainable matrix.

[2]We also try dot and MLP, while matrix dot get better performance with fewer parameters.

3.2 Sample-level Relevance

To acquire the sample-level domain relevance, we make use of the domain label to carry out sample-level text classification (two class, source domain or target domain). The weight $\mathbf{w}^{\text{elem}}$ is normalized across the sample length using the softmax function, then the sample representation can be obtained by the weighted sum of hidden states. The process can be expressed as:

$$\hat{\mathbf{w}}_j^{\text{elem}} = \frac{\exp(\mathbf{w}_j^{\text{elem}})}{\sum_k \exp(\mathbf{w}_k^{\text{elem}})} \tag{7}$$

$$\mathbf{r} = \sum_{j=1}^{L} \hat{\mathbf{w}}_j{}^{\text{elem}} \cdot \mathbf{h}_j \tag{8}$$

$\mathbf{r} \in \mathbb{R}^{2d_h}$ is the sample representation and L is the sample length.

Once the sample representation is obtained, the multi-layer perceptron (MLP) and softmax do sample classification next:

$$[w^{\text{samp}}, 1 - w^{\text{samp}}] = [\text{softmax}(\text{MLP}(\mathbf{r}))]^\top \tag{9}$$

where w^{samp} is the sample relevance weight.

4 Fine-grained Knowledge Fusion for Adaptation

With the relevance modeling, the fine-grained knowledge fusion model is proposed to fusion the knowledge from the source domain and the target domain at different levels. The overall architecture is shown in Figure 2.

4.1 Sample-level Knowledge Fusion

Different samples of target domain tend to show different domain relevance, and as a result, they need to acquire different amount of knowledge from the source domain. Different α is assigned to each target sample based on its domain relevance to achieve the sample-level knowledge fusion. The new α can be computed as:

$$\boldsymbol{\alpha}_i^{\text{samp}} = \sigma(\tau \cdot \mathbf{w}_i^{\text{samp}} + \gamma) \tag{10}$$

where $\boldsymbol{\alpha}_i^{\text{samp}}$ is the α of the i^{th} sample and $\mathbf{w}_i^{\text{samp}}$ is the relevance weight of it; σ denotes the sigmoid function; τ is temperature and γ is bias.

The loss functions of the target model can be computed as:

$$\mathcal{L}^T = \mathcal{L}^T_{\text{SEQ}} + \mathcal{L}^T_{\text{KD}} \tag{11}$$

$$\mathcal{L}^T_{\text{SEQ}} = -\frac{1}{n}\sum_{i=1}^{n}(1 - \boldsymbol{\alpha}_i^{\text{samp}})\mathbf{y}_i^T \log \hat{\mathbf{y}}_i^T \tag{12}$$

$$\mathcal{L}^T_{\text{KD}} = -\frac{1}{n}\sum_{i=1}^{n}\boldsymbol{\alpha}_i^{\text{samp}}\mathbf{p}_i^S \log \mathbf{p}_i^T \tag{13}$$

The sample classification losses of the source model $\mathcal{L}^S_{sc}$ and target model $\mathcal{L}^T_{sc}$ are both cross entropy.

4.2 Element-level Knowledge Fusion

Besides the sample-level domain relevance, different elements within a sample tend to present diverse domain relevance. In this method, we assign different α to each element based on its domain relevance weight to achieve the element-level knowledge fusion. The new α can be computed as:

$$\boldsymbol{\alpha}_i^{\text{elem}} = \sigma(\mathbf{W}_\alpha \mathbf{w}_i^{\text{elem}} + \mathbf{b}_\alpha)] \tag{14}$$

where $\boldsymbol{\alpha}_i^{\text{elem}} \in \mathbb{R}^L$ is a vector, in which $\boldsymbol{\alpha}_{ij}^{\text{elem}}$ denotes the α of the j^{th} element in the i^{th} sample. $\mathbf{w}_i^{\text{elem}}$ is the relevance weight of the i^{th} sample. $\mathbf{W}_\alpha$ and $\mathbf{b}_\alpha$ are trainable parameters.

The loss functions of the target model can be expressed as:

$$\mathcal{L}^T_{\text{SEQ}} = -\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{L}(1 - \boldsymbol{\alpha}_{ij}^{\text{elem}})\mathbf{y}_{ij}^T \log \hat{\mathbf{y}}_{ij}^T \tag{15}$$

$$\mathcal{L}^T_{\text{KD}} = -\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{L}\boldsymbol{\alpha}_{ij}^{\text{elem}}\mathbf{p}_{ij}^S \log \mathbf{p}_{ij}^T \tag{16}$$

where $*_{ij}$ denotes the $*$ of the j^{th} element in the i^{th} sample, and the final loss function is the same with Eq.(11).

4.3 Multi-level Knowledge Fusion

In this method, we take both the sample-level and element-level relevance diversities into account to implement the multi-level knowledge fusion, and the multi-level α can be computed as:

$$\boldsymbol{\alpha}^{\text{multi}} = \boldsymbol{\alpha}^{\text{samp}} \odot \boldsymbol{\alpha}^{\text{elem}} \tag{17}$$

where $\odot$ denotes the element-wise product. $\boldsymbol{\alpha}^{\text{multi}} \in \mathbb{R}^{n \times L}$ is a matrix as well.

The loss functions of the target model can be obtained by replacing $\boldsymbol{\alpha}_{ij}^{\text{elem}}$ with $\boldsymbol{\alpha}_{ij}^{\text{multi}}$ in Eq.(15) and Eq.(16).

19. **end while**
20. **until** converge

4.4 Training Process

Both the source model and the target model can be pre-trained on the source domain data (warm up, optional). In the fine-grained knowledge fusion method, the source model and the target model are trained alternately. Within an episode, we use I steps to train the source model ahead, then the soft target ($\mathbf{p}^S$) can be obtained and the target model will be trained. During the training of the target model, the parameters of the source model are fixed (gradient block). Every training step includes the sequence labeling training and the sample classification training. We conduct early stopping according to the performance of the target model. The whole training process is shown in Algorithm 1.

5 Experiments

5.1 Datasets

We conduct three sequence labeling tasks: CWS, POS and NER, and the latter two tasks containing both Chinese and English settings. Detailed datasets are shown in Table 2. There are two kinds of source-target domain pairs: news-novels and news-social media. To be consistent with the setting where there is only small-scale target domain data, we use 5% training data of Weibo for both CWS and POS. For the different NER tag sets, we only focus on three types of entities: Person (PER), Location (LOC) and Organization (ORG) and regard other types as Other (O).

5.2 Settings

For each task, hyper-parameters are set via grid search on the target domain development set. Embedding size and the dimension of LSTM hidden states is set to 100. Batch size is set to 64. Learning rate is set to 0.01. We employ the dropout strategy on the embedding and MLP layer with the rate of 0.2. The l_2 regularization term is set to 0.1. The gradient clip is set to 5. The teach step I is set to 100. The routing iteration is set to 3 and the number of the output capsules is set to 60. The temperature τ is initialized to 1 and the probability bias γ is initialized to 0.5. We set the α of the basicKD method to 0.5 according to Hinton et al. (2015). We randomly initialize the embedding matrix without using extra data to pre-train, unless specified otherwise.

5.3 Baselines

We implement several baseline methods, including: **source only** (training with only source domain data), **target only** (training with only target domain data) and **basicKD** (see §2).

We also re-implement state-of-the-art sequence labeling domain adaptation methods, following their settings except for unifying the embedding size and the dimension of LSTM hidden states:

- **Pre-trained methods: Pre-trained embedding** incorporates source domain data with its gold label to pre-train context-aware character embedding (Zhou et al., 2017), which is used to initialize the target model; **Pre-trained model** trains the model on the source domain and then finetune it on the target domain.

Table 3: Results of domain adaptation on three tasks, where zh denotes the Weibo datasets (in Chinese), and en denotes the Twitter dataset (in English).

- **Projection methods: Linear projection** (Peng and Dredze, 2017) uses the domain-relevant matrix to transform the learned representation from different domains into the shared space; **Domain mask** (Peng and Dredze, 2017) masks the hidden states of Bi-LSTM to split the representations into private and public regions to do the projection; **Neural adaptation layer** (NAL) (Lin and Lu, 2018) incorporates adaptation layers at the input and output to conduct private-public-private projections.

- **Adversarial method: Adversarial multi-criteria learning** (AMCL) (Chen et al., 2017) uses the shared-private architecture with the adversarial strategy to learn the shared representations across domains.

5.4 Overall Results on CWS

We use the F1-score (F) and the recall of out-of-vocabulary words (R_{oov}) to evaluate the domain adaptation performance on CWS. We compare methods with different relevance modeling schemes and different levels of knowledge fusion, without warm up. And we denote our final model as **FGKF**, which is the multi-level knowledge fusion with the sample-q relevance modeling and warm up.

The results in Table 4 show that both the basicKD method and fine-grained methods achieve performance improvements through domain adaptation. Compared with the basicKD method, FGKF behaves better (+1.1% F and +2.8% R_{oov} v.s. basicKD on average), as it takes multi-level relevance discrepancies into account. The sample-q method performs better than the domain-q method, which shows the domain feature is better represented at the sample level, not at the domain level. As for the granularity of α, the performances of $\boldsymbol{\alpha}^{\text{elem}}$ is better than $\boldsymbol{\alpha}^{\text{samp}}$, showing the necessity of modeling element-level relevance. And there isn't a distinct margin between $\boldsymbol{\alpha}^{\text{elem}}$ and $\boldsymbol{\alpha}^{\text{multi}}$ as most of the multi-level domain relevance can be included by the element level. Results of FGKF with warm up indicate that starting from sub-optimal point is better than starting from scratch for the target model.

Methods	Zhuxian		5% Weibo	
	F	R_{OOV}	F	R_{OOV}
Source only	83.86	62.40	83.75	70.74

FGKF	**95.01**	**77.26**	**90.45**	77.27

Table 4: Results of baselines and fine-grained knowledge fusion methods on CWS.

Among related works (Table 3), AMCL and Pre-trained model methods have better performances in CWS. Compared with other methods, FGKF achieves the best results in both F and R_{OOV}. Results demonstrate the effectiveness of our fine-grained knowledge fusion architecture for domain adaptation, and also show the significance of considering sample-level and element-level relevance discrepancies.

5.5 Overall Results on POS and NER

To further verify the effectiveness of FGKF, we conduct experiments on POS and NER tasks, using F1-score as the evaluation criterion. Detailed results are shown in Table 3. In these tasks, FGKF

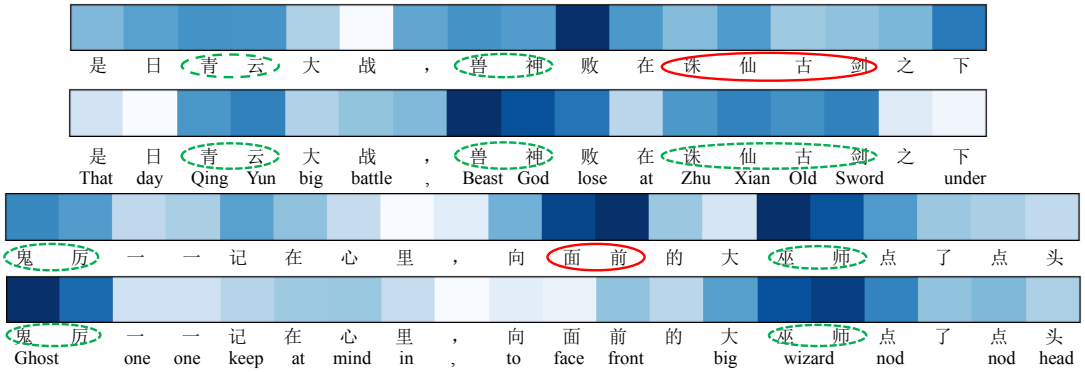

Figure 4: Two cases of the element-level relevance modeling visualization, where the upper one belongs to the domain-q method and the lower one belongs to the sample-q method. The green dotted circle indicates the correct domain relevant element and the red solid circle indicates the ignored or mistaken extracted element.

achieves better results than other adaptation methods. Extra gain could be obtained by using pre-trained embedding. These results also verify the generalization of our method over different tasks and languages.

6 Analysis

In this section, we will display and discuss the domain adaptation improvements provided by our fine-grained knowledge fusion method.

6.1 Performances of Elements with Different Relevance

To further probe into the experimental results of the fine-grained knowledge fusion, we classify the target test data (in element level) into two classes: strongly relevant and weakly relevant, based on their relevance degrees to the source domain. The partition threshold is according to the average relevance score of the target training data. Detailed results on Twitter are depicted in Table 5.

Methods	POS		NER	
	Strong	Weak	Strong	Weak
Source only	87.47	82.48	68.27	46.30
Target only	86.46	87.41	62.01	56.29
BasicKD	91.92	83.82	70.20	52.63
FGKF	**92.55**	**89.93**	**71.81**	**57.92**

Table 5: Results of the strongly/weakly relevant elements on the Twitter test set.

It is reasonable that both the basicKD and FGKF enhance the performance of the strongly relevant part, while FGKF get larger improvements because it is able to enhance the knowledge fusion by learning more from the source model. For the weakly relevant part, the basicKD method damages the performance on it (from 87.41 to 83.82 for POS and from 56.29 to 52.63 for NER), which indicate the negative transfer. On the contrary, FGKF improves the performance of the weakly relevant part compared with the target only baseline with a large margin. It is shown that the fine-grained domain adaptation method can reduce the negative transfer on the weakly relevant part and contribute to the transfer on the strongly relevant one.

6.2 Relevance Weight Visualization

We carry out the visualization of the element-level relevance weight to illustrate the effects of the two relevance modeling schemes (domain-q and sample-q). Figure 4 exhibits two cases of element-level relevance modeling results, from which we can explicitly observe that the two schemes capture different domain relevance within a sample. In the first case, the sample-q method extracts more domain relevant elments, like “Qingyun”, “Beast God” and “Zhuxian Old Sword”, while the domain-q method ignores the last one. In the second case, the domain-q method extracts “front” incorrectly. These results indicate that the sample-q method can implement better relevance modeling than the domain-q method to some extent, and prove that the domain relevant feature is better represented at the sample level, not at the domain level.

6.3 Case Study

We take two samples in Twitter test set as examples to show how the element-level relevance affects the adaptation. Results in Table 6 show that both basicKD and FGKF can improve the performance of strongly relevant elements, e.g. “got (VBD)”, “Lovis (B-PER)”. However, only FGKF

Tasks	POS					NER				
Sentence	I	got	u	next	week	Louis	interview	with	The	Sun
Source only	PN	VBD	NN	JJ	NN	B-PER	O	O	O	O
Target only	PN	VBZ	PN	JJ	NN	O	O	O	B-ORG	I-ORG
BasicKD	PN	VBD	NN	JJ	NN	B-PER	O	O	O	O
FGKF	PN	VBD	PN	JJ	NN	B-PER	O	O	B-ORG	I-ORG

Table 6: Two cases of domain adaptation, where the underlined tags are wrong.

reduces the transfer of source domain errors, e.g. "u (NN)", "The (B-ORG) Sun (I-ORG)".

6.4 Ablation Study

We conduct the ablation study on Twitter dataset (Table 7). Results show the gradient block and the multi-level knowledge fusion are of vital importance to FGKF. The embedding sharing and warm up also make contributions.

Methods	POS		NER	
	F	Δ	F	Δ
FGKF	91.33	-	63.81	-
w/o share embedding	90.75	-0.58	62.47	-1.34
w/o gradient block	88.48	-2.85	58.83	-4.98
w/o α^{samp}	90.94	-0.39	63.52	-0.30
w/o α^{elem}	90.23	-1.10	62.43	-1.38
w/o α^{multi}	90.12	-1.21	62.32	-1.49
w/o warm up	90.89	-0.44	63.17	-0.64

Table 7: Ablation results of the Twitter test set.

6.5 Influence of Target Data Size

Here we investigate the impact of the target domain data size on FGKF. As is depicted in Figure 5, when the size is small (20%), the gap is pretty huge between FGKF and basicKD, which verifies the significance of fine-grained knowledge fusion in the low-resource setting. Even with the size of target data increasing, there are still stable margins between the two methods.

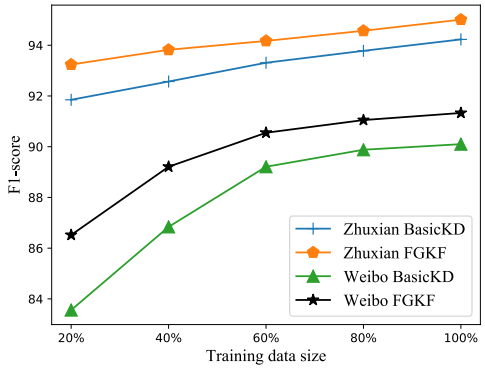

Figure 5: Results of CWS target test set with varying target training data size. Only 10% training data of Weibo is utilized.

7 Related Work

Besides the source domain data, some methods utilize the target domain lexicons (Liu et al., 2014; Zhang et al., 2014), unlabeled (Liu and Zhang, 2012) or partial-labeled target domain data (Liu et al., 2014) to boost the sequence labeling adaptation performance, which belong to unsupervised or semi-supervised domain adaptation. However, we focus on supervised sequence labeling domain adaptation, where huge improvement can be achieved by utilizing only small-scale annotated data from the target domain.

Previous works in domain adaptation often try to find a subset of source domain data to align with the target domain data (Chopra et al., 2013; Ruder and Plank, 2017) which realizes a kind of source data sample or construct a common feature space, while those methods may wash out informative characteristics of target domain samples. Instance-based domain adaptation (Jiang and Zhai, 2007; Zhang and Xiong, 2018) implement the source sample weighting by assigning higher weights to source domain samples which are more similar to the target domain. There are also some methods (Guo et al., 2018; Kim et al., 2017; Zeng et al., 2018) explicitly weighting multiple source domain models for target samples in multi-source domain adaptation. However, our work focuses on the supervised single source domain adaptation, which devote to implementing the knowledge fusion between the source domain and the target domain, not within multiple source domains. Moreover, considering the important characteristics of sequence labeling tasks, we put more attention to the finer-grained adaptation, considering the domain relevance in sample level and element level.

8 Conclusion

In this paper, we propose a fine-grained knowledge fusion model for sequence labeling domain adaptation to take the domain relevance diversity of target data into account. With the relevance modeling on both the sample level and element

level, the knowledge of the source model and target data can achieve multi-level fusion. Experimental results on different tasks demonstrate the effectiveness of our approach, and show the potential of our approach in a broader range of domain adaptation applications.

Abstract

While target-side monolingual data has been proven to be very useful to improve neural machine translation (briefly, NMT) through back translation, source-side monolingual data is not well investigated. In this work, we study how to use both the source-side and target-side monolingual data for NMT, and propose an effective strategy leveraging both of them. First, we generate synthetic bitext by translating monolingual data from the two domains into the other domain using the models pre-trained on genuine bitext. Next, a model is trained on a noised version of the concatenated synthetic bitext where each source sequence is randomly corrupted. Finally, the model is fine-tuned on the genuine bitext and a clean version of a subset of the synthetic bitext without adding any noise. Our approach achieves state-of-the-art results on WMT16, WMT17, WMT18 English↔German translations and WMT19 German→French translations, which demonstrate the effectiveness of our method. We also conduct a comprehensive study on how each part in the pipeline works.

1 Introduction

Neural machine translation (briefly, NMT) (Bahdanau et al., 2014; Gehring et al., 2017; Wu et al., 2016; Vaswani et al., 2017) is well-known for its outstanding performance (Hassan et al., 2018), which usually relies on large-scale bitext for training. However, high quality bitext is always limited and costly to collect. In contrast, there exists large amount of monolingual data which can be leveraged to augment the training corpus. How to effectively leverage monolingual data is an important research topic for NMT and there are plenty of works studying this problem (Gulcehre et al., 2015, 2017; Sennrich et al., 2016a; He et al., 2016; Zhang and Zong, 2016; Zhang et al., 2018; Cheng et al., 2016; Wang et al., 2018; Chinea-Rios et al., 2017; Wu et al., 2018).

Among them, one of the most cited approach is back translation (briefly, BT) (Sennrich et al., 2016a), which leverages the target-side monolingual data. Specifically, a target-to-source translation model (trained on the genuine bitext) is used to translate target-side monolingual sentences into the source domain to generate a set of synthetic bitext, which is then used together with the genuine bitext to train a source-to-target NMT model. While target-side monolingual data is well utilized by NMT through BT and its variants (Sennrich et al., 2016a; Edunov et al., 2018; Hassan et al., 2018; He et al., 2016), the investigation on source-side monolingual data is very limited. Only few attempts (Zhang and Zong, 2016; Ueffing et al., 2007) are made to explore source-side monolingual data, with a common high-level idea that a source-to-target translation model is trained to translate the source-side monolingual data into target domain, the resulted synthetic data is then used for further training. In this work, we study how to leverage both source-side and target-side monolingual data to boost the accuracy of NMT.

We propose a simple yet effective strategy to leverage two-side monolingual data for NMT, which consists of three steps:
(1) *Preparation*: We pretrain a source-to-target and a target-to-source NMT models on the genuine bitext, and use them to generate synthetic bitext by translating the monolingual data from the source/target domain to the other domain respectively.
(2) *Large-scale Noised training*: The source sentences of the synthetic parallel corpus (including both the genuine source-side monolingual sentences and the synthetic source sentences back-

translated from the target domain) are first corrupted. We then train an NMT model on this noised dataset together with the genuine bitext. We find that this step benefits from a large amount of monolingual data. The NMT model obtained from noised training can be further improved in the next finetune step.
(3) *Clean training*: We randomly generate a subset of the clean synthetic bitext without adding any noise, and leverage them together with the genuine bitext to finetune the output model of step (2). This step only needs a small set of synthetic bitext.

We conduct a comprehensive study of our proposed method on WMT English↔German translation and German↔French translation and have the following empirical observations:

- Using both source-side and target-side monolingual data is better than using monolingual data from only one domain (see Section 5.1).
- Adding noise to large-scale synthetic bitext improves the accuracy of NMT (see Section 5.2 and Section 5.3).
- Clean training/tuning of the model obtained from noised training further improves its accuracy (see Section 5.4).
- Our method achieves state-of-the-art results on English↔German newstest 2016, 2017 and 2018 and German→French newstest 2019 (see Section 4.2).

2 Related Work

Our work is related to several important research directions of NMT, and we describe the previous relevant works in this section.

2.1 Neural Machine Translation

NMT adopts the sequence-to-sequence framework, which consists of an encoder and a decoder in the network architecture. The encoder and decoder are usually built upon deep neural networks, which can be recurrent neural network (Sutskever et al., 2014), convolutional neural network (Gehring et al., 2017) or simple self-attention based transformer network (Vaswani et al., 2017). The encoder encodes the source sentence into a continuous representation space, and the decoder will decodes the target sentence based on the encoder representations word-by-word. The objective of the NMT model training is to maximize the conditional probability of the target sentence given the source sequence. Different model architectures and modifications have been proposed to improve the training efficiency and NMT accuracy (Hassan et al., 2018; Luong et al., 2015; Gu et al., 2016).

Different from the view of model architecture, in this paper, we study the NMT training from the data aspect. Specifically, we study the effect of both source-side and target-side monolingual data at scale and investigate how to make the best utilization of the monolingual data.

2.2 Improving NMT by Monolingual Data

NMT heavily relies on large-scale parallel dataset for training. To augment the limited bilingual data, there are plenty of works attempt to leverage the monolingual data to help the training, which includes the language model fusion (Gulcehre et al., 2015), back translation (Sennrich et al., 2016a), dual learning (He et al., 2016; Wang et al., 2018, 2019) and self learning (Zhang and Zong, 2016).

Gulcehre et al. (2017) integrates the hidden states from the target language model into the NMT decoder to improve the accuracy. Sennrich et al. (2016a) propose the back translation (BT) approach to leverage the target-side monolingual data, which is simple and effective. BT requires training an additional target-to-source NMT model given the bilingual dataset, the model will be used to back translate the target-side monolingual data. The translation output and the target-side monolingual data then paired as synthetic parallel corpus to augment the original bilingual dataset in order to further train the source-to-target NMT model. Dual learning (He et al., 2016) extends the BT approach to train NMT systems in both translation directions. When jointly training the source-to-target and target-to-source NMT models, the two models can provide back translated data for each other direction and perform multi-rounds BT. This strategy is also successfully adopted to build the unsupervised translation system (Lample et al., 2017).

There exists few attempts working on using the source-side monolingual data. Zhang and Zong (2016) propose self learning approach to generate the synthetic data for the source-side monolingual data, which is a semi-supervised method. Wu et al. (2017) leverage the source-side monolingual data to train the NMT system by learning reward func-

tion in a reinforcement learning framework.

2.3 Study of the Back Translation

Since BT is widely acknowledged and effective to improve the NMT model, there has been several works investigating back translation from different views. Poncelas et al. (2018) study on how using the back translated data as a training corpus (separately usage or combined with bilingual data) affects the performance of an NMT model. Burlot and Yvon (2019) analyze the accuracy impact from the quality of the BT data, the alternative uses of BT data to give explanations of why BT works. Cotterell and Kreutzer (2018) provide an interpretation of back translation as approximate inference in a generative model of bitext and give a new algorithm. However, above studies are all based on the small-scale monolingual data, therefore it remains unclear in the large-scale setting.

Edunov et al. (2018) firstly provide an extensive analysis of the back translation at scale. They investigate the different synthetic data generation methods, and also compare the different combination of the synthetic data with bitext. They finally build a strong system with millions of target-side monolingual sentences.

3 Training Strategy

In this section, we give a detailed introduction of our training strategy.

Notations: Let X and Y denote two languages, and let $\mathcal{X}$ and $\mathcal{Y}$ denote two corresponding language sentence domains, which are the collection of all sentences. Let $\mathcal{B} = \{(x_i, y_i)\}_{i=1}^{N}$ denote the bilingual training pairs, where $x_i \in \mathcal{X}$, $y_i \in \mathcal{Y}$, N is the number of sentence pairs. Let $\mathcal{M}_x = \{x_j\}_{j=1}^{M_x}$ and $\mathcal{M}_y = \{y_j\}_{j=1}^{M_y}$ denote the collections of monolingual sentences, where M_x and M_y are the sizes of the two sets, $x_j \in \mathcal{X}$, $y_j \in \mathcal{Y}$. Our objective is to obtain a translation model $f : \mathcal{X} \mapsto \mathcal{Y}$, that can translate sequences from language X to language Y.

There are three steps of our training strategy:

Step-1: Preparation. We first train two translation models $f_b : \mathcal{X} \mapsto \mathcal{Y}$ and $g_b : \mathcal{Y} \mapsto \mathcal{X}$ on the given bilingual data $\mathcal{B}$ by minimizing the negative log-likelihood. After that, we build the following two synthetic datasets through the trained models:

$$\begin{aligned} \bar{\mathcal{B}}_s &= \{(x, f_b(x)) | x \in \mathcal{M}_x\}, \\ \bar{\mathcal{B}}_t &= \{(g_b(y), y) | y \in \mathcal{M}_y\}, \end{aligned} \tag{1}$$

where $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ can be seen the forward-translation (i.e., self learning) of source-side monolingual data (Zhang and Zong, 2016) and back-translation of target-side monolingual data (Sennrich et al., 2016a). In practice, f_b and g_b will output one translation by either beam search or random sampling according to the model output distribution. Random sampling explores more possibility for the unknown generated sentence, which may benefit the data augmentation. In this work, we mainly adopt beam search to generate the sentences, but we will also compare different sequence generation methods in Section 5.2.

Step-2: Large-scale noised training. Inspired from the noised back translation (Edunov et al., 2018) and denoising auto-encoder (Vincent et al., 2008), we add noise to the source-side data of both $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ for training instead of directly using them to train models. We build two following noised versions of the two augmented datasets,

$$\begin{aligned} \bar{\mathcal{B}}_s^n &= \{(\sigma(x), y) | (x, y) \in \bar{\mathcal{B}}_s\}, \\ \bar{\mathcal{B}}_t^n &= \{(\sigma(x), y) | (x, y) \in \bar{\mathcal{B}}_t\}, \end{aligned} \tag{2}$$

where σ is the operator of adding noise. We follow Edunov et al. (2018) to design σ. Specifically,
(1) we randomly replace a word in the sentence to be a special token "<UNK>" (representing unknown words) with probability 0.1;
(2) we randomly drop the words in each position with probability 0.1;
(3) we randomly shuffle (swap) the words in the sentence, with constraint that the words will not be shuffled further than three positions distance.

We then train an NMT model f_n for X to Y translation on $\mathcal{B} \cup \bar{\mathcal{B}}_s^n \cup \bar{\mathcal{B}}_t^n$ by minimizing the negative log-likelihood. Compared with Edunov et al. (2018), we enlarge the noised data from $\bar{\mathcal{B}}_t^n$ to $\bar{\mathcal{B}}_s^n \cup \bar{\mathcal{B}}_t^n$, instead of using the target-side monolingual data only. The intuition behind noised training is to force the encoder to discover more robust features and thus improve the generalization ability (Vincent et al., 2008). Besides, the output model of noised training has great potential to be improved in further finetune. Adding noise is widely acknowledged in other NLP tasks, like unsupervised NMT (Lample et al., 2017), BERT pretaining (Devlin et al., 2019), etc. There are some

other ways to augment/add noise to the training data (Artetxe et al., 2017) and we leave the combination with those approaches as future work.

Step-3: Clean data tuning. After obtaining noised training model from step-2, we further finetune it on the clean version of the synthetic data without adding noise manually. For the efficiency, we can randomly subsample $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ to form the clean $\bar{\mathcal{B}}_s^s$ and $\bar{\mathcal{B}}_t^s$ dataset. Then we continue tuning f_n on the new datasets:

$$\min \sum_{(x,y)\in\mathcal{B}\cup\bar{\mathcal{B}}_s^s\cup\bar{\mathcal{B}}_t^s} -\log P(y|x;f), \quad (3)$$

where f is initialized by f_n.

There are different ways to obtain $\bar{\mathcal{B}}_s^s$ and $\bar{\mathcal{B}}_t^s$, such as the subset of $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ we described here. A more effective way is to train another $\bar{f}_b$ for X to Y translation and another $\bar{g}_b$ for Y to X translation, and use them to build new synthetic data for step-3. In this way, more diverse samples are included and we are able to achieve better results. We will provide more discussions in Section 4.1 and study in Section 5.4.

4 Experiments

We verify the effectiveness of our proposed training strategy in this section. We conduct experiments on four different translation tasks. We also make a comprehensive study about the effect of the monolingual data usage in our approach from various aspects.

4.1 Experimental Setup

Datasets We carry out experiments on four different translation tasks from WMT19 competition[1], including En→De, De→En, De→Fr and Fr→De, where En, De and Fr are short for English, German and French.

For En↔De translation tasks, the bilingual data consists of two parts: (1) We concatenate "Europarl v9", "News Commentary v14", "Common Crawl corpus" and "Document-split Rapid corpus", remove the empty and duplicate lines and eventually get a clean dataset of news domain. (2) We also use the Paracrawl dataset to extend the bilingual corpus. Consider Paracrawl is noisy, we apply a series of filtration rules to this dataset and remove the low-quality sentences, including sentences with too many punctuation marks or invalid characters, and those with too many or too few words, etc. All the rules are available in the `preprocess.py` in the supplementary document. These two parts of data are then merged together to get the bilingual dataset. We eventually get a clean corpus with about $5M$ clean data and $18M$ Paracrawl data, which are denoted as `WMT` and `WMTPC` respectively for ease of reference. The monolingual data we use is from newscrawl released by WMT19. We combine the newscrawl data from year 2016 to 2018 for the English and German monolingual corpus. After filtering with similar rules applied in Paracrawl (`preprocess_mono.py` in the supplementary document), an additional step is that we further perform language detection (Lui and Baldwin, 2012) on each side monolingual data. Finally, we randomly select about 120M sentences for each of English and German language. We choose newstest2015 as the validation set and use newstest2016 to newstest2019 as test sets.

For De↔Fr translation data, we follow the same process as that used in En↔De. Eventually, the `WMT` and ParaCrawl data of De↔Fr contains about 2M and 4.8M sentence pairs respectively. As for the French monolingual data, we use all the available newscrawl from previous years due to its small size compared to En and De. After filtering, we keep 60M monolingual data. We use the validation and test set provided by WMT19 for De↔Fr translation.

All datasets are tokenized with Moses (Koehn et al., 2007) toolkit[2]. The vocabulary is built based on the Byte-Pair-Encoding (BPE) (Sennrich et al., 2016b) with 35K merge operations[3] for both En↔De and De↔Fr datasets. We learn the BPE vocabulary jointly on the source and target language sentences.

Models We choose the state-of-the-art Transformer network as our model structure, which consists of an encoder with 6 layers and a decoder with 6 layers. We use `transformer_big` configuration for all experiments: the dimension of word embedding and the inner feed-forward layer is 1024 and 4096 respectively. The parameters of

[2] https://github.com/moses-smt/mosesdecoder/tree/master

[3] https://github.com/rsennrich/subword-nmt

source and target word embeddings, as well as the projection layer before softmax are shared. The number of attention heads is 16. The dropout is fixed as 0.2 due to validation performance. We conduct experiments on the fairseq (Ott et al., 2019) codebase[4].

Training The models are trained by the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.98$. We use the default learning rate schedule used in Vaswani et al. (2017) with the initial learning rate 5×10^{-4}. Label smoothing (Szegedy et al., 2016) is adopted with value 0.1. The batch size is set to be 4096 tokens per GPU. We use 4 P40 GPUs for training and update the parameters every 16 minibatches. The pretraining and the noised training both take about one week, and the finetune process takes about one day training.

To effectively leverage monolingual data, as mentioned in Section 3, we use two different groups of models to generate synthetic data for noised training and finetuning. For noised training, the models used for translating monolingual data are trained on WMT; for finetuning, the models are trained on WMTPC. The intuition behind using different generation models is that each optimization stage can benefit from the new/unseen generated synthetic training data. Therefore, we adopt this way in our experiments. As for the data size, in noised training, $|\bar{\mathcal{B}}_s| = |\bar{\mathcal{B}}_t| = 60M$, and during finetuning, $|\bar{\mathcal{B}}_s^s| = |\bar{\mathcal{B}}_t^s| = 20M$.

Evaluation To evaluate the model performance, we use beam search generation with beam width 5 and without length penalty. The BLEU score is measured by the de-tokenized case-sensitive SacreBLEU (Post, 2018), which is widely adopted in the WMT competitions[5].

4.2 Results

We summarize the results of our training strategy for En↔De and De↔Fr translations in Table 1 and Table 2.

As can be seen from Table 1, the Paracrawl dataset improves the model accuracy by a large margin. Compared with the baseline of using WMT only, on average, Paracrawl brings more than 3.0 and 4.0 BLEU improvements to En→De and De→En tasks respectively, indicating the effectiveness of leveraging more data. After large-scale noised training, the accuracy of each task is further boosted. On average, we improve the BLEU scores of En→De and De→En by 1.6 and 2.2 points, demonstrating the effectiveness of noised training. At last, the output models are tuned on the clean synthetic data. This step further brings 1.7 and 1.5 points gain over the previous step. For En↔De translation tasks, we finally achieve 40.9, 32.9, 49.2 and 43.8 BLEU scores from newstest2016 to newstest2019; for De→En, the eventual BLEU scores of the four test sets end up at 47.5, 41.0, 49.5 and 41.9. Such strong improvements over the baseline reveal the great potential of our proposed strategy.

	De→Fr	Fr→De
WMT	31.2	26.1
WMTPC	34.2	28.6
+*Noised Training*	36.1	30.8
+*Clean Tuning*	**37.3**	**33.1**

Table 2: De-tokenized case-sensitive SacreBLEU on WMT De↔Fr newstest2019. "+" is conducted upon WMTPC dataset.

Prior to this work, the most common way to leverage monolingual data is BT (Sennrich et al., 2016a). We also compare our strategy to the vanilla BT, which consists of $20M$ synthetic data and WMTPC. The results are shown in the last row of Table 1. Without finetuning, our noised training strategy surpasses the BT by 0.92 and 0.55 points respectively. This shows that our strategy is more effective than standard BT.

In Table 2, we show the results of De↔Fr translation tasks. We have similar observation as that for En↔De translations. Specifically, the noised training can improve WMTPC by 1.9 and 2.2 points on De→Fr and Fr→De. When turning to clean tuning, we can obtain another 1.2 and 2.3 points improvement. The results on De↔Fr demonstrate that our strategy works across different languages.

Our method achieves state-of-the-art results on En↔De newstest2016, newstest2017 and newstest2018 and De→Fr newstest2019. We list several widely acknowledged systems on En→De translation in Table 3: MS-Marian (Junczys-Dowmunt, 2018), which is the champion of

WMT18 En→De competition, and FAIR's model (Edunov et al., 2018) which leverages a large amount of monolingual data. Note that results of MS-Marian and FAIR are from ensemble models, while ours are from a single model. We find that our single model successfully surpasses the previous best systems in all test sets. Especially, for newstest2016 and newstest2018, we achieve 1.0 BLEU score improvement over the MS-Marian and set new records for these tasks. We also list the WMT18 top-2 systems for De→En translation in Table 4: RWTH (Graça et al., 2018) and UCAM (Stahlberg et al., 2018) systems, which are both ensemble models. Similarly, our single model surpasses these ensemble systems by a large margin.

5 Analysis

In this section, we provide a comprehensive study on the effect of monolingual data from different aspects, including data combination ways, data scale and the data generation methods. The experiments are conducted on the En→De translation and evaluated on newstest2016, newstest2017 and newstest2018. In this section, without specific clarification, the training data of each setting contains WMTPC.

5.1 Source or Target Monolingual Data

We first investigate the effect about different combinations of monolingual data. Specifically, we compare three different ways to use monolingual data, including leveraging source-side monolingual data only (i.e., $\bar{\mathcal{B}}_s$), target-side monolingual data only (i.e., $\bar{\mathcal{B}}_t$), and the monolingual data from both two sides (i.e., $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$).

We keep the number of total synthetic data to be same across the three settings, that is, (i) 120M $\bar{\mathcal{B}}_s$; (ii) 120M $\bar{\mathcal{B}}_t$, and (iii) the combination of 60M $\bar{\mathcal{B}}_s$ and 60M $\bar{\mathcal{B}}_t$. We conduct this study on the clean synthetic data without noise, in order to verify which kind of data is more helpful for boosting performances.

The results are shown in Figure 1. From the figure, we can clearly observe that the best configuration is the combination of $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$. With the same data size, on average, the model trained with combined synthetic dataset outperforms those trained with $\bar{\mathcal{B}}_s$ only and $\bar{\mathcal{B}}_t$ only by 2.6 and 3.5 points respectively. In particular, on newstest2018, the advantage of the combined dataset is nearly 5 points compared to $\bar{\mathcal{B}}_t$, which is extremely significant. This result strongly supports us that our training strategy by leveraging both the source-side and target-side monolingual

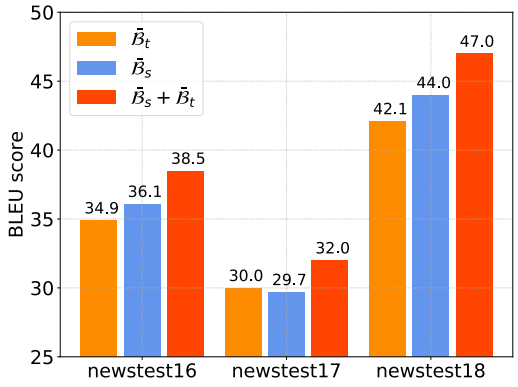

Figure 1: The de-tokenized SacreBLEU scores on En→De newstest2016, newstest2017 and newstest2018 of the models trained by different synthetic data: (1) $\bar{\mathcal{B}}_s$ from source-side monolingual data only, (2) $\bar{\mathcal{B}}_t$ from target-side monolingual data only and (3) the combination of $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$.

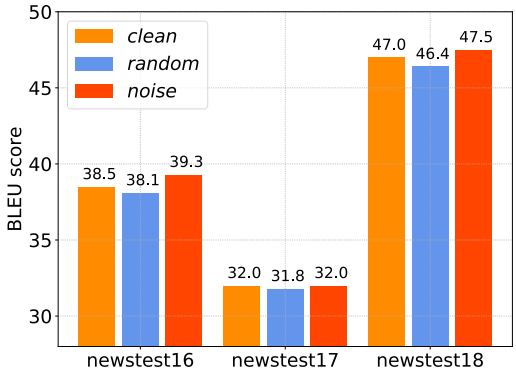

Figure 2: The de-tokenized SacreBLEU scores on En→De newstest2016, newstest2017 and newstest2018 of the models trained by synthetic data generated in different ways: (1) clean $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ data, (2) $\bar{\mathcal{B}}_s^r$ and randomly sampled $\bar{\mathcal{B}}_t^r$ data, and (3) noised $\bar{\mathcal{B}}_s^n$ and $\bar{\mathcal{B}}_t^n$ data.

data is helpful. Another point is that on such large-scale dataset, the $\bar{\mathcal{B}}_t$ data from back translation seems to be worse than the $\bar{\mathcal{B}}_s$ data generated by source-side monolingual data, which also supports the point that source-side monolingual is helpful.

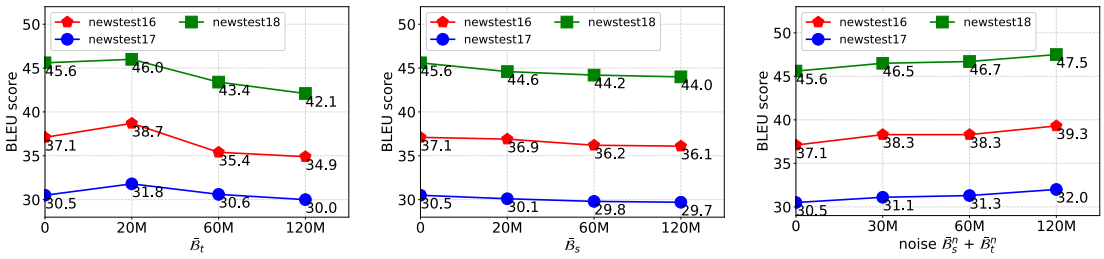
5.2 Synthetic Data Generation

We conduct experiments on different generated synthetic data, to verify whether adding noise is essential. We use the same combined dataset (i.e., $60M$ $\bar{\mathcal{B}}_s$ and $60M$ $\bar{\mathcal{B}}_t$) as that used in Section 5.1 since the effectiveness has been verified.

We compare our noised training data $\bar{\mathcal{B}}_s^n$ and $\bar{\mathcal{B}}_t^n$ with another two baselines: 1) $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ without any transformation; 2) $\bar{\mathcal{B}}_s$ and the randomly sampled synthetic data $\bar{\mathcal{B}}_t^r$, where each token in the translation is sampled from the multinomial distribution determined by the NMT model. Random sampling is an alternative way to introduce noise, where the resulted synthetic dataset is more diverse but the translation quality is relatively poor. The data sizes for all settings are 120M.

We present the result in Figure 2. Overall, noised traininig outperforms the clean training, e.g., 0.8 and 0.5 points advantage on newstest2016 and newstest2018 respectively. Compared with randomly sampled data, our noised data training achieves more than 1.0 BLEU improvement on newstest2016 and newstest2018, and similar performance on newstest2017. The above results suggest that our noised training is effective.

5.3 Scale of Monolingual Data



In this section, we give a comparison of different data scales for each kind of synthetic data.

(a) Scale of Target-side (BT) Data We first look into the widely adopted back translation data $\bar{\mathcal{B}}_t$. We vary the data scale from 20M to 60M, which are obtained by random selection from the 120M corpus, and then to 120M.

From Figure 3(a), we can observe that model performance is improved when we add 20M $\bar{\mathcal{B}}_t$ data. However, adding more clean back translated data starts to hurt the model performances. We suspect the reason is that the data distribution of $\bar{\mathcal{B}}_t$ shifts from the groundtruth distribution. Adding too much $\bar{\mathcal{B}}_t$ will enforce the model training to fit a biased distribution, making the generalization ability drop and thus, we observe that the BLEU scores drop. This result implies that we should choose a proper data size when using $\bar{\mathcal{B}}_T$ only, such as same size of bitext (e.g., 20M as we used).

(b) Scale of Source-side Data We then investigate the effect of data scale of source-side monolingual data, i.e., $\bar{\mathcal{B}}_s$ data. We also set the data sizes as {20M,60M,120M}.

The results are shown in Figure 3(b). We do not observe any improvement over the bilingual system when adding $\bar{\mathcal{B}}_s$ data, and with more data added, the performance slightly drops. It seems to be contrary to the experimental results in Zhang and Zong (2016) which are conducted on RNN models. We speculate the self learning approach

(a) Different scales of $\bar{\mathcal{B}}_t$ data. (b) Different scales of $\bar{\mathcal{B}}_s$ data. (c) Different scales of noised $\bar{\mathcal{B}}_s + \bar{\mathcal{B}}_t$ data.

Figure 3: The de-tokenized SacreBLEU scores on newstest2016, newstest2017, newstest2018 of the models trained with varied data scales of (a) $\bar{\mathcal{B}}_t$ data, (b) $\bar{\mathcal{B}}_s$ data, and (c) combined $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ data.

is actually hard for the model to boost itself, since there are no other signals to help the learning. The results demonstrate that leveraging source-side monolingual data alone is not a good choice.

(c) Scale of Noised Synthetic Data We finally study our noised training on different sizes of noised synthetic data. The experiments are conducted on the combination of noised 30M, 60M and 120M $\bar{\mathcal{B}}_s^n$ and $\bar{\mathcal{B}}_t^n$ with the same number of source-side and target-side monolingual sentences[6]. We choose the maximum data size as 120M due to GPU memory limitation. The results are shown in Figure 3(c).

We can see that the performances are consistently improved as the number of the noised synthetic data increases on all test sets. The result again proves that the hybrid usage of source-side and target-side monolingual data is an effective approach which outperforms using the two kinds of data individually.

In summary, first, we verify that source-side monolingual data is helpful and the best way to use it is to combine with target-side monolingual data. Next, we show that adding noise to synthetic data outperforms that without noise. Finally, we empirically prove that our strategy benefits from more monolingual data, while BT does not, demonstrating our strategy has great potential of utilizing more data.

5.4 Synthetic Tuning

We further study the clean tuning step in our training strategy. Two questions remain to be answered: (1) Is it helpful to use two groups of models of building synthetic data for noised training and clean training as we discussed before? (2) Is it helpful to use noised training first regarding future BLEU score achieved by the finetune step?

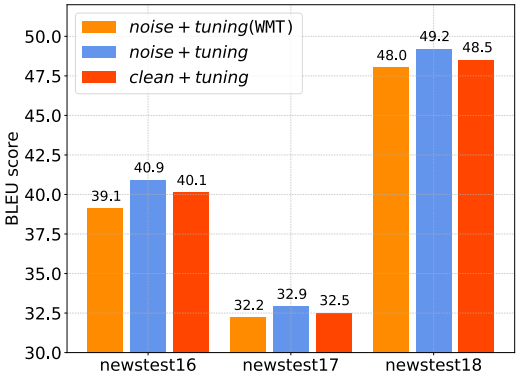


Figure 4: The de-tokenized SacreBLEU scores on En→De newstest2016, newstest2017 and newstest2018 of the models tuned by different synthetic data and pretrained models: (1) noised training model tuned on the subset of $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ (WMT in the figure), (2) noised training model tuned on the synthetic data as introduced in Section 4.1, and (3) clean training model tuned on the same synthetic data generated as (2).

To answer these questions, we conduct another two experiments: (1) At finetuning step, use a subsample of synthetic data of noised training step, which is $\bar{\mathcal{B}}_s^s \subset \bar{\mathcal{B}}_s, \bar{\mathcal{B}}_t^s \subset \bar{\mathcal{B}}_t$. (2) Training without noise first and then finetuning using clean data.

We present the results in Figure 4. Obviously, we can see that tuning on the subset of $\bar{\mathcal{B}}_s$ and $\bar{\mathcal{B}}_t$ is worse than tuning on another set of synthetic data used in our experiments (e.g., 49.2 v.s. 48.0 on newstest2018). In addition, first training on the clean synthetic data and then tuning on other clean synthetic data also makes improvement, but similar to the results shown in Section 5.2, it is still not as good as our noised pretraining. Above results

[6]For example, same as combined 120M data, 60M combined data contains 30M $\bar{\mathcal{B}}_s^n$ and 30M $\bar{\mathcal{B}}_t^n$ data.

again prove the importance of our noised training and tuning on more diverse dataset is effective.

6 Conclusion

In this work, we exploit the monolingual data at scale for the neural machine translation. Different from previous works which usually adopt back translation on target-side monolingual data only, we propose an effective training strategy to boost the NMT performance by leveraging both source-side and target-side monolingual data. Our approach contains three steps: synthetic data generation, large-scale noised training on synthetic data and clean data training/tuning. We verify our approach on the widely acknowledged WMT English↔German translation tasks and achieve state-of-the-art results, as well as that for the WMT German↔French translations. We also make a comprehensive study on the monolingual data utilization.

For future work, we would like to verify our training strategy on more language pairs and other sequence-to-sequence tasks. Furthermore, we are interested in studying our noised training with other data augmentation approaches.

Abstract

Link prediction is an important way to complete knowledge graphs (KGs), while embedding-based methods, effective for link prediction in KGs, perform poorly on relations that only have a few associative triples. In this work, we propose a Meta Relational Learning (MetaR) framework to do the common but challenging few-shot link prediction in KGs, namely predicting new triples about a relation by only observing a few associative triples. We solve few-shot link prediction by focusing on transferring relation-specific meta information to make model learn the most important knowledge and learn faster, corresponding to relation meta and gradient meta respectively in MetaR. Empirically, our model achieves state-of-the-art results on few-shot link prediction KG benchmarks.

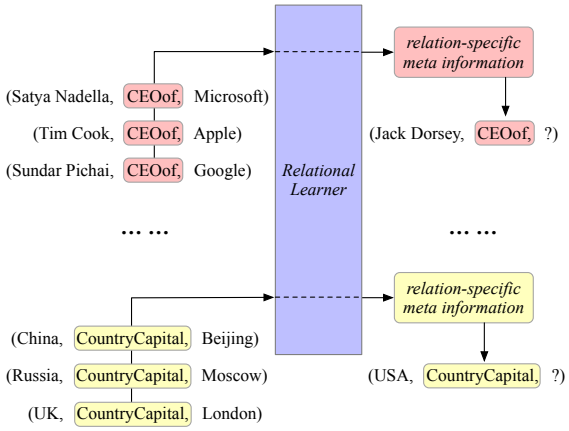

Figure 1: An example of 3-shot link prediction in KGs. One task represents observing only three instances of one specific relation and conducting link prediction on this relation. Our model focuses on extracting relation-specific meta information by a kind of relational learner which is shared across tasks and transferring this meta information to do link prediction within one task.

1 Introduction

A knowledge graph is composed by a large amount of triples in the form of $(head\ \ entity, relation, tail\ \ entity)$ ((h, r, t) in short), encoding knowledge and facts in the world. Many KGs have been proposed (Vrandei and Krtzsch, 2014; Bollacker et al., 2008; Carlson et al., 2010) and applied to various applications (Bordes et al., 2014; Zhang et al., 2016, 2019a).

Although with huge amount of entities, relations and triples, many KGs still suffer from incompleteness, thus knowledge graph completion is vital for the development of KGs. One of knowledge graph completion tasks is link prediction, predicting new triples based on existing ones. For link prediction, KG embedding methods (Bordes et al., 2013; Nickel et al., 2011; Trouillon et al., 2016; Yang et al., 2015) are promising ways. They learn latent representations, called embeddings, for entities and relations in continuous vector space and accomplish link prediction via calculation with embeddings.

The effectiveness of KG embedding methods is promised by sufficient training examples, thus results are much worse for elements with a few instances during training (Zhang et al., 2019c). However, few-shot problem widely exists in KGs. For example, about 10% of relations in Wikidata (Vrandei and Krtzsch, 2014) have no more than 10 triples. Relations with a few instances are called few-shot relations. In this paper, we devote to discuss *few-shot link prediction in knowledge graphs*, predicting tail entity t given head entity h and relation r by only observing K triples about r, usually K is small. Figure 1 depicts an example of 3-shot link prediction in KGs.

To do few-shot link prediction, Xiong et al.

(2018) made the first trial and proposed GMatching, learning a matching metric by considering both learned embeddings and one-hop graph structures, while we try to accomplish few-shot link prediction from another perspective based on the intuition that *the most important information to be transferred from a few existing instances to incomplete triples should be the common and shared knowledge within one task.* We call such information *relation-specific meta information* and propose a new framework Meta Relational Learning (MetaR) for few-shot link prediction. For example, in Figure 1, relation-specific meta information related to the relation *CEOof* or *CountryCapital* will be extracted and transferred by MetaR from a few existing instances to incomplete triples.

The relation-specific meta information is helpful in the following two perspectives: 1) transferring common relation information from observed triples to incomplete triples, 2) accelerating the learning process within one task by observing only a few instances. Thus we propose two kinds of relation-specific meta information: *relation meta* and *gradient meta* corresponding to afore mentioned two perspectives respectively. In our proposed framework MetaR, relation meta is the high-order representation of a relation connecting head and tail entities. Gradient meta is the loss gradient of relation meta which will be used to make a rapid update before transferring relation meta to incomplete triples during prediction.

Compared with GMatching (Xiong et al., 2018) which relies on a background knowledge graph, our MetaR is independent with them, thus is more robust as background knowledge graphs might not be available for few-shot link prediction in real scenarios.

We evaluate MetaR with different settings on few-shot link prediction datasets. MetaR achieves state-of-the-art results, indicating the success of transferring relation-specific meta information in few-shot link prediction tasks. In summary, main contributions of our work are three-folds:

- Firstly, we propose a novel meta relational learning framework (MetaR) to address few-shot link prediction in knowledge graphs.
- Secondly, we highlight the critical role of relation-specific meta information for few-shot link prediction, and propose two kinds of relation-specific meta information, *relation meta* and *gradient meta*. Experiments show that both of them contribute significantly.
- Thirdly, our MetaR achieves state-of-the-art results on few-shot link prediction tasks and we also analyze the facts that affect MetaR's performance.

2 Related Work

One target of MetaR is to learn the representation of entities fitting the few-shot link prediction task and the learning framework is inspired by knowledge graph embedding methods. Furthermore, using loss gradient as one kind of meta information is inspired by MetaNet (Munkhdalai and Yu, 2017) and MAML (Finn et al., 2017) which explore methods for few-shot learning by meta-learning. From these two points, we regard knowledge graph embedding and meta-learning as two main kinds of related work.

2.1 Knowledge Graph Embedding

Knowledge graph embedding models map relations and entities into continuous vector space. They use a score function to measure the truth value of each triple (h, r, t). Same as knowledge graph embedding, our MetaR also need a score function, and the main difference is that representation for r is the learned relation meta in MetaR rather than embedding of r as in normal knowledge graph embedding methods.

One line of work is started by TransE (Bordes et al., 2013) with distance score function. TransH (Wang et al., 2014) and TransR (Lin et al., 2015b) are two typical models using different methods to connect head, tail entities and their relations. DistMult (Yang et al., 2015) and ComplEx (Trouillon et al., 2016) are derived from RESCAL (Nickel et al., 2011), trying to mine latent semantics in different ways. There are also some others like ConvE (Dettmers et al., 2018) using convolutional structure to score triples and models using additional information such as entity types (Xie et al., 2016) and relation paths (Lin et al., 2015a). Wang et al. (2017) comprehensively summarize the current popular knowledge graph embedding methods.

Traditional embedding models are heavily rely on rich training instances (Zhang et al., 2019b; Xiong et al., 2018), thus are limited to do few-shot link prediction. Our MetaR is designed to fill this vulnerability of existing embedding models.

2.2 Meta-Learning

Meta-learning seeks for the ability of learning quickly from only a few instances within the same concept and adapting continuously to more concepts, which are actually the rapid and incremental learning that humans are very good at.

Several meta-learning models have been proposed recently. Generally, there are three kinds of meta-learning methods so far: (1) *Metric-based* meta-learning (Koch et al., 2015; Vinyals et al., 2016; Snell et al., 2017; Xiong et al., 2018), which tries to learn a matching metric between query and support set generalized to all tasks, where the idea of matching is similar to some nearest neighbors algorithms. Siamese Neural Network (Koch et al., 2015) is a typical method using symmetric twin networks to compute the metric of two inputs. GMatching (Xiong et al., 2018), the first trial on one-shot link prediction in knowledge graphs, learns a matching metric based on entity embeddings and local graph structures which also can be regarded as a metric-based method. (2) *Model-based* method (Santoro et al., 2016; Munkhdalai and Yu, 2017; Mishra et al., 2018), which uses a specially designed part like memory to achieve the ability of learning rapidly by only a few training instances. MetaNet (Munkhdalai and Yu, 2017), a kind of memory augmented neural network (MANN), acquires meta information from loss gradient and generalizes rapidly via its fast parameterization. (3) *Optimization-based* approach (Finn et al., 2017; Lee and Choi, 2018), which gains the idea of learning faster by changing the optimization algorithm. Model-Agnostic Meta-Learning (Finn et al., 2017) abbreviated as MAML is a model-agnostic algorithm. It firstly updates parameters of task-specific learner, and meta-optimization across tasks is performed over parameters by using above updated parameters, it's like "a gradient through a gradient".

As far as we know, work proposed by Xiong et al. (2018) is the first research on few-shot learning for knowledge graphs. It's a metric-based model which consists of a neighbor encoder and a matching processor. Neighbor encoder enhances the embedding of entities by their one-hop neighbors, and matching processor performs a multi-step matching by a LSTM block.

Table 1: The training and testing examples of 1-shot link prediction in KGs.

3 Task Formulation

In this section, we present the formal definition of a knowledge graph and few-shot link prediction task. A knowledge graph is defined as follows:

Definition 3.1 *(Knowledge Graph $\mathcal{G}$) A knowledge graph $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{TP}\}$. $\mathcal{E}$ is the entity set. $\mathcal{R}$ is the relation set. And $\mathcal{TP} = \{(h, r, t) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}\}$ is the triple set.*

And a few-shot link prediction task in knowledge graphs is defined as:

Definition 3.2 *(Few-shot link prediction task $\mathcal{T}$) With a knowledge graph $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{TP}\}$, given a support set $\mathcal{S}_r = \{(h_i, t_i) \in \mathcal{E} \times \mathcal{E} | (h_i, r, t_i) \in \mathcal{TP}\}$ about relation $r \in \mathcal{R}$, where $|\mathcal{S}_r| = K$, predicting the tail entity linked with relation r to head entity h_j, formulated as $r : (h_j, ?)$, is called K-shot link prediction.*

As defined above, a few-shot link prediction task is always defined for a specific relation. During prediction, there usually is more than one triple to be predicted, and with *support set* $\mathcal{S}_r$, we call the set of all triples to be predicted as *query set* $\mathcal{Q}_r = \{r : (h_j, ?)\}$.

The goal of a few-shot link prediction method is to gain the capability of predicting new triples about a relation r with only observing a few triples about r. Thus its training process is based on a set of tasks $\mathcal{T}_{train} = \{\mathcal{T}_i\}_{i=1}^{M}$ where each task $\mathcal{T}_i = \{\mathcal{S}_i, \mathcal{Q}_i\}$ corresponds to an individual few-shot link prediction task with its own support and query set. Its testing process is conducted on a set of new tasks $\mathcal{T}_{test} = \{\mathcal{T}_j\}_{j=1}^{N}$ which is similar to $\mathcal{T}_{train}$, other than that $\mathcal{T}_j \in \mathcal{T}_{test}$ should be about relations that have never been seen in $\mathcal{T}_{train}$.

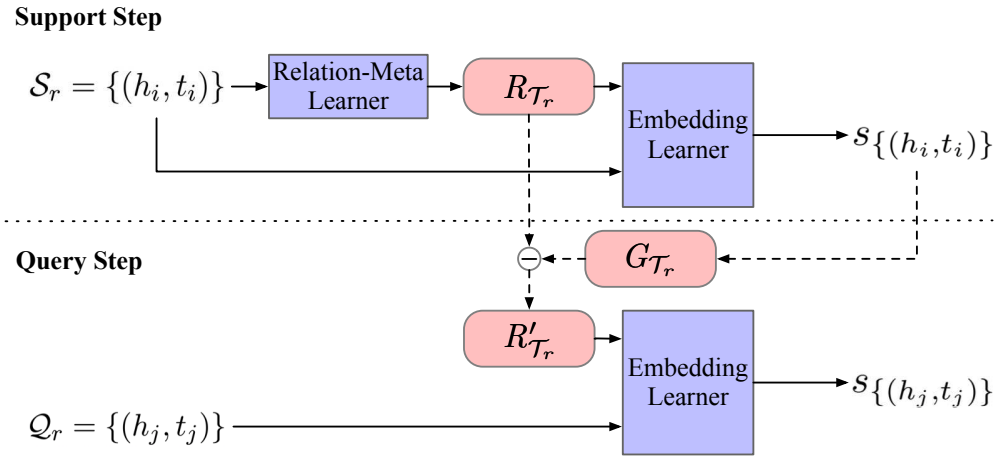

Figure 2: Overview of MetaR. $\mathcal{T}_r = \{\mathcal{S}_r, \mathcal{Q}_r\}$, $R_{\mathcal{T}_r}$ and $R'_{\mathcal{T}_r}$ represent relation meta and updated relation meta, and $G_{\mathcal{T}_r}$ represents gradient meta.

Table 1 gives a concrete example of the data during learning and testing for few-shot link prediction.

4 Method

To make one model gain the few-shot link prediction capability, the most important thing is transferring information from support set to query set and there are two questions for us to think about: (1) what is the most transferable and common information between support set and query set and (2) how to learn faster by only observing a few instances within one task. For question (1), within one task, all triples in support set and query set are about the same relation, thus it is naturally to suppose that relation is the key common part between support and query set. For question (2), the learning process is usually conducted by minimizing a loss function via gradient descending, thus gradients reveal how the model's parameters should be changed. Intuitively, we believe that gradients are valuable source to accelerate learning process.

Based on these thoughts, we propose two kinds of meta information which are shared between support set and query set to deal with above problems:

- **Relation Meta** represents the relation connecting head and tail entities in both support and query set and we extract relation meta for each task, represented as a vector, from support set and transfer it to query set.
- **Gradient Meta** is the loss gradient of relation meta in support set. As gradient meta shows how relation meta should be changed in order to reach a loss minima, thus to accelerate the learning process, relation meta is updated through gradient meta before being transferred to query set. This update can be viewed as the rapid learning of relation meta.

In order to extract relation meta and gradient mate and incorporate them with knowledge graph embedding to solve few-shot link prediction, our proposal, **MetaR**, mainly contains two modules:

- **Relation-Meta Learner** generates relation meta from heads' and tails' embeddings in the support set.
- **Embedding Learner** calculates the truth values of triples in support set and query set via entity embeddings and relation meta. Based on the loss function in embedding learner, gradient meta is calculated and a rapid update for relation meta will be implemented before transferring relation meta to query set.

The overview and algorithm of MetaR are shown in Figure 2 and Algorithm 1. Next, we introduce each module of MetaR via one few-shot link prediction task $\mathcal{T}_r = \{\mathcal{S}_r, \mathcal{Q}_r\}$.

4.1 Relation-Meta Learner

To extract the relation meta from support set, we design a relation-meta learner to learn a mapping from head and tail entities in support set to relation meta. The structure of this relation-meta learner can be implemented as a simple neural network.

In task $\mathcal{T}_r$, the input of relation-meta learner is head and tail entity pairs in support set $\{(h_i, t_i) \in \mathcal{S}_r\}$. We firstly extract entity-pair specific relation

meta via a L-layers fully connected neural network,

$$\begin{aligned} \mathbf{x}^0 &= \mathbf{h}_i \oplus \mathbf{t}_i \\ \mathbf{x}^l &= \sigma(\mathbf{W}^l \mathbf{x}^{l-1} + b^l) \\ R_{(h_i,t_i)} &= \mathbf{W}^L \mathbf{x}^{L-1} + b^L \end{aligned} \tag{1}$$

where $\mathbf{h}_i \in \mathbb{R}^d$ and $\mathbf{t}_i \in \mathbb{R}^d$ are embeddings of head entity h_i and tail entity t_i with dimension d respectively. L is the number of layers in neural network, and $l \in \{1, \ldots, L-1\}$. $\mathbf{W}^l$ and $\mathbf{b}^l$ are weights and bias in layer l. We use LeakyReLU for activation σ. $\mathbf{x} \oplus \mathbf{y}$ represents the concatenation of vector $\mathbf{x}$ and $\mathbf{y}$. Finally, $R_{(h_i,t_i)}$ represent the relation meta from specific entity pare h_i and t_i.

With multiple entity-pair specific relation meta, we generate the final relation meta in current task via averaging all entity-pair specific relation meta in current task,

$$R_{\mathcal{T}_r} = \frac{\sum_{i=1}^{K} R_{(h_i,t_i)}}{K} \tag{2}$$

4.2 Embedding Learner

As we want to get gradient meta to make a rapid update on relation meta, we need a score function to evaluate the truth value of entity pairs under specific relations and also the loss function for current task. We apply the key idea of knowledge graph embedding methods in our embedding learner, as they are proved to be effective on evaluating truth value of triples in knowledge graphs.

In task $\mathcal{T}_r$, we firstly calculate the score for each entity pairs (h_i, t_i) in support set $\mathcal{S}_r$ as follows:

$$s_{(h_i,t_i)} = \|\mathbf{h}_i + R_{\mathcal{T}_r} - \mathbf{t}_i\| \tag{3}$$

where $\|\mathbf{x}\|$ represents the L2 norm of vector $\mathbf{x}$. We design the score function inspired by TransE (Bordes et al., 2013) which assumes the head entity embedding $\mathbf{h}$, relation embedding $\mathbf{r}$ and tail entity embedding $\mathbf{t}$ for a true triple (h, r, t) satisfying $\mathbf{h}+\mathbf{r} = \mathbf{t}$. Thus the score function is defined according to the distance between $\mathbf{h} + \mathbf{r}$ and $\mathbf{t}$. Transferring to our few-show link prediction task, we replace the relation embedding $\mathbf{r}$ with relation meta $R_{\mathcal{T}_r}$ as there is no direct general relation embeddings in our task and $R_{\mathcal{T}_r}$ can be regarded as the relation embedding for current task $\mathcal{T}_r$.

With score function for each triple, we set the following loss,

$$L(\mathcal{S}_r) = \sum_{(h_i,t_i) \in \mathcal{S}_r} [\gamma + s_{(h_i,t_i)} - s_{(h_i,t_i')}]_+ \tag{4}$$

where $[x]_+$ represents the positive part of x and γ represents margin which is a hyperparameter. $s_{(h_i,t_i')}$ is the score for negative sample (h_i, t_i') corresponding to current positive entity pair $(h_i, t_i) \in \mathcal{S}_r$, where $(h_i, r, t_i') \notin \mathcal{G}$.

$L(\mathcal{S}_r)$ should be small for task $\mathcal{T}_r$ which represents the model can properly encode truth values of triples. Thus gradients of parameters indicate how should the parameters be updated. Thus we regard the gradient of $R_{\mathcal{T}_r}$ based on $L(\mathcal{S}_r)$ as gradient meta $G_{\mathcal{T}_r}$:

$$G_{\mathcal{T}_r} = \nabla_{R_{\mathcal{T}_r}} L(\mathcal{S}_r) \tag{5}$$

Following the gradient update rule, we make a rapid update on relation meta as follows:

$$R'_{\mathcal{T}_r} = R_{\mathcal{T}_r} - \beta G_{\mathcal{T}_r} \tag{6}$$

where β indicates the step size of gradient meta when operating on relation meta.

When scoring the query set by embedding learner, we use updated relation meta. After getting the updated relation meta R', we transfer it to samples in query set $\mathcal{Q}_r = \{(h_j, t_j)\}$ and calculate their scores and loss of query set, following the same way in support set:

$$s_{(h_j,t_j)} = \|\mathbf{h}_j + R'_{\mathcal{T}_r} - \mathbf{t}_j\| \tag{7}$$

$$L(\mathcal{Q}_r) = \sum_{(h_j,t_j) \in \mathcal{Q}_r} [\gamma + s_{(h_j,t_j)} - s_{(h_j,t_j')}]_+ \tag{8}$$

where $L(\mathcal{Q}_r)$ is our training objective to be minimized. We use this loss to update the whole model.

Dataset	Fit	# Train	# Dev	# Test
NELL-One	Y	321	5	11
Wiki-One	Y	589	16	34

Background Conf.	Description
BG:Pre-Train	Use background to train entity embedding in advance.
BG:In-Train	Fit background graph into training tasks.
BG:Discard	Discard the background graph.

Table 3: Three forms of datasets in our experiments.

4.3 Training Objective

During training, our objective is to minimize the following loss L which is the sum of query loss for all tasks in one minibatch:

$$L = \sum_{(\mathcal{S}_r, \mathcal{Q}_r) \in \mathcal{T}_{train}} L(\mathcal{Q}_r) \tag{9}$$

5 Experiments

With MetaR, we want to figure out following things: 1) can MetaR accomplish few-shot link prediction task and even perform better than previous model? 2) how much relation-specific meta information contributes to few-shot link prediction? 3) is there any requirement for MetaR to work on few-shot link prediction? To do these, we conduct the experiments on two few-shot link prediction datasets and deeply analyze the experiment results [1].

5.1 Datasets and Evaluation Metrics

We use two datasets, NELL-One and Wiki-One which are constructed by Xiong et al. (2018). NELL-One and Wiki-One are derived from NELL (Carlson et al., 2010) and Wikidata (Vrandei and Krtzsch, 2014) respectively. Furthermore, because these two benchmarks are firstly tested on GMatching which consider both learned embeddings and one-hop graph structures, a background graph is constructed with relations out of training/validation/test sets for obtaining the pre-train entity embeddings and providing the local graph for GMatching.

Unlike GMatching using background graph to enhance the representations of entities, our MetaR can be trained without background graph. For NELL-One and Wiki-One which have background graph originally, we can make use of such background graph by fitting it into training tasks or using it to train embeddings to initialize entity representations. Overall, we have three kinds of dataset settings, shown in Table 3. For setting of *BG:In-Train*, in order to make background graph included in training tasks, we sample tasks from triples in background graph and original training set, rather than sampling from only original training set.

Note that these three settings don't violate the task formulation of few-shot link prediction in KGs. The statistics of NELL-One and Wiki-One are shown in Table 2.

We use two traditional metrics to evaluate different methods on these datasets, MRR and Hits@N. MRR is the mean reciprocal rank and Hits@N is the proportion of correct entities ranked in the top N in link prediction.

5.2 Implementation

During training, mini-batch gradient descent is applied with batch size set as 64 and 128 for NELL-One and Wiki-One respectively. We use Adam (Kingma and Ba, 2015) with the initial learning rate as 0.001 to update parameters. We set $\gamma = 1$ and $\beta = 1$. The number of positive and negative triples in query set is 3 and 10 in NELL-One and Wiki-One. Trained model will be applied on validation tasks each 1000 epochs, and the current model parameters and corresponding performance will be recorded, after stopping, the model that has the best performance on Hits@10 will be treated as final model. For number of training epoch, we use early stopping with 30 patient epochs, which means that we stop the training when the performance on Hits@10 drops 30 times continuously. Following GMatching, the embedding dimension of NELL-One is 100 and Wiki-One is 50. The

sizes of two hidden layers in relation-meta learner are 500, 200 and 250, 100 for NELL-One and Wiki-One.

5.3 Results

The results of two few-shot link prediction tasks, including 1-shot and 5-shot, on NELL-One and Wiki-One are shown in Table 4. The baseline in our experiment is GMatching (Xiong et al., 2018), which made the first trial on few-shot link prediction task and is the only method that we can find as baseline. In this table, results of GMatching with different KG embedding initialization are copied from the original paper. Our MetaR is tested on different settings of datasets introduced in Table 3.

In Table 4, our model performs better with all evaluation metrics on both datasets. Specifically, for 1-shot link prediction, MetaR increases by 33%, 28.1%, 29.2% and 27.8% on MRR, Hits@10, Hits@5 and Hits@1 on NELL-One, and 41.4%, 18.8%, 37.9% and 62.2% on Wiki-One, with average improvement of 29.53% and 40.08% respectively. For 5-shot, MetaR increases by 29.9%, 40.5%, 32.6% and 17.5% on MRR, Hits@10, Hits@5 and Hits@1 on NELL-One with average improvement of 30.13%.

Thus for the first question we want to explore, the results of MetaR are no worse than GMatching, indicating that MetaR has the capability of accomplishing few-shot link prediction. In parallel, the impressive improvement compared with GMatching demonstrates that the key idea of MetaR, transferring relation-specific meta information from support set to query set, works well on few-shot link prediction task.

Ablation Conf.	BG:Pre-Train	BG:In-Train
standard	.331	.401
-g	.234	.341
-g -r	.052	.052

Table 5: Results of ablation study on Hits@10 of 1-shot link prediction in NELL-One.

Furthermore, compared with GMatching, our MetaR is independent with background knowledge graphs. We test MetaR on 1-shot link prediction in partial NELL-One and Wiki-One which discard the background graph, and get the results of 0.279 and 0.348 on Hits@10 respectively. Such results are still comparable with GMatching in fully datasets with background.

5.4 Ablation Study

We have proved that relation-specific meta information, the key point of MetaR, successfully contributes to few-shot link prediction in previous section. As there are two kinds of relation-specific meta information in this paper, relation meta and gradient meta, we want to figure out how these two kinds of meta information contribute to the performance. Thus, we conduct an ablation study with three settings. The first one is our complete MetaR method denoted as *standard*. The second one is removing the gradient meta by transferring un-updated relation meta directly from support set to query set without updating it via gradient meta, denoted as *-g*. The third one is removing the relation meta further which makes the model rebase to a simple TransE embedding model, denoted as *-g -r*. The result under the third setting is copied from Xiong et al. (2018). It uses the triples from background graph, training tasks and one-shot training triples from validation/test set, so it's neither *BG:Pre-Train* nor *BG:In-Train*. We conduct the ablation study on NELL-one with metric Hit@10 and results are shown in Table 5.

Table 5 shows that removing gradient meta decreases 29.3% and 15% on two dataset settings, and further removing relation meta continuous decreases the performance with 55% and 72% compared to the *standard* results. Thus both relation meta and gradient meta contribute significantly and relation meta contributes more than gradient meta. Without gradient meta and relation meta, there is no relation-specific meta information transferred in the model and it almost doesn't work. This also illustrates that relation-specific meta information is important and effective for few-shot link prediction task.

5.5 Facts That Affect MetaR's Performance

We have proved that both relation meta and gradient meta surely contribute to few-shot link prediction. But is there any requirement for MetaR to ensure the performance on few-shot link prediction? We analyze this from two points based on the results, one is the sparsity of entities and the other is the number of tasks in training set.

The sparsity of entities We notice that the best result of NELL-One and Wiki-One appears in different dataset settings. With NELL-One, MetaR performs better on *BG:In-Train* dataset setting, while with Wiki-One, it performs better on *BG:Pre-Train*. Performance difference between two dataset settings is more significant on Wiki-One.

Most datasets for few-shot task are sparse and the same with NELL-One and Wiki-One, but the entity sparsity in these two datasets are still significantly different, which is especially reflected in the proportion of entities that only appear in one triple in training set, 82.8% and 37.1% in Wiki-One and NELL-One respectively. Entities only have one triple during training will make MetaR unable to learn good representations for them, because entity embeddings heavily rely on triples related to them in MetaR. Only based on one triple, the learned entity embeddings will include a lot of bias. Knowledge graph embedding method can learn better embeddings than MetaR for those one-shot entities, because entity embeddings can be corrected by embeddings of relations that connect to it, while they can't in MetaR. This is why the best performance occurs in *BG:Pre-train* setting on Wiki-One, pre-train entity embeddings help MetaR overcome the low-quality on one-shot entities.

The number of tasks From the comparison of MetaR's performance between with and without background dataset setting on NELL-One, we find that the number of tasks will affect MetaR's performance significantly. With *BG:In-Train*, there are 321 tasks during training and MetaR achieves 0.401 on Hits@10, while without background knowledge, there are 51, with 270 less, and MetaR achieves 0.279. This makes it reasonable that why MetaR achieves best performance on *BG:In-Train* with NELL-One. Even NELL-One has 37.1% one-shot entities, adding background knowledge into dataset increases the number of training tasks significantly, which complements the sparsity problem and contributes more to the task.

Thus we conclude that both the sparsity of entities and number of tasks will affect performance of MetaR. Generally, with more training tasks, MetaR performs better and for extremely sparse dataset, pre-train entity embeddings are preferred.

6 Conclusion

We propose a meta relational learning framework to do few-shot link prediction in KGs, and we design our model to transfer relation-specific meta information from support set to query set. Specif-

ically, using relation meta to transfer common and important information, and using gradient meta to accelerate learning. Compared to GMatching which is the only method in this task, our method MetaR gets better performance and it is also independent with background knowledge graphs. Based on experimental results, we analyze that the performance of MetaR will be affected by the number of training tasks and sparsity of entities. We may consider obtaining more valuable information about sparse entities in few-shot link prediction in KGs in the future.

Abstract

Language models are generally trained on data spanning a wide range of topics (e.g., news, reviews, fiction), but they might be applied to an a priori unknown target distribution (e.g., restaurant reviews). In this paper, we first show that training on text outside the test distribution can degrade test performance when using standard maximum likelihood (MLE) training. To remedy this without the knowledge of the test distribution, we propose an approach which trains a model that performs well over a wide range of potential test distributions. In particular, we derive a new distributionally robust optimization (DRO) procedure which minimizes the loss of the model over the *worst-case* mixture of topics with sufficient overlap with the training distribution. Our approach, called *topic conditional value at risk (topic CVaR)*, obtains a 5.5 point perplexity reduction over MLE when the language models are trained on a mixture of Yelp reviews and news and tested only on reviews.

1 Introduction

Large-scale language modeling plays a central role in both text generation (Sordoni et al., 2015; Nallapati et al., 2016) and unsupervised pre-training (Vaswani et al., 2013; Dai and Le, 2015; McCann et al., 2017; Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018). In both settings, a single language model is trained on a large corpus containing a range of topics (e.g. news, fiction, and reviews). This language model is then applied in many different tasks, each with a specific test distribution (e.g., analyzing the sentiment of restaurant reviews). Can we train a single general-purpose language model that works across a wide range of potential test distributions?

In this work, we first demonstrate that standard maximum likelihood training on a large, heterogeneous dataset can fail to achieve this goal.

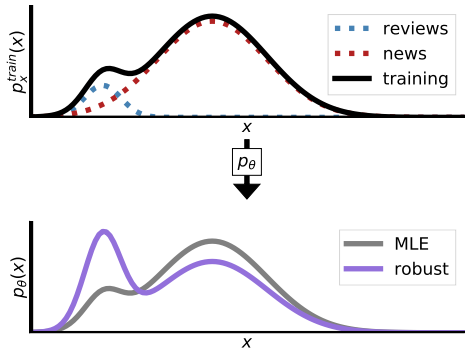

Figure 1. Illustration of a training corpus as a density (black) with mostly news stories (red) and a small number of restaurant reviews (blue). The standard MLE model (gray) reflects the underlying data and assigns little weight to reviews, and thus performs poorly on reviews. A more robust model should try to equalize the weight across all topics so that it can perform well regardless of which topics appear at test time.

While more data is generally better, the presence of text outside the target distribution actually *degrades* performance on a target test distribution. For example, a language model trained on Yelp reviews achieves a perplexity of 32, and this perplexity increases to 43 when trained on a mixture of 10% Yelp and 90% newswire sentences from the One Billion Word Benchmark (Chelba et al., 2013). Performance degrades because existing maximum likelihood estimation (MLE) objectives tend to emphasize model performance on more common sentences and topics at the expense of infrequent ones (Figure 1).

While the above performance degradation can be mitigated by fine-tuning and domain adaptation techniques (Shimodaira, 2000; Quiñonero-Candela et al., 2009; Daume III, 2007; Ben-David et al., 2010; Blitzer et al., 2011; Pryzant et al., 2017; Ganin and Lempitsky, 2015; Tzeng et al., 2014), these methods require knowing the test distribution and training a separate model specific to each target distribution. Instead, we aim to train a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4227–4237, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

single model that performs well across many unknown test distributions.

In order to do this, we will train a model that performs uniformly well over an entire family of potential test distributions. Since we cannot expect to do well on all possible test distributions, we consider the *subpopulation shift* setting, in which the test distribution is a subpopulation of the training distribution, and seek good performance across all such test distributions (e.g. Yelp reviews in a Yelp-newswire mixture). [1] In other words, adding data from topics outside the test topics should not hurt. It seems reasonable to protect against subpopulation shifts, intuitively because large-scale data collection schemes are designed to cover a diverse array of topics as a way to generalize to potential test distributions.

We train a model that performs well over all subpopulations by minimizing the risk for the *worst-case* subpopulation, following the distributionally robust optimization (DRO) literature (Ben-Tal et al., 2013). While an existing DRO framework called the conditional value at risk (CVaR) ensures uniformly good performance across subpopulations (Rockafellar and Uryasev, 2000; Duchi and Namkoong, 2018), we demonstrate that naïvely applying this approach to language modeling fails due to three challenges. First, the existing CVaR approach is too conservative because it considers robustness to *arbitrary* subpopulations. Such worst-case subpopulations are attained by adversarially choosing the hardest, most unusual sentences. Instead, we propose to consider *meaningful* subpopulations, defined by topics in a corpus (Hu et al., 2018). Second, applying CVaR directly to log loss results in a loss which is biased towards topics with high entropy, instead of those for which the model performs poorly relative to what is possible. We correct this by introducing a new *baselined* loss function which measures losses relative to the entropy of each topic. Finally, existing optimization algorithms for CVaR are either inapplicable to topic-based robustness sets or unscalable because they require batch optimization. We develop a scalable online algorithm which identifies the worst-performing topics at each iteration and upweights examples from those topics.

With these methodological improvements, we demonstrate that our approach, *topic CVaR*, improves robustness against subpopulation shifts. Topic CVaR reduces perplexity on the Yelp review corpus by 5.5 points compared to MLE when trained on the Yelp-One Billion Word Benchmark mixture from before. We also show improved robustness even when the shift is not strictly a subpopulation shift. Topic CVaR also achieves a 4 point perplexity reduction on a test distribution (TripAdvisor hotel reviews) that is similar to, but not strictly a subpopulation of the training distribution (Yelp and newswire text).

[1] The subpopulation assumption refers to overlaps in *distributions*, rather than individual examples. Our assumptions do not require overlap in the training and test data.

2 Problem Statement

Our goal is to learn a language model p_θ based on sentences sampled from the training distribution $x \sim p_{\text{x}}^{\text{train}}$, such that p_θ performs well on unknown test distributions $p_{\text{x}}^{\text{test}}$.

Language models p_θ are generally trained to approximate $p_{\text{x}}^{\text{train}}$ by minimizing the KL divergence $\text{KL}\big(p_{\text{x}}^{\text{train}} \,\big\|\, p_\theta\big)$ via maximum likelihood estimation (MLE),

$$\inf_\theta \mathbb{E}\left[-\log p_\theta(x)\right]. \tag{1}$$

When $p_{\text{x}}^{\text{test}} = p_{\text{x}}^{\text{train}}$, classical statistical theory guarantees that a model trained via MLE performs well on the test distribution given sufficient data. However, when $p_{\text{x}}^{\text{test}}$ is not identical to $p_{\text{x}}^{\text{train}}$, MLE can perform poorly no matter how much data is observed. This is because the test set might consist solely of sentences from topics that are infrequent during training, to which MLE would assign low probabilities.

To illustrate this point, consider the toy example drawn in Figure 2. In this example, the training distribution $p_{\text{x}}^{\text{train}}$ is a multinomial distribution over six possible sentences A–F, with two from reviews and four from news. Sentence F is ungrammatical and thus has an extremely low probability. The training distribution includes 10% reviews and 90% news, whereas the test distribution could be all reviews, all news, or a mixture. MLE assigns low probabilities to any review and thus performs poorly when evaluated solely on reviews. To be robust, we intuitively need a more conservative objective that encourages models to assign higher probabilities to rare but valid sentences.

In order to achieve this, we want to learn a model p_θ which performs well in situations where $p_{\text{x}}^{\text{train}} \neq p_{\text{x}}^{\text{test}}$ for a large set of potential test distributions $\mathcal{P}$, termed the uncertainty set. By training

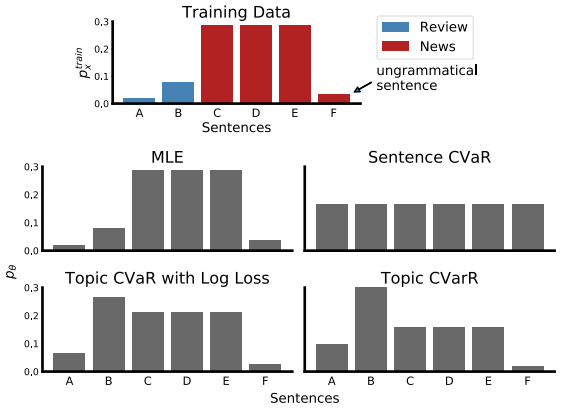

Figure 2. Toy example of a multinomial distribution over six sentences (top). Different panels illustrate models learned by different training procedures. MLE fits common topics (news) at the expense of rare ones (reviews). Sentence CVaR is too conservative, overemphasizing the ungrammatical sentence. Topic CVaR with log loss overemphasizes difficult topics (news) over easy ones (review). Topic CVaR (with baselining) balances the weight assigned to each topics, as desired.

a model that performs well on all distributions in the uncertainty set $\mathcal{P}$, we can ensure good test performance as long as $p_{\text{x}}^{\text{test}} \in \mathcal{P}$.

More formally, this approach falls under the framework of distributionally robust optimization (DRO) (Ben-Tal et al., 2013). With DRO, we optimize a model for loss ℓ and a set of potential test distributions $\mathcal{P}$ by minimizing the risk under the *worst-case* distribution in $\mathcal{P}$,

$$\sup_{p_{\text{x}} \in \mathcal{P}} \mathbb{E}_{p_{\text{x}}}[\ell(x;\theta)]. \tag{2}$$

Observe that the above worst-case objective does not depend on the unknown quantity $p_{\text{x}}^{\text{test}}$. The objective also upper bounds the test risk for all $p_{\text{x}}^{\text{test}} \in \mathcal{P}$ as

$$\mathbb{E}_{p_{\text{x}}^{\text{test}}}[\ell(x;\theta)] \leq \sup_{p_{\text{x}} \in \mathcal{P}} \mathbb{E}_{p_{\text{x}}}[\ell(x;\theta)], \tag{3}$$

so optimizing the above objective gives guarantees on test performance whenever $p_{\text{x}}^{\text{test}} \in \mathcal{P}$.

DRO provides a conceptually appealing framework for learning under train-test mismatch. However, it crucially depends on both the choice of uncertainty set $\mathcal{P}$ and loss ℓ, and we will discuss these choices in the next section.

3 Robust Language Modeling

We will begin by applying standard distributionally robust optimization approaches to the log loss (Section 3.1), and showing that this naïve approach suffers from two drawbacks:

1. Existing DRO uncertainty sets $\mathcal{P}$ are too conservative.
2. The log loss overemphasizes topics with inherently high entropy.

These drawbacks will motivate our development of a new approach we call topic CVaR, which addresses these two problems (Sections 3.2 and 3.3).

3.1 Robustness to arbitrary subpopulations

Observing that MLE is not robust because it assigns low probabilities (i.e. incurs high losses) on rare sentences, we might initially try to define $\mathcal{P}$ as individual training examples to ensure low loss on *all* data points. However, this is far too conservative, since the worst-case distribution would consist of exactly one data point. Therefore, we may want to optimize a slightly more realistic uncertainty set consisting of all sufficiently large subpopulations of the training distribution.

Minimizing losses over all subpopulations of the training distribution can be formulated as a type of distributionally robust optimization (DRO) problem (Duchi and Namkoong, 2018), which has been used to regularize models (Duchi and Namkoong, 2016), defend against adversarial examples (Sinha et al., 2018), and improve the fairness of models (Hashimoto et al., 2018).

One type of distributionally robust loss is known as conditional value at risk (CVaR) which guarantees low losses on all α-fraction subpopulations of the training distribution (Rockafellar and Uryasev, 2000). This corresponds to defining the uncertainty set $\mathcal{P}$ as all sentence distributions that are α-*covered* by $p_{\text{x}}^{\text{train}}$,

$$\mathcal{P}_{\text{x}}^{\alpha} := \{p_{\text{x}} : \alpha p_{\text{x}}(x) \leq p_{\text{x}}^{\text{train}}(x) \ \ \forall x\}. \tag{4}$$

This is equivalent to defining $\mathcal{P}_{\text{x}}^{\alpha}$ as the set of p_{x} which fulfills $p_{\text{x}}^{\text{train}} = \alpha p_{\text{x}} + (1-\alpha) p_{\text{x}}^{\text{other}}$ for some distribution $p_{\text{x}}^{\text{other}}$.

To achieve low loss on all possible test distributions in $\mathcal{P}_{\text{x}}^{\alpha}$, we minimize the expected loss under the worst-case distribution,

$$\sup_{p_{\text{x}} \in \mathcal{P}_{\text{x}}^{\alpha}} \mathbb{E}_{x \sim p_{\text{x}}}[\ell(x;\theta)]. \tag{5}$$

For the remainder of the paper, we will refer to this approach as *sentence CVaR*, highlighting the fact that it considers robustness over arbitrary sets of sentences. It intuitively encourages uniform performance across all subpopulations of sentences

by downweighting sentences with low loss, and upweighting sentences with high loss.

Because sentence CVaR considers *arbitrary* groups of examples, it can be too conservative in our problem setting. While sentence CVaR can prevent modeling common sentences at the cost of rare ones, it can also encourage modeling invalid sentences at the expense of valid ones. Returning to our example in Figure 2 with $\ell(x;\theta) = -\log p_\theta(x)$, sentence CVaR with for sufficiently low α achieves perfectly uniform performance. It equalizes likelihoods across all sentences, which unfortunately also results in high probabilities assigned to the ungrammatical sentence F.

3.2 Robustness over Topics

Sentence CVaR is too conservative since it allows for arbitrary groups — including ones consisting of purely invalid sentences. To remedy this, we will optimize models for all *meaningful* subpopulations instead of *arbitrary* ones.

One way to achieve this is through robustness over topics, rather than individual examples. For example, a news corpus often contains a variety of topics (politics, business, opinion, food) and a test corpus may contain these topics with different proportions. A robust language model should perform well on a wide range of topic mixtures without taking the topic identity as an input.

Formally, we posit that each sentence x belongs to some latent topic z, which has a sentence distribution $p_{\mathrm{x}|z}$. We want our models to be robust to shifts in the topic distribution, where we have $z \sim p_{\mathrm{z}}^{\text{train}}$ and $z \sim p_{\mathrm{z}}^{\text{test}}$. In this case, we can define a natural uncertainty set for CVaR, defined over latent topics rather than individual examples. Extending the definition of α-covered distributions to topics, we have the set

$$\mathcal{P}_{\mathrm{z}}^{\alpha} := \{p_{\mathrm{z}} : \alpha p_{\mathrm{z}}(z) \le p_{\mathrm{z}}^{\text{train}}(z) \ \ \forall z\} \tag{6}$$

and the objective is the expected loss under the worst-case topic distribution,

$$\sup_{p_{\mathrm{z}} \in \mathcal{P}_{\mathrm{z}}^{\alpha}} \mathbb{E}_{z\sim p_{\mathrm{z}}} \left[\mathbb{E}_{x \sim p_{\mathrm{x}|z}} \left[\ell(x;\theta) \right] \right]. \tag{7}$$

This objective intuitively encourages uniform loss across topics by upweighting topics incurring high losses and downweighting topics with low losses, while keeping the conditional distribution of sentences given a topic constant.

3.3 Baselined Loss Function

Recall that DRO depends critically on the choice of uncertainty set and loss function. Having specified the uncertainty set, we now turn to the choice of loss $\ell(x;\theta)$. While the log loss $\ell(x;\theta) = -\log p_\theta(x)$ is the standard choice in language modeling, we show that this approach has a flaw in the robust setting and propose a corrected loss.

Log Loss. Using log loss on CVaR encourages uniform *absolute* log-likelihoods across topics even if some topics are much harder than others. For example, consider a model which performs nearly optimally on difficult topics and highly suboptimally on easy topics. Since log loss measures absolute performance, it would force the model to focus on the difficult topic *even if the model can't improve further on this topic*. In the example in Figure 2, news is emphasized over reviews because news has higher entropy and thus higher difficulty. Empirically, we observe that log loss with CVaR forces the models to focus almost entirely on the difficult topics such as long news stories.

Baselined Loss. We now propose a new baselined loss, which encourages uniform *relative* performance across topics. We refer to our approach with the baselined loss as *topic CVaR*.

The baselined loss function $\ell(x, z; \theta) = \log p_{\mathrm{x}|z}(x \mid z) - \log p_\theta(x)$ evaluates the performance of the model relative to the best possible model for the topic, $\log p_{\mathrm{x}|z}(x \mid z)$. Although we do not observe $\log p_{\mathrm{x}|z}(x \mid z)$, we will show later in section 4.2 that we can estimate sufficient statistics of $\log p_{\mathrm{x}|z}(x \mid z)$ that allow us to compute the baselined loss. By using baselined loss, we intuitively encourage models to perform as well as it can on each topic while making optimal trade-offs among topics.

Plugging the baselined loss into the robust objective (7), the optimization problem is

$$\sup_{p_{\mathrm{z}} \in \mathcal{P}_{\mathrm{z}}^{\alpha}} \mathbb{E}_{z\sim p_{\mathrm{z}}} \left[\mathbb{E}_{x \sim p_{\mathrm{x}|z}} \left[\log p_{\mathrm{x}|z}(x \mid z) - \log p_\theta(x) \right] \right], \tag{8}$$

which can be simplified to

$$\sup_{p_{\mathrm{z}} \in \mathcal{P}_{\mathrm{z}}^{\alpha}} \mathbb{E}_{z\sim p_{\mathrm{z}}} \left[\mathrm{KL}\big(p_{\mathrm{x}|z} \,\big\|\, p_\theta\big) \right]. \tag{9}$$

Topic CVaR thus minimizes the per-topic KL divergences, and this interpretation fits nicely with

a general goal of training p_θ that matches the test distribution. Unlike in the MLE case, minimizing the KL is not equivalent to minimizing the log loss. In MLE, minimizing $\mathrm{KL}(p_{\mathrm{x}}^{\text{train}} \| p_\theta) = \mathbb{E}\left[\log p_{\mathrm{x}}^{\text{train}}(x) - \log p_\theta(x)\right]$ is equivalent to minimizing the log loss because $\log p_{\mathrm{x}}^{\text{train}}(x)$ can be treated as a constant. However, in topic CVaR, the analogous baseline entropy term $\log p_{\mathrm{x}|z}(x \mid z)$ depends on z and thus is not a constant with respect to the outer supremum.

In the running toy example (Figure 2), topic CVaR results in robust models that perform relatively well on both news and reviews. The resulting model is a mixture of news and review distribution with equal weights on the two topics.

In summary, topic CVaR contains two improvements over existing DRO approaches: using the latent topic distribution $p_{\mathrm{z}}^{\text{train}}$ to specify the uncertainty set and defining the baselined loss. In the following section, we will describe an algorithm which optimizes this topic CVaR objective.

4 Algorithm

We now operationalize the principles in the previous section, specifying (i) how we choose topics (Section 4.1), (ii) how we estimate the baseline (Section 4.2), and (iii) how to efficiently optimize the robust objective (7) (Section 4.3).

4.1 Identifying Topics

The topic CVaR objective requires topic assignments z for each sentence in order to define the uncertainty set $\mathcal{P}$. Since the topics determine the set of $p_{\mathrm{x}}^{\text{test}}$ distribution for which the model performs well, we seek topics whose subpopulation shifts capture realistic potential test settings.

We use latent Dirichlet allocation (LDA) (Blei et al., 2003) to cluster the sentences into latent topics. LDA assigns each word in a sentence to a topic, and we assign each sentence to the topic with highest total posterior probability.

4.2 Estimating Baselined Losses

Recall that topic CVaR uses KL-divergence as the loss term (Eq. (9)),

$$\mathrm{KL}\big(p_{\mathrm{x}|z} \,\big\|\, p_\theta\big) := \mathbb{E}_{p_{\mathrm{x}|z}}[\log p_{\mathrm{x}|z}(x \mid z)] - \mathbb{E}_{p_{\mathrm{x}|z}}[\log p_\theta(x)].$$

While we can estimate the log loss term $\mathbb{E}[\log p_\theta(x)]$ from samples, the entropy term $H(X \mid Z = z) := \mathbb{E}_{p_{\mathrm{x}|z}}[-\log p_{\mathrm{x}|z}(x \mid z)]$ is not something we can easily estimate.

We thus propose to estimate the entropies $H(X \mid Z = z)$ by fitting a *baseline model* p_β for each topic, and computing $H_\beta(X \mid Z = z) := \mathbb{E}_{p_{\mathrm{x}|z}}[-\log p_\beta(x \mid z)]$.[2] In practice, we use a bigram model, which was fast enough to scale and worked sufficiently well in experiments.

4.3 Online Optimization of topic CVaR

No scalable, online algorithm exists for optimizing the topic CVaR objective. Many DRO problems admit efficient batch optimization procedures based on Lagrangian duality (Duchi et al., 2016). However, this approach fails for topic CVaR, since the dual form requires exact computations rather than stochastic estimates of $\mathbb{E}_{p_{\mathrm{x}|z}}[-\log p_\theta(x)]$. Online algorithms for DRO exist (Namkoong and Duchi, 2016), but do not handle the nested maximization-expectation structure arising in topic CVaR (Eq. (7)).

Because of this, we develop an online optimization procedure for topic CVaR compatible with stochastic gradient descent methods. The topic CVaR problem is a two-player minimax game between the model parameter θ and the potential test distribution p_{z}. Intuitively, p_{z} attempts to be the worst-case distribution and maximize the robust objective, while θ attempts to minimize the robust objective. The precise two-player minimax game is

$$\inf_\theta \sup_{p_{\mathrm{z}} \in \mathcal{P}_z^\alpha} \mathbb{E}_{z \sim p_{\mathrm{z}}}[L(z;\theta)], \tag{10}$$

where the expected loss for each z (inner expectation) is $L(z;\theta) := \mathbb{E}_{x \sim p_{\mathrm{x}|z}}[\ell(x;\theta)]$.

In the above two-player game, the game proceeds in multiple rounds $t = 1, 2, \ldots$. At each round, the players select $p_{\mathrm{z}}{}^{(t)}$ and $\theta^{(t)}$. It is standard to interleave parameter updates between the two players in minimax optimization, and we describe the precise update rules in subsequent paragraphs. To carry out these updates, we keep track of an empirical estimate of the probability $p_{\mathrm{z}}^{\text{train}}(z)$ at each iteration t, which we refer to as $\hat{p}_{\mathrm{z}}^{\text{train}(t)}(z)$. We also keep track of the historical average of losses incurred for each topic so far, up to the current round t, which we call $\hat{L}^{(t)}(z;\theta^{(1:t)})$. Con-

[2] H_β yields accurate solutions to the topic CVaR problem as long as they capture the entropy up to a constant (i.e. $H_\beta(X \mid Z = z) \approx H(X \mid Z = z) + c$)

cretely, $\hat{L}^{(t)}(z;\theta^{(1:t)})$ is computed as an average of $\{\ell(x^{(t')};\theta^{(t')}) : t' \in [t], z^{(t')} = z\}$.

At each iteration t, p_{z} is updated by selecting an optimal value with respect to historical losses up to the current iteration, loosely inspired by the "Be The Leader" algorithm. This results in the following update rule to p_{z},

$$p_{\mathrm{z}}{}^{(t)} = \operatorname*{argmax}_{p_z \in \mathcal{P}_z^{\alpha}} \mathbb{E}_{z \sim p_z}\left[\hat{L}^{(t)}(z;\theta^{(1:t)})\right]. \quad (11)$$

The above argmax can computed efficiently by ordering topics in the order of decreasing average loss, and assigning each topic either $\frac{\hat{p}_{\mathrm{z}}^{\mathrm{train}}(z)}{\alpha}$ or the probability left to be assigned, whichever is lower.[3]

We update θ with online gradient descent,

$$\theta^{(t)} = \theta^{(t-1)} - \epsilon \frac{p_{\mathrm{z}}{}^{(t)}(z^{(t)})}{\hat{p}_{\mathrm{z}}^{\mathrm{train}(t)}(z^{(t)})} \nabla \ell(x^{(t)};\theta^{(t-1)}),$$

where ϵ is the learning rate.

To give intuition for the two updates, first note that $\frac{p_{\mathrm{z}}{}^{(t)}(z)}{p_{\mathrm{z}}^{\mathrm{train}(t)}(z)} = \frac{1}{\alpha}$ on approximately α fraction of the data and this ratio acts as an indicator function which determines if an example is part of the worst-case set or not. If it is, we update the model and otherwise we ignore it.

5 Experiments

We demonstrate that topic CVaR improves maximum likelihood language models when $p_{\mathrm{x}}^{\mathrm{train}} \neq p_{\mathrm{x}}^{\mathrm{test}}$. Section 5.1 outlines the experimental setup while Section 5.2 shows the robustness improvements and analysis of topic CVaR.

5.1 Evaluation Details

Datasets. We use the following three corpora: the Yelp review corpus (YELP, (2017)), One Billion Word benchmark corpus (ONEBWORD), and the TripAdvisor Annotated Dataset (TRIPADV, Marcheggiani et al. (2014)).

We preprocess the corpora using SPACY (Honnibal and Johnson (2015)) by removing sentences with fewer than 10 characters, segmenting sentences, tagging named-entities, and replacing each entity with its corresponding OntoNotes tag.

[3]For example with $\alpha = 0.2$, $\hat{L}^{(t)} = [40, 30, 60]$, and $\hat{p}_{\mathrm{z}}^{\mathrm{train}} = [0.2, 0.8, 0.1]$, then $p_{\mathrm{z}}{}^{(t)} = [0.5, 0, 0.5]$.

Vocabulary. Our experiments will evaluate models using perplexity, which depends on the choice of vocabulary. To make perplexity comparable for models trained on different datasets, we use a single, fixed vocabulary formed by combining the most frequently occurring $10,000$ words in each corpus. All words in the mixtures which are not in the vocabulary ($1-3\%$ in our experiments) are replaced with a special *unk* token.

Clustering. To cluster sentences in the training set, we ran LightLDA (Yuan et al. (2015)) for 100 iterations with prior hyperparameters $\alpha = 0.1$, $\beta = 1.0$ and 2 Metropolis-Hastings steps. We set the model to find 10 topics, as this resulted in stable clusters consisting of semantically similar sentences.

Models. Our models are Transformer (Vaswani et al., 2017) based language models trained using the FAIRSEQ sequence-to-sequence toolkit (2017). We use the same model architecture, optimizers, and hyperparameters for both MLE and CVaR. For both models, we use Nesterov's accelerated gradient descent, a fixed learning rate of 0.01, minibatch size of 500 sentences, and 30k minibatches (corresponding to 100 epochs on the YELP corpus). These values were derived by tuning a MLE model trained on the YELP data and tested on the YELP dev set.

Hyperparameters Topic CVaR can be unstable at small α values due to the fact that we are optimizing for worst-case errors. Because of this, we make three small but important modifications to the algorithm. (i) We use $\alpha = 0.2$ to estimate models for $\alpha^* < 0.2$, as small αs can cause gradients to become unstable; (ii) we set a minimum $p_{\mathrm{z}}(z)/p_{\mathrm{z}}^{\mathrm{train}}(z)$ value of 0.1; and (iii) we compute historical losses using exponentially weighted moving averages. With these modifications, the model reliably converges to similar validation losses.

5.2 Language Model Robustness

We seek to assess the performance of MLE and CVaR models under subpopulation shift. In order to do this, we train language models on various mixtures of YELP and ONEBWORD corpora and evaluate the models on a held-out set of YELP sentences.

We will construct a training corpus, whose distribution α^*-*covers* the test distribution (i.e. α^*

fraction of the training distribution corresponds to the Yelp distribution). In this case, we expect that topic CVaR with $\alpha = \alpha^*$ to perform well since the test set exactly fulfills the subpopulation shift assumption.

To form a training corpus, whose distribution α^*-covers the YELP distribution, we mix a fixed set of 500,000 sentences from YELP training subset with $500,000(1 - \alpha^*)/\alpha^*$ sentences from ONEBWORD. This results in a dataset where α^* of the training data comes from YELP. The test corpus is composed of sentences from the YELP test subset, with no sentence overlap with the training corpora. Since the absolute number of YELP samples in the training corpora remains constant across different values of α^*, we expect that a model which is robust to added nuisance data will perform equally well on a YELP-only test set, even as the mixture proportion of ONEBWORD samples in the training corpus increases.

Oracle model. We estimate the *oracle* performance of a robust language model as running topic CVaR where the topic $z = \{\text{YELP}, \text{ONEBWORD}\}$ and the topic assignments use the ground truth corpus identities rather than a clustering algorithm. In this case, when $\alpha^* = \alpha$ we are directly minimizing the worst-case baselined test loss over both YELP and ONEBWORD.

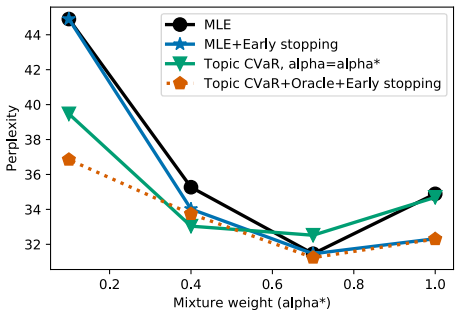

Figure 3. Topic CVaR (green) provides substantial improvements in perplexity compared to MLE (black and blue) as the amount of train-test mismatch increases ($\alpha^* \to 0$). This performance is close to the oracle performance which uses ground truth corpus labels and early stopping (orange).

Topic CVaR improves robustness over MLE. Using the YELP-ONEBWORD mixtures, we evaluate the robustness of topic CVaR and MLE to added nuisance data. We find that with no nuisance data, the MLE model matches the topic CVaR model (Figure 3 $\alpha^* = 1.0$). As we add data from ONEBWORD and α^* decreases to 0.7, we find some *positive transfer* effects where the increased data from the ONEBWORD corpus improves the performance on Yelp. However, as the fraction of nuisance data grows further and α^* drops below 0.4 the MLE models suffer large increases in perplexity, incurring up to 10 additional points of perplexity. Early stopping according to validation perplexity on YELP does not improve this substantially beyond the basic MLE model (blue star). On the other hand, applying topic CVaR with $\alpha^* = \alpha$ provides substantial boosts to language model performance for small α^*, with nearly no loss of performance for large α^* (green triangle). Finally, we find that the topic CVaR method we propose is close to the best possible *oracle* performance.

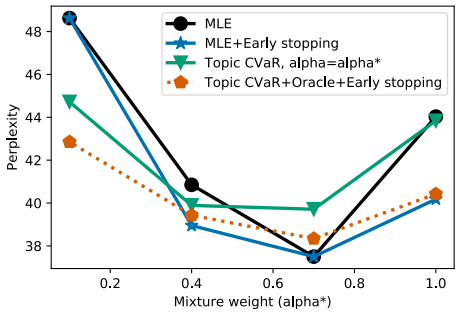

Figure 4. The robustness improvements from topic CVaR (black vs green and orange) apply even when the test set (TRIPADV reviews) is not a subpopulation shift from the training set (YELP and ONEBWORD).

Topic CVaR robustness beyond subpopulation shift. The prior YELP-ONEBWORD experiment showed that topic CVaR is more robust than MLE under subpopulation shift.

We now explore the more realistic setting in which the test distribution is not a subpopulation shift, but merely "similar" to the training distribution. We do this by testing the same model on the TRIPADV hotel review corpus. The hotel and restaurant review distributions are similar (i.e. they both frequently mention service) but differ in that hotels reviews often mention the location and room, while restaurant reviews often mention food items.

We find a similar result consistent with the earlier subpopulation shift experiment (Figure 4). The MLE model performance degrades rapidly between $\alpha^* = 0.7$ and 0.1, while topic CVaR substantially reduces this degradation. This suggests that topic CVaR models provide robustness bene-

fits in real-world settings where the topic overlaps are not exact, and the subpopulation shift assumption no longer holds.

Ablations. Topic CVaR extends the standard CVaR objective in two ways: the use of topics and the use of a baseline. We investigate the effect of these choices via an ablation experiment. Removing the topic structure results in dramatic loss of performance for our models: the perplexity exceeds 80 with $\alpha = 0.2$ for all α^*. This is because the worst case group can consist of solely of disfluent sentences that do not match any real test distribution. If we remove the baseline, the resulting model is not completely degenerate, but it is not as robust as α^* decreases (Figure 5, teal). This is because ONEBWORD is a higher entropy corpus than YELP, and forcing the model to achieve equal *absolute* losses causes the model to focus nearly entirely on ONEBWORD, resulting in low YELP performance.

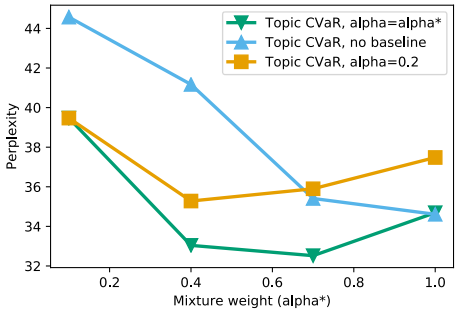

Figure 5. The robustness of topic CVaR degrades when the baseline is removed (teal), but is resistant to being over-conservative in choosing α (yellow).

Choice of α. Since the true train-test overlap α^* is not always known, we cannot always set our hyperparameter α equal to α^*. We find that selecting suboptimal values of α degrades perplexity between 2–3 points depending on α^*. Figure 5 shows that setting α to the most conservative choice of 0.2 outperforms MLE on small α^* while incurring only 2 points of perplexity loss over MLE at $\alpha^* = 1.0$. Figure 6 further demonstrates that when $\alpha^* = 0.1$, any choice of α outperforms MLE, and incorrectly selecting α seems to incur a linear penalty in perplexity.

Error analysis and examples. Evaluating both models trained with $\alpha^* = 0.1$ on both the YELP and ONEBWORD test sets, we find that topic CVaR assigns higher probabilities (and therefore

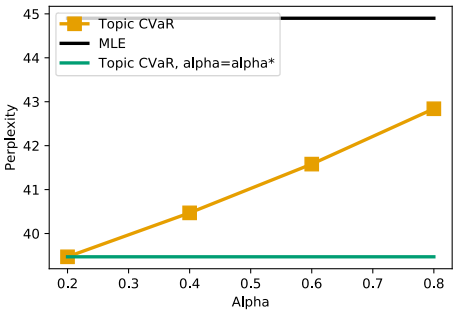

Figure 6. Topic CVaR outperforms MLE in the $p_x^{\text{train}} \neq p_x^{\text{test}}$ setting ($\alpha^* = 0.1$) for any small α (x-axis). The performance degradation is linear, implying topic CVaR is robust to small errors in the choice of α.

incurs lower losses) on sentences from Yelp (Figure 7, top right). We also see that MLE does particularly well on low loss examples (bottom left) while topic CVaR does well on high-loss ones (top right) as we might expect from optimizing the worst-case losses.

Examining examples from the YELP test set (Table 1), we identify examples which have substantially higher probabilities under MLE than topic CVaR (left column) and vice versa (right column). These examples show that topic CVaR performs well by assigning high probabilities to stereotypical YELP sentences that discuss food and service, while MLE performs better on sentences about accidents and locations. These examples are consistent with the observation that topic CVaR assigns higher probabilities to typical YELP sentences and thus has lower perplexity, while the MLE model has high perplexity since it assigns probabilities to YELP sentences primarily based on their similarity to examples from ONEBWORD.

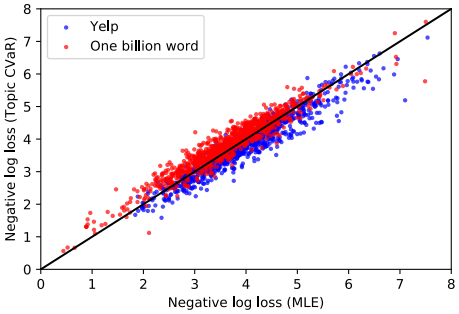

Figure 7. Log losses for sentences (points) from YELP (blue) and ONEBWORD (red) under topic CVaR (y-axis) and MLE (x-axis). Topic CVaR performs well on YELP and infrequent sentences (top right). MLE performs better on frequent sentences from ONEBWORD (bottom left).

$p_{\text{MLE}} > p_{\text{CVaR}}$	$p_{\text{CVaR}} > p_{\text{MLE}}$
my girlfriend had an awful accident that hurt her leg & ankle which resulted in a fire and rescue ride	huge servings, so plenty for leftovers.
the address [PERSON] has listed is their old address	it tastes the way food should taste!
wonderful location in a up and coming part of [GPE].	every single person we spoke to on staff was absolutely incredible.

Table 1. Examples from the YELP corpus for which MLE outperforms topic CVaR (left column) and vice versa. Brackets indicate ONTONOTES named-entity tags. The examples preferred by topic CVaR are stereotypical Yelp sentences, while those preferred by MLE refer to locations and accidents.

6 Related Work

Domain Adaptation: In the case of known source (train) and target (test) domains, there exist a variety of techniques to learn robust models (Shimodaira, 2000; Quiñonero-Candela et al., 2009; Daume III, 2007; Ben-David et al., 2010; Blitzer et al., 2011; Pryzant et al., 2017) or domain-invariant features (Ganin and Lempitsky, 2015; Tzeng et al., 2014). However, such methods require accurate domain membership annotations.

In the absence of domain membership annotations, prior multi-source domain adaptation (Mansour et al., 2009) approaches propose the use of clustering to identify candidate domains. For instance, Hoffman et al. (2012) and Xiong et al. (2014) discover latent domains in classification by clustering data using class labels. Gong et al. (2013) extend this work by identifying subsets which are distinct and learnable. More recent work consider errors in estimating the target domain (Hoffman et al., 2018) and derive learning bounds with respect to such errors. While these approaches make use of cluster and topic structures as prior, they still require some knowledge of the target distribution and train a model tailored to the target distribution. Instead, we assume no knowledge on the target distribution and train a single model by considering the worst case.

In *conditional* settings such as machine translation, prior works connect topic modeling and domain adaptation (Hu et al., 2014; Eidelman et al., 2012). However, unlike our work, these approaches use topics at *test time* by inferring the domain from the input variable x. In language modeling, we have no inputs and thus must find models robust to unknown domain shifts at test time. In addition, it can be difficult to infer the test distribution as the distribution can rapidly change across users and time.

Distributional Robustness: Our approach is based upon existing work in the distributionally robust optimization (DRO) literature. Optimizing on a ball of distributions around the empirical distribution has been considered in prior work (Ben-Tal et al., 2013; Namkoong and Duchi, 2017; Duchi and Namkoong, 2016; Sinha et al., 2018). Using DRO to minimize losses over subpopulations was proposed earlier in Hashimoto et al. (2018) and Duchi and Namkoong (2018), and Hu et al. (2018) proposed incorporating problem structure via class labels. Our work derives an efficient optimization procedure for DRO with topic-based uncertainty sets, and demonstrates that naively applying DRO to log losses fails to provide robustness due to the lack of baselining.

7 Discussion

In this work, we show that the performance of language models degrade as the amount of text from outside the test distribution grows. We hypothesize that this problem arises from the tendency of MLE to optimize for common sentences in the corpus, and we propose a solution based on distributionally robust optimization.

Empirically, we demonstrate that the DRO-based topic CVaR is more robust than MLE to subpopulation shifts and similar shifts. While this work focuses on DRO for language modeling, train-test mismatches under subpopulation shifts are more broadly applicable to any task where there are trade-offs between potential test distributions, and potential test distributions can be described with topics. Our work shows that topics are an effective way to encode prior information about test distributions, and baselines can properly normalize for the difficulty across these topics.

Unsupervised Domain Adaptation of Contextualized Embeddings for Sequence Labeling

Xiaochuang Han and **Jacob Eisenstein**
Georgia Institute of Technology*
hxc@cmu.edu, me@jacob-eisenstein.com

Abstract

Contextualized word embeddings such as ELMo and BERT provide a foundation for strong performance across a wide range of natural language processing tasks by pretraining on large corpora of unlabeled text. However, the applicability of this approach is unknown when the target domain varies substantially from the pretraining corpus. We are specifically interested in the scenario in which labeled data is available in only a canonical source domain such as newstext, and the target domain is distinct from both the labeled and pretraining texts. To address this scenario, we propose *domain-adaptive fine-tuning*, in which the contextualized embeddings are adapted by masked language modeling on text from the target domain. We test this approach on sequence labeling in two challenging domains: Early Modern English and Twitter. Both domains differ substantially from existing pretraining corpora, and domain-adaptive fine-tuning yields substantial improvements over strong BERT baselines, with particularly impressive results on out-of-vocabulary words. We conclude that domain-adaptive fine-tuning offers a simple and effective approach for the unsupervised adaptation of sequence labeling to difficult new domains.[1]

1 Introduction

Contextualized word embeddings are becoming a ubiquitous component of natural language processing (Dai and Le, 2015; Devlin et al., 2019; Howard and Ruder, 2018; Radford et al., 2018; Peters et al., 2018). Pretrained contextualized word embeddings can be used as feature for downstream tasks; alternatively, the contextualized word embedding module can be incorporated into an end-to-end system, allowing the embeddings to be fine-tuned from task-specific labeled data. In either case, a primary benefit of contextualized word embeddings is that they seed the learner with distributional information from large unlabeled datasets.

However, the texts used to build pretrained contextualized word embedding models are drawn from a narrow set of domains:

- **Wikipedia** in BERT (Devlin et al., 2019) and ULMFiT (Howard and Ruder, 2018);
- **Newstext** (Chelba et al., 2013) in ELMo (Peters et al., 2018);
- **BooksCorpus** (Zhu et al., 2015) in BERT (Devlin et al., 2019) and GPT (Radford et al., 2018).

All three corpora consist exclusively of text written since the late 20th century; furthermore, Wikipedia and newstext are subject to restrictive stylistic constraints (Bryant et al., 2005).[2] It is therefore crucial to determine whether these pretrained models are transferable to texts from other periods or other stylistic traditions, such as historical documents, technical research papers, and social media.

This paper offers a first empirical investigation of the applicability of domain adaptation to pretrained contextualized word embeddings. As a case study, we focus on sequence labeling in historical texts. Historical texts are of increasing interest in the computational social sciences and digital humanities, offering insights on patterns of

[1]Trained models for Early Modern English and Twitter are available at https://github.com/xhan77/AdaptaBERT

[2]While it might be desirable to completely retrain contextualized word embedding models in the target domain (e.g., Lee et al., 2019), this requires data and computational resources that are often unavailable.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4238–4248,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

language change (Hilpert and Gries, 2016), social norms (Garg et al., 2018), and the history of ideas and culture (Michel et al., 2011). Syntactic analysis can play an important role: researchers have used part-of-speech tagging to identify syntactic changes (Degaetano-Ortlieb, 2018) and dependency parsing to quantify gender-based patterns of adjectival modification and possession in classic literary texts (Vuillemot et al., 2009; Muralidharan and Hearst, 2013). But despite the appeal of using NLP in historical linguistics and literary analysis, there is relatively little research on how performance is impacted by diachronic transfer. Indeed, the evidence that does exist suggests that accuracy degrades significantly, especially if steps are not taken to adapt: for example, Yang and Eisenstein (2015) compare the accuracy of tagging 18th century and 16th century Portuguese text (using a model trained on 19th century text), and find that the error rate is twice as high for the older text.

We evaluate the impact of diachronic transfer on a contemporary pretrained part-of-speech tagging system. First, we show that a BERT-based part-of-speech tagger outperforms the state-of-the-art unsupervised domain adaptation method (Yang and Eisenstein, 2016), without taking any explicit steps to adapt to the target domain of Early Modern English. Next, we propose a simple unsupervised domain-adaptive fine-tuning step, using a masked language modeling objective over unlabeled text in the target domain. This yields significant further improvements, with more than 50% error reduction on out-of-vocabulary words. We also present a secondary evaluation on named entity recognition in contemporary social media (Strauss et al., 2016). This evaluation yields similar results: a direct application of BERT outperforms most of the systems from the 2016 WNUT shared task, and domain-adaptive fine-tuning yields further improvements. In both Early Modern English and social media, domain-adaptive fine-tuning does not decrease performance in the original source domain; the adapted tagger performs well in both settings. In contrast, fine-tuning BERT on *labeled* data in the target domain causes catastrophic forgetting (McCloskey and Cohen, 1989), with a significant deterioration in tagging performance in the source domain.

2 Tagging Historical Texts

Before describing our modeling approach, we highlight some of the unique aspects of tagging historical texts, focusing on the target dataset of the Penn-Helsinki Corpus of Early Modern English (Kroch et al., 2004).

2.1 Early Modern English

Early Modern English (EME) refers to the dominant language spoken in England during the period spanning the 15th-17th centuries, which includes the time of Shakespeare. While the English of this period is more comprehensible to contemporary readers than the Middle English that immediately preceded it, EME nonetheless differs from the English of today in a number of respects.

Orthography. A particularly salient aspect of EME is the variability of spelling and other orthographic conventions (Baron and Rayson, 2008). For example:

(1) If this marsch waulle (marsh wall) were not kept, and the canales of eche partes of Sowey river kept from abundance of wedes, al the plaine marsch ground at sodaine raynes (sudden rains) wold be overflowen, and the profite of the meade lost.

While these differences are not too difficult for fluent human readers of English, they affect a large number of tokens, resulting in a substantial increase in the out-of-vocabulary rate (Yang and Eisenstein, 2016). Some of the spelling differences are purely typographical, such as the substitution of *v* for *u* in words like *vnto*, and the substitution of *y* for *i* in words like *hym*. These are common sources of errors for baseline models. Another source of out-of-vocabulary words is the addition of a silent *e* to the end of many words. This generally did not cause errors for wordpiece-based models (like BERT), perhaps because the final 'e' is segmented as a separate token, which does not receive a tag. Capitalization is also used inconsistently, making it difficult to distinguish proper and common nouns, as in the following examples:

(2) And that those **Writs** which shall be awarded and directed for returning of **Juryes** ...

(3) ... shall not then have **Twenty** pounds or **Eight** pounds respectively ...

Morphosyntax. Aside from orthography, EME is fairly similar to contemporary English, with a few notable exceptions. EME includes several inflections that are rare or nonexistent today, such as the *-th* suffix for third person singular conjugation, as in *hath* (has) and *doth* (does). Another difference is in the system of second-person pronouns. EME includes the informal second person *thou* with declensions *thee, thine, thy*, and the plural second-person pronoun *ye*. These pronouns are significant sources of errors for baseline models: for example, a BERT-based tagger makes 216 errors on 272 occurrences of the pronoun *thee*.

2.2 Part-of-Speech Tags in the Penn Parsed Corpora of Historical English

The Penn Parsed Corpora of Historical English (PPCHE) include part-of-speech annotations for texts from several historical periods (Kroch et al., 2004). We focus on the corpus covering Early Modern English, which we refer to as PPCEME. As discussed in § 7, prior work has generally treated tagging the PPCEME as a problem of *domain adaptation*, with a post-processing stage to map deterministically between the tagsets. Specifically, we train on the Penn Treebank (PTB) corpus of 20th century English (Marcus et al., 1993), and then evaluate on the PPCEME test set, using a mapping between the PPCHE and PTB tagsets defined by Moon and Baldridge (2007).

Unfortunately, there are some fundamental differences in the approaches to verbs taken by each tagset. Unlike the PTB, the PPCHE has distinct tags for the modal verbs *have*, *do*, and *be* (and their infections); unlike the PPCHE, the PTB has distinct tags for third-person singular present indicative (VBZ) and other present indicative verbs (VBP). Moon and Baldridge map only to VBP, and Yang and Eisenstein report an error when VBZ is predicted, even though the corresponding PPCHE tag would be identical in both cases. We avoid this issue by focusing most of our evaluations on a coarse-grained version of the PTB tagset, described in § 4.3.

3 Adaptation with Contextualized Embeddings

The problem of processing historical English can be treated as one of unsupervised domain adaptation. Specifically, we assume that labeled data is available only in the "source domain" of contemporary modern English, and adapt to the "target domain" of historical text by using unlabeled data. We now explain how contextualized word embeddings can be applied in this setting.

Contextualized word embeddings provide a generic framework for semi-supervised learning across a range of natural language processing tasks, including sequence labeling tasks like part-of-speech tagging and named entity recognition (Peters et al., 2018; Devlin et al., 2019). Given a sequence of tokens $w_1, w_2, \ldots, w_T$, these methods return a sequence of vector embeddings $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_T$. The embeddings are *contextualized* in the sense that they reflect not only each token but also the context in which each token appears. The embedding function is trained either from a language modeling task (Peters et al., 2018) or a related task of recovering masked tokens (Devlin et al., 2019); these methods can be seen as performing semi-supervised learning, because they benefit from large amounts of unlabeled data.

3.1 Task-specific fine-tuning

Contextualized embeddings are powerful features for a wide range of downstream tasks. Of particular relevance for our work, Devlin et al. (2019) show that a state-of-the-art named entity recognition system can be constructed by simply feeding the contextualized embeddings into a linear classification layer. The log probability can then be computed by the log softmax,

$$\log p(y_t \mid \mathbf{w}_{1:T}) = \beta_{y_t} \cdot \mathbf{x}_t - \log \sum_{y \in \mathcal{Y}} \exp\left(\beta_y \cdot \mathbf{x}_t\right), \tag{1}$$

where the contextualized embedding $\mathbf{x}_t$ captures information from the entire sequence $\mathbf{w}_{1:T} = (w_1, w_2, \ldots, w_T)$, and β_y is a vector of weights for each tag y.

To fine-tune the contextualized word embeddings, the model is trained by minimizing the negative conditional log-likelihood of the labeled data. This involves backpropagating from the tagging loss into the network that computes contextualized word embeddings. We refer to this procedure as *task-tuning*.

To borrow from the terminology of domain adaptation (Daumé III and Marcu, 2006), a *direct transfer* of contextualized word embeddings to the problem of tagging historical text works as follows:

1. Fine-tune BERT for the part-of-speech tagging task, using the Penn Treebank (PTB) corpus of 20th century English;

2. Apply BERT and the learned tagger to the test set of the Penn Parsed Corpus of Early Modern English (PPCEME).

We evaluate this approach in § 5.

3.2 Domain-adaptive fine-tuning

When the target domain differs substantially from the pretraining corpus, the contextualized word embeddings may be ineffective for the tagging task. This risk is particularly serious in unsupervised domain adaptation, because the labeled data may also differ substantially from the target text. In this case, task-specific fine-tuning may help adapt the contextualized embeddings to the labeling task, but not to the domain. To address this issue, we propose the *AdaptaBERT* model for unsupervised domain adaptation, which adds an additional fine-tuning objective: masked language modeling in the target domain. Specifically, we apply a simple two-step approach:

1. **Domain tuning**. In the first step, we fine-tune the contextualized word embeddings by backpropagating from the BERT objective, which is to maximize the log-probability of randomly masked tokens.

   We apply this training procedure to a dataset that includes all available target domain data, and an equal amount of unlabeled data in the source domain.[3] We create ten random maskings of each instance; in each masking, 15% of the tokens are randomly masked out, following the original BERT training procedure. We then perform three training iterations over this masked data.

2. **Task tuning**. In the second step, we fine-tune the contextualized word embeddings and learn the prediction model by backpropagating from the labeling objective on the source domain labeled data (Equation 1). This step fine-tunes the contextualized embeddings for the desired labeling task.

Attempts to interleave these two steps did not yield significant improvements in performance. While Peters et al. (2019) report good results on named entity recognition without task tuning, we found this step to be essential in our transfer applications.

[3] If the source domain dataset is smaller than the target domain data, then all of the unlabeled source domain data is included.

	Domain tuning	Task tuning
Prediction	masked tokens	tags
Data	source + target	source

Table 1: Overview of domain tuning and task tuning

4 Evaluation Setting

We evaluate on the task of part-of-speech tagging in the Penn Parsed Corpus of Early Modern English (PPCEME). There is no canonical training/test split for this data, so we follow Moon and Baldridge in randomly selecting 25% of the documents for the test set. Details of this split are described in supplement.

4.1 Systems

We evaluate the following systems:

Frozen BERT. This baseline applies the pretrained "BERT-base" contextualized embeddings, and then learns a tagger from the top-level embeddings, supervised by the PTB labeled data. The embeddings are from the pretrained case-sensitive BERT model, and are not adjusted during training. Peters et al. (2019) refer to this as a "feature extraction" application of pretrained embeddings. [4]

Task-tuned BERT. This baseline starts with pretrained BERT contextualized embeddings, and then fine-tunes them for the part-of-speech tagging task, using the PTB labeled data. This directly follows the methodology for named entity recognition proposed by Devlin et al. (2019) in the original BERT paper.

AdaptaBERT. Here we fine-tune the BERT contextualized embedding first on unlabeled data as described in § 3, and then on source domain labeled data. The target domain data is the unlabeled PPCEME training set.

Fine-tuned BERT. In *supervised* learning, we fine-tune the BERT contextualized embeddings on the labeled PPCEME training set.

[4] Note that this baseline learns only a linear final layer over the pretrained embeddings. We do not adopt weighted combination of internal contextual layers or any non-linear final layers in Peters et al. (2019).

Performance of this method should be viewed as an upper bound, because large-scale labeled data is not available in many domains of interest.

All BERT systems use the pretrained models from Google and the PyTorch implementation from huggingface.[5] Fine-tuning was performed using one NVIDIA GeForce RTX 2080 TI GPU. Domain-adaptive fine-tuning took 12 hours, and task tuning took an additional 30 minutes.

4.2 Previous results

We compare the above systems against prior published results from three feature-based taggers:

SVM A support vector machine baseline tagger, using the surface features described by Yang and Eisenstein (2015).

FEMA This is a feature-based unsupervised domain adaptation method for structured prediction (Yang and Eisenstein, 2015), which has the best reported performance on tagging the PPCEME. Unlike AdaptaBERT, the reported results for this system are based on feature induction from the entire PPCEME, including the (unlabeled) test set.

4.3 Tagset mappings

Because we focus on unsupervised domain adaptation, it is not possible to produce tags in the historical English (PPCHE) tagset, which is not encountered at training time. Following Moon and Baldridge (2007), we evaluate on a coarsened version of the PTB tagset, using the first letter of each tag (e.g., VBD → V). For comparison with Yang and Eisenstein (2016), we also report results on the full PTB tagset. In these evaluations, the ground truth is produced by applying the mapping of Moon and Baldridge to the PPCEME tags.

5 Results

Fine-tuning to the task and domain each yield significant improvements in performance over the Frozen BERT baseline (Table 2, line 1). Task-tuning improves accuracy by 7.6% on the coarse-grained tagset (line 2), and domain-adaptive fine-tuning yields a further 4.5% in accuracy (line 3). AdaptaBERT's performance gains are almost entirely due to the improvement on out-of-vocabulary terms, as discussed below.

The rightmost column of the table shows performance on the Penn Treebank test set. Interestingly, domain-adaptive fine-tuning has no impact on the performance on the original tagging task. This shows that adapting the pretrained BERT embeddings to the target domain does not make them less useful for tagging in the source domain, as long as task-tuning is performed after domain-adaptive tuning. In contrast, *supervised* fine-tuning in the target domain causes performance on the PTB to decrease significantly, as shown in line 4. This can be viewed as a form of *catastrophic forgetting* (McCloskey and Cohen, 1989).

As a secondary evaluation, we measure performance on the full PTB tagset in Table 3, thereby enabling direct comparison with prior work (Yang and Eisenstein, 2016). AdaptaBERT outperforms task-tuned BERT by 3.9%, again due to improvements on OOV terms. Task-tuned BERT is on par with the best previous unsupervised domain adaptation result (FEMA), showing the power of contextualized word embeddings, even across disparate domains. Note also that FEMA's representation was trained on the entire PPCEME, including the unlabeled test set, while the AdaptaBERT model uses the test set only for evaluation.

5.1 Out-of-vocabulary terms

We define out-of-vocabulary terms as those that are not present in the PTB training set. Of the out-of-PTB-vocabulary words in the PPCEME test set, 52.7% of the types and 82.2% of the tokens appear in the PPCEME training set. This enables domain-adaptive fine-tuning to produce better representations for these terms, making it possible to tag them correctly. Indeed, AdaptaBERT's gains come almost entirely from these terms, with an improvement in OOV accuracy of 25.8% over the frozen BERT baseline and 15.7% over task-tuned BERT. Similarly, on the full PTB tagset, AdaptaBERT attains an improvement in OOV accuracy of 11.3% over FEMA, which was the previous state-of-the-art.

5.2 Errors on in-vocabulary terms

The final two lines of Table 2 indicate that there remains a significant gap between AdaptaBERT and the performance of taggers trained with in-domain data: fine-tuning BERT on the PPCEME train-

2. FEMA (Yang and Eisenstein, 2016)	77.9	82.3	63.2
3. Task-tuned BERT	78.4	84.4	58.4
4. AdaptaBERT (this work)	**82.3**	**84.7**	**74.5**

Table 3: Tagging accuracy on PPCEME, using the full PTB tagset to compare with Yang and Eisenstein (2016).

ing set reduces the error rate to 1.2%. This improvement is largely attributable to *in-vocabulary* terms: although fine-tuned BERT does better than AdaptaBERT on both IV and OOV terms, the IV terms are far more frequent. The most frequent errors for AdaptaBERT are on tags for *to* (5337), *all* (2054), and *that* (1792). The OOV term with the largest number of errors is *al* (306), which is a shortening of *all*.

These errors on in-vocabulary terms can be explained by inconsistencies in annotation across the two domains:

- In the PPCEME, *to* may be tagged as either infinitival (to, e.g., *I am going to study*) or as a preposition (p, e.g., *I am going to Italy*). However, in the PTB, *to* is tagged exclusively as TO, which is a special tag reserved for this word.[6] Unsupervised domain adaptation generally fails predict the preposition tag for *to* when it appears in the PPCEME.
- In the PPCEME, *all* is often tagged as a quantifier (q), which is mapped to adjective (JJ) in the PTB. However, in the PTB, these cases are tagged as determiners (DT), and as a result, the domain adaptation systems always tag *all* as a determiner.
- In the PTB, the word *that* is sometimes tagged as a wh-determiner (WDT), in cases such as *symptoms that showed up decades later*. In the PPCEME, all such cases are tagged as complementizers (c), and this tag is then mapped to the preposition IN. AdaptaBERT often incorrectly tags *that* as WDT, when IN would be correct.

These examples point to the inherent limitations of unsupervised domain adaptation when there are inconsistencies in the annotation protocol.

6 Social Media Microblogs

As an additional evaluation, we consider social media microblogs, of which Twitter is the best known example in English. Twitter poses some of the same challenges as historical text: orthographic variation leads to a substantial mismatch in vocabulary between the target domain and source training documents such as Wikipedia (Baldwin et al., 2013; Eisenstein, 2013). We hypothesize that domain-adaptive fine-tuning can help to produce better contextualized word embeddings for microblog text.

Our evaluation is focused on the problem of identifying named entity spans in Tweets, which was the shared task of the 2016 Workshop on Noisy User Text (WNUT; Strauss et al., 2016). In

[6] In this discussion, sans-serif is used for PPCEME tags, and SMALL CAPS is used for the PTB tags.

the shared task, systems were given access to labeled data in the target domain; in contrast, we are interested to measure whether it is possible to perform this task without access to such data. As training data, we use the canonical CoNLL 2003 shared task dataset, in which named entity spans were annotated on a corpus of newstext (Tjong Kim Sang and De Meulder, 2003). Because the entity types are different in the WNUT and CoNLL corpora, we focus on the *segmentation task* of identifying named entity spans. Participants in the 2016 WNUT shared task competed on this metric, enabling a direct comparison with the performance of these supervised systems.

Results are shown in Table 4. A baseline system using task-tuned BERT (trained on the CoNLL labeled data) achieves an F1 of 57.7 (line 1). This outperforms six of the ten submissions to the WNUT shared task, even though these systems are trained on in-domain data. AdaptaBERT yields marginal improvements when domain-adaptive fine-tuning is performed on the WNUT training set (line 2); expanding the target domain data with an additional million unlabeled tweets yields a 2.3% improvement over the BERT baseline (line 3). Performance improves considerably when the domain-adaptive fine-tuning is performed on the combined WNUT training and test sets (line 4).

Test set adaptation is controversial: it is not realistic for deployed systems that are expected to perform well on unseen instances without retraining, but it may be applicable in scenarios in which we desire good performance on a predefined set of documents. The WNUT test set was constructed by searching for tweets in a narrow time window on two specific topics: shootings and cybersecurity events. It is therefore unsurprising that test set adaptation yields significant improvements, since it can yield useful representations of the names of the relevant entities, which might not appear in a random sample of tweets. This is a plausible approach for researchers who are interested in finding the key entities participating in such events in an pre-selected corpus of text.

When BERT is fine-tuned on labeled data in the target domain, the performance of the resulting tagger improves to 64.3% (line 5). This would have achieved second place in the 2016 WNUT shared task. The state-of-the-art system makes use of character-level information that is not available to our models (Limsopatham and Collier, 2016). As with the evaluation on Early Modern English, we find that domain-adaptive fine-tuning does not impair performance on the source domain (CoNLL), but supervised in-domain training increases the source domain error rate dramatically.

7 Related Work

Adaptation in neural sequence labeling. Most prior work on adapting neural networks for NLP has focused on supervised domain adaptation, in which a labeled data is available in the target domain (Mou et al., 2016). RNN-based models for sequence labeling can be adapted across domains by manipulating the input or output layers individually (e.g., Yang et al., 2016) or simultaneously (Lin and Lu, 2018). Unlike these approaches, we tackle unsupervised domain adaptation, which assumes only unlabeled instances in the target domain. In this setting, prior work has focused on *domain-adversarial* objectives, which construct an auxiliary loss based on the capability of an adversary to learn to distinguish the domains based on a shared encoding of the input (Ganin et al., 2016; Purushotham et al., 2017). However, adversarial methods require balancing between at least two and as many as six different objectives (Kim et al., 2017), which can lead to instability (Arjovsky et al., 2017) unless the objectives are carefully balanced (Alam et al., 2018).

In addition to supervised and unsupervised domain adaptation, there are "distantly supervised" methods that construct noisy target domain instances, e.g., by using a bilingual dictionary (Fang and Cohn, 2017). Normalization dictionaries exist for Early Modern English (Baron and Rayson, 2008) and social media (Han et al., 2012), but we leave their application to distant supervision for future work.

Finally, language modeling objectives have previously been used for domain adaptation of text classifiers (Ziser and Reichart, 2018), but this prior work has focused on representation learning from scratch, rather than adaptation of a pretrained contextualized embedding model. Our work shows that models that are pretrained on large-scale data yield very strong performance even when applied out-of-domain, making them a natural starting point for further adaptation.

Semi-supervised learning. Universal Language Model Fine-tuning (ULMFiT) also involves fine-tuning on a language modeling task on the target

Table 4: Named entity segmentation performance on the WNUT test set and CoNLL test set A. Limsopatham and Collier (2016) had the winning system at the 2016 WNUT shared task. Their results are reprinted from their paper, which did not report performance on the CoNLL dataset.

text (Howard and Ruder, 2018), but the goal is semi-supervised learning: prior work shows that accurate text classification can be achieved with fewer labeled examples, but does not consider the issue of domain shift. ULMFiT involves a training regime in which the layers of the embedding model are gradually "unfrozen" during task-tuning, to avoid catastrophic forgetting. We do not employ this approach, nor did we experiment with ULMFiT's elaborate set of learning rate schedules. Finally, contemporaneous unpublished work has applied the BERT objective to target domain data, but like ULMFiT, this work focuses on semi-supervised classification rather than cross-domain sequence labeling (Xie et al., 2019).

Tagging historical texts. Moon and Baldridge (2007) approach part-of-speech tagging of Early Modern English by projecting annotations from labeled out-of-domain data to unlabeled in-domain data. The general problem of adapting part-of-speech tagging over time was considered by Yang and Eisenstein (2015). Their approach projected source (contemporary) and target (historical) training instances into a shared space, by examining the co-occurrence of hand-crafted features. This was shown to significantly reduce the transfer loss in Portuguese, and later in English (Yang and Eisenstein, 2016). However, this approach relies on hand-crafted features, and does not benefit from contemporary neural pretraining architectures. We show that pretrained contextualized embeddings yield significant improvements over feature-based methods.

Normalization. Another approach to historical texts and social media is spelling normalization (e.g., Baron and Rayson, 2008; Han et al., 2012), which has been shown to offer improvements in tagging historical texts (Robertson and Goldwater, 2018). In Early Modern English, Yang and Eisenstein (2016) found that domain adaptation and normalization are complementary. In this paper, we have shown that domain-adaptive fine-tuning (and wordpiece segmentation) significantly improves the OOV tagging accuracy from FEMA, so future research must explore whether normalization is still necessary for state-of-the-art tagging of historical texts.

Domain-specific pretraining. Given sufficient unlabeled data in the target domain, the simplest approach may be to retrain a BERT-like model from scratch. BioBERT is an application of BERT to the biomedical domain, which was achieved by pretraining on more than 10 billion tokens of biomedical abstracts and full-text articles from PubMed (Lee et al., 2019); SciBERT is a similar approach for scientific texts (Beltagy et al., 2019). Data on this scale is not available in Early Modern English, but retraining might be applicable to social media text, assuming the user has access to both large-scale data and sufficient computing power. The mismatch between pretrained contextualized embeddings and technical NER corpora was explored in recent work by Dai et al. (2019).

8 Conclusion

This paper demonstrates the applicability of contextualized word embeddings to two difficult un-

supervised domain adaptation tasks. On the task of adaptation to historical text, BERT works relatively well out-of-the-box, yielding equivalent performance to the best prior unsupervised domain adaptation approach. Domain-adaptive fine tuning on unlabeled target domain data yields significant further improvements, especially on OOV terms. On the task of adaptation to contemporary social media, a straightforward application of BERT yields competitive results, and domain-adaptive fine tuning again offers improvements.

A potentially interesting side note is that while supervised fine-tuning in the target domain results in *catastrophic forgetting* of the source domain, unsupervised target domain tuning does not. This suggests the intriguing possibility of training a single contextualized embedding model that works well across a wide range of domains, genres, and writing styles. However, further investigation is necessary to determine whether this finding is dependent on specific details of the source and target domains in our experiments, or whether it is a general difference between unsupervised domain tuning and supervised fine-tuning. We are also interested to more thoroughly explore how to combine domain-adaptive and task-specific fine-tuning within the framework of continual learning (Yogatama et al., 2019), with the goal of balancing between these apparently conflicting objectives.

Abstract

Incorporating Item Response Theory (IRT) into NLP tasks can provide valuable information about model performance and behavior. Traditionally, IRT models are learned using human response pattern (RP) data, presenting a significant bottleneck for large data sets like those required for training deep neural networks (DNNs). In this work we propose learning IRT models using RPs generated from artificial crowds of DNN models. We demonstrate the effectiveness of learning IRT models using DNN-generated data through quantitative and qualitative analyses for two NLP tasks. Parameters learned from human and machine RPs for natural language inference and sentiment analysis exhibit medium to large positive correlations. We demonstrate a use-case for latent difficulty item parameters, namely training set filtering, and show that using difficulty to sample training data outperforms baseline methods. Finally, we highlight cases where human expectation about item difficulty does not match difficulty as estimated from the machine RPs.

1 Introduction

What is the most difficult example in the Stanford Natural Language Inference (SNLI) data set (Bowman et al., 2015) or in the Stanford Sentiment Treebank (SSTB) (Socher et al., 2013)? *A priori* the answer is not clear. How does one quantify the difficulty of an example and does it pertain to a specific model, or more generally?

There has been much recent work trying to assess the quality of data sets used for NLP tasks, (e.g. Lalor et al., 2016; Sakaguchi and Van Durme, 2018; Kaushik and Lipton, 2018). In particular, a common finding is that different examples within the same class have very different qualities such as difficulty, and these differences affect models' performance. For example, one study found that a subset of reading comprehension questions were so difficult as to be unanswerable (Kaushik and Lipton, 2018). In another work, the difficulty of specific items was found to be a significant predictor of whether a model would classify the item correctly (Lalor et al., 2018).

While a number of methods exist for estimating difficulty, in this work we focus on Item Response Theory (IRT) (Baker, 2001; Baker and Kim, 2004), a widely used method in psychometrics. IRT models fit parameters of data points (called "items") such as difficulty based on a large number of annotations ("response patterns" or RPs), typically gathered from a human population ("subjects"). It has been shown to be an effective way to evaluate and analyze NLP models with respect to human populations (Lalor et al., 2016, 2018).

While IRT models are designed to be learned with human RPs for at most 100 items, data sets used in machine learning, particularly for training deep neural networks (DNNs), are on the order of tens or hundreds of thousands of examples or more. It is not possible to ask humans to label every example in a data set of that size. In this work we hypothesize that IRT models can be fit using RPs from artificial crowds of DNNs as inputs, thereby removing the expense of gathering human RPs. Recent work has shown that DNNs encode linguistic knowledge (Tenney et al., 2019b,a) and can reach or surpass human-level performance on classification tasks (Lake et al., 2015). In addition, generating IRT data with deep learning models

is much cheaper compared to employing human annotators.

We demonstrate that learned parameters from IRT models fit with artificial crowd data are positively correlated with parameters learned with human data for small data sets. We then use variational inference (VI) methods (Jordan et al., 1999; Hoffman et al., 2013) to fit a large-scale IRT model. Using VI allows us to scale IRT models to deep-learning-sized data sets. Finally, we show why learning such models is useful by demonstrating how learned difficulties can improve training set subsampling.

Our contributions are as follows: (1) We show that IRT models can be fit using machine RPs by comparing item parameters learned from human and from machine RPs for two NLP tasks; (2) we show that RPs from more complex models lead to higher correlations between parameters from human and machine RPs; (3) we demonstrate a use-case for latent difficulty item parameters, namely training set filtering, and show that using difficulty to sample training data outperforms baseline methods; (4) we provide a qualitative analysis of items with the largest human-machine disagreement in terms of difficulty to highlight cases where human intuition is inconsistent with model behavior.

These results provide a direct comparison between humans and machine learning models in terms of identifying easy and difficult items. They also provide a foundation for large-scale IRT models to be fit by using ensembles of machine learning models to obtain RPs instead of humans, greatly reducing the cost of data-collection.[1]

2 Fitting Item Response Theory Models

2.1 Traditional Item Response Theory

Here we briefly describe IRT and the specific model under consideration, the Rasch model (also known as the one-parameter logistic or 1PL model) (Rasch, 1960).

We refer the reader to (Baker, 2001; Baker and Kim, 2004) for additional details on IRT, and to (Martınez-Plumed et al., 2016; Lalor et al., 2016, 2018) for more details on previous applications of IRT to machine learning.

IRT models are designed to estimate latent ability parameters (θ) of subjects and latent item parameters such as difficulty of items (b). For a 1PL model, the probability that subject j will answer item i correctly is a function of the subject's latent ability θ_j and the item's latent difficulty b_i:

$$p(y_{ij} = 1|\theta_j, b_i) = \frac{1}{1 + e^{-(\theta_j - b_i)}} \quad (1)$$

The probability that subject j will answer item i incorrectly is:

$$p(y_{ij} = 0|\theta_j, b_i) = 1 - p(y_{ij} = 1|\theta_j, b_i) \quad (2)$$

The likelihood of a data set of RPs Y from J subjects to a set of I items is:

$$p(Y|\theta, b) = \prod_{j=1}^{J} \prod_{i=1}^{I} p(Y_{ij} = y_{ij}|\theta_j, b_i) \quad (3)$$

For the 1PL model, the difficulty parameter represents the ability level at which the probability of an individual answering an item correctly is 50%. This occurs when item difficulty is equal to subject ability ($\theta_j = b_i$ in Eq. 1).

The item parameters are typically estimated by marginal maximum likelihood (MML) via an Expectation-Maximization (EM) algorithm (Bock and Aitkin, 1981), in which subject parameters are considered random effects $\theta_i \sim N(0, \sigma_\theta^2)$ and marginalized out. Once item parameters are learned, subjects' θ parameters are scored typically with maximum a posteriori (MAP) estimation. IRT models are usually fitted to RPs of hundreds or thousands of human subjects, who usually answer at most 100 questions. Therefore the methods for fitting these models have not been scaled to huge data sets and large numbers of subjects (e.g. tens of thousands of machine learning models).

2.2 IRT with Variational Inference

VI is a model fitting method that approximates an intractable posterior distribution in Bayesian inference by a simpler variational distribution. Prior work has compared VI methods with traditional IRT methods (Natesan et al., 2016) and found it effective, but was primarily concerned with fitting IRT models for human-scale data.

Bayesian methods in IRT assume that the individual θ and b parameters in Eq. (2) both follow Gaussian prior distributions and make inference through the resultant joint posterior distribution $\pi(\theta, b|Y)$. As this posterior is usually intractable, VI approximates it by the variational distribution:

$$q(\theta, b) = \prod_{j=1}^{J} \pi_j^{\theta}(\theta_j) \prod_{i=1}^{I} \pi_i^{b}(b_i) \quad (4)$$

[1] Code for IRT model fitting is available at `https://github.com/jplalor/py-irt`.

Where $\pi_j^{\theta}()$ and $\pi_i^{b}()$ denotes different Gaussian densities for different parameters whose means and variances are determined by minimizing the KL-Divergence between $q(\theta, b)$ and $\pi(\theta, b|Y)$.

The choice of priors in Bayesian IRT can vary. Prior work has shown that vague and hierarchical priors are both effective (Natesan et al., 2016). We experiment with both in this work. A vague prior assumes $\theta_j \sim N(0, 1)$ and $b_i \sim N(0, 10^3)$, where the large variance indicates a lack of information on the difficulty parameters. A hierarchical Bayesian model assumes

$$\begin{aligned} \theta_j \mid m_\theta, u_\theta &\sim N(m_\theta, u_\theta^{-1}) \\ b_i \mid m_b, u_b &\sim N(m_b, u_b^{-1}) \\ m_\theta, m_b &\sim N(0, 10^6) \\ u_\theta, u_b &\sim \Gamma(1, 1) \end{aligned}$$

Our results for these two options were very similar, so we only report those for hierarchical priors.

3 Data and Models

Here we describe the data sets used to conduct our experiments, as well as the DNN model architectures for both generating response patterns and conducting our training set filtering experiment.

SNLI The SNLI data set (Bowman et al., 2015) is a popular data set for the natural language inference task. Briefly, each example in the data set consists of two sentences in English: the premise and the hypothesis, and a corresponding label. The correct label is "entailment" if the premise implies the hypothesis, "contradiction" if the premise implies that the hypothesis must be false, and "neutral" if the premise implies neither the hypothesis nor its negation. SNLI consists of 550k/10k/10k training/validation/testing examples examples.

SSTB The Stanford Sentiment Treebank (SSTB) (Socher et al., 2013) is a collection of English phrases extracted from movie reviews with fine-grained sentiment annotations (very negative, negative, neutral, positive, very positive). In this work we focus on binary sentiment classification, using the SST-2 split of the data set, where neutral examples have been removed. The data set consists of 67k/873/1.8k training/validation/testing examples.

Human RP Data The human RP data sets for SNLI and SSTB were previously collected from Amazon Mechanical Turk (AMT) workers (Lalor et al., 2016, 2018). For a randomly selected sample of items from SNLI and SSTB, new labels were gathered from 1000 AMT workers (Turkers). Each Turker labeled each item, so that for each item there were 1000 new labels. For each Turker, a RP was generated by grading the provided labels against the known gold-standard label.

Building an Artificial Crowd As mentioned earlier, it is not feasible to have humans provide RPs for data sets used to train DNN models. Can we instead use RPs from DNNs? We trained an ensemble of DNN models with varying amount of training data to simulate an artificial crowd so that enough responses were obtained to fit the IRT models. The goal here is not to build an ensemble of DNNs to surpass current classification state of the art results, but instead to test our hypothesis to determine if machine RPs can fit IRT models that can benefit NLP tasks.

Specifically, we trained 1000 LSTM models for NLI classification using the SNLI data set and 1000 LSTM models for binary SA classification using the SSTB data set (Bowman et al., 2015; Socher et al., 2013). The SNLI model consists of two LSTM sequence-embedding models (Hochreiter and Schmidhuber, 1997), one to encode the premise and another to encode the hypothesis. The two sentence encodings are then concatenated and passed through three tanh layers. Finally, the output is passed to a softmax classifier layer to output class probabilities. For SSTB, we used a single LSTM model without the concatenation step. The models were implemented in DyNet (Neubig et al., 2017). Models were trained with SGD for 100 epochs with a learning rate of 0.1, and validation set accuracy was used for early stopping.

For each model m_i, we randomly sampled a subset of the task training set, x^i_{train}. We corrupted a random selection of training labels by replacing the gold standard label with an incorrect label. For each model-training set pair, we trained the model, used the held out validation set for early stopping, and wrote the model's graded (correct/incorrect) outputs to disk as that model's RP. The set of RPs for all models is our input data for the IRT models.

We also looked at a more complex model to determine if the learned parameters would differ given the different model architectures. For our more complex model we used the Neural Semantic Encoder model (NSE), a memory-augmented recur-

rent neural network (Munkhdalai and Yu, 2017):

$$
\begin{aligned}
o_t &= f_{\mathrm{r}}^{LSTM}(x^t) \\
z_t &= softmax(o_t^\top M_{t-1}) \\
m_{r,t} &= z_t^\top M_{t-1} \\
c_t &= f_{\mathrm{c}}^{MLP}(o_t, m_{r,t}) \\
h_t &= f_{\mathrm{w}}^{LSTM}(c_t) \\
M_t = M_{t-1}(\mathbf{1} &- (z_t \otimes e_k)^\top) \\
&+ (h_t \otimes e_t)(z_t \otimes e_k)^\top
\end{aligned}
$$

where f_r^{LSTM} is the read function, f_c^{MLP} is the composition function, f_w^{LSTM} is the write function, M_t is the external memory at time t, and $e_l \in R^l$ and $e_k \in R^k$ are vectors of ones.

The goal with the data set restriction and label corruption was to build an ensemble of models with widely varying performance on the SNLI test set. Training with different training set sizes and levels of noise corruption means that certain models will perform very well on the test set (large training sets and low label corruption) while others will perform poorly (small training sets and high label corruption). This way we will get a variety of response patterns to simulate performance on the task across a spectrum of ability levels. While we could have modified the networks in any number of ways (e.g. changing layer sizes, learning rates, etc.), modifying the training data is a straightforward method for generating a variety of response patterns, and has been shown to have an impact on performance in terms of item difficulty (Lalor et al., 2018). Further investigations of network modifications is left for future work.

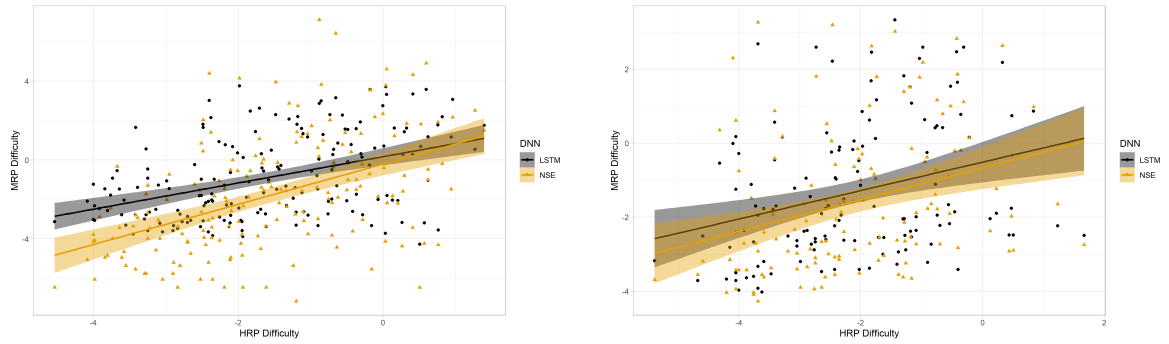
4 Methods

We conduct the following experiments: (i) a comparison of IRT parameters learned from human and machine RP data, using existing IRT data sets (Lalor et al., 2016, 2018) as the baseline for comparison, (ii) a comparison between MML and VI parameter estimates, and (iii) a demonstration of the effectiveness of learned IRT parameters via training data set selection experiments.

4.1 Validating Variational Inference

Before using VI to fit IRT models for DNN data, we must first show that VI produces estimates similar to traditional methods. This was established in prior work on synthetic data (Natesan et al., 2016). Here we compare them on an existing human data set (Lalor et al., 2016).

A traditional Rasch model was fit with both MML and VI. MML was implemented in the R package mirt (Chalmers et al., 2015) and VI in Pyro (Bingham et al., 2018), a probabilistic programming language built on PyTorch (Paszke et al., 2017) that implements typical VI model fitting and variance reduction (Kingma and Welling, 2014; Ranganath et al., 2014). We calculate the root mean squared difference (RMSD) between MML and VI estimates for subject and item parameters. Our expectation is that the RMSD will be sufficiently small to confirm that the VI parameters are similar enough to those learned by MML, since we will not be able to use MML when we attempt to scale up to larger data sets.



4.2 Human Machine Correlation

We further compare item difficulty parameters learned from machine RPs to those learned from human RPs. These two sets of parameters cannot be compared directly as they can only be interpreted in reference to their respective subject populations. Instead, we compute the correlation between these two sets of parameters to see whether items that are easy for humans are also easy for machines. We fit two Rasch models, one with existing human RPs (Lalor et al., 2016, 2018). and one with the machine RPs. Both models were fit with MML using the mirt R package (Chalmers et al., 2015). Learned item difficulty parameters were extracted and compared via Spearman ρ rank order correlations.

4.3 Training Set Subsampling

To demonstrate the usefulness of the learned IRT parameters, we next describe a downstream use case: training set filtering for more efficient learning. Can we maintain model performance by removing the easiest and/or hardest items from the training set? Once difficulty parameters for each data set were learned, we trained a new DNN model using only a subset of the original training data. We trained a number of models, each with a different cutoff in terms of training data to observe how generalization was impacted in each case.

We looked at 4 filtering strategies (in each case d is the item difficulty threshold): (i) absolute value inner (AVI), where all training items with $|b_i| < d$ were retained, (ii) absolute value outer (AVO), where all training items with $|b_i| > d$

(a) NLI (b) SA

Figure 1: Comparison of learned item difficulty parameters for human (x-axis) and machine data (y-axis) for NLI (Fig. 1a) and SA (Fig. 1b). Spearman ρ (NLI): 0.409 (LSTM) and 0.496 (NSE). Spearman ρ (SA): 0.332 (LSTM) and 0.392 (NSE).

were retained, (iii) an upper bound (UB), where items with $b_i < d$ were retained, and (iv) a lower bound (LB), where items with $b_i > d$ were retained. These methods were compared against two baselines that consider the percentage of models that label an item correctly ($0 \leq pc \leq 1$) as an inexpensive proxy for difficulty: (i) percent-correct upper bound (PCUB), where items with $pc_i < d$ were retained, and (ii) percent-correct lower bound (PCLB), where items with $pc_i > d$ were retained. Setting an upper bound on difficulty (UB) is similar to setting a lower bound on percent correct (PCLB) (i.e., we are excluding the hardest items from training). Similarly, setting a lower bound on difficulty (LB) is analogous to setting an upper bound on percent correct (PCUB) in that they both exclude the easiest items from training.

Each of the filtering strategies have arguments in favor of their potential effectiveness. AVI includes "average" items in terms of training examples, none that are too easy or too difficulty. AVO is the opposite, where only the easiest and most difficult examples are retained, so that the extremes for each class can be learned. UB ensures that those examples that are too difficult are not included, and LB ensures that the examples that are too easy are not included so that the model doesn't spend time learning very easy examples.

5 Results

5.1 Human Machine Model Correlations

We first look at the results of our human-machine model comparison (Figures 1a and 1b). As an upper bound for correlations, we split the human annotation data in half for both SNLI and SSTB, fit two IRT Rasch models, and calculated the correlation between the learned parameters. Spearman ρ values were 0.992 and 0.987 for SNLI and SSTB items, respectively.

For both SNLI and SSTB, we find a positive correlation between the item difficulties of IRT models fit using human and machine RPs. In addition, the more complex NSE model has consistently a higher correlation with the human-learned difficulty parameters than the LSTM model. This suggests that creating more complex DNN architectures has bearing on how the model identifies difficult items with regards to human expectations.

The correlation is not perfect, and we would argue that this is an expected and encouraging result. A close to perfect correlation would indicate that the DNN models and the human population agree closely on the difficulty ranking for the data sets and would be an incredible finding and evidence for the argument that DNN models encode human knowledge well, at least with respect to the difficulty of specific items. This of course is not true, and the positive but not perfect correlation coefficients indicate this as such. That said, it is encouraging that the positive correlation exists. One would expect that training ensembles of more sophisticated NLP models such as BERT (Devlin et al., 2018) would further increase correlation scores.

5.2 Learning IRT Models with VI

Our next goal was to determine if VI could be used to fit IRT models and confirm prior work to that effect (Natesan et al., 2016). The RMSDs between MML and VI estimates were 0.158 and 0.154, respectively, for the difficulty and ability

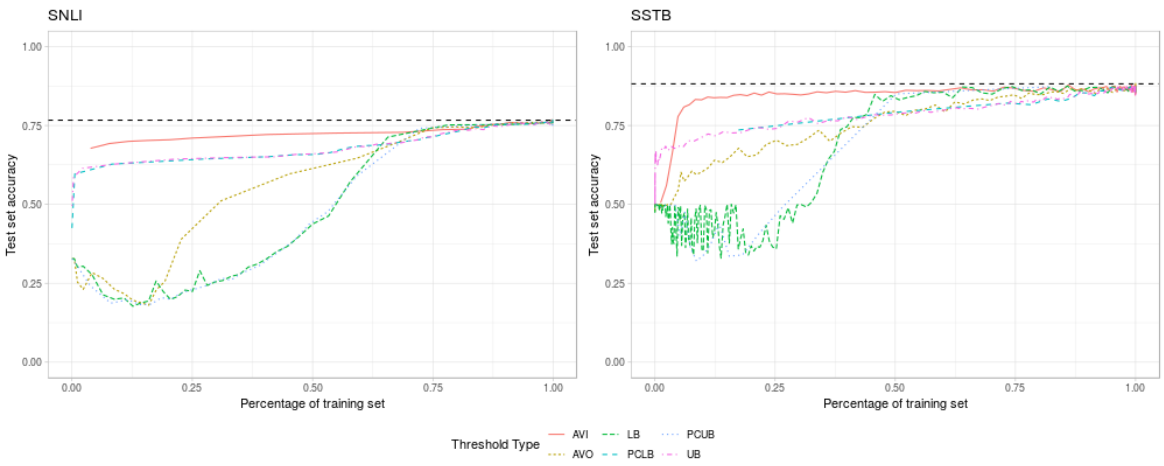


Figure 2: Test set accuracy by filtering strategy for NLI (left) and SA (right) plotted against percentage of training data retained. In both tasks filtering using the AVI strategy is most efficient in terms of high accuracy for small training set sizes.

parameters. Learned parameters are very similar between the two methods, which is to be expected. This echos the results of prior work showing that VI is a good alternative to traditional MML methods for learning IRT models (Natesan et al., 2016). This result holds not only with synthetic data, as was used in the prior work, but also with human data collected for the development of an actual IRT test (Lalor et al., 2016).

5.3 Data Filtering

Finally we consider training new DNN models on the filtered training data sets, restricted according to latent difficulty and the strategies described above (Figure 2). The horizontal dotted lines in each plot represent the test set accuracy for a model trained with the full training data set. For both SNLI and SSTB, the AVI strategy of selecting "average" examples leads to very good test set accuracy scores with less than 25% of the original training data. This shows that the strategy of selecting training data in terms of average difficulty, and gradually adding easier and harder examples at the same time provides examples that allows trained models to generalize well. For both tasks, there is a large number of examples that are very easy in terms of latent difficulty (Figure 3). Sampling with AVI avoids selecting too many examples that are too easy and instead selects examples that are of average difficulty for the task, which may be better for learning. In both cases LB and PCUB are the least effective strategies, indicating that it is not enough to only include the most difficult examples.

The plots show that PCUB and LB provide very

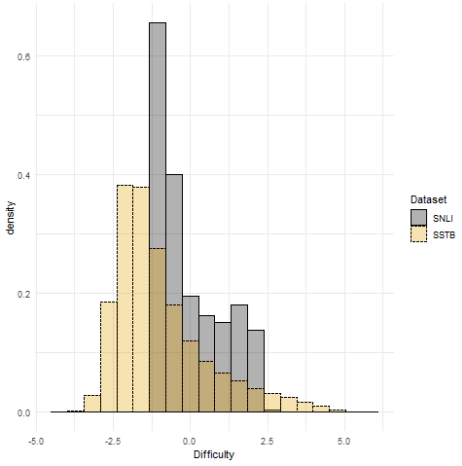

Figure 3: Density plot of learned difficulties for SNLI and SSTB data sets.

similar results, as do PCLB and UB, which is to be expected. Difficulty parameters learned from IRT are very similar to metrics such as percent correct, but as the plots show are not exactly the same. Differences in RPs (i.e. which specific items were answered correctly/incorrectly) have an effect on item difficulty that is not captured by calculating percent correct.

It is worth noting here that the filtering strategy we used did not take class labels into consideration.[2] The only determining factor as to whether a training item was included was the learned difficulty parameter b_i, which led to class imbalances in the training set. This imbalance, however did

[2]This is true for only the filtering step. Class labels are needed for learning the difficulty parameters needed for filtering (§2).

Strategy	% of Training Data		
	0.1%	1%	10%
Random (reported)	82.1	85.2	**88.4**
Random (small batch)	81.79	84.90	88.32
Lower-bound	43.68	41.56	39.89
Upper-bound	81.62	80.46	79.06
AVI	**82.44**	**85.44**	86.73
AVO	43.60	42.05	40.81

Table 1: Dev accuracy results for MT-DNN model with different training set sampling strategies.

not seem to have a significant negative effect in terms of performance. More advanced sampling strategies that maintain training set distribution or sample data using a Bayesian approach are left for future work.

As an additional experiment, we used the learned difficulty parameters to compare data sampling strategies for a state-of-the-art NLI model, MT-DNN (Liu et al., 2019). We sampled training data for SNLI at several intervals (0.1%, 1%, 10%) and trained the MT-DNN model with the sampled data. We trained each model, as well as the random sample baseline, using the publicly available MT-DNN code.[3] Results are reported in Table 1. Note that we report two random baselines: (i) those reported in the original work, which were obtained by training the MT-DNN model with a batch size of 32. Due to GPU resource constraints we had to train each MT-DNN model with a batch size of 8, and therefore report our reproduced random baseline results that we obtained as well ("Random (small batch)"). For very small samples of data, the AVI strategy outperforms random sampling and all other methods as well. As more data is sampled, the random models perform better. This indicates that a more advanced sampling strategy that starts with AVI then incorporates outliers (very easy/hard examples) at certain thresholds may improve learning as well.

6 Analysis

Qualitative Evaluation of Difficulty Table 2 shows examples of premise-hypothesis sentence pairs from SNLI with the learned difficulty parameter from the machine RP IRT model. The easy sentence pairs for each class seem to be very obvious, whereas the most difficult examples are difficult due to ambiguity. For example, the hardest contradiction example could be classified as neutral instead of contradiction. It could be the case that the man is sweeping while on vacation, though it isn't likely. The hypothesis doesn't directly contradict the premise like the easy example does (cats instead of dogs, sleeping instead of playing).

Analysis of Differences An interesting question comes up as a result of the less-than-perfect correlation scores (§5.1): Where are the differences? To examine these more closely we identified those examples from the data sets where the rank order was most different between the human- and machine-response pattern models (Table 3). That is, we calculated the absolute difference in ranking between the human model and the DNN model, and selected those where that value was highest. The average absolute difference in ranking was around 40 for the SNLI task and around 30 for SSTB, for both the LSTM and NSE ensembles.

We can see interesting patterns in the discrepancies. For SNLI, the easiest sentence pair for the LSTM model (which is also very easy for the NSE model) is one of the hardest for humans (Table 3, row 1). Upon inspection of the gathered labels, the high difficulty comes from the fact that there were many Turkers who labeled the data as neutral and also many who labeled it as contradiction.

On the other hand, an example that is easy for humans but difficult for the DNN models (Table 2, row 2) requires more abstract thinking than the earlier example. The humans are able to infer that because the girl is unwrapping an item, she will discover what is under the wrapping paper when the unwrapping is complete. The models find this pair to be one of the most difficult in the data set.

For SSTB, we see similar patterns (Table 3, rows 3-4). For humans, one of the easiest review snippets is clearly positive (row 3), mainly because we know who Anthony Hopkins is and know how to rate his quality as an actor. However for the DNN models, the text itself does not have a lot of positive or negative signal and therefore the item is considered very difficult. On the other hand, the last example is very difficult for humans (row 4), possibly due to the relatively neutral text. However, for the DNN models certain terms such as "stultifyingly contrived" may signal a more negative review and lead to the item being easier.

In both cases, it is not clear if there is a "gold standard" for difficulty. Estimating difficulty using IRT relies on responses from a group of humans or an ensemble of models, and the resulting difficulty estimates may be biased based on who or what

Premise	Hypothesis	Label	Difficulty
Two men and a woman are inspecting the front tire of a bicycle.	There are a group of people near a bike.	Entailment	-3.7
A girl in a newspaper hat with a bow is unwrapping an item.	The girl is going to find out what is under the wrapping paper.	Entailment	3.1
Two dogs playing in snow.	A cat sleeps on floor	Contradiction	-4.0
Man sweeping trash outside a large statue.	A man is on vacation.	Contradiction	3.8
People sitting in chairs with a row flags hanging over them.	A family reunion for Fourth of July	Neutral	-3.6
A group of dancers are performing.	The audience is silent.	Neutral	3.8

Table 2: The easiest and hardest items judged by machine responses for each class in the SNLI test data set.

Task	Label	Item Text	Difficulty ranking		
			Humans	LSTM	NSE
SNLI	Contradiction	*P:* Two dogs playing in snow. *H:* A cat sleeps on floor	168	1	5
	Entailment	*P:* A girl in a newspaper hat with a bow is unwrapping an item. *H:* The girl is going to find out what is under the wrapping paper.	55	172	176
SSTB	Positive	Only two words will tell you what you know when deciding to see it: Anthony. Hopkins.	9	103	110
	Negative	...are of course stultifyingly contrived and too stylized by half. Still, it gets the job done–a sleepy afternoon rental.	128	46	41

Table 3: Examples from the SNLI and SSTB data sets where the ranking in terms of difficulty varies widely between human and DNN models. In all cases difficulty is ranked from easy to hard (1=easiest).

provides the labels. Human intuitions or model architecture decisions impact the response patterns collected, which in turn affect the learned parameters. An investigation into what upstream information drives downstream effects such as learned difficulty is an interesting and important direction for future work.

7 Related Work

Prior work has considered IRT in the context of evaluating ML models using human (Lalor et al., 2016) and machine-generated (Martınez-Plumed et al., 2016) response patterns. Martınez-Plumed et al. (2016) attempted to fit IRT models using machine generated response patterns on small data sets (i.e. 200-300 items), but obtain results that are difficult to interpret using the existing IRT assumptions. Lalor et al. (2016) develop new IRT test sets for NLI using human-generated data, and present new ways to interpret and understand model performance beyond raw accuracy. Due to the need for human annotations the resulting tests are short (i.e. 124 examples). To the best of our knowledge no one has attempted to fit IRT models using DNN-generated response patterns on large data sets.

There have been a number of studies on modeling latent traits of data to identify a correct label, (e.g. Bruce and Wiebe, 1999). There has also been work in modeling individuals to identify poor annotators (Hovy et al., 2013), but neither jointly model the ability of individuals and data points, nor apply the resulting metrics to interpret DNN models. Other work has modeled the probability a label is correct along with the probability of an annotator to label an item correctly according to the (Dawid and Skene, 1979) model, but do not consider difficulty or discriminatory ability of the data points (Passonneau and Carpenter, 2014). In the above models an annotator's response depends on an item only through its correct label. IRT assumes a more sophisticated response mechanism involving both annotator qualities and item characteristics. The DARE model (Bachrach et al., 2012) jointly estimates ability, difficulty and response using probabilistic inference. It was evaluated on an intelligence test of 60 multiple choice questions administered to 120 individuals.

There are several other areas of study regarding how best to use training data that are related to this work. Re-weighting or re-ordering training examples is a well-studied and related area of supervised learning. Often examples are re-weighted according to some notion of difficulty, or model uncertainty (Chang et al., 2017). In particular, the

internal uncertainty of the model is used as the basis for selecting how training examples are weighted. However, model uncertainty depends upon the original training data the model was trained on, while here we use an external measure of uncertainty.

Curriculum learning (CL) is a training procedure where models are trained to learn simple concepts before more complex concepts are introduced (Bengio et al., 2009). CL training for neural networks can improve generalization and speed up convergence. In curriculum learning the difficulty of items is typically assigned based on heuristics of the data (e.g. the number of sides of a shape). IRT models directly estimate difficulty from the responses of human or machine test-takers themselves instead of relying on heuristics. Self-paced learning and the Leitner method use model performance to estimate difficulties, but are restricted to a single model's performance, not a more global notion of difficulty (Kumar et al., 2010; Amiri et al., 2018).

8 Conclusion

In this work we have described how large-scale IRT models can be trained with DNN response patterns using VI. Learning the difficulty parameters of items and the ability parameters of DNN models allows for more nuanced interpretation of model performance and enables us to filter training data so that DNN models can be trained on less data while maintaining generalization as measured by test set performance. IRT models with machine RPs can be fit not only for NLP data sets but also data sets in other machine learning domains such as computer vision (additional results on two computer vision data sets are included in Appendix A).

One limitation of this work is the up-front cost of generating RPs from the DNN ensemble. However, the cost of running a large number of DNN models to generate response pattern data is significantly less than the cost of obtaining those labels from human annotators in two ways. First, the monetary cost of asking thousands of humans to label tens or hundreds of thousands of images or sentence pairs is prohibitive. Second, since the response patterns require that a single individual provide labels for all (or most) of the data set, each individual would need to label a huge number of items. Each individual would most likely get bored or burned out and the quality of the labels would suffer.

That said, consider for example a large company (or research lab) that runs hundreds or thousands of experiments each day on some internal data set. Many of the experiments would not lead to significant improvements in model performance, and the outputs from those experiments would be discarded. With the methods proposed here those outputs can be used to learn the latent parameters of the data to focus in on what exactly is working well and what isn't with respect to the models being tested and the data used to train them. Using the previously discarded data to learn IRT models and estimate latent difficulty and ability parameters can be used to improve a variety of tasks such as model selection, data selection, and curriculum learning strategies.

IRT models assume difficulty is a latent parameter of the items and can be estimated from response pattern data. Difficulty is directly linked to subject ability, in contrast to heuristics such as sentence length or word rarity. Certain items may be easy or difficult for a variety of reasons. With the methods presented here, an interesting direction for future work is to further examine why certain examples are more difficult than others.

We have shown that it is possible to fit IRT models using RPs from DNN models. Prior work relied on human RPs to investigate the impact of difficulty on model performance (Lalor et al., 2018), but it is now possible to conduct similar IRT analyses with machine RPs. This work also opens the possibility of fitting IRT models on much larger data sets. By removing the human bottleneck, we can use ensembles of DNN models to generate RPs for large data sets (e.g. all of SNLI or SSTB instead of a sample). Having difficulty and ability estimates for machine learning data sets and models can lead to very interesting work around such areas as active learning, curriculum learning, and meta learning.

Parallel Iterative Edit Models for Local Sequence Transduction

Abhijeet Awasthi*, **Sunita Sarawagi** , **Rasna Goyal** , **Sabyasachi Ghosh** , **Vihari Piratla**
Department of Computer Science and Engineering, IIT Bombay

Abstract

We present a Parallel Iterative Edit (PIE) model for the problem of local sequence transduction arising in tasks like Grammatical error correction (GEC). Recent approaches are based on the popular encoder-decoder (ED) model for sequence to sequence learning. The ED model auto-regressively captures full dependency among output tokens but is slow due to sequential decoding. The PIE model does parallel decoding, giving up the advantage of modelling full dependency in the output, yet it achieves accuracy competitive with the ED model for four reasons: 1. predicting edits instead of tokens, 2. labeling sequences instead of generating sequences, 3. iteratively refining predictions to capture dependencies, and 4. factorizing logits over edits and their token argument to harness pre-trained language models like BERT. Experiments on tasks spanning GEC, OCR correction and spell correction demonstrate that the PIE model is an accurate and significantly faster alternative for local sequence transduction. The code and pre-trained models for GEC are available at https://github.com/awasthiabhijeet/PIE.

1 Introduction

In local sequence transduction (LST) an input sequence $x_1, \ldots, x_n$ needs to be mapped to an output sequence $y_1, \ldots, y_m$ where the $\mathbf{x}$ and $\mathbf{y}$ sequences differ only in a few positions, m is close to n, and x_i, y_j come from the same vocabulary Σ. An important application of local sequence transduction that we focus on in this paper is Grammatical error correction (GEC). We contrast local transduction with more general sequence transduction tasks like translation and paraphrasing which might entail different input-output vocabulary and non-local alignments. The general sequence transduction task is cast as sequence to sequence (seq2seq) learning and modeled popularly using an attentional encoder-decoder (ED) model. The ED model auto-regressively produces each token y_t in the output sequence conditioned on all previous tokens $y_1, \ldots, y_{t-1}$. Owing to the remarkable success of this model in challenging tasks like translation, almost all state-of-the-art neural models for GEC use it (Zhao et al., 2019; Lichtarge et al., 2019; Ge et al., 2018b; Chollampatt and Ng, 2018b; Junczys-Dowmunt et al., 2018).

We take a fresh look at local sequence transduction tasks and present a new parallel-iterative-edit (PIE) architecture. Unlike the prevalent ED model that is constrained to sequentially generating the tokens in the output, the PIE model generates the output in parallel, thereby substantially reducing the latency of sequential decoding on long inputs. However, matching the accuracy of existing ED models without the luxury of conditional generation is highly challenging. Recently, parallel models have also been explored in tasks like translation (Stern et al., 2018; Lee et al., 2018; Gu et al., 2018; Kaiser et al., 2018) and speech synthesis (van den Oord et al., 2018), but their accuracy is significantly lower than corresponding ED models. The PIE model incorporates the following four ideas to achieve comparable accuracy on tasks like GEC in spite of parallel decoding.

1. Output edits instead of tokens: First, instead of outputting tokens from a large vocabulary, we output edits such as copy, appends, deletes, replacements, and case-changes which generalize better across tokens and yield a much smaller vocabulary. Suppose in GEC we have an input sentence: `fowler fed dog`. Existing seq2seq learning approaches would need to output the four tokens `Fowler`, `fed`, `the`, `dog` from a word vocabulary whereas we

would predict the edits {`Capitalize token 1, Append(the) to token 2, Copy token 3`}.

2. Sequence labeling instead of sequence generation: Second we perform in-place edits on the source tokens and formulate local sequence transduction as *labeling* the input tokens with edit commands, rather than solving the much harder whole *sequence generation* task involving a separate decoder and attention module. Since input and output lengths are different in general such formulation is non-trivial, particularly due to edits that insert words. We create special compounds edits that merge token inserts with preceding edits that yield higher accuracy than earlier methods of independently predicting inserts (Ribeiro et al., 2018; Lee et al., 2018).

3. Iterative refinement: Third, we increase the inference capacity of the parallel model by iteratively inputting the model's own output for further refinement. This handles dependencies implicitly, in a way reminiscent of Iterative Conditional Modes (ICM) fitting in graphical model inference (Koller and Friedman, 2009). Lichtarge et al. (2019) and Ge et al. (2018b) also refine iteratively but with ED models.

4. Factorize pre-trained bidirectional LMs: Finally, we adapt recent pre-trained bidirectional models like BERT (Devlin et al., 2018) by factorizing the logit layer over edit commands and their token argument. Existing GEC systems typically rely on conventional forward directional LM to pretrain their decoder, whereas we show how to use a bi-directional LM in the encoder, and that too to predict edits.

Novel contributions of our work are as follows:

- Recognizing GEC as a local sequence transduction (LST) problem, rather than machine translation. We then cast LST as a fast non-autoregressive, sequence labeling model as against existing auto-regressive encoder-decoder model.
- Our method of reducing LST to non-autoregressive sequence labeling has many novel elements: outputting edit operations instead of tokens, append operations instead of insertions in the edit space, and replacements along with custom transformations.
- We show how to effectively harness a pre-trained language model like BERT using our factorized logit architecture with edit-specific attention masks.
- The parallel inference in PIE is 5 to 15 times faster than a competitive ED based GEC model like (Lichtarge et al., 2019) which performs sequential decoding using beam-search. PIE also attains close to state of the art performance on standard GEC datasets. On two other local transduction tasks, viz., OCR and spell corrections the PIE model is fast and accurate w.r.t. other existing models developed specifically for local sequence transduction.

2 Our Method

We assume a fully supervised training setup where we are given a parallel dataset of incorrect, correct sequence pairs: $D = \{(\mathbf{x}^i, \mathbf{y}^i) : i = 1 \dots N\}$, and an optional large corpus of unmatched correct sequences $\mathcal{L} = \{\tilde{\mathbf{y}}^1, \dots, \tilde{\mathbf{y}}^U\}$. In GEC, this could be a corpus of grammatically correct sentences used to pre-train a language model.

Background: existing ED model Existing seq2seq ED models factorize $\Pr(\mathbf{y}|\mathbf{x})$ to capture the full dependency between a y_t and all previous $\mathbf{y}_{<t} = y_1, \dots, y_{t-1}$ as $\prod_{t=1}^{m} \Pr(y_t|\mathbf{y}_{<t}, \mathbf{x})$. An encoder converts input tokens $x_1, \dots, x_n$ to contextual states $\mathbf{h}_1, \dots, \mathbf{h}_n$ and a decoder summarizes $\mathbf{y}_{<t}$ to a state $\mathbf{s}_t$. An attention distribution over contextual states computed from $\mathbf{s}_t$ determines the relevant input context $\mathbf{c}_t$ and the output token distribution is calculated as $\Pr(y_t|\mathbf{y}_{<t}, \mathbf{x}) = \Pr(y_t|\mathbf{c}_t, \mathbf{s}_t)$. Decoding is done sequentially using beam-search. When a correct sequence corpus $\mathcal{L}$ is available, the decoder is pre-trained on a next-token prediction loss and/or a trained LM is used to re-rank the beam-search outputs (Zhao et al., 2019; Chollampatt and Ng, 2018a; Junczys-Dowmunt et al., 2018).

2.1 Overview of the PIE model

We move from generating tokens in the output sequence $\mathbf{y}$ using a separate decoder, to labelling the input sequence $x_1, \dots, x_n$ with edits $e_1, \dots, e_n$. For this we need to design a function Seq2Edits that takes as input an $(\mathbf{x}, \mathbf{y})$ pair in D and outputs a sequence $\mathbf{e}$ of edits from an edit space $\mathcal{E}$ where $\mathbf{e}$ is of the same length as $\mathbf{x}$ in spite of $\mathbf{x}$ and $\mathbf{y}$ being of different lengths. In Section 2.2 we show how we design such a function.

Training: We invoke Seq2Edits on D and learn the parameters of a probabilistic model $\Pr(\mathbf{e}|\mathbf{x}, \theta)$ to assign a distribution over the edit labels on tokens of the input sequence. In Section 2.3 we describe the PIE architecture in more detail. The correct corpus $\mathcal{L}$, when available, is used to pre-train the encoder to predict an arbitrarily masked token y_t in a sequence $\mathbf{y}$ in $\mathcal{L}$, much like in BERT. Unlike in existing seq2seq systems where $\mathcal{L}$ is used to pre-train the decoder that only captures forward dependencies, in our pre-training the predicted token y_t is dependent on both forward and backward contexts. This is particularly useful for GEC-type tasks where future context $y_{t+1} \dots y_m$ can be approximated by $x_{t+1}, \dots, x_n$.

Inference: Given an input $\mathbf{x}$, the trained model predicts the edit distribution for each input token independent of others, that is $\Pr(\mathbf{e}|\mathbf{x}, \theta) = \prod_{t=1}^{n} \Pr(e_t|\mathbf{x}, t, \theta)$, and thus does not entail the latency of sequential token generation of the ED model. We output the most probable edits $\hat{\mathbf{e}} = \text{argmax}_{\mathbf{e}} \Pr(\mathbf{e}|\mathbf{x}, \theta)$. Edits are designed so that we can easily get the edited sequence $\hat{\mathbf{y}}$ after *applying* $\hat{\mathbf{e}}$ on $\mathbf{x}$. $\hat{\mathbf{y}}$ is further refined by iteratively applying the model on the generated outputs $\hat{\mathbf{y}}$ until we get a sequence identical to one of the previous sequences upto a maximum number of iterations I.

2.2 The Seq2Edits Function

Given a $\mathbf{x} = x_1, \dots, x_n$ and $\mathbf{y} = y_1, \dots, y_m$ where m may not be equal to n, our goal is to obtain a sequence of edit operations $\mathbf{e} = (e_1, \dots, e_n) : e_i \in \mathcal{E}$ such that applying edit e_i on the input token x_i at each position i reconstructs the output sequence $\mathbf{y}$. Invoking an off-the-shelf edit distance algorithm between $\mathbf{x}$ and $\mathbf{y}$ can give us a sequence of copy, delete, replace, and insert operations of arbitrary length. The main difficulty is converting the insert operations into in-place edits at each x_i. Other parallel models (Ribeiro et al., 2018; Lee et al., 2018) have used methods like predicting insertion slots in a pre-processing step, or predicting zero or more tokens in-between any two tokens in $\mathbf{x}$. We will see in Section 3.1.4 that these options do not perform well. Hence we design an alternative edit space $\mathcal{E}$ that merges inserts with preceding edit operations creating compound append or replace operations. Further, we create a dictionary Σ_a of common q-gram insertions or replacements observed in the training data.

Our edit space ($\mathcal{E}$) comprises of copy (C) x_i, delete (D) x_i, append (A) a q-gram $w \in \Sigma_a$ after copying x_i, replace (R) x_i with a q-gram $w \in \Sigma_a$. For GEC, we additionally use transformations denoted as $\text{T}_1, \dots, \text{T}_k$ which perform word-inflection (e.g. `arrive` to `arrival`). The space of all edits is thus:

$$\mathcal{E} = \{\text{C}, \text{D}, \text{T}_1, \dots, \text{T}_k\} \cup \{\text{A}(w) : w \in \Sigma_a\} \cup \{\text{R}(w) : w \in \Sigma_a\} \quad (1)$$

Require: $\mathbf{x} = (x_1, \dots, x_n), \mathbf{y} = (y_1, \dots, y_m)$ and $\mathcal{T}$: List of Transformations
diffs $\leftarrow$ LEVENSHTEIN-DIST($\mathbf{x}, \mathbf{y}$) with modified cost.
diffs $\leftarrow$ In diffs break substitutions, merge inserts into q-grams
$\Sigma_a \leftarrow M$ most common inserts in training data
$\mathbf{e} \leftarrow$ EMPTYARRAY(n)
for $t \leftarrow 1$ to LENGTH(diffs) **do**
  if diffs[t] = (C, x_i) or (D, x_i) **then**
    $e_i \leftarrow$ diffs[t].op
  else if diffs[t] = (I, x_i, w) **then**
    if e_i = D **then**
      if (x_i, w) match transformation T $\in \mathcal{T}$ **then**

Table 1: Two example sentence pairs converted into respective edit sequences.

We present our algorithm for converting a sequence $\mathbf{x}$ and $\mathbf{y}$ into in-place edits on $\mathbf{x}$ using the above edit space in Figure 1. Table 1 gives examples of converting ($\mathbf{x}$, $\mathbf{y}$) pairs to edit sequences. We first invoke the Levenshtein distance algorithm (Levenshtein, 1966) to obtain `diff` between $\mathbf{x}$ and $\mathbf{y}$ with delete and insert cost as 1 as usual, but

with a modified substitution cost to favor matching of related words. We detail this modified cost in the Appendix and show an example of how this modification leads to more sensible edits. The `diff` is post-processed to convert substitutions into deletes followed by inserts, and consecutive inserts are merged into a q-gram. We then create a dictionary Σ_a of the M most frequent q-gram inserts in the training set. Thereafter, we scan the `diff` left to right: a copy at x_i makes e_i = C, a delete at x_i makes e_i = D, an insert w at x_i and a e_i = C flips the e_i into a e_i = A(w) if w is in Σ_a, else it is dropped, an insert w at x_i and a e_i = D flips the e_i into a e_i = T(w) if a match found, else a replace R(w) if w is in Σ_a, else it is dropped.

The above algorithm does not guarantee that when $\mathbf{e}$ is applied on $\mathbf{x}$ we will recover $\mathbf{y}$ for all sequences in the training data. This is because we limit Σ_a to include only the M most frequently inserted q-grams. For local sequence transduction tasks, we expect a long chain of consecutive inserts to be rare, hence our experiments were performed with $q = 2$. For example, in NUCLE dataset (Ng et al., 2014) which has roughly 57.1K sentences, less than 3% sentences have three or more consecutive inserts.

2.3 The Parallel Edit Prediction Model

We next describe our model for predicting edits $\mathbf{e}$: $e_1, \ldots, e_n$ on an input sequence $\mathbf{x}$: $x_1, \ldots, x_n$. We use a bidirectional encoder to provide a contextual encoding of each x_i. This can either be multiple layers of bidirectional RNNs, CNNs or deep bidirectional transformers. We adopt the deep bidirectional transformer architecture since it encodes the input in parallel. We pre-train the model using $\mathcal{L}$ much like in BERT pre-training recently proposed for language modeling(Devlin et al., 2018). We first give an overview of BERT and then describe our model.

Background: BERT The input is token embedding $\mathbf{x}_i$ and positional embedding $\mathbf{p}_i$ for each token x_i in the sequence $\mathbf{x}$. Call these jointly as $\mathbf{h}_i^0 = [\mathbf{x}_i, \mathbf{p}_i]$. Each layer ℓ produces a $\mathbf{h}_i^\ell$ at each position i as a function of $\mathbf{h}_i^{\ell-1}$ and self-attention over all $\mathbf{h}_j^{\ell-1}$, $j \in [1, n]$. The BERT model is pre-trained by masking out a small fraction of the input tokens by a special MASK, and predicting the masked word from its bidirectional context captured as the last layer output: $\mathbf{h}_1, \ldots, \mathbf{h}_n$.

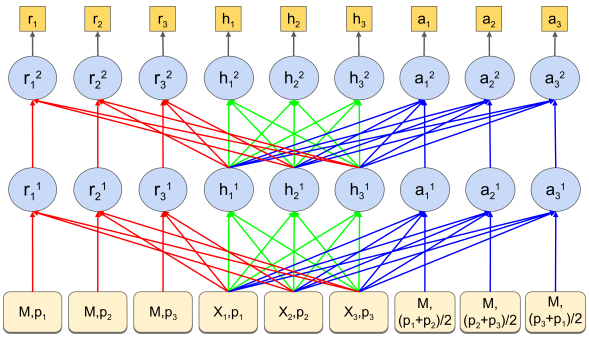

Figure 2: A Parallel Edit Architecture based on a 2-layer bidirectional transformer. Input sequence length is 3. Arrows indicate attention mask for computation of $\mathbf{h}_i^l, \mathbf{r}_i^l, \mathbf{a}_i^l$ at position i for layer l.

2.3.1 A Default use of BERT

Since we have cast our task as a sequence labeling task, a default output layer would be to compute $\Pr(e_i|\mathbf{x})$ as a softmax over the space of edits $\mathcal{E}$ from each $\mathbf{h}_i$. If W_e denotes the softmax parameter for edit e, we get:

$$\Pr(e_i = e|\mathbf{x}) = \text{softmax}(W_e^\intercal \mathbf{h}_i) \qquad (2)$$

The softmax parameters, W_e in Equation 2, have to be trained from scratch. We propose a method to exploit token embeddings of the pre-trained language model to warm-start the training of edits like appends and replaces which are associated with a token argument. Furthermore, for appends and replaces, we provide a new method of computing the hidden layer output via alternative input positional embeddings and self-attention. We do so without introducing any new parameters in the hidden layers of BERT.

2.3.2 An Edit-factorized BERT Architecture

We adapt a pre-trained BERT-like bidirectional language model to learn to predict edits as follows. For suitably capturing the contexts for replace edits, for each position i we create an additional input comprising of $\mathbf{r}_i^0 = [\text{M}, \mathbf{p}_i]$ where M is the embedding for MASK token in the LM. Likewise for a potential insert between i and $i+1$ we create an input $\mathbf{a}_i^0 = [\text{M}, \frac{\mathbf{p}_i + \mathbf{p}_{i+1}}{2}]$ where the second component is the average of the position embedding of the ith and $i+1$th position. As shown in Figure 2, at each layer ℓ we compute self-attention for the ith replace unit $\mathbf{r}_i^\ell$ over $\mathbf{h}_j^\ell$ for all $j \neq i$ and itself. Likewise, for the append unit $\mathbf{a}_i^\ell$ the self-attention is over all $\mathbf{h}_j^\ell$ for all js and itself. At the last layer we have $\mathbf{h}_1, \ldots, \mathbf{h}_n, \mathbf{r}_1, \ldots, \mathbf{r}_n, \mathbf{a}_1, \ldots, \mathbf{a}_n$. Using these we compute logits factorized over edits

and their token argument. For an edit $e \in \mathcal{E}$ at position i, let w denote the argument of the edit (if any). As mentioned earlier, w can be a q-gram for append and replace edits. Embedding of w, represented by $\phi(w)$ is obtained by summing up individual output embeddings of tokens in w. Additionally, in the outer layer we allocate edit-specific parameters $\boldsymbol{\theta}$ corresponding to each distinct command in $\mathcal{E}$. Using these, various edit logits are computed as follows:

$$\Pr(e_i|\mathbf{x}) = \text{softmax}(\text{logit}(e_i|\mathbf{x})) \quad \text{where}$$
$$\text{logit}(e_i|\mathbf{x}) = \tag{3}$$
$$\begin{cases} \theta_{\text{C}}^{\intercal}\mathbf{h}_i + \phi(x_i)^{\intercal}\mathbf{h}_i + 0 & \text{if } e_i = \text{C} \\ \theta_{\text{A}(w)}^{\intercal}\mathbf{h}_i + \phi(x_i)^{\intercal}\mathbf{h}_i + \phi(w)^{\intercal}\mathbf{a}_i & \text{if } e_i = \text{A}(w) \\ \theta_{\text{R}(w)}^{\intercal}\mathbf{h}_i + 0 + (\phi(w) - \phi(x_i))^{\intercal}\mathbf{r}_i & \text{if } e_i = \text{R}(w) \\ \theta_{\text{D}}^{\intercal}\mathbf{h}_i + 0 + 0 & \text{if } e_i = \text{D} \\ \theta_{T_k}^{\intercal}\mathbf{h}_i + \phi(x_i)^{\intercal}\mathbf{h}_i + 0 & \text{if } e_i = T_k \end{cases}$$

The first term in the RHS of above equations captures edit specific score. The second term captures the score for copying the current word x_i to the output. The third term models the influence of a new incoming token in the output obtained by a replace or append edit. For replace edits, score of the replaced word is subtracted from score of the incoming word. For transformation we add the copy score because they typically modify only the word forms, hence we do not expect meaning of the transformed word to change significantly.

The above equation provides insights on why predicting independent edits is easier than predicting independent tokens. Consider the append edit ($\text{A}(w)$). Instead of independently predicting x_i at i and w at $i+1$, we jointly predict the tokens in these two slots and contrast it with not inserting any new w after x_i in a single softmax. We will show empirically (Sec 3.1.4) that such selective joint prediction is key to obtaining high accuracy in spite of parallel decoding.

Finally, loss for a training example $(\mathbf{e}, \mathbf{x})$ is obtained by summing up the cross-entropy associated with predicting edit e_i at each token x_i.

$$\mathcal{L}(\mathbf{e}, \mathbf{x}) = -\Sigma_i \log(\Pr(e_i|\mathbf{x})) \tag{4}$$

3 Experiments

We compare our parallel iterative edit (PIE) model with state-of-the-art GEC models that are all based on attentional encoder-decoder architectures. In Section 3.2 we show that the PIE model is also effective on two other local sequence transduction tasks: spell and OCR corrections. Hyperparameters for all the experiments are provided in Table 12, 13 of the Appendix.

3.1 Grammatical error correction (GEC)

We use Lang-8 (Mizumoto et al., 2011), NUCLE (Ng et al., 2014) and FCE (Yannakoudakis et al., 2011) corpora, which jointly comprise 1.2 million sentence pairs in English. The validation dataset comprises of 1381 sentence pairs from CoNLL-13 (Ng et al., 2013) test set. We initialize our GEC model with the publicly available BERT-LARGE[1] model that was pre-trained on Wikipedia (2500M words) and Book corpus (Zhu et al., 2015) (800M words) to predict 15% randomly masked words using its deep bidirectional context. Next, we perform 2 epochs of training on a synthetically perturbed version of the One-Billion-word corpus (Chelba et al., 2013). We refer to this as synthetic training. Details of how we create the synthetic corpus appear in Section A.3 of the appendix. Finally we fine-tune on the real GEC training corpus for 2 epochs. We use a batch size of 64 and learning rate 2e-5.

The edit space consists of copy, delete, 1000 appends, 1000 replaces and 29 transformations and their inverse. Arguments of Append and Replace operations mostly comprise punctuations, articles, pronouns, prepositions, conjunctions and verbs. Transformations perform inflections like add suffix `s, d, es, ing, ed` or replace suffix `s to ing`, `d to s`, etc. These transformations were chosen out of common replaces in the training data such that many replace edits map to only a few transformation edits, in order to help the model better generalize replaces across different words. In Section 3.1.4 we see that transformations increase the model's recall. The complete list of transformations appears in Table 10 of the Appendix. We evaluate on $F_{0.5}$ score over span-level corrections from the MaxMatch (M2) scorer (Dahlmeier and Ng, 2012) on CONLL-2014-test. Like most existing GEC systems, we invoke a spell-checker on the test sentences before applying our model. We also report GLEU$^+$ (Napoles et al., 2016) scores on JFLEG corpus (Napoles et al., 2017) to evaluate fluency.

Table 2: Comparison of non-ensemble model numbers for various GEC models. Best non-ensemble results are reported for each model.

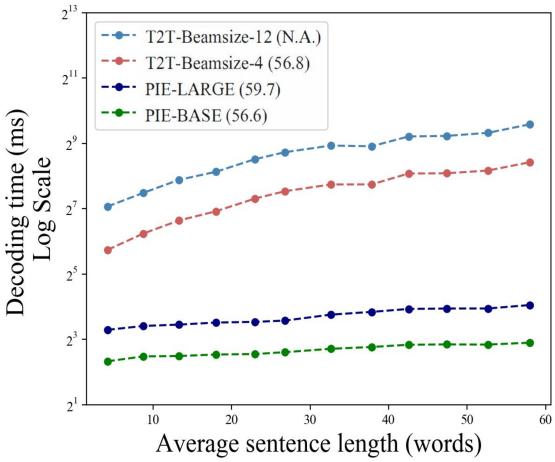

Figure 3: Comparing average decoding time in milliseconds (log scale) of PIE Vs transformer based ED model with two beam widths. Numbers in legend denote M2 score.

3.1.1 Overall Results

Table 3 compares ensemble model results of PIE and other state of the art models, which all happen to be seq2seq ED models and also use ensemble decoding. For PIE, we simply average the probability distribution over edits from 5 independent ensembles. In Table-2 we compare non-ensemble numbers of PIE with the best available non-ensemble numbers of competing methods. On CoNLL-14 test-set our results are very close to the highest reported by Zhao et al. (2019). These results show that our parallel prediction model is competitive without incurring the overheads of beam-search and slow decoding of sequential models. GLEU$^+$ score, that rewards fluency, is somewhat lower for our model on the JFLEG test set because of parallel predictions. We do not finetune our model on the JFLEG dev set. We expect these to improve with re-ranking using a LM. All subsequent ablations and timing measurements are reported for non-ensemble models.

3.1.2 Running Time Comparison

Parallel decoding enables PIE models to be considerably faster than ED models. In Figure 3 we compare wall-clock decoding time of PIE with 24 encoder layers (PIE-LARGE, $F_{0.5} = 59.7$), PIE with 12 encoder layers (PIE-BASE, $F_{0.5} = 56.6$) and competitive ED architecture by Lichtarge et al. (2019) with 6 encoder and 6 decoder layers (T2T, $F_{0.5} = 56.8$) on CoNLL-14 test set. All decoding experiments were run and measured on a n1-standard-2[2] VM instance with a single TPU shard (v-2.8). We observe that even PIE-LARGE is between a factor of 5 to 15 faster than an equivalent transformer-based ED model (T2T) with beam-size 4. The running time of PIE-LARGE increases sub-linearly with sentence length whereas the ED model's decoding time increases linearly.

3.1.3 Impact of Iterative Refinement

We next evaluate the impact of iterative refinements on accuracy in Table 4. Out of 1312 sentences in the test set, only 832 sentences changed in the first round which were then fed to the second round where only 156 sentences changed, etc. The average number of refinement rounds per example was 2.7. In contrast, a sequential model on this dataset would require 23.2 steps corresponding to the average number of tokens in a sentence. The $F_{0.5}$ score increases from 57.9 to 59.5 at the end of the second iteration.

Table 5 presents some sentences corrected by PIE. We see that PIE makes multiple parallel edits in a round if needed. Also, we see how refinement over successive iterations captures output space dependency. For example, in the second sentence `interact` gets converted to `interacted` followed by insertion of `have` in the next round.

3.1.4 Ablation study on the PIE Architecture

In this section we perform ablation studies to understand the importance of individual features of the PIE model.

Synthetic Training We evaluate the impact of training on the artifically generated GEC corpus in row 2 of Table 6. We find that without it the $F_{0.5}$ score is 3.4 points lower.

Factorized Logits We evaluate the gains due to

Table 4: Statistics on successive rounds of iterative refinement. First row denotes number changed sentences (out of 1312) with each round on CONLL-14 (test).

our edit-factorized BERT model (Section 2.3.2) over the default BERT model (Section 2.3.1). In Table 6 (row 3) we show that compared to the factorized model (row 2) we get a 1.2 point drop in $F_{0.5}$ score in absence of factorization.

Inserts as Appends on the preceding word was another important design choice. The alternative of predicting `insert` independently at each gap with a null token added to Σ_a performs 2.7 $F_{0.5}$ points poorly (Table 6 row 4 vs row 2).

Transformation edits are significant as we observe a 6.3 drop in recall without them (row 5).

Impact of Language Model We evaluate the benefit of starting from BERT's pre-trained LM by reporting accuracy from an un-initialized network (row 6). We observe a 20 points drop in $F_{0.5}$ establishing the importance of LMs in GEC.

Impact of Network Size We train the BERT-Base model with one-third fewer parameters than BERT-LARGE. From Table 6 (row 7 vs 1) we see once again that size matters in deep learning!

3.2 More Sequence Transduction Tasks

We demonstrate the effectiveness of PIE model on two additional local sequence transduction tasks recently used in (Ribeiro et al., 2018).

Spell Correction We use the twitter spell correction dataset (Aramaki, 2010) which consists of 39172 pairs of original and corrected words obtained from twitter. We use the same train-dev-valid split as (Ribeiro et al., 2018) (31172/4000/4000). We tokenize on characters, and our vocabulary Σ and Σ_a comprises the 26 lower cased letters of English.

Correcting OCR errors We use the Finnish OCR data set[3] by (Silfverberg et al., 2016) comprising words extracted from Early Modern

Seq2Seq (Hard,lstm)	52.2	58.4
Seq2Seq (Soft-T2T)	67.6	84.5
Ribeiro2018 (best model)	54.1	81.8
PIE	67.0	87.6

Table 7: Comparing PIE with Seq2Seq models (top-part) and Ribeiro's parallel model on two other local sequence transduction tasks.

Finnish corpus of OCR processed newspaper text. We use the same train-dev-test splits as provided by (Silfverberg et al., 2016). We tokenize on characters in the word. For a particular split, our vocabulary Σ and Σ_a comprises of all the characters seen in the training data of the split.

Architecture For all the tasks in this section, PIE is a 4 layer self-attention transformer with 200 hidden units, 400 intermediate units and 4 attention heads. No $\mathcal{L}$ pre-initialization is done. Also, number of iterations of refinements is set to 1.

Results Table 7 presents whole-word 0/1 accuracy for these tasks on PIE and the following methods: Ribeiro et al. (2018)'s local transduction model (described in Section 4), and LSTM based ED models with hard monotonic attention (Aharoni and Goldberg, 2017) and soft-attention (Bahdanau et al., 2015) as reported in (Ribeiro et al., 2018). In addition, for a fair decoding time comparison, we also train a transformer-based ED model referred as Soft-T2T with 2 encoder, 2 decoder layers for spell-correction and 2 encoder, 1 decoder layer for OCR correction. We observe that PIE's accuracy is comparable with ED models in both the tasks. Table 8 compares decoding speed of PIE with Soft-T2T in words/second. Since more than 90% of words have fewer than 9 tokens and the token vocabulary Σ is small, decoding speed-ups of PIE over ED model on these tasks is modest compared to GEC.

	PIE	Soft-T2T
Spell	80.43	36.62
OCR	65.44	43.02

4 Related Work

Grammar Error Correction (GEC) is an extensively researched area in NLP. See Ng et al. (2013) and Ng et al. (2014) for past shared tasks on GEC, and this[4] website for current progress. Approaches attempted so far include rules (Felice et al., 2014), classifiers (Rozovskaya and Roth, 2016), statistical machine translation (SMT) (Junczys-Dowmunt and Grundkiewicz, 2016), neural ED models (Chollampatt and Ng, 2018a; Junczys-Dowmunt et al., 2018; Ge et al., 2018a), and hybrids (Grundkiewicz and Junczys-Dowmunt, 2018). All recent neural approaches are sequential ED models that predict either word sequences (Zhao et al., 2019; Lichtarge et al., 2019) or character sequences (Xie et al., 2016) using either multi-layer RNNs (Ji et al., 2017; Grundkiewicz and Junczys-Dowmunt, 2018) or CNNs(Chollampatt and Ng, 2018a; Ge et al., 2018a) or Transformers (Junczys-Dowmunt et al., 2018; Lichtarge et al., 2019). Our sequence labeling formulation is similar to (Yannakoudakis et al., 2017) and (Kaili et al., 2018) but the former uses it to only detect errors and the latter only corrects five error-types using separate classifiers. Edits have been exploited in earlier GEC systems too but very unlike our method of re-architecting the core model to label input sequence with edits. Schmaltz et al. (2017) interleave edit tags in target tokens but use seq2seq learning to predict the output sequence. Chollampatt and Ng (2018a) use edits as features for rescoring seq2seq predictions. Junczys-Dowmunt et al. (2018) use an edit-weighted MLE objective to emphasise corrective edits during seq2seq learning. Stahlberg et al. (2019) use finite state transducers, whose state transitions denote possible edits, built from an unlabeled corpus to constrain the output of a neural beam decoder to a small GEC-feasible space.

[4] https://nlpprogress.com/english/grammatical_error_correction.html

Parallel decoding in neural machine translation Kaiser et al. (2018) achieve partial parallelism by first generating latent variables sequentially to model dependency. Stern et al. (2018) use a parallel generate-and-test method with modest speed-up. Gu et al. (2018) generate all tokens in parallel but initialize decoder states using latent fertility variables to determine number of replicas of an encoder state. We achieve the effect of fertility using delete and append edits. Lee et al. (2018) generate target sequences iteratively but require the target sequence length to be predicted at start. In contrast our in-place edit model allows target sequence length to change with appends.

Local Sequence Transduction is handled in Ribeiro et al. (2018) by first predicting insert slots in $\mathbf{x}$ using learned insertion patterns and then using a sequence labeling task to output tokens in $\mathbf{x}$ or a special token `delete`. Instead, we output edit operations including word transformations. Their pattern-based insert pre-slotting is unlikely to work for more challenging tasks like GEC. Koide et al. (2018) design a special edit-invariant neural network for being robust to small edit changes in input biological sequences. This is a different task than ours of edit prediction. Yin et al. (2019) is about neural representation of edits specifically for structured objects like source code. This is again a different problem than ours.

5 Conclusion

We presented a parallel iterative edit (PIE) model for local sequence transduction with a focus on the GEC task. Compared to the popular encoder-decoder models that perform sequential decoding, parallel decoding in the PIE model yields a factor of 5 to 15 reduction in decoding time. The PIE model employs a number of ideas to match the accuracy of sequential models in spite of parallel decoding: it predicts in-place edits using a carefully designed edit space, iteratively refines its own predictions, and effectively reuses state-of-the-art pre-trained bidirectional language models. In the future we plan to apply the PIE model to more ambitious transduction tasks like translation.

Abstract

Most of the existing generative adversarial networks (GAN) for text generation suffer from the instability of reinforcement learning training algorithms such as policy gradient, leading to unstable performance. To tackle this problem, we propose a novel framework called Adversarial Reward Augmented Maximum Likelihood (ARAML). During adversarial training, the discriminator assigns rewards to samples which are acquired from a stationary distribution near the data rather than the generator's distribution. The generator is optimized with maximum likelihood estimation augmented by the discriminator's rewards instead of policy gradient. Experiments show that our model can outperform state-of-the-art text GANs with a more stable training process.

1 Introduction

Natural text generation, as a key task in NLP, has been advanced substantially thanks to the flourish of neural models (Bengio et al., 2003; Mikolov et al., 2010). Typical frameworks such as sequence-to-sequence (seq2seq) have been applied to various generation tasks, including machine translation (Sutskever et al., 2014) and dialogue generation (Vinyals and Le, 2015). The standard paradigm to train such neural models is maximum likelihood estimation (MLE), which maximizes the log-likelihood of observing each word in the text given the ground-truth proceeding context (Graves, 2013).

Although widely used, MLE suffers from the exposure bias problem (Bengio et al., 2015; Ranzato et al., 2016): during test, the model sequentially predicts the next word conditioned on its previous generated words while during training conditioned on ground-truth words. To tackle this problem, generative adversarial networks (GAN) with reinforcement learning (RL) training approaches have been introduced to text generation tasks (Yu et al., 2017; Che et al., 2017; Lin et al., 2017; Fedus et al., 2018; Guo et al., 2018; Shi et al., 2018; Xu et al., 2018), where the discriminator is trained to distinguish real and generated text samples to provide reward signals for the generator, and the generator is optimized via policy gradient (Yu et al., 2017).

However, recent studies have shown that potential issues of training GANs on discrete data are more severe than exposure bias (Semeniuta1 et al., 2018; Caccia et al., 2018). One of the fundamental issues when generating discrete text samples with GANs is training instability. Updating the generator with policy gradient always leads to an unstable training process because it's difficult for the generator to derive positive and stable reward signals from the discriminator even with careful pretraining (Che et al., 2017). As a result, the generator gets lost due to the high variance of reward signals and the training process may finally collapse (Li et al., 2017).

In this paper, we propose a novel adversarial training framework called Adversarial Reward Augmented Maximum Likelihood (ARAML) to deal with the instability issue of training GANs for text generation. At each iteration of adversarial training, we first train the discriminator to assign higher rewards to real data than to generated samples. Then, inspired by reward augmented maximum likelihood (RAML) (Norouzi et al., 2016), the generator is updated on the samples acquired from a stationary distribution with maximum likelihood estimation (MLE), weighted by the discriminator's rewards. This stationary distribution is designed to guarantee that training samples are surrounding the real data, thus the exploration space of our generator is indeed restricted by the

MLE training objective, resulting in more stable training. Compared to other text GANs with RL training techniques, our framework acquires samples from the stationary distribution rather than the generator's distribution, and uses RAML training paradigm to optimize the generator instead of policy gradient. Our contributions are mainly as follows:

- We analyze the fundamental issue of current GANs for text generation from the perspectives of training instability.
- We propose a novel framework called Adversarial Reward Augmented Maximum Likelihood (ARAML), which incorporates stable RAML training into adversarial training paradigm. Experimental results on three text generation tasks show the effectiveness of our method.

2 Related Work

Recently, text generation has been widely studied with neural models trained with maximum likelihood estimation (Graves, 2013). However, MLE tends to generate universal text (Li et al., 2016). Various methods have been proposed to enhance the generation quality by refining the objective function (Li et al., 2016; Mou et al., 2016) or modifying the generation distribution with external information like topic (Xing et al., 2017), sentence type (Ke et al., 2018), emotion (Zhou et al., 2018a) and knowledge (Zhou et al., 2018b).

As mentioned above, MLE suffers from the exposure bias problem (Bengio et al., 2015; Ranzato et al., 2016). Thus, reinforcement learning has been introduced to text generation tasks such as policy gradient (Ranzato et al., 2016) and actor-critic (Bahdanau et al., 2017). (Norouzi et al., 2016) proposed an efficient and stable approach called Reward Augmented Maximum Likelihood (RAML), which connects the log-likelihood and expected rewards to incorporate MLE training objective into RL framework.

Since some text generation tasks have no explicit metrics to be directly optimized, adversarial training has been applied to generating discrete text samples with a discriminator to learn a proper reward. For instance, SeqGAN (Yu et al., 2017) devised a discriminator to distinguish the real data and generated samples, and a generator to maximize the reward from the discriminator via policy gradient. Other variants of GANs have been proposed to improve the generator or the discriminator. To improve the generator, MaliGAN (Che et al., 2017) developed a normalized maximum likelihood optimization target for the generator to stably model the discrete sequences. LeakGAN (Guo et al., 2018) guided the generator with reward signals leaked from the discriminator at all generation steps to deal with long text generation task. MaskGAN (Fedus et al., 2018) employed an actor-critic architecture to make the generator fill in missing text conditioned on the surrounding context, which is expected to mitigate the problem of mode collapse. As for the discriminator, RankGAN (Lin et al., 2017) replaced traditional discriminator with a ranker to learn the relative ranking information between the real texts and generated ones. Inverse reinforcement learning (Shi et al., 2018) used a trainable reward approximator as the discriminator to provide dense reward signals at each generation step. DPGAN (Xu et al., 2018) introduced a language model based discriminator and regarded cross-entropy as rewards to promote the diversity of generation results.

The most similar works to our model are RAML (Norouzi et al., 2016) and MaliGAN (Che et al., 2017): 1) Compared with RAML, our model adds a discriminator to learn the reward signals instead of choosing existing metrics as rewards. We believe that our model can adapt to various text generation tasks, particularly those without explicit evaluation metrics. 2) Unlike MaliGAN, we acquire samples from a fixed distribution near the real data rather than the generator's distribution, which is expected to make the training process more stable.

3 Model

3.1 Task Definition and Model Overview

Text generation can be formulated as follows: given the real data distribution $P_{\text{data}}(X)$, the task is to train a generative model G_θ where $P_{G_\theta}(X)$ can fit $P_{\text{data}}(X)$ well. In this formulation, $X = x_1 x_2 \cdots x_m$ and $x_t (1 \leq t \leq m)$ denotes a word in the vocabulary $\mathcal{V}$.

Figure 1 shows the overview of our model ARAML. This adversarial training framework consists of two phases: 1) The discriminator is trained to assign higher rewards to real data than to generated data. 2) The generator is trained on the samples acquired from a stationary distribu-

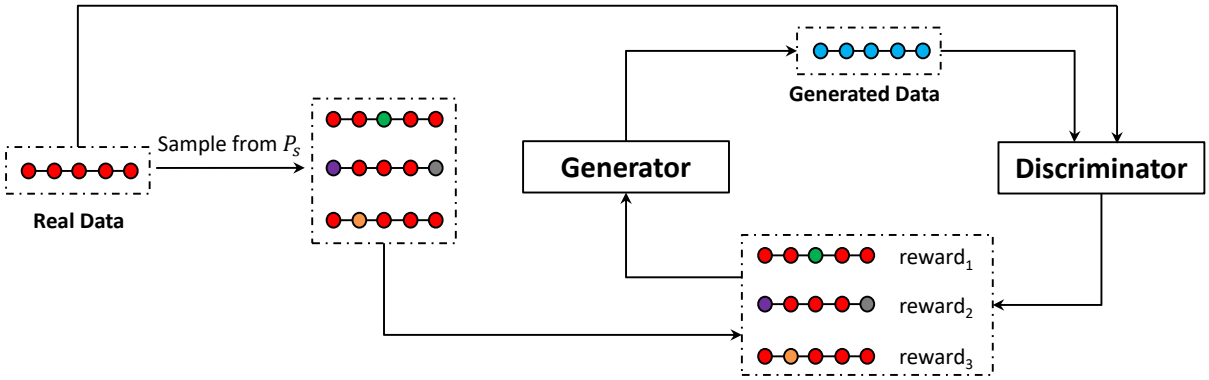

Figure 1: Overview of ARAML. The training samples are acquired from a stationary distribution P_s based on the real data. The generator is then trained on the samples augmented by the discriminator's rewards. The discriminator is trained to distinguish real data and generated data.

tion with reward augmented MLE training objective. This training paradigm of the generator indeed constrains the search space with the MLE training objective, which alleviates the issue of unstable training.

3.2 Discriminator

The discriminator D_ϕ aims to distinguish real data and generated data like other GANs. Inspired by Least-Square GAN (Mao et al., 2017), we devise the loss function as follows:

$$\mathcal{L}_{D_\phi} = \frac{1}{2}\mathbb{E}_{X\sim P_{\text{data}}(X)}\left[(D_\phi(X)-1)^2\right] + \frac{1}{2}\mathbb{E}_{X\sim P_{G_\theta}(X)}\left[(D_\phi(X))^2\right] \quad (1)$$

This loss function forces the discriminator to assign higher rewards to real data than to generated data, so the discriminator can learn to provide more proper rewards as the training proceeds.

3.3 Generator

The training objective of our generator G_θ is derived from the objective of other discrete GANs with RL training method:

$$\mathcal{L}_{\text{RL},\theta} = -\mathbb{E}_{X\sim P_{G_\theta}(X)}[r_\phi(X)] - \tau\mathbb{H}(P_{G_\theta}(X)) \quad (2)$$

where $r_\phi(X)$ denotes the rewards from the discriminator D_ϕ and the entropy regularized term $\mathbb{H}(P_{G_\theta}(X))$ encourages G_θ to generate diverse text samples. τ is a temperature hyper-parameter to balance these two terms.

As mentioned above, discrete GANs suffer from the instability issue due to policy gradient, thus they are consequently difficult to train. Inspired by RAML (Norouzi et al., 2016), we introduce an exponential payoff distribution $Q_\phi(X)$ to connect RL loss with RAML loss:

$$Q_\phi(X) = \frac{1}{Z}\exp(r_\phi(X)/\tau) \quad (3)$$

where $Z = \sum_X \exp(r_\phi(X)/\tau)$. Thus, we can rewrite $\mathcal{L}_{\text{RL},\theta}$ with $P_{G_\theta}(X)$ and $Q_\phi(X)$ as follows:

$$\mathcal{L}_{\text{RL},\theta} = \tau KL(P_{G_\theta}(X)||Q_\phi(X)) + constant \quad (4)$$

Following RAML, we remove the constant term and optimize the KL divergence in the opposite direction:

$$\begin{aligned}\mathcal{L}_{\text{RAML},\theta} &= KL(Q_\phi(X)||P_{G_\theta}(X)) \\ &= -\mathbb{E}_{X\sim Q_\phi(X)}[\log P_{G_\theta}(X)] - \mathbb{H}(Q_\phi(X)) \\ &= -\mathbb{E}_{X\sim Q_\phi(X)}[\log P_{G_\theta}(X)] + constant \quad (5)\end{aligned}$$

where $\mathbb{H}(Q_\phi(X))$ is a constant in the training phase of the generator. It has been proved that $\mathcal{L}_{\text{RL},\theta}$ and $\mathcal{L}_{\text{RAML},\theta}$ are equivalent up to their first order Taylor approximations, and they have the same global optimum (Norouzi et al., 2016). $\mathcal{L}_{\text{RAML},\theta}$ can be trained in a MLE-like fashion but sampling from the distribution $Q_\phi(X)$ is intractable in the adversarial setting, because $Q_\phi(X)$ varies with the discriminator D_ϕ. Thus, we introduce importance sampling to separate sampling process from D_ϕ and obtain the final loss function:

$$\mathcal{L}_{G_\theta} = -\mathbb{E}_{X\sim P_s(X)}[W_\phi(X)\log P_{G_\theta}(X)] \quad (6)$$

where $P_s(X)$ denotes a stationary distribution and $W_\phi(X) \propto Q_\phi(X)/P_s(X)$. To optimize this loss function, we first construct the fixed distribution $P_s(X)$ to get samples, and devise the proper reward function $r_\phi(X)$ to train the generator in a stable and effective way.

3.3.1 Sampling

We construct the distribution P_s based on P_{data}:

$$P_s(X) = \mathbb{E}_{X \sim P_{\text{data}}(X)}[P_s(X_s|X)] \quad (7)$$

In this way, $P_s(X_s|X)$ can be designed to guarantee that $P_s(X)$ is near $P_{\text{data}}(X)$, leading to a more stable training process. To obtain a new sample X_s from a real data sample X, we can design three steps which contain sampling an edit distance d, the positions $\{p_1, p_2, \cdots, p_d\}$ for substitution and the new words $\{w_1, w_2, \cdots, w_d\}$ filled into the corresponding positions. Thus, $P_s(X_s|X)$ can be decomposed into three terms:

$$\begin{aligned} P_s(X_s|X) &= P(d, p, w|X) \\ &= P(d|X)P(p|X, d)P(w|X, d, p) \end{aligned} \quad (8)$$

The first step is to sample an edit distance based on a real data sample X, where $X = x_1 x_2 \cdots x_m$ is a sequence of length m. The number of sentences which have the edit distance e to some input sentence can be computed approximately as below:

$$c(e, m) = \binom{m}{e} \cdot (|\mathcal{V}| - 1)^e \quad (9)$$

where $c(e, m)$ denotes the number of sentences which have an edit distance $e (e \in \{0, 1, ..., m\})$ to a sentence of length m, and $|\mathcal{V}|$ indicates the size of vocabulary. We then follow (Norouzi et al., 2016) to re-scale the counts by $\exp\{-e/\tau\}$ and do normalization, so that we can sample an edit distance d^* from:

$$P(d = d^*|X) = \frac{\exp\{-d^*/\tau\}c(d^*, m)}{\sum_{e=0}^{m} \exp\{-e/\tau\}c(e, m)} \quad (10)$$

where τ, as a temperature hyper-parameter, restricts the search space surrounding the original sentence. Larger τ brings more samples with long edit distances.

The next step is to select positions for substitution based on the sampled edit distance d^*. Intuitively, we can randomly choose d^* distinct positions in X to be replaced by new words. The probability of choosing the position p^* is calculated as follows:

$$P(p = p^*|X, d = d^*) = \frac{d^*}{m} \quad (11)$$

Following this sampling strategy, we can obtain the position set $\{p_1, p_2, \cdots, p_{d^*}\}$. This strategy approximately guarantees that the edit distance between a new sentence and the original sentence is d^*.

At the final step, our model determines new words for substitution at each sampled position $p_j (j = 1, 2, ..., d^*)$. We can formulate this sampling process from the original sequence X to a new sample X_s as a sequential transition $X = X_0 \to X_1 \to \cdots \to X_{d^*} = X_s$. At each step from X_{j-1} to X_j $(j = 1, \cdots, d^*)$, we first sample a new word w_j from the distribution $P(w|X_{j-1}, p = p_j)$, then replace the old word at position p_j of X_{j-1} to obtain X_j. The whole sampling process can be decomposed as follows:

$$\begin{aligned} &P(w|X, d = d^*, p = \{p_1, p_2, \cdots, p_{d^*}\}) \\ &\qquad = \prod_{j=1}^{d^*} P(w_j|X_{j-1}, p = p_j) \end{aligned} \quad (12)$$

There are two common sampling strategies to model $P(w|X_{j-1}, p = p_j)$, i.e. random sampling and constrained sampling. Random sampling strategy samples a new word w_j according to the uniform distribution over the vocabulary $\mathcal{V}$ (Norouzi et al., 2016), while constrained sampling strategy samples w_j to maximize the language model score of the target sentence X_j (Su et al., 2018; Miao et al., 2019). Here, we adopt constrained sampling in our model and compare the performances of two strategies in the experiment.

3.3.2 Training

We devise the reward function $r_\phi(X)$ according to the discriminator's output $D_\phi(X)$ and the stationary distribution $P_s(X)$:

$$r_\phi(X) = \tau \cdot [\log P_s(X) + D_\phi(X)] \quad (13)$$

Intuitively, this reward function encourages the generator to generate sentences with large sampling probability and high rewards from the discriminator. Thus, the weight of samples $W_\phi(X)$ can be calculated as follows:

$$W_\phi(X) \propto \frac{Q_\phi(X)}{P_s(X)} \propto \exp\{D_\phi(X)\} \quad (14)$$

So far, we can successfully optimize the generator's loss $\mathcal{L}_{G_\theta}$ via Equation 6. This training paradigm makes our generator avoid possible variances caused by policy gradient and get more stable reward signals from the discriminator, because our generator is restricted to explore the training samples near the real data.

Algorithm 1 Adversarial Reward Augmented Maximum Likelihood

3.4 Extension to Conditional Text Generation

We have shown our adversarial training framework for text generation tasks without an input. Actually, it can also be extended to conditional text generation tasks like dialogue generation. Given the data distribution $P_{\text{data}}(C, X)$ where C, X denote contexts and responses respectively, the objective function of ARAML's generator can be modified as below:

$$\mathcal{L}_{G_\theta} = -\mathbb{E}_{(C,X)\sim P_{\text{data}}(C,X)}\big[\mathbb{E}_{X_s\sim P_s(X_s|C,X)}\left[W_\phi(C, X_s)\log P_{G_\theta}(X_s|C)\right]\big] \tag{15}$$

where $W_\phi(C, X_s) \propto \exp\{D_\phi(C, X_s)\}$ and $D_\phi(C, X_s)$ is trained to distinguish whether X_s is the true response to C.

3.5 Comparison with RAML and MaliGAN

The most similar works to our framework are RAML (Norouzi et al., 2016) and MaliGAN (Che et al., 2017). The main difference among them is the training objective of their generators. We have shown different objective functions in Table 1. For comparison, we use the form with no input for all the three models.

Our model is greatly inspired by RAML, which gets samples from a non-parametric distribution $Q(X)$ constructed based on a specific reward. Compared to RAML, our reward comes from a learnable discriminator which varies as the adversarial training proceeds rather than a specific reward function. This difference equips our framework with the ability to adapt to the text generation tasks with no explicit evaluation metrics as rewards.

Our model is also similar to MaliGAN, which gets samples from the generator's distribution. In MaliGAN's training objective, $G_{\theta'}$ also indicates the generator's distribution but it's used in the sampling phase and fixed at each optimization step. The weight of samples $W'_\phi(X) \propto \frac{D_\phi(X)}{1-D_\phi(X)}$. Different from our model, MaliGAN acquires samples from the generator's distribution $P_{G_{\theta'}}$, which usually brings samples with low rewards even with careful pre-training for the generator, leading to training instability. Instead, our framework gets samples from a stationary distribution P_s around real data, thus our training process is more stable.

Model	Training Objective of Generator
RAML	$\mathcal{L}_{G_\theta} = -\mathbb{E}_{X\sim Q(X)}[\log P_{G_\theta}(X)]$
MaliGAN	$\mathcal{L}_{G_\theta} = -\mathbb{E}_{X\sim P_{G_{\theta'}}(X)}[W'_\phi(X)\log P_{G_\theta}(X)]$
ARAML	$\mathcal{L}_{G_\theta} = -\mathbb{E}_{X\sim P_s(X)}[W_\phi(X)\log P_{G_\theta}(X)]$

Table 1: Training objectives of generators for RAML, MaliGAN and ARAML.

4 Experiment

4.1 Datasets

Dataset	Amount(Train/Test)	Vocabulary	Length
COCO	80,000/5,000	4,839	12.8
EMNLP2017	49,996/10,000	5,721	27.8
WeiboDial	100,000/5,000	7,998	7.3/10.8

Table 2: Statistics of COCO, EMNLP2017 WMT and WeiboDial. The average lengths 7.3/10.8 of WeiboDial indicate the lengths of posts and responses, respectively.

We evaluated ARAML on three datasets: COCO image caption dataset (Chen et al., 2015), EMNLP2017 WMT dataset[1] and WeiboDial single-turn dialogue dataset (Qian et al.,

[1] http://statmt.org/wmt17/translation-task.html

2018). COCO and EMNLP2017 WMT are the common benchmarks with no input to evaluate the performance of discrete GANs, and we followed the existing works to preprocess these datasets (Shi et al., 2018; Guo et al., 2018). WeiboDial, as a dialogue dataset, was applied to test the performance of our model with input trigger. We simply removed post-response pairs containing low-frequency words and randomly selected a subset for our training/test set. The statistics of three datasets are presented in Table 2.

4.2 Baselines

We compared our model with MLE, RL and GAN baselines. Since COCO and EMNLP2017 WMT don't have input while WeiboDial regards posts as input, we chose the following baselines respectively:

MLE: a RNN model trained with MLE objective (Graves, 2013). Its extension, Seq2Seq, can work on the dialogue dataset (Sutskever et al., 2014).

SeqGAN: The first text GAN model that updates the generator with policy gradient based on the rewards from the discriminator (Yu et al., 2017).

LeakGAN: A variant of SeqGAN that provides rewards based on the leaked information of the discriminator for the generator (Guo et al., 2018).

MaliGAN: A variant of SeqGAN that optimizes the generator with a normalized maximum likelihood objective (Che et al., 2017).

IRL: This inverse reinforcement learning method replaces the discriminator with a reward approximator to provide dense rewards (Shi et al., 2018).

RAML: A RL approach to incorporate MLE objective into RL training framework, which regards BLEU as rewards (Norouzi et al., 2016).

DialogGAN: An extension of SeqGAN tuned to dialogue generation task with MLE objective added to the adversarial objective (Li et al., 2017).

DPGAN: A variant of DialogGAN which uses a language model based discriminator and regards cross-entropy as rewards (Xu et al., 2018).

Note that MLE, SeqGAN, LeakGAN, MaliGAN and IRL are the baselines on COCO and EMNLP2017 WMT, while MLE, RAML, DialogGAN, and DPGAN on WeiboDial. The original codes are used to test the baselines.

4.3 Implementation Details

The implementation details of our model are shown in Table 3. For COCO / EMNLP2017, the generator is a LSTM unit (Hochreiter and Schmidhuber, 1997) with 128 cells, and the discriminator is implemented based on (Yu et al., 2017). For WeiboDial, the generator is an encoder-decoder structure with attention mechanism, where both the encoder and the decoder consist of a two-layer GRU (Cho et al., 2014) with 128 cells. The discriminator is implemented based on (Tao et al., 2018). The language model used in the constrained sampling of ARAML is implemented in the same setting as the generators, and is pre-trained on the training set of each dataset. The codes and the datasets are available at `https://github.com/kepei1106/ARAML`.

Dataset	COCO / EMNLP2017	WeiboDial
Generator	LSTM	GRU
Discriminator	GRU & CNN	GRU & MLP
Temperature	0.85 (COCO) 0.9 (EMNLP2017)	0.95
Sampling size	5	5
Dimension of word embedding	128	100
Batch size	100	100
Pretraining epochs (G/D/LM)	50 / 15 / 50	50 / 10 / 30
Optimizer	Adam	Adam
Learning rate(G/D)	0.001 / 0.0001	0.001 / 0.0001

Table 3: Implementation details of ARAML. G/D/LM indicates the generator / discriminator / language model used in constrained sampling, respectively.

As for the details of the baselines, the generators of all the baselines except LeakGAN are the same as ours. Note that the generator of LeakGAN consists of a hierarchical LSTM unit, thus we followed the implementation in the original paper. In terms of the differences, the discriminators of GAN baselines are implemented based on the original papers. Other hyper-parameters of baselines including batch size, learning rate, and pre-training epochs, were set based on the original codes, because the convergence of baselines is sensitive to these hyper-parameters.

4.4 Language Generation on COCO and EMNLP2017 WMT

We adopted forward/reverse perplexity (Zhao et al., 2018) and Self-BLEU (Zhu et al., 2018) to evaluate the quality of generated texts. Forward perplexity (PPL-F) indicates the perplexity on the generated data provided by a language model trained on real data to measure the fluency of generated samples. Reverse perplexity (PPL-R) switches the roles of generated data and real data

Model	COCO			EMNLP2017 WMT		
	PPL-F	PPL-R	S-BLEU-2/3/4	PPL-F	PPL-R	S-BLEU-2/3/4
MLE	18.83 ± 0.51	38.81 ± 0.97	0.790 ± 0.006 / 0.598 ± 0.009 / 0.419 ± 0.010	55.64 ± 1.03	192.33 ± 9.51	0.771 ± 0.005 / 0.505 ± 0.009 / 0.304 ± 0.008
SeqGAN	33.07 ± 1.98	49.24 ± 2.36	0.814 ± 0.005 / 0.619 ± 0.008 / 0.430 ± 0.007	67.60 ± 3.48	276.82 ± 5.12	0.786 ± 0.019 / 0.500 ± 0.029 / 0.276 ± 0.023
LeakGAN	**11.43 ± 2.74**	87.54 ± 6.42	0.877 ± 0.032 / 0.762 ± 0.045 / 0.645 ± 0.049	**17.92 ± 1.77**	491.70 ± 18.29	0.890 ± 0.013 / 0.751 ± 0.011 / 0.604 ± 0.009
MaliGAN	47.16 ± 2.94	54.40 ± 1.29	0.786 ± 0.005 / 0.572 ± 0.008 / 0.370 ± 0.007	126.84 ± 11.18	288.20 ± 16.48	0.780 ± 0.019 / 0.494 ± 0.032 / 0.265 ± 0.028
IRL	41.86 ± 11.82	84.23 ± 7.02	0.857 ± 0.014 / 0.687 ± 0.031 / 0.499 ± 0.062	285.20 ± 36.47	1124.57 ± 109.80	0.890 ± 0.008 / 0.656 ± 0.052 / 0.406 ± 0.077
ARAML	26.97 ± 0.55	**35.79 ± 0.49**	**0.777 ± 0.005 / 0.560 ± 0.006/ 0.366 ± 0.008**	77.90 ± 0.70	**188.41 ± 3.18**	**0.745 ± 0.002 / 0.455 ± 0.006 / 0.257 ± 0.006**

Table 4: Automatic evaluation on COCO and EMNLP2017 WMT. Each metric is presented with mean and standard deviation.

to reflect the discrepancy between the generated distribution and the data distribution. Self-BLEU (S-BLEU) regards each sentence in the generated collection as hypothesis and the others as reference to obtain BLEU scores, which evaluates the diversity of generated results.

Results are shown in Table 4. LeakGAN performs best on forward perplexity because it can generate more fluent samples. As for reverse perplexity, our model ARAML beats other baselines, showing that our model can fit the data distribution better. Other GANs, particularly LeakGAN, obtain high reverse perplexity due to mode collapse (Shi et al., 2018), thus they only capture limited fluent expressions, resulting in large discrepancy between the generated distribution and data distribution. ARAML also outperforms the baselines in terms of Self-BLEU, indicating that our model doesn't fall into mode collapse with the help of the MLE training objective and has the ability to generate more diverse sentences.

We also provide standard deviation of each metric in Table 4, reflecting the stability of each model's performance. Our model ARAML nearly achieves the smallest standard deviation in all the metrics, indicating that our framework outperforms policy gradient in the stability of adversarial training.

4.5 Dialogue Generation on WeiboDial

Dialogue evaluation is an open problem and existing works have found that automatic metrics have low correlation to human evaluation (Liu et al., 2016; Novikova et al., 2017; Chaganty et al., 2018). Thus, we resorted to manual evaluation to assess the generation quality on WeiboDial. We randomly sampled 200 posts from the test set and collected the generated results from all the models. For each pair of responses (one from ARAML and the other from a baseline, given the same input post), five annotators were hired to label which response is better (i.e. win, lose or tie) in terms of *grammaticality* (whether a response itself is grammatical and logical) and *relevance* (whether a response is appropriate and relevant to the post). The two metrics were evaluated independently.

The evaluation results are shown in Table 5. To measure the inter-annotator agreement, we calculated Fleiss' kappa (Fleiss, 1971) for each pairwise comparison where results show *moderate agreement* ($0.4 \leq \kappa \leq 0.6$). We also conducted sign test to check the significance of the differences.

As shown in Table 5, ARAML performs significantly better than other baselines in all the cases. This result indicates that the samples surrounding true responses provide stable rewards for the generator, and stable RAML training paradigm significantly enhances the performance in both metrics.

4.6 Further Analysis on Stability

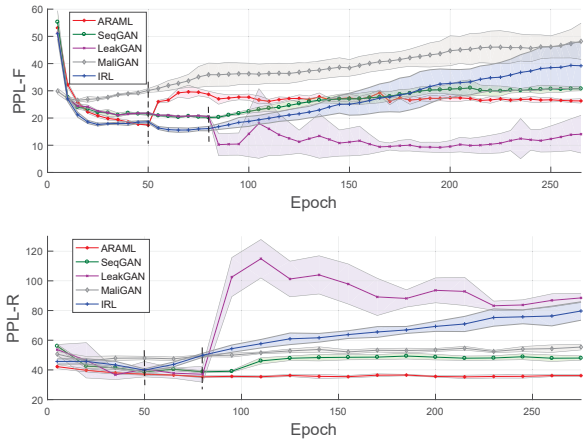

Figure 2: PPL-F/PPL-R curves of ARAML, SeqGAN, LeakGAN, MaliGAN and IRL in the training process. The shade area indicates the standard deviation at each data point. The dotted vertical lines separate pre-training and adversarial training phases (50 for ARAML, IRL and MaliGAN, 80 for SeqGAN and LeakGAN).

To verify the training stability, we conducted experiments on COCO many times and chose the best 5 trials for SeqGAN, LeakGAN, IRL, MaliGAN and ARAML, respectively. Then, we presented the forward/reverse perplexity in the train-

Model	Grammaticality			κ	Relevance			κ
	Win (%)	Lose (%)	Tie (%)		Win (%)	Lose (%)	Tie (%)	
ARAML vs. MLE	56.5**	36.5	7.0	0.456	50.5**	37.5	12.0	0.465
ARAML vs. RAML	54.5**	37.5	8.0	0.416	47.0*	40.5	12.5	0.480
ARAML vs. DialogGAN	75.5**	13.5	11.0	0.445	73.0**	11.0	16.0	0.460
ARAML vs. DPGAN	57.5**	36.0	6.5	0.435	56.5**	30.5	13.0	0.529

Table 5: Human evaluation on WeiboDial. The scores represent the percentages of *Win*, *Lose* or *Tie* when our model is compared with a baseline. κ denotes Fleiss' kappa (all are *moderate agreement*). The scores marked with * mean *p-value*< 0.05 and ** indicates *p-value*< 0.01 in sign test.

ing process in Figure 2. We can see that our model with smaller standard deviation is more stable than other GAN baselines in both metrics. Although LeakGAN reaches the best forward perplexity, its standard deviation is extremely large and it performs badly in reverse perplexity, indicating that it generates limited expressions that are grammatical yet divergent from the data distribution.

4.7 Ablation Study

4.7.1 Impact of Temperature

The temperature τ controls the search space surrounding the real data as we analyze in Section 3.3.1. To investigate its impact on the performance of our model, we fixed all the other hyperparameters and test ARAML with different temperatures on COCO.

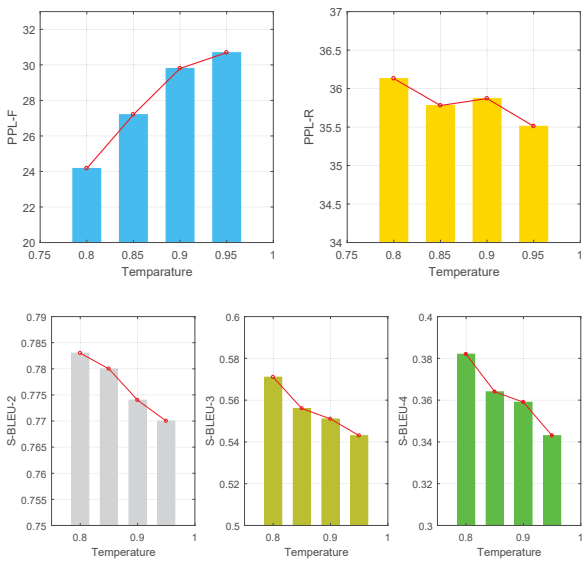

Figure 3: PPL-F, PPL-R and S-BLEU of ARAML with different temperatures $\tau \in \{0.8, 0.85, 0.9, 0.95\}$ on COCO.

The experimental results are shown in Figure 3. We can see that as the temperature becomes larger, forward perplexity increases gradually while Self-BLEU decreases. As mentioned in Section 3.3.1, large temperatures encourage our generator to explore the samples that are distant from real data distribution, thus the diversity of generated results will be improved. However, these samples distant from the data distribution are more likely to be poor in fluency, leading to worse forward perplexity. Reverse perplexity is influenced by both generation quality and diversity, so the correlation between temperature and reverse perplexity is not intuitive. We can observe that the model with $\tau = 0.95$ reaches the best reverse perplexity.

4.7.2 Impact of Sampling Strategy

We have mentioned two common sampling strategies in Section 3.3.1, i.e. random sampling and constrained sampling. To analyze their impact, we keep all the model structures and hyperparameters fixed and test ARAML with these two strategies on COCO.

Model	PPL-F	PPL-R	S-BLEU-2/3/4
ARAML-R	37.48±0.53	37.44±0.56	**0.752**/0.571/0.384
ARAML-C	**26.97±0.55**	**35.79±0.49**	0.777/**0.560/0.366**

Table 6: PPL-F, PPL-R and S-BLEU of ARAML with random sampling (ARAML-R) and constrained sampling (ARAML-C) on COCO.

Table 6 shows the results. It's obvious that random sampling hurts the model performance except Self-BLEU-1, because it indeed allows low-quality samples available to the generator. Exploring these samples degrades the quality and diversity of generated results. Despite the worse performance on automatic metrics, random sampling doesn't affect the training stability of our framework. The standard deviation of ARAML-R is still smaller than other GAN baselines.

4.8 Case Study

Table 7 presents the examples generated by the models on COCO. We can find that other baselines suffer from grammatical errors (e.g. *"in front of flying her kite"* from MLE), repetitive expressions

Model	Generated Samples
MLE	A little girl sitting on a beach in front of flying her kite at the beach. A little boy standing in a room next to a desk.
SeqGAN	A man sitting on a bench with snow board in the background. A brown gray cat is in the corner of a street.
LeakGAN	A person that is holding something while another kid is standing in the water. A room with a television, mantle, and a chair.
MaliGAN	A man with a shirt on holding one large pink giant and white kite. A couple and vases are outside on the bed.
IRL	A group of people wearing helmet sitting down on a cell phone. A group of people sitting in the middle of tracks.
ARAML	A man is wearing a hat and holding a toothbrush as he stands on the grass of a field. A boy reading a book on a sofa in a room.

Table 7: Examples of generated sentences on COCO. Grammatical errors are in red, while blue text represents repetitive expressions and green part indicates incoherent statements.

(e.g. *"A group of people"* from IRL) and incoherent statements (e.g. *"A group of people sitting on a cell phone"* from IRL). By contrast, our model performs well in these sentences and has the ability to generate grammatical and coherent results.

Post:	你还迟到哪？你没这习惯啊 Are you late? You don't have this habit.
MLE:	你是不是要好好照顾自己的！！！ Would you take care of yourself !!!
RAML:	这是我的生活，我也不想干 This is my life. I don't want to do this.
DialogGAN:	这社会的温度快到了。周末，要躺床上！ The temperature of the society has nearly reached. I'll lie on my bed on the weekend!
DPGAN:	我在上班，我就不习惯了 I'm working and I'm used to doing this.
ARAML:	嗯，周末就不迟到了！ Hum. I won't be late on the weekend!

Table 8: Examples of generated responses on WeiboDial.

Table 8 shows the generated examples on WeiboDial. It's obvious that other baselines don't capture the topic word "late" in the post, thus generate irrelevant responses. ARAML can provide a response that is grammatical and closely relevant to the post.

5 Conclusion

We propose a novel adversarial training framework to deal with the instability problem of current GANs for text generation. To address the instability issue caused by policy gradient, we incorporate RAML into the adversarial training paradigm to make our generator acquire stable rewards. Experiments show that our model performs better than several state-of-the-art GAN baselines with lower training variance, yet producing better performance on three text generation tasks.

Abstract

Most sequence-to-sequence (seq2seq) models are *autoregressive*; they generate each token by conditioning on previously generated tokens. In contrast, non-autoregressive seq2seq models generate all tokens in one pass, which leads to increased efficiency through parallel processing on hardware such as GPUs. However, directly modeling the joint distribution of all tokens simultaneously is challenging, and even with increasingly complex model structures accuracy lags significantly behind autoregressive models. In this paper, we propose a simple, efficient, and effective model for non-autoregressive sequence generation using latent variable models. Specifically, we turn to generative flow, an elegant technique to model complex distributions using neural networks, and design several layers of flow tailored for modeling the conditional density of sequential latent variables. We evaluate this model on three neural machine translation (NMT) benchmark datasets, achieving comparable performance with state-of-the-art non-autoregressive NMT models and almost constant decoding time w.r.t the sequence length.[1]

1 Introduction

Neural sequence-to-sequence (seq2seq) models (Bahdanau et al., 2015; Rush et al., 2015; Vinyals et al., 2015; Vaswani et al., 2017) generate an output sequence $\mathbf{y} = \{y_1, \ldots, y_T\}$ given an input sequence $\mathbf{x} = \{x_1, \ldots, x_{T'}\}$ using conditional probabilities $P_\theta(\mathbf{y}|\mathbf{x})$ predicted by neural networks (parameterized by θ).
